In a 3-week, double-blind study of the cognitive effects of lithium (serum concentration about 0.8 mmol/l; $n = 15$) versus placebo ($n = 15$) in healthy subjects, lithium did not impair implicit recall, ability to process two tasks concurrently and simultaneously, short-term memory, or selective attention, but caused impaired learning during repeated administration of memory tests (161). Since neuropsychological testing could not distinguish lithium treatment from pre- and post-treatment in the lithium group, any lithium effects must be considered subtle at best.

It has been suggested that thyroid hormone may minimize the cognitive effects of lithium (157) and a review of this suggested benefit in those patients taking lithium who had subclinical hypothyroidism (157).

Lithium has diverse effects on creativity. While creativity can suffer from the absence of mania or from lithium-induced adverse effects, it can also be improved by the mood stabilization that lithium produces, or may be unaffected by treatment (162).

Four of seventeen studies of the cognitive effects of lithium were deemed to have acceptable methods. Reported adverse effects included effects on memory, speed of information processing, and reaction time (often in the absence of subjective complaints), suggesting that the risk of driving accidents might be increased when patients are taking lithium (155,156). Interventions for lithium-induced cognitive impairment include dosage reduction, use of a modified-release formulation, treatment of thyroid dysfunction, and assessing the role of concomitant illness and medication. When 67 patients who complained of cognitive deterioration while taking lithium were treated with aniracetam, 97% reported subjective improvement (163).

Delirium

In a case-control study, lithium was found to be one of several risk factors for delirium in 91 psychiatric inpatients (odds ratio 2.23), although the authors concluded that this observation may have been confounded by an association with manic episodes (164).

- A 38-year-old woman who had tolerated lithium for 20 years developed delirium following a manic episode, despite therapeutic concentrations of lithium (0.7–1.0 mmol/l); the episode remitted fully after lithium was withdrawn (165).
- A 36-year-old developed a febrile confusional state in the absence of infection while taking lithium (serum concentrations 0.37 and 0.58 mmol/l) and cyamemazine, resulting in a persistent cerebellar syndrome (166).
- A 62-year-old woman became delirious when lithium at therapeutic concentrations was added to valproate, haloperidol, and biperiden (167). The delirium resolved after all drugs were withdrawn, but 6 months later she still had choreoathetoid movements.

Endocrine

Corticotropin (ACTH)

Calcium infusion in lithium patients ($n = 7$) and controls ($n = 7$) caused similar increases in ACTH concentrations across a physiological range of calcium (168).

Prolactin

Serum prolactin concentrations in patients taking long-term ($n = 15$) or short-term ($n = 15$) lithium did not differ from controls (169). In another study, when compared with 17 healthy controls, 20 euthymic bipolar patients who had taken lithium for more than 6 months had significantly lower serum prolactin concentrations (9.72 ng/ml versus 15.56 ng/ml), but prolactin concentrations in short-term lithium users ($n = 15$) did not differ from controls (170). Antipsychotic drugs were not involved.

Diabetes insipidus

Two of ten patients taking long-term lithium therapy were thought to have hypothalamic diabetes insipidus, because of a positive response to desmopressin (171).

Hypothalamic–pituitary–adrenal axis

Hypothalamic–pituitary–adrenal axis function in bipolar disorder has been reviewed, but lithium was mentioned only in passing (172). Two studies ($n = 25$, $n = 24$), possibly reporting many of the same patients, showed that lithium augmentation of antidepressant-resistant unipolar depression increased hypothalamic–pituitary–adrenal axis activity, measured by the dexamethasone suppression test, either alone or combined with the corticotropin releasing hormone test (173,174). However, the tests did not distinguish between lithium responders and nonresponders.

Thyroid

The many effects of lithium on thyroid physiology and on the hypothalamic–pituitary axis and their clinical impact (goiter, hypothyroidism, and hyperthyroidism) have been reviewed (175). Lithium has a variety of effects on the hypothalamic–pituitary–thyroid axis, but it predominantly inhibits the release of thyroid hormone. It can also block the action of thyroid stimulating hormone (TSH) and enhance the peripheral degradation of thyroxine (175). Most patients have enough thyroid reserve to remain euthyroid during treatment, although some initially have modest rises in serum TSH that normalize over time.

© 2006 Elsevier BV All rights reserved.

Both goiter and hypothyroidism continue to be reported as complications of lithium therapy (81,176,177).

In a cross-sectional study of 121 patients taking lithium, there was no difference in thyroid function tests among those taking treatment for 0.7–6 months, 7–10 months, or 61–240 months. However, when compared with healthy volunteers ($n = 24$) and prelithium controls ($n = 11$), there was a significant increase in radioiodine uptake in all lithium groups. Serum TSH concentrations were higher in prelithium patients than controls and highest in those taking lithium. Being from an iodine-deficient area appeared to predispose lithium patients to abnormally high TSH values and clinical hypothyroidism (178).

In 1989, in 150 patients at different stages of lithium therapy, thyroid function was assessed and subsequently 118 were reassessed at least once and 54 completed a 10-year follow-up (179). The annual rates of new cases of thyroid dysfunction were subclinical hypothyroidism 1.7%, goiter 2.1%, and autoimmunity 1.4%. While these figures were little different from those found in the general population, the authors acknowledged that lithium was a potential cause of thyroid dysfunction.

Of 42 bipolar patients who had taken lithium for 4–156 months, three had subclinical hypothyroidism, three had subclinical hyperthyroidism, and one was overtly hyperthyroid (177). Ultrasonography showed that goiter was present in 38% and mild thyroid dysfunction was suggested in 48% because of an apparent increased conversion of free T4 to free T3. There was no correlation between the duration of lithium therapy and thyroid abnormalities.

Hypothyroidism

Lithium-induced hypothyroidism has been briefly reviewed (180). Some patients develop more persistent subclinical hypothyroidism (TSH over 5 mU/l, free thyroxine normal) and others overt hypothyroidism (higher risk in women, in those with pre-existing thyroid dysfunction, and those with a family history of hypothyroidism). Since subclinical hypothyroidism is not necessarily asymptomatic, treatment with thyroxine may be necessary in this group (181), as well as in those with more obvious hypothyroidism (182).

The prevalence of thyroperoxidase antibodies was higher in 226 bipolar patients (28%) than in population- and psychiatric-control groups (3–18%). While there was no association with lithium exposure, the presence of antibodies increased the risk of lithium-induced hypothyroidism (183).

Thyroid function tests in 101 lithium maintenance patients were compared with their baseline values and with results in 82 controls without psychiatric or endocrine diagnoses. With hypothyroidism defined as a serum TSH above the reference range, 8 patients were hypothyroid at baseline, and another 40 became so during treatment. Women over 60 years of age were at slightly higher risk and had higher TSH values. Patients with a positive family history of hypothyroidism had raised TSH concentrations sooner after starting lithium (3.7 versus 8.7 years). Whether any patients became clinically hypothyroid was not noted (it was stated that those with grade II hypothyroidism were almost free of symptoms) (184).

Serum TSH concentrations were raised (10 mU/l or more) in 13 of 61 children aged 5–17 years taking lithium and valproate for up to 20 weeks (185).

In a review of lithium-induced subclinical hypothyroidism (TSH over 5 mU/l, free thyroxine normal), a prevalence of up to 23% in lithium patients was contrasted with up to 10% in the general population. It was stressed that subclinical hypothyroidism from any cause can be associated with subtle neuropsychiatric symptoms, such as depression, impaired memory and concentration, and mental slowing and lethargy, as well as with other somatic symptoms. Management guidelines were discussed (181).

An abstract reported that 23% of 61 children and adolescents taking lithium and divalproex sodium for up to 20 weeks had a TSH concentration over 10 mU/l (reference range 0.2–6.0); however, no clinical information was provided (186). Another abstract reported that the prevalence of thyroperoxidase antibodies was higher in bipolar outpatients (28% of 226) than in psychiatric inpatients with any diagnosis (10% of 2782) or healthy controls (14% of 225), but this was not related to lithium exposure; on the other hand, hypothyroidism was associated with lithium exposure, especially in the presence of antithyroid antibodies (187).

When 22 men and 38 women who had taken lithium for at least a year (mean 6.9 years) for bipolar disorder were evaluated for adverse effects, hypothyroidism requiring thyroid supplementation was found in 16 (14 women and 2 men); 9 had a goiter (56). The area from which some of the patients came was known to have a high background incidence of thyroid dysfunction.

The observation that Canada, with ample nutritional iodine, has a relatively high rate of lithium-related hypothyroidism compared with relatively low rates in iodine-deficient countries such as Italy, Spain, and Germany led to the suggestion that ambient iodine may play a role in the genesis of this condition (188). This is reminiscent of the association of amiodarone with hypothyroidism or hyperthyroidism in iodine-replete and iodine-deficient areas respectively (SEDA-10, 148).

Case reports of adverse thyroid effects of lithium have included the following:

- A 56-year-old man taking lithium whose TSH concentration was abnormally high (50 mU/l) (189).
- A 44-year-old woman who had taken lithium for 10 years and who developed swelling of the right lobe of the thyroid and hypothyroidism (65).
- A 63-year-old woman taking long-term lithium who developed subclinical hypothyroidism and primary hyperparathyroidism (190).

Hyperthyroidism

Despite the predominantly antithyroid effects of lithium, thyrotoxicosis continues to be described during treatment and after withdrawal (191–193). In a retrospective review of 201 patients taking lithium (mean duration 6.4 years), hypothyroidism requiring supplemental thyroxine developed in 10% (3.4% of men, 15% of women) after a mean duration of 56 months. Women over 50 years of age tended to have an earlier onset. Two patients developed

© 2006 Elsevier BV All rights reserved.

goiter requiring surgery and two others developed thyrotoxicosis (182).

Reports of hyperthyroidism associated with lithium include one in a woman who was also hypercalcemic with a normal parathyroid hormone (PTH) concentration (194) and two discovered while treating lithium toxicity (195).

- A 27-year-old man developed thyrotoxicosis while taking lithium (193).
- A 52-year-old woman became thyrotoxic 2 months after stopping long-term lithium therapy; the authors briefly reviewed 10 previous reports (196).
- A woman with lithium-associated hyperthyroidism lost 2 kg over 3 months, suggesting that lithium may have indirectly caused the weight loss (197).

Thyroiditis

A retrospective record review of 300 patients with Graves' disease and 100 with silent thyroiditis who had undergone thyroid scans showed that the likelihood of lithium exposure was 4.7 times higher in the latter, suggesting a link between lithium and thyrotoxicosis caused by silent thyroiditis (198).

- A 30-year-old man, who had taken lithium for 16 years for bipolar disorder and long-term ciclosporin and prednisolone after a bone-marrow transplant, developed subacute thyroiditis associated with a diffusely enlarged gland that showed heterogeneous echogenicity, but without a clear relation to lithium (199).

Goiter

Euthyroid or hypothyroid goiter can also complicate lithium therapy, although the goiter is seldom of clinical importance and tends to resolve on withdrawal or with thyroxine treatment. In one ultrasound study, there was a 44% incidence of goiter in patients who had taken lithium for 1–5 years compared with 16% in a control group; cigarette smoking was associated with a greater size and frequency of goiter in both groups (200).

Hyperthyroidism has also been associated with lithium use and withdrawal, although a cause-and-effect relation has been more difficult to establish. In fact, lithium has been used with some success to treat hyperthyroidism, particularly in conjunction with propylthiouracil (201) and ^{131}I (16).

Parathyroid and calcium

Mild rises in serum calcium and PTH concentrations have been associated with long-term use of lithium, and, in a review, 27 reports of parathyroid adenoma and 11 of hyperplasia were mentioned (202). The hypercalcemia and raised PTH concentrations are often reversible on withdrawal, but surgical intervention may be necessary. So far, long-term lithium therapy has not emerged as a risk factor for reduced bone mineral density or osteoporosis (203). In one study, there was a greater frequency of electrocardiographic conduction defects in hypercalcemic patients taking lithium than in normocalcemic patients taking lithium (66).

Of 537 patients who had parathyroid glands excised for hyperparathyroidism, 12 (2.2%) had been taking lithium and 11 (2.0%) had been taking it long-term (mean 15.3 years, range 2–30). Manifestations included fatigue, bone pain and fracture, and abdominal pain and constipation. Six had a single adenoma and five had multigland hyperplasia. All resumed lithium, but one had a recurrence after 3 years and one had increased PTH concentrations, but a normal serum calcium. A literature review detected 27 prior reports of parathyroid adenoma and 11 of hyperplasia associated with lithium (202).

When 15 euthymic bipolar patients who had taken lithium for a mean of 49 months were compared with 10 nonlithium euthymic bipolar controls, the former had significantly higher total serum calcium concentrations and intact PTH (iPTH) concentrations (204). The authors advised baseline and periodic serum calcium and iPTH concentrations and bone density measurements in all lithium patients, although whether the benefit outweighs cost is open to question.

Ten patients who had taken lithium for less than 1 year and 13 who had taken it for more than 3 years were assessed for alterations in bone metabolism and parathyroid function (203). There were no differences in bone mineral density, serum calcium concentration, or PTH concentration, but both groups had increased bone turnover and the long-term group had nonsignificantly higher calcium and PTH concentrations (including one hyperparathyroid patient who had an adenoma excised). The authors' conclusion that lithium therapy is not a risk factor for osteoporosis needs to be tempered by the small sample size, the case of adenoma, and the blood concentration trends.

Total serum calcium and iPTH concentrations were measured in 15 patients taking long-term lithium and 10 lithium-naïve patients; both were significantly higher in the lithium group (205). While the number of lithium patients with abnormally high concentrations was not stated, mean iPTH concentrations were almost twice the upper limit of the reference range (102 versus 55 pg/ml).

Parathyroid tumors from nine patients with lithium-associated hyperparathyroidism (six multiglandular, three uniglandular) were compared with 13 nonlithium-associated sporadic parathyroid tumors with regard to gross genomic alterations (206). Gross chromosomal alterations were absent in most of the lithium group and were more common in the sporadic group.

In 53 patients studied prospectively at 1, 6, 12, and 24 months, lithium increased serum PTH concentrations (apparent by 6 months) and increased renal reabsorption of calcium in the absence of a significant change in serum calcium (207). A prospective study of 101 lithium maintenance patients and 82 healthy controls showed higher serum calcium concentrations during lithium treatment than at baseline or in the controls, and higher calcium serum concentrations in those lithium patients over 60 years of age (184).

When compared with 12 healthy matched controls, 13 women who had taken lithium for a mean of 8 (range 3–16) years had higher mean ionized and total calcium concentrations, but mean plasma parathormone concentrations did not differ. In eight of the women taking lithium, the calcium concentration was above the upper end of the reference range, and in one the parathormone concentration was abnormally high (208).

Of 15 patients taking long-term lithium who had surgery for primary hyperparathyroidism, 14 had adenomas

© 2006 Elsevier BV All rights reserved.

(11 single, 3 double) and one had four-gland hyperplasia. All restarted lithium successfully after surgery, except one who again developed hyperparathyroidism, resulting in removal of another adenoma (209).

Hyperparathyroidism was considered a possible cause of treatment-resistant manic psychosis in a patient taking lithium (210).

- Hypercalcemia and raised PTH concentrations improved in a woman who had taken lithium for over 20 years after she was switched to divalproex (211).
- A 64-year-old woman who had taken lithium for over 10 years was admitted with altered consciousness, agitation, and disorientation. The serum calcium was 3.35 mmol/l (reference range 2.1–2.6 mmol/l) and the PTH concentration was raised. With hydration and conversion from lithium to valproate, the serum calcium concentration normalized, but 2 years later disorientation and hypercalcemia recurred and a 150 mg parathyroid adenoma was removed surgically (212).
- A 53-year-old woman who had taken lithium for 9 years and carbamazepine for 3 years and had a 3-month history of lethargy was found to be hypercalcemic with a raised concentration of iPTH. She was saved from parathyroid surgery when withdrawal of lithium resolved the hypercalcemia (213).
- A 51-year-old man who had taken lithium for over 10 years presented with nausea, vomiting, anorexia, hypercalcemia (3.1 mmol/l), and increased PTH concentration (iPTH 110 ng/l). Abnormalities resolved after an oxyphilic parathyroid adenoma was excised (214).

Other reports of hyperparathyroidism in patients taking lithium have included the following:

- Three cases among 26 cases of chronic lithium poisoning (215).
- A 78-year-old man who had taken lithium for 30 years who presented with dehydration, azotemia, hypernatremia, hypercalcemia, and increased PTH concentrations (216).
- A 63-year-old woman taking long-term lithium therapy (190).
- A woman who had taken lithium for 15 years who became hypercalcemic and stopped taking lithium, but 2 years later had two parathyroid adenomas removed surgically (217).
- A 42-year-old man who had taken lithium for 17 years and who had raised serum calcium and PTH concentrations which normalized after removal of a parathyroid adenoma (218).
- A 59-year-old man with hypercalcemia and increased PTH concentrations 3 months after starting lithium, which normalized after lithium was withdrawn (82).
- Three cases from Denmark (219) and one from Spain (220);
- A 78-year-old woman who had taken lithium for 25 years (221).
- A 74-year-old man who had an adenoma resected (81).
- Two 77-year-old women who developed hyperparathyroidism which was managed medically (81).
- A 39-year-old (sex unspecified) whose adenoma was resected after taking lithium for 10 years (209).
- A 59-year-old woman with hyperparathyroidism (222).

A lithium chloride solution caused changes in gravicurvature, statocyte ultrastructure, and calcium balance in pea root, believed to be due to effects of lithium on the phosphoinositide second messenger system (223). The implications with regard to human parathyroid function are obscure.

Metabolism

Diabetes mellitus

It has been reported that diabetes mellitus is three times more common in bipolar patients than in the general population (224). However, lithium does not appear to increase the risk of diabetes mellitus, and its use in patients with pre-existing diabetes is generally safe, assuming that the diabetes is well controlled.

When lithium toxicity has been reported in patients with diabetes mellitus, it has been attributed to impaired glucose intolerance (225).

- An increased lithium dosage requirement in a hyperglycemic 40-year-old woman was attributed to the osmotic diuretic effect of glycosuria, increasing lithium excretion (226).
- Two patients with diabetes mellitus developed lithium toxicity (serum concentrations 3.3 and 3.0 mmol/l) in association with impaired consciousness, and hyperglycemia that resolved after intravenous insulin and fluids (227).

While the authors of the second report concluded that impaired glucose tolerance had predisposed to lithium intoxication, the opposite is also possible.

When a 45-year-old man with severe lithium-induced diabetes insipidus developed hyperosmolar, nonketotic hyperglycemia, it was suggested that poorly controlled diabetes mellitus may have contributed to the polyuria (228). Prior contact with a female patient who had developed hyperosmolar coma secondary to lithium-induced diabetes insipidus (229) allowed physicians 4 years later to treat her safely after a drug overdose and a surgical procedure, by avoiding intravenous replacement fluids with a high dextrose content (despite stopping lithium several years earlier, the patient continued to put out 10 liters of urine daily) (230).

Difficulty in attaining a therapeutic serum concentration of lithium despite increased doses was attributed to increased renal clearance due to the osmotic effect of glycosuria in a 44-year-old man with poorly controlled diabetes mellitus (226).

Weight gain

Weight gain, a well-recognized adverse effect of lithium, occurs in one-third to two-thirds of patients (231). It is more common in those with prior weight problems and at higher dosages of lithium. Possible mechanisms include complex effects on carbohydrate and lipid metabolism, mood stabilization itself, lithium-induced hypothyroidism, the use of high-calorie beverages to treat lithium-induced polydipsia, and the concomitant use of other weight-gaining drugs (for example valproate, olanzapine, mirtazapine). Recognizing and managing weight gain early in the course of treatment can do much to ensure continued

© 2006 Elsevier BV All rights reserved.

adherence to lithium regimens. Two reviews of weight gain with psychotropic drugs mentioned lithium (232,233).

Risk and magnitude

In a review of psychotropic drug-induced weight gain, the prevalence and magnitude of the problem with lithium was discussed together with risk factors, mechanisms, and management (231). Adolescent inpatients treated with risperidone ($n = 18$) or conventional antipsychotic drugs ($n = 19$) over 6 months gained more weight than a control group but concomitant treatment with lithium was not a contributing factor (234).

A review of psychotropic drugs and weight gain included a brief summary of lithium-related weight gain (235). A retrospective evaluation of 176 patients taking long-term lithium showed that weight gain was an adverse effect in 18%. While 34% of the total did not adhere to treatment because of somatic adverse effects, no specific adverse effect (including weight gain) was associated with nonadherence (236).

The prevalence of overweight (BMI 25–29) and obesity (BMI 30 or more) was determined in 89 euthyroid bipolar patients and 445 reference subjects. The rate of obesity in patients taking only lithium was 1.5 times greater than in the reference population (a nonsignificant difference), compared with a statistically significant 2.5 times greater rate associated with antipsychotic drugs (237).

The prevalence of overweight (BMI 20 or more) and obesity (BMI 30 or more) has been evaluated in 89 euthymic bipolar patients and 445 age- and sex-matched controls (237). The bipolar women were more overweight and more obese than the controls and the bipolar men were more obese but not more overweight. Obesity was clearly related to antipsychotic drug use and less so to lithium and anticonvulsants (but patients taking lithium alone had an obesity rate 1.5 times that of the general population).

A review of the effects of mood stabilizers on weight included a section on lithium in which the authors concluded that lithium-related weight gain occurs in one-third to two-thirds of patients, with a mean increase of 4–7 kg; possible mechanisms were discussed (238).

An open chart review of 74 hospitalized patients showed a mean weight gain of 6.3 kg and an increase in BMI of 2.1 kg/m^2 after they had taken lithium for a mean of 89 days (239). Of 47 lithium-treated patients, 14 gained at least 5% of their baseline BMI, 6 gained over 10%, and 2 gained over 15% during an acute treatment phase of unspecified duration, while during the 1-year maintenance phase 11 gained over 5% and 2 gained over 10% (240).

Comparative studies

In a 1-year, placebo-controlled study of bipolar I prophylaxis ($n = 372$), weight gain with divalproex, but not with lithium, was significantly more common than with placebo (52). A patient who gained 18 kg over 18 months while taking lithium and perphenazine lost 16 kg when the latter was changed to loxapine (she also participated in a weight loss program) (241). Whether lithium played a role in the weight gain was unclear.

In a 12-month maintenance study, weight gain was an adverse event in 21% of patients taking divalproex, 13% of those taking lithium, and 7% of those taking placebo (52). The divalproex/placebo difference was statistically significant, but the lithium/placebo difference was not.

Mechanism

In 15 consecutive patients, serum leptin concentrations were measured at baseline and after 8 weeks of lithium treatment. There was a significant mean increase of 3.5 ng/ml and serum leptin correlated positively with weight gain (5.9 kg), increased BMI (24–27), and clinical efficacy (242). The authors suggested that leptin might play a role in lithium-induced weight gain.

Management

The Expert Consensus Guideline Series, Medication Treatment of Bipolar Disorder 2000, has recommended to "continue present medication, focus on diet and exercise" as the preferred first-line treatment for managing weight gain in patients taking lithium or divalproex. The next approach was to continue medication and add topiramate. Second-line treatments included switching from divalproex to lithium or vice versa, reducing the dosage, and switching to another drug. The addition of an appetite suppressant was a lower second-line recommendation (243).

Nutrition

In a review of naturally occurring dietary lithium (food and water sources), the author acknowledged that human lithium deficiency states have not been identified, but concluded that lithium should be considered an essential element, a conclusion reached on rather shaky grounds (244).

Electrolyte balance

Potassium

Episodes of acute hypokalemic paralysis have been associated with long-term lithium therapy (245).

- A 25-year-old man, who had taken lithium for 5 years, awakened from sleep unable to move his limbs and had a generalized flaccid paralysis with a serum potassium concentration of 2.1 mmol/l (245). Lithium was withdrawn and he responded to treatment with intravenous potassium chloride.

The diagnosis of acute hypokalemic paralysis was attributed to lithium but without confirmation by rechallenge it was unclear whether this was causal or coincidental.

Sodium

Hypernatremia can occur secondary to dehydration in patients taking lithium and is not uncommon in association with lithium poisoning. Lithium-induced diabetes insipidus is often a contributing factor.

Mineral balance

Fluid and sodium balance are important to the safe use of lithium. Both dehydration and a negative sodium balance (for example a low salt intake, diuretic-induced sodium loss) will reduce renal lithium clearance and predispose to toxicity (246). Hyponatremia (for example, secondary to polydipsia or SIADH) may also increase the risk of lithium toxicity (247).

© 2006 Elsevier BV All rights reserved.

When nine trace elements were measured in whole blood (oven dried, moisture-free) from controls, pre-lithium, and lithium patients, there were many changes related to lithium, but none appeared to be clinically important (248).

Fluid balance

Edema associated with lithium is uncommon (249,250). It is usually restricted to the legs, and is usually transient or intermittent. If treatment is necessary, the intermittent and cautious use of a loop diuretic may be helpful (but see drug–drug interactions).

Dehydration, secondary to lithium-induced nephrogenic diabetes insipidus, was thought to be the cause of a superior sagittal sinus thrombosis in a 30-year-old woman who presented with confusion, papilledema, and a left hemiparesis (251).

Hematologic

The most common hematological effect of lithium is a benign leukocytosis (252), consisting primarily of mature granulocytes, which is reversible on withdrawal. An increase in platelet count is a much less consistent finding (253), and there are no clinically important effects on erythrocytes. Despite anecdotal reports to the contrary, epidemiological studies have shown no increased risk of leukemia with lithium (254). The leukocyte-inducing effects of lithium have been used with some success to treat granulocytopenia (25,26).

The effects of lithium on hemopoiesis have been studied in 100 patients who had developed chronic granulocytopenia after cancer chemotherapy or radiotherapy (255). The mean leukocyte count rose by 46%, but there were no changes in platelet or erythrocyte counts. However, there was a significant increase in platelet count in those whose baseline values were below 150×10^9/l. Lithium was well tolerated (mean serum concentration 0.59 mmol/l).

Granulocyte counts and granulocyte colony-stimulating factor (G-CSF) concentrations were measured in 18 patients before and after 1 and 4 weeks of lithium treatment, and compared with values in 20 patients taking long-term lithium (256). At week 4, the granulocyte count was significantly higher than at baseline or at week 1, or in the long-term group. There was only a nonsignificant increase in G-CSF concentration at weeks 1 and 4. The granulocyte count in those taking long-term lithium did not differ significantly from the baseline values in the other group.

A retrospective review of inpatients showed higher leukocyte and granulocyte counts in those taking lithium alone ($n = 38$) compared with those taking antipsychotic drugs alone ($n = 207$); lymphocyte counts were not affected. Rises in leukocyte counts above normal occurred in 18% of those taking lithium and 6% of those taking antipsychotic drugs (252). The neutrophil-stimulating effect of lithium was used to advantage to successfully re-treat a patient with clozapine several years after stopping it because of neutropenia (257). Likewise, lithium was used to successfully stimulate neutrophil production in a patient with clozapine-induced neutropenia and in another with clozapine-induced agranulocytosis (recovery was as fast as seen with colony-stimulating factor and twice as rapid as expected spontaneously) (25).

In eight patients with bipolar disorder, lithium for 3–4 weeks increased neutrophil count by 88% and also caused a significant increase in CD34+ cells (although three patients had no increase in either) (258).

- A lithium-treated bipolar patient with acute myeloid leukemia had an unusually great increase in CD34+ cells following administration of G-CSF, suggesting a boosting effect from lithium (259).
- After he had failed to respond to combined treatment with corticosteroids and androgens and to antilymphocyte globulin, a 16-year-old with aplastic anemia responded to lithium combined with an androgen derivative, relapsed when lithium was stopped, and responded again when it was restarted (31).

Of 39 patients taking lithium, 18% had neutrophilia and 15% had raised activity of polymorphonuclear elastase (a marker of granulocyte activation) (260). In keeping with these observations, a chart review of 38 patients taking clozapine showed an increase in leukocyte count when lithium was added (32). A man with olanzapine-induced neutropenia (with a prior history of risperidone-induced neutropenia), which normalized with drug withdrawal, had no difficulty when the drug was reintroduced after the patient had been treated with lithium (33).

When 50 bipolar lithium patients were compared with 30 healthy controls, platelet counts were similar, but the lithium group had higher concentrations of plasma beta-thromboglobulin and platelet factor 4, suggesting lithium-induced platelet activation (253).

A cross-sectional study showed a 20% lower serum vitamin B12 concentration in patients taking lithium ($n = 81$) than in controls ($n = 14$) (serum and erythrocyte folate concentrations were normal) (261).

Mouth and teeth

A comprehensive review of psychoactive drug-induced hyposalivation and hypersalivation included a discussion of lithium-induced dry mouth (common) and sialorrhea (262). A review of dental findings and their management in patients with bipolar disorder briefly mentioned that xerostomia, sialadenitis, dysgeusia, and stomatitis have been attributed to lithium (263). Dry mouth is common and can be due to lithium-induced polyuria, a direct effect on thirst, salivary gland hypofunction, or other drugs (262). Hypersalivation attributable to lithium is rare (264).

A review of drug-induced oral ulceration mentioned lithium as a possible cause, based on two older references (265,266).

- An 8-year-old taking lithium citrate for 6 months developed waxing and waning areas of denuded papillae on her tongue, diagnosed as benign migratory glossitis (geographic tongue) and attributed to lithium (267).

The issue has been raised of whether oral lithium therapy was responsible for failure of titanium dental implants in a 62-year-old man (268).

© 2006 Elsevier BV All rights reserved.

Gastrointestinal

Lithium can cause loss of appetite, nausea, and at times vomiting and loose stools, especially early in therapy, but these can be minimized by the passage of time and by making dosage increases gradually (52). Gastrointestinal symptoms can also be an early warning sign of lithium intoxication.

In a 12-month maintenance study, lithium ($n = 94$) was not unexpectedly associated with more nausea (45 versus 31%) and diarrhea (46 versus 30%) than placebo ($n = 94$) (52).

- A 72-year-old man who had recently started to take lithium developed severe nausea, vomiting, and oliguric renal insufficiency which was initially attributed to lithium toxicity, until a serum lithium concentration of only 0.35 mmol/l directed evaluation to the correct diagnosis of acute gastric volvulus (269).
- An 80-year-old woman taking lithium developed constipation, nausea, vomiting, and abdominal pain after starting to take amfebutamone. A diagnosis of acute paralytic ileus was made and attributed to amfebutamone, although an amfebutamone–lithium interaction could not be excluded (270).
- In an 80-year-old woman a 2-month history of diarrhea, nausea, and abdominal distress attributed to irritable bowel syndrome was ultimately determined to be due to early lithium intoxication (271). Her lithium concentration when she was hospitalized was 1.2 mmol/l, although she had taken no lithium for the previous 10 days. Treatment with a thiazide diuretic contributed to the toxicity.

Pancreas

Of 47 cases of drug-induced pancreatitis reported to the Danish Committee on Adverse Drug Reactions between 1968 and 1999, one involved lithium (plus a neuroleptic drug) (272). Whether lithium was causally involved is not known.

- A 78-year-old woman taking lithium had hyperamylasemia and hyperlipasemia in the absence of gastrointestinal symptoms. Ultrasound examination showed the pancreas and liver to be normal. She also had hyperparathyroidism and renal dysfunction (221).

Urinary tract

There have been several reviews of the effects of lithium on the kidney (273–276).

In a retrospective study, 114 patients who had taken lithium for 4–30 years were compared with 94 unmedicated age- and sex-matched controls with regard to changes in creatinine concentrations (277). Of the patients taking lithium, 21% had blood creatinine concentrations that had increased gradually and were now over the top of the reference range. This finding was associated with episodes of lithium intoxication and with diseases and other medications that could also affect glomerular function. Sex, psychiatric diagnosis, duration of treatment, cumulative dose, and serum lithium concentrations did not predict an abnormal creatinine concentration.

Renal function was assessed in 10 patients taking long-term lithium (over 3 years, mean 80 months), 10 taking short-term lithium (3 years or less, mean 16 months), and 10 lithium-naïve patients (171). Blood urea nitrogen and serum creatinine concentrations were within the reference ranges and did not differ among the groups, but 24-hour creatinine clearance was significantly lower in those taking long-term lithium (73 versus 125 and 150 ml/minute). There were no significant differences among the groups in urine osmolality after 8-hour water deprivation and desmopressin, but partial nephrogenic diabetes insipidus was diagnosed in four long-term and two short-term patients and hypothalamic diabetes insipidus in two long-term patients. The authors concluded that long-term lithium therapy is a risk factor for renal impairment.

In a retrospective review of lithium concentrations in 2210 psychiatric hospital patients, 151 (6.8%) had serum lithium concentrations of 1.5 mmol/l or more. Of those with high serum concentrations, 10 (6.6%) had a raised blood urea nitrogen or serum creatinine concentration (278). In a retrospective study of 114 patients who had taken lithium for 4–30 years and 94 matched unmedicated subjects, 21% of those taking lithium had blood creatinine concentrations greater than 1.5 mg/ml [sic]; comparative figures were not given for the controls (277). Raised creatinine concentrations tended to be associated with episodes of lithium toxicity and drugs or diseases that could alter glomerular function.

Renal disease is not a contraindication to lithium, but it does complicate its use, and alternative mood stabilizers should be considered. Despite the diverse effects of lithium on the kidney, most patients find it to be generally well tolerated; nevertheless, monitoring should include periodic testing of renal function. In one case, a psychiatrist and family physician were sued for failing to monitor renal function in a patient who developed renal insufficiency (279). The distribution of monitoring guidelines in the area of Aberdeen, Scotland, led to an increase in the number of lithium patients who had at least once-yearly serum creatinine concentration measurements from 71% to 78%, still leaving 22% without adequate renal function monitoring (280).

To what extent long-term treatment with lithium impairs GFR is a matter of continued study (275). Lithium does not appear to impair GFR consistently, especially if correction is made for age-related changes in kidney function, although in one study there was an age-related reduction in 21% of 142 patients who had taken lithium for at least 15 years (281). There have been a few case reports of progressive renal insufficiency attributed to lithium, but it has not been possible to establish a cause-and-effect relation with absolute certainty.

In a review of the renal and metabolic complications of lithium, the example of a 78-year-old woman taking long-term lithium who had urinary incontinence, moderate renal insufficiency, a 5–7 litres 24-hour urine volume, and thyroid and parathyroid abnormalities was used to set the scene (221).

In a historical cohort study, changes in renal function in 86 patients taking lithium were evaluated first after a median treatment duration of 5.8 years and again after 16 years (282). Maximum plasma osmolality was reduced in nine of 63 patients in the initial study and in 24 of 63 at follow-up. Other findings included increased serum

© 2006 Elsevier BV All rights reserved.

creatinine (in one of 76 patients initially and eight of 76 at follow-up) and reduced GFR (in three of 29 patients initially and six of 29 at follow-up); only the latter of these changes was not significant. The authors noted that this progressive impairment in renal dysfunction was greater than expected for age and advised strict surveillance of renal function in patients taking long-term lithium.

In a retrospective review of 6514 renal biopsies, there were 24 patients with renal insufficiency who had taken lithium for a mean duration of 13.6 years (range 2–25 years); the histological changes included chronic tubulointerstitial nephropathy (100%), cortical and medullary tubular cysts (63%) or tubular dilatation (33%), global glomerulosclerosis (100%), and focal segmental glomerulosclerosis (50%) (283). Only two had a history of acute lithium toxicity. Clinical findings included proteinuria (42%), nephrotic syndrome (25%), nephrogenic diabetes insipidus (87%), and hypertension (33%). Despite lithium withdrawal, either seven (abstract) or eight (text) of nine patients with an initial serum creatinine of over 221 μmol/l (2.5 mg/dl) progressed to end-stage renal insufficiency, whereas this occurred in only one of ten with lower creatinine concentrations. The study design was such that the risk of renal insufficiency with long-term lithium therapy could not be established and the possibility of alternative causes could not be excluded.

Two studies in rats have potential implications for humans. In rats with mild to severe lithium-induced nephropathy, urine *N*-acetyl-β-D-glucosaminidase was an early indicator of renal insufficiency (284). Both ^{6}Li and ^{7}Li caused reduced urine concentrating ability and increased urine volume and renal tubular lesions, but ^{6}Li was more nephrotoxic (285). The authors suggested that eliminating ^{6}Li from pharmaceutical products might reduce nephrotoxicity (although ^{6}Li accounts for only about 7% of the lithium in such products).

Concentrating ability

Lithium often impairs renal concentrating ability, an effect that is related in part to both dosage and duration of treatment (273,275). While it is initially reversible on withdrawal, it may eventually become irreversible and indicative of structural tubular damage. Impaired concentration is of no clinical consequence in itself, but it may go hand in hand with polyuria (lithium-induced nephrogenic diabetes insipidus), which can sometimes be a social and occupational nuisance and can increase the risk of toxicity secondary to dehydration. These problems can be minimized if the maintenance serum concentration is low, but whether single daily dosing is kinder to the kidney has yet to be resolved. Since the defect is at the level of the kidney (both before and after the site of cyclic AMP generation and probably involving the water channel protein aquaporin-2, a vasopressin-regulated water channel protein (286)), vasopressin (ADH) is unlikely to be effective. A thiazide and/or potassium-sparing diuretic (especially amiloride) can reduce the urine volume, although serum lithium concentrations can rise at the same time. Avoiding hypokalemia is essential, but whether dietary potassium supplementation can also be helpful is not known. Inositol is no longer considered promising.

In a comparison of patients taking long-term lithium ($n = 10$) or short-term lithium ($n = 9$) and bipolar patients not taking lithium ($n = 10$), there was significantly lower creatinine clearance and renal concentrating ability in the long-term group (287).

Acute and chronic renal insufficiency

Renal insufficiency was attributed to lithium in a 40-year-old who had had nontoxic concentrations for 15 years (interstitial nephropathy on biopsy) (288) and in a 55-year-old woman who had taken lithium for 6 years (serum creatinine 141 μmol/l (289). A few patients develop progressive renal insufficiency that can best be attributed to lithium (275).

Chronic renal insufficiency (creatinine clearance under 80 ml/minute), for which there was no apparent alternative explanation, developed in 53 patients taking long-term lithium (mean 17.7 years); 7 required periodic dialysis (290).

After taking lithium for 6 years, a 55-year-old woman developed mild renal insufficiency (serum creatinine 1.6 mg/dl) and lithium was withdrawn (289).

Interstitial nephritis

Lithium-associated changes in kidney morphology include an acute, reversible, and possibly lithium-specific distal tubular lesion and a chronic, nonspecific, and tubulointerstitial nephritis (291). The differential diagnosis of the latter is extensive, and it is not clear if lithium is causative. Lithium received a brief mention in a review of tubulointerstitial nephritis (291).

- A 48-year-old man taking lithium and chlorprothixene had a creatinine clearance of 60 ml/minute and a renal biopsy showing chronic interstitial nephritis (292).
- Lithium-induced interstitial nephritis (serum creatinine 2.3 mg/dl) occurred in an 89-year-old woman who had taken lithium for 29 years (81).

Nephrogenic diabetes insipidus

There have been several case reports of lithium-related nephrogenic diabetes insipidus, sometimes associated with dehydration and lithium intoxication (216,293–296).

Nephrogenic diabetes insipidus has been specifically reviewed in the context of a case in which resolution did not occur despite withdrawal of lithium (297).

Nephrogenic diabetes insipidus secondary to lithium led to severe dehydration in two patients who required intravenous rehydration followed by a thiazide diuretic to reduce urine volume (294). One patient had persistent polyuria (6.7 l/day) 57 months after stopping lithium (211).

- A 77-year-old woman who had taken lithium for 10 years developed delirium, hypernatremia, prerenal azotemia, and a serum lithium concentration of 1.4 mmol/l; her condition was attributed to dehydration related to partial nephrogenic diabetes insipidus (293).
- Eight years after stopping lithium because of polydipsia and polyuria, a 55-year-old woman was hospitalized with lethargy, coma, and hypernatremia (sodium concentration 156 mmol/l) after her fluid intake had been restricted (297).

© 2006 Elsevier BV All rights reserved.

- A 30-year-old woman who became dehydrated secondary to lithium-induced nephrogenic diabetes insipidus developed a superior sagittal sinus thrombosis (251).
- A 78-year-old woman who had taken lithium for 25 years had hypotonic polyuria (4.7 l/day), mild renal insufficiency, and hyperparathyroidism attributed to lithium (221).
- Nephrogenic diabetes insipidus resulted in dehydration and hypernatremia in a 78-year-old man who had taken lithium for 30 years (216).
- Nephrogenic diabetes insipidus in a 63-year-old woman was treated successfully with lithium withdrawal and amiloride (298).

Nephrotic syndrome

Nephrotic syndrome (proteinuria, edema, hypoalbuminemia, hyperlipidemia) is a rare and idiosyncratic complication of lithium therapy; it usually resolves on withdrawal, and can recur on rechallenge (299,300). Lithium-associated nephrotic syndrome occurred in a 59-year-old woman with lithium toxicity (serum concentration 1.9 mmol/l) whose renal biopsy showed focal segmental glomerulosclerosis. Lithium withdrawal led to resolution of edema and marked improvement in proteinuria and albuminemia (300).

- An 83-year-old man developed nephrotic syndrome while taking lithium (301).
- An 11-year-old boy who had taken lithium for an unstated duration developed nephrotic syndrome with focal glomerulosclerosis which remitted fully after lithium was withdrawn (299).
- A 59-year-old woman with lithium-associated nephrotic syndrome (focal segmental glomerulosclerosis on biopsy) had resolution of edema and pleural effusions and marked improvement in albuminemia and proteinuria after withdrawal of lithium (300).

Renal tubular acidosis

Incomplete distal renal tubular acidosis has been attributed to lithium, but appears to be of no clinical significance (302).

Skin

In a review of skin reactions to mood stabilizers, a wide variety of reactions attributed to lithium were mentioned, but the authors did not critically evaluate the data on which the reports had been based (303).

In a review of acute skin reactions to psychotropic drugs, alopecia, psoriasiform, acneiform, and lichenoid eruptions, and drug-induced lupus were attributed to lithium, but critical comment was not provided (304).

There have been anecdotal reports of papular and nonpapular rashes, pityriasis versicolor, hidradenitis suppurativa, and nail dystrophy (305,306), although causal relations are difficult to establish.

In a review of lichenoid drug eruptions, lithium was implicated in one patient with ulcerative oral lesions and in another with ulcerative genital lesions (307).

- A 60-year-old man developed systemic swelling, redness, and pruritus 1 month after starting to take lithium; it was attributed to the drug based on positive patch and challenge tests (308).
- A 55-year-old man who had taken lithium and haloperidol for 11 years developed hyperkeratotic follicular papules on his scalp, extremities, and trunk, which on biopsy were suggestive of follicular mycoses fungoides (309). He also had a 1-year history of scalp, axillary, and pubic hair loss. Following replacement of lithium with valproate, his hair regrew and the papules cleared almost completely in 3 months.

A man and a woman developed vegetating plaques with peripheral pustules (halogenoderma) after taking lithium for 6 and 8 years respectively (310). No follow-up information was provided and it could not be established whether the lesions were caused by, worsened by, or unrelated to lithium.

Acne

Acne can occur or worsen during lithium treatment (311). In a comparison of 51 patients taking lithium with 57 patients taking other psychotropic drugs, there were secondary skin reactions in 45% of the former and 25 of the latter; while acne (33 versus 9%) and psoriasis (6 versus 0%) were more common in the lithium group, the only statistically significant association was acne in males (312).

- Six months after beginning lithium, a man in his late twenties developed severe truncal acne which worsened over 5 years, at which time lithium was withdrawn (313). Nevertheless, the lesions were still present 4 years later, leading to the conclusion that lithium had caused irreversible acne.

In this case, the association could have been coincidental.

Alopecia

Hair loss in psychopharmacology has been reviewed (314). It appears to be an uncommon and unpredictable adverse effect of lithium. Hypothyroidism is occasionally involved. Hair texture can also be altered (315).

- A 36-year-old woman had taken lithium for 4 months when her scalp hair became thinner and stopped growing. She continued to take lithium, and 2 months later was diagnosed and treated for hypothyroidism, after which her hair became curlier but did not grow longer or fuller.

Darier's disease

Darier's disease (follicular keratosis) can be exacerbated by lithium (316,317).

- In a woman who had had keratosis follicularis (Darier's disease) since she was 16, the condition worsened when she was given lithium at age 50 (and improved when she switched to valproate) (317).

However, despite reports that Darier's disease is worsened by lithium, a 52-year-old man noted no exacerbation despite taking lithium for many years (318).

Psoriasis

Psoriasis can occur or worsen during lithium treatment (311). Before psoriasis can be treated effectively, lithium may have to be withdrawn. In a comparison of 51 patients taking lithium with 57 patients taking other psychotropic drugs, there were secondary skin reactions in 45% of the

© 2006 Elsevier BV All rights reserved.

former and 25% of the latter; while acne (33 versus 9%) and psoriasis (6 versus 0%) were more common in the lithium group, the only statistically significant association was acne in males (312).

- A 42-year-old woman taking lithium developed psoriasis which resolved when the drug was withdrawn (319). Brief mention was made of two patients (age and sex unstated) taking lithium whose psoriasis improved with oral omega-3 fatty acids (320).
- Lithium worsened psoriasis in a 54-year-old woman; improvement followed withdrawal (321).

Hair, nails, sweat glands

Hair loss in psychopharmacology has been reviewed (314). It appears to be an uncommon and unpredictable adverse effect of lithium. Hypothyroidism is occasionally involved. Hair texture can also be altered (315).

- A 36-year-old woman had taken lithium for 4 months when her scalp hair became thinner and stopped growing. She continued to take lithium, and 2 months later was diagnosed and treated for hypothyroidism, after which her hair became curlier but did not grow longer or fuller.

Musculoskeletal

Despite lithium-induced increases in serum calcium and PTH concentrations, most recent studies have not shown a reduction in bone mineral density or increased risks of osteoporosis or bone fractures (322). In 26 patients who had taken lithium for at least 10 years, bone mineral density did not differ from controls (323).

A patient with a diffuse sensorimotor peripheral neuropathy also developed rhabdomyolysis during the acute episode in association with a serum lithium concentration of 3.1 mmol/l and a serum sodium of 163 mmol/l (114).

Sexual function

Despite occasional reports of reduced libido and erectile dysfunction, lithium causes little in the way of sexual dysfunction in men or women (324). In a brief review of the sexual adverse effects of psychotropic drugs, reduced libido and arousal with lithium were mentioned in passing, particularly when it was combined with other drugs (which, of course, makes it difficult to implicate lithium) (325).

Reproductive system

In a cross-sectional pilot study of 22 bipolar women taking lithium ($n = 10$), divalproex ($n = 10$), or both ($n = 10$), there was an increased number of ovarian follicles in one woman taking lithium, but no evidence of hormonal changes suggestive of polycystic ovary syndrome in any patient (326). The small sample size was a limiting factor.

When 22 women with bipolar disorder (10 taking lithium alone, 10 taking divalproex alone, and 2 taking both) were evaluated for polycystic ovary syndrome, none had typical hormonal screening abnormalities (326). Some type of menstrual dysfunction was present in all ten women taking lithium alone, but it predated use of the drug in all but one.

Compared with 13 women taking placebo, 10 women taking lithium carbonate 900 mg/day for one menstrual cycle had no significant alterations in reproductive hormone concentrations (327).

In an in vitro study, LY294002, a phosphatidylinositol-3-kinase inhibitor, overcame impaired human sperm motility induced by lithium chloride (328).

At blood concentrations within the human target range, oral lithium caused degenerative changes in testicular morphology in spotted munia (*Lonchura punctulata*), a seasonally breeding subtropical finch (329). Lithium at a serum concentration of about 0.6 mmol/l reduced sperm motility, number, and viability, and markedly altered testicular histopathology in *Viscacha*, a nocturnal rodent from the pampas of Argentina (330). How these findings might relate to effects in men is open to question.

Immunologic

Lithium is not an allergen. Allergic reactions that have been reported in patients taking lithium have been attributed to excipients in the formulation (331), as in a case of leukocytoclastic vasculitis (332).

In a brief report, evidence has been presented that short-term exposure to lithium (less than 2 months) caused alterations in the expression of histocompatibility antigens (333).

In 10 healthy volunteers, lithium caused increases in interleukin-4 and interleukin-10 concentrations and falls in interleukin-2 and interferon concentrations (334). In in vitro studies of monocytes from women with breast cancer, lithium chloride suppressed production of interleukin-8 and induced production of interleukin-15 (335,336). The clinical implications of these findings are unclear.

The immunomodulatory effects of lithium have been reviewed (337,338). Lithium

(a) stimulated the production of pro-inflammatory cytokines and negative immunoregulatory cytokines or proteins in nine healthy subjects (339);
(b) altered the expression of human leukocyte antigens (HLA) in 11 of 15 subjects (333);
(c) normalized manifestations of mild immune activation in 17 rapid cycling bipolar patients (340).

The clinical implications of these findings are unclear.

The very complex antiviral and immunomodulatory effects of lithium have been reviewed (341). In 15 inpatients, lithium produced changes in a number of histocompatibility antigens, but whether these have any clinical implications is unknown (342).

Death

The 1997 Annual Report of the American Association of Poison Control Centers Toxic Exposure Surveillance System listed nine lithium-associated deaths and provided some clinical details in seven cases, including serum concentrations of 2.4–7.8 mmol/l (343).

Long-Term Effects

Drug abuse

Lithium is not a drug of abuse or dependence, although when one bipolar alcohol abuser was prevented from drinking, he tried to get a "buzz" by increasing his lithium

© 2006 Elsevier BV All rights reserved.

dose to the point of toxicity (serum concentration 3.0 mmol/l) (344). The only other suggestion of abuse appeared in 1977 when passing mention to the "fairly recent (over the past 2 years or so) abuse of lithium" by poly-drug abusers (345).

Drug tolerance

In a review of whether the prophylactic efficacy of lithium was transient or persistent, the authors concluded that "the balance of evidence does not indicate a general loss of lithium efficacy" (346). A similar conclusion was reached in a study of 22 patients who had taken lithium for at least 20 years (347). There was no change in affective morbidity over the second 10 years compared with the first 10 years. However, individual exceptions could not be excluded.

Drug withdrawal

Three issues have been addressed:

(a) does rapid withdrawal increase recurrence risk?
(b) how common is post-withdrawal refractoriness to the reinstitution of lithium?
(c) does withdrawal increase the risk of thyrotoxicosis?

Recurrence risk

Abrupt or rapid withdrawal of lithium is not associated with a physical withdrawal reaction, but there does appear to be an increased risk of early recurrence of mania and depression compared with more gradual withdrawal (348,349), although this conclusion has been questioned (350). Data from Italy have suggested that gradual withdrawal of lithium (over 15–30 days) was associated with a markedly reduced risk of early recurrence of mania and depression and a much greater likelihood of prolonged stability compared with rapid discontinuation (over 1–14 days) (348). There was a marked increase in suicidal acts during the first year after lithium withdrawal; after that the risk returned to what it had been before the start of lithium treatment. The increased risk in the first year exceeded that expected from increased affective morbidity alone. There was a 1.95-fold greater risk, during this first year in those who discontinued lithium rapidly, although this was not statistically significant (351).

Of 30 patients with major depressive disorder who had responded to lithium augmentation for antidepressant-resistant depression, 15 were switched to placebo over 1–7 days (352). Two became manic, and it was suggested that lithium withdrawal may have uncovered latent bipolar disorder (353).

When 21 elderly patients with a major depressive episode who had responded to lithium augmentation had lithium withdrawn gradually (over 2–12 weeks), 9 relapsed but none became manic (354). Whether gradual withdrawal protected against withdrawal mania or whether there were no latent bipolar patients in the study is unknown.

A retrospective study of lithium withdrawal in pregnant and nonpregnant women showed similar rates and times of recurrence, including a higher risk of early occurrence with rapid withdrawal (1–14 days) versus gradual withdrawal (15–30 days) (355). How to balance the first trimester fetal risk of greater lithium exposure during gradual withdrawal with the greater maternal risk of potentially devastating relapse after rapid withdrawal remains a challenge.

There is a higher risk of postpartum recurrence of bipolar disorder in women who have discontinued lithium; the protective effect of restarting lithium late in pregnancy or soon after delivery has been emphasized (355).

The observation that rapid or abrupt lithium withdrawal might be associated with a more immediate or higher likelihood of recurrence has gathered further support from a reanalysis of data from a double-blind lithium maintenance study, in which the benefits of low serum concentrations (0.4–0.6 mmol/l) and standard serum concentrations (0.8–1.0 mmol/l) were compared (356). Recurrence rates were greater only in those whose concentrations were abruptly reduced from standard to low at the start of the study. The authors suggested that rapid dosage reduction, rather than a low maintenance concentration itself, accounted for their initial conclusion that standard concentrations were more effective than low concentrations.

Others have concluded that withdrawal mania is "a major and sinister complication of the everyday use of lithium" (357). Withdrawal of effective lithium therapy was associated with an increased risk of suicide and suicidal acts, especially during the first 12 months. Gradual withdrawal (over 15–30 days) was associated with half the rate of suicidal acts compared with more rapid withdrawal (strong trend toward statistical significance) (358).

Refractoriness to retreatment

In 28 patients who had responded to lithium treatment of mania or schizoaffective mania and who had recurrences after withdrawal, there were equally good responses to retreatment with lithium (359). These findings add to the evidence that lithium discontinuation-induced refractoriness is the exception rather than the rule. However, the issue of whether post-withdrawal refractoriness to reintroduction of lithium is a real phenomenon and, if so, how often it occurs continues to be debated (360). Three patients failed to respond to the reintroduction of lithium, despite having had sustained beneficial responses before withdrawal (361).

Risk of thyrotoxicosis

Lithium withdrawal may be associated with an outpouring of thyroid hormone in predisposed individuals; there have been reports of thyrotoxicosis (192) and a thyrotoxic crisis (192) after lithium withdrawal.

- A 37-year-old man who had taken lithium and sulpiride for 14 years and who was a long-time smoker without respiratory symptoms or a history of asthma had lithium withdrawn because of an asymptomatic bradycardia (44 beats/minute) (70). Six weeks later, he developed symptoms of asthma, including nocturnal cough, exertional wheezing, increased airway resistance, and a low FEV1, attributed to lithium withdrawal.

© 2006 Elsevier BV All rights reserved.

Mutagenicity

In 18 patients taking benzodiazepines and/or neuroleptic drugs, there were increased chromosomal aberrations and increased sister chromatid exchange, but there were no significant differences between this group and another group of 18 patients taking lithium in addition to benzodiazepines and/or antipsychotic drugs (362).

Tumorigenicity

There is no evidence that lithium causes or promotes the growth of tumors. Since tumors are not rare events over a lifetime, and since lithium is taken for long periods of time, any apparent association is likely to be coincidental.

Second-Generation Effects

Fertility

Intramuscular lithium chloride produced subtherapeutic blood concentrations (by human standards) in male rose-ringed parakeets, but significantly reduced testicular weight and caused widespread degenerative changes in the testes (363). Fertility was not assessed directly.

Pregnancy

The treatment of bipolar disorder during pregnancy and lactation has been reviewed, with reference to lithium-related maternal, fetal, and neonatal toxicity, morphological and behavioral teratogenicity, carcinogenicity and mutagenicity, and miscellaneous effects (364–376). Elsewhere, the effects of lithium, valproic acid, and carbamazepine during pregnancy (377) and drug-induced congenital defects (with only a brief mention of lithium) (378) have been reviewed. A more specific review dealing with the use of drugs during pregnancy in women with renal disease mentioned the need for lithium-dosage reduction in such cases (379).

Pregnancy in bipolar women was found to be a "risk-neutral" condition, in that it neither protected against nor increased episode risk in a comparison of 42 pregnant with 42 nonpregnant women who stopped lithium either rapidly (over 1–14 days) or gradually (over 15–30 days). Stopping lithium was not "risk-neutral," and the risk was especially high in those who stopped rapidly (380) (see also Withdrawal effects). These observations must be balanced against the low but real risk of teratogenesis from first trimester lithium exposure (381).

- A 37-year-old woman with severe bipolar disorder, who continued to take lithium throughout pregnancy, had a normal delivery (382).

Teratogenicity

While there is an increased risk of teratogenesis (particularly cardiovascular) from exposure to lithium in the first trimester, this risk has been overstated initially because of selection bias (380,381,383,384). Subsequently, case-control and cohort studies have substantially reduced, but not eliminated, such concerns (385). The risk of major malformations from exposure to lithium in the first trimester appears to be lower than from exposure to carbamazepine or valproate.

The teratogenic effects of lithium have been reviewed in several articles (364,365,386); two reviews of drug-related congenital malformation briefly mentioned lithium and cardiovascular teratogenesis (378,387). The authors concluded that while the risk of cardiovascular malformation is lower than once believed, it is nevertheless increased.

The cardiovascular teratogenicity of lithium has been summarized in a review of managing bipolar disorder during pregnancy and postpartum (371). While the risk of Ebstein's anomaly is increased, likely 10–20 times more than in the general population, the absolute risk (0.05–0.10%) is small. Fetal ultrasonography was advised at 18–20 weeks of gestation in cases of first trimester lithium exposure (386).

In a review of all pregnancies in Leiden in The Netherlands between 1994 and 2002, none of the 20 children of mothers who had taken lithium had major problems or congenital anomalies (388).

There is no evidence that children exposed to lithium during pregnancy who are born without malformations develop other than normally.

Fetotoxicity

Hypoglycemia, requiring temporary glucagon and glucose supplementation, was noted in a neonate whose mother had taken lithium throughout pregnancy (cord lithium concentration 1.73 mmol/l) (370).

Reports of fetal goiter and a variety of other lithium-related adverse events in newborns have been reviewed (386).

In 20 infants exposed to lithium during labor and delivery, there were higher rates of perinatal complications (65%) and special care nursery admissions (45%) than in nonexposed infants, although most complications were transient (389). An infant who died shortly after birth had oromandibular-limb hypogenesis spectrum which was speculatively attributed to lithium that the mother had taken during most of her pregnancy (390).

A neonate whose mother had taken lithium throughout pregnancy developed a supraventricular tachycardia (240/minute) which was treated successfully with adenosine (391). Another newborn girl exposed to lithium in utero had asymptomatic cardiomegaly that resolved by 1 month of age (226).

Transient polyuria in two newborns was attributed to the lithium their mothers had taken throughout pregnancy (370,391).

Neonates born to mothers taking lithium included a boy with a goiter and chemical hypothyroidism who required temporary treatment with oral thyroxine for 11 weeks (392), a girl with respiratory distress, cardiomegaly, hyperbilirubinemia, nephrogenic diabetes insipidus, and hypoglycemia who responded to various treatments and eventually remitted fully (370), and a preterm infant with a supraventricular tachycardia and temporary polyuria associated with 20% weight loss (391). The mother of the preterm infant developed polyhydramnios during pregnancy, which was attributed to lithium-induced fetal polyuria.

Lactation

Lithium concentrations in breast milk are about 40% of maternal serum concentrations, although the range is

© 2006 Elsevier BV All rights reserved.

wide (369,393,394). Because of this, breastfeeding is often discouraged (394), although the authors of a comprehensive review of the use of mood stabilizers during breastfeeding have pointed out that there is a paucity of information to support adverse effects of lithium in breastfeeding infants—one case of toxicity in a 2-month-old with an intercurrent infection (serum lithium 1.4 mmol/l) and one report of lethargy and cyanosis at days 5 and 6 (infant serum concentration 0.6 mmol/l on day 5) secondary to fetal and breast milk exposure. However, there have been only two reports of lithium toxicity attributed to breastfeeding (395,396). Others, however, have stated that "lithium should only be used with great caution . . ." (397); "[breastfeeding by women taking lithium] has been repeatedly discouraged in the literature" (398); ". . . it also seems unwise to expose infants unnecessarily to lithium" (394). Lithium has also been stated to be "an excellent example of a drug that requires monitoring and case-by-case assessment so that nursing mothers can be successfully treated" (393).

In a review of the use of psychotropic drugs during breastfeeding, it was briefly mentioned that lithium was not advisable, but was justified under certain circumstances (399). Lithium was also briefly discussed in a review of xenobiotics and breastfeeding (400).

Breast-milk lithium concentrations were measured in 11 women taking lithium carbonate 600–1,500 mg/day (401). Maternal serum concentrations were available in only three and infant concentrations in two. No infants had adverse effects that could be attributed to lithium, and the authors calculated that infant lithium exposure was low, leading them to challenge the general contraindication to breastfeeding under such circumstances.

In its 2001 Policy Statement, the American Academy of Pediatrics Committee on Drugs modified its earlier contraindication to lithium during breastfeeding by listing it with "drugs that have been associated with significant effects on some nursing infants, and should be given to nursing mothers with caution" (402).

The Motherisk Team in Toronto has recommended use of the Exposure Index (the maternal milk/plasma ratio times 100 divided by the infants' clearance in ml/kg/minute) to determine the advisability of breastfeeding when a mother is taking lithium (396). However, this approach does not seem very practical.

Given the extremely high risk of postpartum recurrence in bipolar patients, the issue is not whether the mother should take a mood stabilizer (she should), but whether the baby should be breastfed. A review of mood stabilizers during breastfeeding reaffirmed that there are only two reported cases of infant lithium toxicity associated with breastfeeding (one of which involved both fetal and breast milk exposure) (395). The following recommendations were made in the case of a mother taking lithium who chooses to breastfeed:

(a) educate her about the manifestations of toxicity;
(b) explain the risks of dehydration;
(c) consider partial or total formula supplements during episodes of illness or dehydration;
(d) suspend breastfeeding if toxicity is suspected;
(e) check infant and maternal serum lithium concentrations.

Susceptibility Factors

Age

Whether elderly patients taking lithium received proper monitoring was questioned in a case note audit of 91 patients, over 40% of whom had deviations from practice standards. These included absence of pretreatment laboratory tests, infrequent monitoring of serum lithium concentrations, lack of adequate adverse effects documentation, and the use of risky concomitant drugs (403). In a placebo-controlled study, there was poor tolerance of lithium augmentation of antidepressants in 76% (13/17) of elderly (mean age 70 years) patients at a mean serum concentration of 0.63 mmol/l, due to tremor and muscle twitches, cognitive disturbance, tiredness and sedation, and gastrointestinal upsets (404).

In a cross-sectional study of 12 octogenarians (average age 84 years) who had taken lithium for an average of 54 months (mean serum concentration 0.42 mmol/l), none became toxic and none had to stop treatment because of adverse effects. Transient renal function abnormalities were noted: one patient developed nephrogenic diabetes insipidus and one became hypothyroidic (405). For lithium therapy in very old people, the authors advised close monitoring in a specialized setting.

Renal disease

While there are no absolute contraindications to lithium, patients with advanced kidney disease or unstable fluid/electrolyte balance may be more safely treated with an alternative mood stabilizer, such as carbamazepine, valproate, lamotrigine, or olanzapine.

Other features of the patient

Factors that put patients at risk of lithium intoxication are those that increase intake (deliberately or accidentally), reduce excretion (kidney disease, dehydration, low sodium intake, drug interactions), or reduce body water (dehydration secondary to fluid restriction, vomiting, diarrhea, or polyuria) (45). Patients with lithium-induced polyuria are at a particular risk of toxicity if their ability to replace fluids is compromised (for example by anesthesia, over-sedation, CNS trauma).

Thyrotoxicosis was considered a possible contributor to lithium toxicity in two patients, possibly by increasing tubular lithium reabsorption through induction of the sodium-hydrogen antiporter (195).

Two patients developed lithium intoxication (serum concentrations 3.3 and 3.0 mmol/l) in association with poorly controlled diabetes mellitus, suggesting that the latter is a risk factor (227).

A review of the effects of obesity on drug pharmacokinetics briefly mentioned that the steady-state volume of distribution of lithium correlated with ideal body weight and fat-free mass but not with total body weight (406). Lithium clearance was greater in those with obesity than in lean controls, suggesting that obese patients may require larger maintenance doses to maintain target serum concentrations.

© 2006 Elsevier BV All rights reserved.

Drug Administration

Drug formulations

Despite the availability of modified-release lithium formulations for several decades, there continues to be a paucity of information about their efficacy and tolerability compared with less expensive immediate-release formulations (407).

Brain lithium concentrations (measured by magnetic resonance spectroscopy) after the use of a modified-release formulation (Lithobid SR) or an immediate-release formulation have been compared in a crossover design in 12 patients with bipolar disorder (408). There were higher brain concentrations with the modified-release formulation, but whether this has clinical implications requires further study.

Formulations of lithium carbonate tablets with various binding substances have been discussed (409).

A modified-release formulation (Carbolithium Once-A-Day) produced a reduction in peak/trough lithium ratio compared with a standard formulation (410), and an interim analysis of an open switch to the modified-release formulation suggested better tolerability and efficacy at 4 weeks ($n = 27$) and 6 weeks ($n = 15$) (411). A paucity of detail, however, prevents firm conclusions.

A modified-release multi-particulate lithium capsule has been described consisting of five copolymer-coated prolonged-release tablets and one standard tablet, each 6 mm in size (412).

Following an overdose with a sustained-release formulation (8,000 mg of Teralithe 400 LP), the appearance of clinical symptoms (vomiting and dizziness) was delayed for 35 hours, despite a serum lithium concentration of 2.38 mmol/l at 15 hours and 3.12 mmol/l at 25 hours (413).

A woman taking conventional lithium developed lithium toxicity after two doses of a homeopathic formulation, "Lithium carb. 30"; a paucity of detail allows no conclusions to be drawn from this observation (414).

Drug additives

Gelatin is derived from natural pork and beef products and is present in some lithium formulations. Since certain religions forbid the consumption of gelatin, knowing that it is present in Eskalith capsules and Eskalith CR and absent in Eskalith tablets (not available in the USA) and Lithobid SR might influence prescribing practices under certain circumstances (415). The same would apply to other lithium products.

Drug dosage regimens

In an open-label pilot study of rapid administration of slow-release lithium (20 mg/kg/day in two divided doses) for acute mania, five of 15 patients completed 10 days of treatment, seven improved sooner and were discharged, two withdrew because of adverse effects (bradycardia in one and tremor, fatigue, and diarrhea in the other; and one patient appears not to have been accounted for) two other patients also had asymptomatic bradycardia (74).

A review of loading strategies in acute mania included a section on lithium (416).

A small study of brain lithium concentrations measured by magnetic resonance spectroscopy showed higher brain:serum lithium concentration ratios in subjects taking a single daily dose ($n = 5$) than in those taking a twice-daily regimen ($n = 3$) (417). Even to speculate about the possible clinical implications of this finding would be premature.

Drug administration route

Intravenous

To determine the safety of using lithium chloride dilution to measure cardiac output, the pharmacokinetic and toxic effects of intravenous lithium chloride have been studied in six conscious healthy Standardbred horses (418). The mean peak serum concentration was 0.56 mmol/l. There were neither toxic effects nor significant changes in laboratory studies, electrocardiograms, or gastrointestinal motility. Three horses had increased urine output.

A similar study was performed in patients undergoing cardiac surgery and healthy volunteers; the highest dose of lithium chloride was 0.6 mmol given intravenously five times at 2-minute intervals (419). Unfortunately, no mention was made of tolerability or adverse effects.

When 10 volunteers were given 500 ml of a 0.1% lithium carbonate solution (13.5 mmol of lithium) intravenously over 1 hour, the peak serum concentration was 0.93 mmol/l, the elimination half-life was 7.8 hours, and there were no adverse effects (420).

Drug overdose

There are three forms of lithium overdose:

(a) acute (abrupt overdose in a drug-naïve person);
(b) chronic (gradual accumulation, reaching toxic concentrations);
(c) acute-on-chronic (abrupt overdose by a person already taking lithium), which can also be due to a drug interaction.

Thus, the term overdose (57,421,422) can be misleading, because poisoning can develop not only as a result of overdosage but also by a fall in lithium clearance. Of 205 cases of lithium poisoning reported to the Ontario Canada Regional Poison Information Centre in 1996, 12 were acute overdoses (someone else's tablets), 19 were chronic poisonings, and 174 were acute-on-chronic poisonings. Over 80% had no or minimal symptoms, two patients died, and one had persistent renal sequelae (423). A retrospective study of 97 cases of lithium poisoning treated at a regional center in Australia over 13 years found severe neurotoxicity in 28 cases (26 were cases of chronic and two of acute-on-chronic poisonings) (215). Risk factors were nephrogenic diabetes insipidus, older age, abnormal thyroid function, and impaired renal function.

Early signs of intoxication include ataxia, dysarthria, coarse tremor, weakness, and drowsiness. More advanced toxicity can involve progressively impaired consciousness, neuromuscular irritability (myoclonic jerks), seizures, cardiac dysrhythmias, and renal insufficiency. A reversible Creutzfeldt–Jakob-like syndrome has been described (103). The severity of intoxication depends on both the extent and duration of exposure to raised lithium concentrations, as well as idiosyncratic factors.

When the Marseilles Poisons Centre analysed information on lithium overdose between 1991 and 2000, in

© 2006 Elsevier BV All rights reserved.

addition to an unspecified number of suicide attempts and accidental poisonings in children, the next most frequent reports were prescription misinterpretation ($n = 43$), dehydration in the elderly ($n = 35$), renal insufficiency ($n = 15$), and diuretic interactions ($n = 8$) (424).

The 2000 Annual Report of the American Association of Poison Control Centers Toxic Exposure Surveillance System listed six lithium-related deaths (four cases of intentional suicide and two of therapeutic error) and two other deaths in which lithium was not listed as the primary cause (425). A total of 4663 lithium-related exposures were reported, in which death was the outcome in 13 and a major life-threatening event or cause of significant disability in 267.

A chart review of psychiatric hospital admissions between 1990 and 1996 showed that 6.8% of 2210 patients who were given lithium had at least one serum concentration of 1.5 mmol/l or over (43% of these were increased at admission) and of those only 28% had signs and symptoms of toxicity (278).

In another case, following an overdose with a modified-release formulation, the appearance of clinical symptoms (vomiting and dizziness) was delayed for 35 hours, despite a serum lithium concentration of 2.38 mmol/l at 15 hours and 3.12 mmol/l at 25 hours (413).

The distribution of clinical practice guidelines in Northeast Scotland had no impact on whether appropriate action was taken for high serum lithium concentrations (80% before the guidelines, 82% after). There was no significant difference in proper attention to high concentrations between those in primary care alone (77%) and those in shared care (85%) (280).

In a retrospective study of 114 patients admitted to a toxicological ICU with suspected lithium intoxication, 81 had definite intoxication; 78% were deliberate overdoses, and 22% were accidental (due, for example, to renal insufficiency, dehydration, drug interactions, poor compliance, drunkenness). Most were treated conservatively with gastric lavage and forced diuresis; hemodialysis was used only in 3–6%. Two of those who took a deliberate overdose and one of those who took an accidental overdose died (426).

Cases of lithium toxicity in a municipal hospital over a 10-year period involved eight women (mean age 66 years); neurological symptoms were the most common presentations (92). Two were acute overdoses and the rest were chronic intoxications. There was one death (group not specified).

Convincing manifestations of toxicity have occasionally been reported in patients with concentrations within the preferred target range (sometimes called "therapeutic" concentrations) (427). While full recovery is often the case, improvement may lag many days behind the fall in serum lithium concentration. Unfortunately, both persistent neurological damage (characteristically cerebellar) and deaths have occurred. The risk of an adverse outcome from toxicity can be minimized by prompt and comprehensive treatment (428–430), which should include gastric lavage and ion exchange resins for acute overdose, volume expansion to restore fluid and electrolyte balance and improve kidney function, and in severe cases, hemodialysis. Hemodiafiltration has also been used, and while this technique eliminates rebound increases in lithium concentration after dialysis, it is also less efficient than hemodialysis.

The 1998 Annual Report of the American Association of Poison Control Centers Toxic Exposure Surveillance System listed three lithium-related fatal exposures (two intentional and one a therapeutic error) and three other fatalities in which lithium was not the primary cause of death. A total of 4486 lithium-related poison exposure cases were reported, in which the outcome was death in five and a major life-threatening event or cause-significant residual disability in 212 (431).

A study of drug intoxication in the south of Brazil reported 2938 cases of drug ingestion, 25 of which involved lithium (including 14 suicide attempts) (432).

Of 133 patients 40 who had begun treatment with lithium died over an observation period of 16 years. Suicide (in 11 cases) was twice as common as in the general population, but it was more likely to occur in lithium noncompliant patients (433). It is important to be aware that suicidal behavior is actually reduced in patients who are compliant with long-term lithium therapy (although still somewhat higher than in the general population).

The 2001 Annual Report of the American Association of Poison Control Centers Toxic Exposure Surveillance System included six fatal exposures to lithium, three of which were intentional suicides. A total of 4607 exposures to lithium were reported, and death was the outcome in eight (434). A retrospective review of eight cases of lithium poisoning included one death (92).

Other reports include the following:

- A 71-year-old woman developed lithium toxicity (serum concentration 2.1 mmol/l) because of increased absorption of urinary lithium from the bowel following urinary diversion with ileal conduits for stress incontinence (435).
- A 29-year-old man who overdosed on 8,000 mg of a sustained-release lithium formulation had a serum concentration of 3.12 mmol/l 25 hours later, but only became symptomatic (with vomiting and dizziness) 35 hours later; his symptoms resolved with hemodialysis (413).
- A 72-year-old woman developed an acute confusional state, gait instability, and blepharospasm and apraxia of eyelid opening (24 hours serum concentration 1.8 mmol/l), which resolved after withdrawal (436).
- In the presence of high lithium concentrations (2.6 and 1.6 mmol/l), two patients had high amplitude of the primary complex in median nerve somatosensory evoked potentials, which normalized as concentrations fell (437).
- Two women with lithium toxicity and stormy clinical courses were found to be hyperthyroid (195).
- A 32-month-old boy developed lithium toxicity after ingesting a relative's tablets (438).
- A 46-year-old man became toxic after an initially unrecognized pontine hemorrhage (439).
- A 39-year-old woman took an overdose of lithium tablets, was given a single dose of haloperidol, and developed neuroleptic malignant syndrome (131).
- A 62-year-old woman developed persistent cerebellar and extrapyramidal sequelae at a serum concentration of 3.61 mmol/l (107).

© 2006 Elsevier BV All rights reserved.

Management

An all too common treatment error in the face of severe toxicity is "watchful waiting," during which the patient's condition is more likely to worsen than improve.

Hemodialysis (295,440,441), sometimes with additional continuous venovenous hemofiltration dialysis (442,443), continues to be described as a successful intervention for lithium poisoning. Peritoneal dialysis is a far less efficient way to clear lithium from the body. One patient treated in this way had permanent neurological abnormalities and another died; a third toxic patient who also had diabetic ketoacidosis died after treatment with hydration and insulin (444). On the other hand, a 51-year-old woman who took 50 slow-release lithium carbonate tablets (450 mg) had a serum lithium concentration of 10.6 mmol/l 13 hours later, but no evidence of neurotoxicity or nephrotoxicity. She was treated conservatively with intravenous fluids and recovered fully (445). Acute lithium overdose is often better tolerated than chronic intoxication.

Several reports have described severe poisoning responding to treatment that included hemodialysis or hemodiafiltration:

- A 57-year-old man, serum lithium concentration 3.1 mmol/l (446).
- A 52-year-old woman, serum lithium concentration 3.2 mmol/l (446).
- A 58-year-old woman, serum lithium concentration 4.0 mmol/l (76).
- A 52-year-old man, serum lithium concentration 4.6 mmol/l (77).
- A 40-year-old man, serum lithium concentration 5.4 mmol/l (447).
- A 39-year-old man, serum lithium concentration 5.9 mmol/l, with renal insufficiency associated with a polydrug overdose (448).

Some patients recovered from severe intoxication without dialysis:

- A 24-year-old woman, who survived a lithium carbonate overdose (5600 mg; serum concentration 4.0 mmol/l) with conservative treatment (449).
- A 55-year-old woman, serum lithium concentration 4.5 mmol/l, who was left with residual slurred speech (450).
- A 52-year-old woman, serum lithium concentration 10.6 mmol/l after an acute overdose (445).

In a small number of patients for whom hemodialysis was recommended, the outcomes were similar in those who were actually dialysed and those who were not, leading the authors to conclude that dialysis should be reserved for the more severe cases (451).

- Two teenagers with neurological toxicity (serum concentrations 5.4 mmol/l and 4.81 mmol/l) were treated successfully with hemodialysis followed by continuous venovenous hemofiltration, which prevented a post-dialysis rebound in serum lithium concentrations (442).
- An agitated, confused, disoriented 52-year-old woman who took an overdose of lithium recovered fully after high-volume continuous venovenous hemofiltration (452).

In an in vitro study, bentonite was an effective adsorbent of lithium; the authors suggested that it be explored as an overdose treatment (450).

Product monographs written by pharmaceutical companies and published by the Canadian Pharmacists Association in the Compendium of Pharmaceutical Specialties have been reviewed with regard to the adequacy of lithium overdose management advice (453). All five were rated "fair" for listing essential interventions for managing overdose but "poor" for warning against contraindicated interventions, and all contained misleading or dangerous information. All in all, a dismal showing.

Drug–Drug Interactions

General

Drug interactions with lithium have been reviewed (454–458); another review focused on interactions in the elderly (458). A review of drug interactions with lithium considered both pharmacokinetic interactions [for example diuretics, nonsteroidal anti-inflammatory drugs (NSAIDs)] and pharmacodynamic interactions (for example antipsychotic drugs, SSRIs) and summarized the most important ones in tabular form (454).

Alcohol

Excessive use of alcohol can interfere with adherence to lithium therapy. Alcohol does not itself appear to alter lithium pharmacokinetics (459).

Anesthetics

Sinus bradycardia (36/minute) developed in a 44-year-old woman taking lithium who received fentanyl and propofol (65).

Angiotensin converting enzyme (ACE) inhibitors

There have been scattered reports of lithium toxicity associated with the use of ACE inhibitors and attributed to reduced lithium excretion (458,460). This is not a predictable interaction.

- A 57-year-old man developed confusion, lethargy, ataxia, and myoclonus in conjunction with a serum lithium concentration of 2.6 mmol/l 4 days after starting to take captopril 50 mg tds (460).

In rats, ramipril reduced renal lithium clearance and increased fractional lithium reabsorption in association with decreased systolic blood pressure and decreased sodium excretion. These effects were attenuated by icatibant, a specific bradykinin B2 receptor antagonist (461).

Angiotensin-2 receptor antagonists

There have been occasional reports of lithium toxicity in patients taking angiotensin receptor blockers.

- A 58-year-old bipolar woman with previously stable therapeutic lithium concentrations was hospitalized with a 10-day history of confusion, disorientation, and agitation 8 weeks after starting to take candesartan 16 mg/day. Both drugs were withdrawn, the serum

© 2006 Elsevier BV All rights reserved.

lithium concentration fell from a high of 3.25 mmol/l, and she was again maintained on her usual therapeutic concentration of lithium (462).
- Lithium toxicity occurred in an elderly patient after the addition of losartan (463).
- A 51-year-old woman developed symptoms of lithium toxicity (serum concentration 1.4 mmol/l) while taking valsartan, which resolved when the valsartan was replaced by diltiazem (serum lithium concentration 0.8 mmol/l) (464).

Anticonvulsants

The combination of lithium with an anticonvulsant mood stabilizer can be beneficial. There have been reports of lithium/carbamazepine neurotoxicity, but on the other hand, lithium can benefit carbamazepine-induced leukopenia. There do not appear to be clinically important pharmacokinetic interactions of lithium with gabapentin (465), lamotrigine, valproate, or topiramate (although one subject did have a 70% fall in lithium concentration) (466). In a review of pharmacokinetic interactions between antiepileptic drugs and psychotropic drugs, there were no clinically significant interactions of lithium with gabapentin, lamotrigine, valproate, or topiramate, although serum lithium concentrations were reduced slightly by topiramate (466).

Although reviews have generally been favorable regarding the combination of lithium with anticonvulsants (466–468), there have been occasional anecdotal reports of possible interactions.

Carbamazepine

Lithium intoxication in a 33-year-old man was attributed to carbamazepine-induced renal insufficiency (469).

A case report suggested an association between lithium and carbamazepine in causing sinus node dysfunction (69).

Lamotrigine

In an open crossover study in 20 healthy men, the serum lithium concentration was slightly lower (0.65 versus 0.71 mmol/l) when lamotrigine 100 mg/day was added for 6 days, but the difference was not statistically significant (470).

Topiramate

In a 42-year-old woman, the serum lithium concentration rose from 0.5 to 1.4 mmol/l after she increased her topiramate dose from 500 to 800 mg/day (471). The authors speculated that topiramate had interfered with lithium excretion. On the other hand, in a crossover study in healthy volunteers, 6 days of treatment with topiramate did not significantly alter serum lithium concentrations; however, the maximum topiramate dose was only 200 mg/day and one subject did have about a 70% fall in lithium C_{max} and AUC (472).

Valproate

In rats, lithium pretreatment reduced the plasma half-life of valproate by 25% and increased urinary excretion of valproate glucuronide (473).

Antidepressants

Adverse interactions of lithium with tricyclic antidepressants, SSRIs, and monoamine oxidase inhibitors have been reviewed (474). In reviews of antidepressants and the serotonin syndrome, a possible contributory role has been suggested for lithium, based on case reports with tricyclic antidepressants, SSRIs, trazodone, and venlafaxine (139,475).

Lithium augmentation of antidepressants is a well-established treatment for resistant depression and is usually well tolerated with all classes of antidepressants, although there have been a few reports of the serotonin syndrome with SSRIs (474). It is possible that shared adverse effects could be magnified by combining lithium with various antidepressants (for example tremor, weight gain, gastrointestinal upset). Hyponatremia secondary to the SIADH has been linked to SSRIs and tricyclic antidepressants, especially in elderly patients, and could predispose to lithium toxicity.

In 28 of 75 patients taking lithium, 24-hour urine volumes were over 3 l/day, and this group had a greater duration of lithium exposure (6.0 versus 3.9 years) (476). There was no relation between polyuria and serum lithium concentrations or dosing regimens, but there was an association with the concurrent use of serotonergic antidepressants (odds ratio 4.25).

Amfebutamone

Although data have suggested that amfebutamone has approximately the same seizure potential as the tricyclic compounds (SEDA-8, 30) (477), the manufacturers reported an increased risk of seizures in patients taking over 600 mg/day in combination with lithium or antipsychotic drugs (SEDA-10, 20) (478).

- A 45-year-old man taking lithium, amfebutamone, and venlafaxine developed a prolonged seizure after ECT, thought to have been caused by a lowering of the seizure threshold due to amfebutamone (although a role of the other two drugs could not be excluded) (123).

Mirtazapine

In a placebo-controlled, crossover study in 12 healthy men, lithium and mirtazapine had no effect on the pharmacokinetics of each other and there was no difference in psychometric testing between the addition of lithium and placebo (479).

Nefazodone

In 12 healthy volunteers, there were no clinically significant alterations in blood concentrations of lithium or nefazodone and its metabolites when the drugs were coadministered (480). The addition of lithium for 6 weeks to nefazodone in 14 treatment-resistant patients produced no serious adverse effects and no dropouts (481). Lithium augmentation of nefazodone in 13 treatment-resistant depressed patients was associated with a variety of annoying adverse effects, but none led to treatment withdrawal (482).

SSRIs

The authors of a thorough literature review of 503 patients treated with lithium and SSRIs (483) acknowledged that

© 2006 Elsevier BV All rights reserved.

conclusions would be hedged with qualifications and equivocations but suggested the following:

(a) "when lithium is added to SSRIs new, nonserious, events occur frequently";
(b) "serotonin syndrome is associated with combined lithium/SSRI therapy, but is rare";
(c) "the evidence for the efficacy of lithium add-on to SSRIs is at best provisional".

There was no systematic evidence that SSRIs alter serum lithium concentrations.

Fluoxetine
Lithium toxicity has also been reported during co-administration with fluoxetine (484).

- After 4 hours of mild, intermittent, hot-weather work, a 45-year-old man taking fluoxetine and lithium (serum concentration not mentioned) collapsed, became comatose, convulsed, and was febrile (42°C); consciousness returned after 6 days but cerebellar symptoms and atrophy persisted (485). It was suggested that disruption of temperature regulation had been caused by a synergistic effect of the two drugs (although he had taken neither drug for 36 hours before the episode).

Fluvoxamine
Six patients taking a stable dose of fluvoxamine had a minor increase in plasma fluvoxamine concentration (from 67 to 76 ng/ml) 2 weeks after starting to take unspecified doses of lithium; this is unlikely to be of clinical significance (486).

Paroxetine
Serum lithium concentrations were unchanged when breakthrough depression was treated double blind by the addition of paroxetine (20–40 mg/day, $n = 19$) and the combination was generally well tolerated (487).

- A 20-year-old woman taking lithium and risperidone became catatonic 5–7 days after the addition of paroxetine, leading to speculation that this was due to an interaction between the three drugs (488). Of 17 patients 4 who had paroxetine added to lithium as an adjunctive antidepressant developed symptoms suggestive of emerging serotonin syndrome (for example nausea, vomiting, diarrhea, sweating, anxiety, oversleeping) (489).

Tricyclic antidepressants
Amitriptyline
Serum lithium concentrations were unchanged when breakthrough depression was treated double blind by the addition of amitriptyline (75–150 mg/day, $n = 23$) and the combination was generally well tolerated (487).

- A 34-year-old woman took amitriptyline 300 mg each night for several years (490). Six days after starting to take lithium 300 mg tds, she had several generalized tonic-clonic seizures. A second episode occurred on re-exposure to lithium.

Doxepin
An interaction of lithium with doxepin has been described.

- A 65-year-old man who took lithium and doxepin for 13 years presented with a 6-month history of myoclonic jerking of both arms, which resolved when both drugs were stopped (491).

Whether this represented a drug interaction or a single drug effect is unclear.

Six patients taking a stable dose of fluvoxamine had a minor increase in plasma fluvoxamine concentration (from 67 to 76 ng/ml) 2 weeks after starting to take unspecified doses of lithium; this is unlikely to be of clinical significance (486).

Antimicrobial drugs

Two reviews of drug interactions with antibiotics briefly and incompletely discussed lithium (492,493).

Quinolones

- A 56-year-old man with normal renal function and therapeutic lithium concentrations became toxic (serum concentration 2.53 mmol/l 24 hours after the last dose) with renal impairment (serum creatinine 141 μmol/l; 1.6 mg/dl) within days of starting levofloxacin. Both symptoms and laboratory abnormalities resolved with withdrawal of both lithium and levofloxacin (494).

Trimethoprim

- A 40-year-old woman developed nausea, malaise, impaired concentration, trembling, unsteadiness, diarrhea, and muscle spasm in association with a serum lithium concentration of 2.1 mmol/l while taking trimethoprim 300 mg/day (495).
- A 42-year-old woman developed symptoms of lithium toxicity and a raised serum concentration (2.1 mmol/l) while taking trimethoprim (495).

This interaction may be due to an amiloride-like diuretic effect of trimethoprim, causing lithium retention.

Antipsychotic drugs

In a discussion of drug interactions with antipsychotic drugs, the literature on lithium was reviewed (496). Caution was advised when lithium is combined with antipsychotic drugs, especially with high dosages of high-potency drugs. In a review of acute, life-threatening, drug-induced neurological syndromes, the controversy of whether lithium increases the risk of neuroleptic malignant syndrome was mentioned briefly (497) (see also Nervous system).

While it is still not clear whether there is a unique encephalopathic interaction of lithium with haloperidol, there is a consensus that the judicious use of these two drugs in combination should be safe. In general, caution is advised if lithium is combined with antipsychotic drugs, especially with high dosages of high-potency drugs (496). There have been reports of neuroleptic malignant syndrome in patients taking lithium plus antipsychotic drugs, but a causal relation has not been established (498).

The risk of extrapyramidal adverse effects may be increased when lithium is combined with antipsychotic drugs.

Erythrocyte/plasma lithium concentration ratios were lower in patients taking phenothiazines or haloperidol

© 2006 Elsevier BV All rights reserved.

than in those taking lithium alone (499,500), and the former group had a higher incidence of neurological and renal adverse effects (500).

- A 59-year-old man taking lithium, haloperidol, and carbamazepine had impaired memory, impaired attention, and an encephalopathy-like pattern on the electroencephalogram that normalized when haloperidol was withdrawn (501). Olanzapine 5 mg/day was added, and 3 weeks later he became disoriented. Surprisingly, the olanzapine was continued and he remained disoriented.

Amisulpride

In a placebo-controlled, parallel-design, double-blind study in 24 male volunteers, amisulpride 100 mg bd for 7 days did not alter lithium pharmacokinetics (502).

Amoxapine

The neuroleptic malignant syndrome occurred in a 63-year-old man when lithium was added to amoxapine (129).

Aripiprazole

A review of aripiprazole included a brief mention of no apparent pharmacokinetic interaction with lithium (503).

Chlorpromazine

The neuroleptic malignant syndrome in a 49-year-old man was attributed to a combination of lithium and chlorpromazine (504).

Clozapine

Seizures and other neurological effects have been described in a few cases when lithium was added to clozapine (505). Five treatment-resistant patients were treated successfully with a combination of clozapine and lithium with no clinically significant adverse events (506). However, a 59-year-old woman developed neurotoxic symptoms 3 days after lithium was added to clozapine; the symptoms resolved when both drugs were stopped and recurred with rechallenge (507).

- Multisystem organ failure occurred shortly after clozapine was added to a therapeutic dose of lithium in a 23-year-old woman (508). Improvement occurred when clozapine was stopped and the toxicity was attributed to clozapine.

Haloperidol

The neuroleptic malignant syndrome has been described when lithium was added to haloperidol (131).

- A pharmacodynamic drug interaction could not be excluded when a 60-year-old man developed delirium at a serum lithium concentration of 0.97 mmol/l when taking lithium and haloperidol (99).

Olanzapine

The neuroleptic malignant syndrome occurred when lithium was added to olanzapine (130).

- A 13-year-old boy with rhabdomyolysis ascribed to olanzapine was also taking lithium, so that a drug interaction could not be excluded (63).
- A 16-year-old boy developed the neuroleptic malignant syndrome when his olanzapine dose was increased (509).

In a double-blind study of 344 patients inadequately responsive to lithium or valproate who were randomized to olanzapine or lithium for 6 weeks, 21% gained weight on lithium plus olanzapine compared with 4.9% taking lithium and placebo (510). Whether lithium contributed to weight gain in the olanzapine group is unclear.

Quetiapine

In an open study in 10 patients, the addition of quetiapine 250 mg tds did not significantly alter serum lithium concentrations (511).

Risperidone

There were no changes in lithium pharmacokinetics when risperidone was substituted open-label for another neuroleptic drug in 13 patients (512). On the other hand, an 81-year-old man had an acute dystonic reaction 4 days after lithium was added to a regimen of risperidone, valproic acid, and benzatropine (513).

- A 17-year-old man had taken risperidone for 2 years without adverse effects, but 12 weeks after lithium was added, he reported prolonged erections (lasting 1–3 hours) 2–5 times daily; risperidone was tapered and withdrawn and the problem resolved (514).

In an in vitro study, there was no visible precipitate formation when lithium citrate syrup was mixed with risperidone solution (515).

Ziprasidone

In 34 healthy men, ziprasidone did not alter serum lithium concentrations or renal lithium clearance (516).

In a placebo-controlled, open-label study in 25 healthy subjects there were no changes in serum lithium concentration or renal lithium clearance when ziprasidone (40–80 mg/day) was added for 7 days (516).

Anxiolytics

There has been a well-documented case of profound hypothermia in a patient taking lithium and diazepam; it did not occur with either drug alone (517). Otherwise, benzodiazepines and lithium have proven to be compatible.

Calcitonin

Serum lithium concentration should be monitored at the start of calcitonin therapy.

Serum lithium concentrations fell significantly within 3 days of starting calcitonin in four women (518), due to increased renal clearance of lithium (518,519).

After they had received 100 units of salmon calcitonin subcutaneously for 3 days, four patients had a 30% mean reduction in serum lithium concentration, which was attributed to reduced absorption and/or increased renal excretion (518).

Calcium channel blockers

Lithium clearance is reduced by about 30% by nifedipine (520).

© 2006 Elsevier BV All rights reserved.

- A 30-year-old man required a reduction in lithium dosage from 1500 to 900 mg/day to maintain his serum lithium concentration in the target range shortly after he started to take nifedipine 60 mg/day (521).

There have been reports of neurotoxicity, bradycardia, and reduced lithium concentrations associated with verapamil (522–524).

Ciclosporin

In rats, lithium chloride alone had no significant renal toxicity, but when it was combined with ciclosporin, the renal toxicity of the latter was worsened (525). There was also a strong ciclosporin dose-dependent increase in serum lithium concentrations (tenfold at the highest dose).

Diuretics

The effects of lithium can be enhanced by sodium depletion caused by any diuretic.

Osmotic diuretics increase lithium clearance, the change being proportional to the increased rate of urine flow.

Acetazolamide increases lithium renal clearance (526).

Furosemide can cause lithium toxicity by inhibiting the tubular excretion of lithium ions (527).

Thiazide diuretics predictably reduce renal lithium clearance and increase the risk of toxicity (528). The same may be true of potassium-sparing diuretics, although this is less well established.

- A 26-year-old woman had been stable on lithium (serum concentration 1.1 mmol/l), but after taking herbal diuretics for 2–3 weeks developed manifestations of lithium toxicity (serum concentration 4.5 mmol/l) (529).

Laxatives

Certain bulk-forming laxatives, such as ispaghula husk and psyllium, can impair the absorption of lithium (530).

Mazindol

There have been reports of lithium toxicity associated with the use of the appetite suppressant mazindol.

- A woman stabilized on lithium developed toxic symptoms 3 days after starting the appetite suppressant mazindol. After 9 days, her serum lithium concentration was 3.2 mmol/l (531).
- A 58-year-old woman developed lithium toxicity (serum concentration 3.2 mmol/l) after the addition of mazindol (532).

Methyldopa

There have been occasional reports of neurotoxic symptoms when methyldopa was combined with lithium, both with and without an increase in serum lithium concentration (533).

Metronidazole

Nephrotoxicity due to lithium was reportedly exacerbated by metronidazole (534).

Neuromuscular blocking drugs

A few cases of potentiation of the neuromuscular blocking effects of suxamethonium and pancuronium were reported about 30 years ago (535,536) and have been reviewed (537).

Nonsteroidal anti-inflammatory drugs

The interaction of NSAIDs with lithium has been reviewed briefly (538). Most NSAIDs, although perhaps not all (for example aspirin, sulindac), if given in sufficient dosages for sufficient time, can increase the serum lithium concentration, sometimes to the point of toxicity (539).

A review of drug interactions with analgesics in the dental literature concluded that NSAIDs should be used briefly, if at all, in patients taking lithium, especially in the elderly (538).

A review of the psychiatric effects of NSAIDs included a section on renal function and lithium clearance (540).

COX-2 inhibitors

In one study, there was a mean increase of only 17% in healthy volunteers taking celecoxib 200 mg bd (541). When celecoxib was co-administered with lithium, celecoxib concentrations were higher for the first 6 hours after the dose but the AUC was not altered significantly (542). In another review it was mentioned that clinically significant interactions with lithium (increased lithium concentrations) had been identified, but no detail was presented (543). Both celecoxib and naproxen reduced the renal clearance of lithium (used as a measure of proximal tubular sodium reabsorption) (544).

There have been several reports of raised serum lithium concentrations and neurotoxic symptoms when COX-2 inhibitors (celecoxib and rofecoxib) were added to an otherwise stable lithium regimen (75)(545,546). In 10 patients taking lithium who took rofecoxib 50 mg/day for 5 days serum lithium concentrations increased in 9 and reached 1.26, 1.47, and 1.63 mmol/l in three (details not provided) (547).

- A 44-year-old woman taking nimesulide and ciprofloxacin developed lithium intoxication (serum concentration 3.23 mmol/l) complicated by renal insufficiency; the interaction was attributed to nimesulide (548).

All in all, the COX-2 inhibitors appear to be similar to non-selective NSAIDs with regard to the likelihood of increasing lithium concentrations.

Diclofenac

Diclofenac increases serum lithium concentrations by impairing its renal excretion (549).

- The serum lithium concentration nearly doubled to 1.3 mmol/l after a 57-year-old woman started to take diclofenac (550).

Ibuprofen

Ibuprofen can increase the serum lithium concentration (SEDA-13, 81) (551,552).

© 2006 Elsevier BV All rights reserved.

- A man of unspecified age developed cognitive impairment and a serum lithium concentration of 2.4 mmol/l after taking ibuprofen for shoulder pain (553).

Ketorolac
Reports of lithium neurotoxicity resulting from interaction with ketorolac have been published (SEDA-22, 117) (554). In five male volunteers, ketorolac 10 mg qds for 5 days increased lithium AUC by 24% and increased the incidence and severity of lithium-related adverse effects (555).

Mefenamic acid
Mefenamic acid may have interacted with lithium in a patient with reduced renal function (SEDA-13, 83) (556).

Meloxicam
In 16 subjects, meloxicam 15 mg increased plasma lithium concentrations by 21% (range −9 to 59%) and reduced total plasma lithium clearance by 18% (557).

Naproxen
There were no significant changes in serum lithium concentrations in 12 men taking over-the-counter doses of naproxen (220 mg tds) or paracetamol (650 mg qds) for 5 days (558).

Piroxicam
Piroxicam may interact with lithium (559–561).

Sulindac
Unlike other NSAIDs, sulindac supposedly does not interact with lithium (SEDA-10, 82). However, there has been a report of a toxic increase in serum lithium concentration in a 23-year-old man and a 27-year-old woman (to 2.0 and 1.7 mmol/l respectively) (562).

Tenidap
Tenidap increased serum lithium concentrations by reducing its renal clearance (563).

Plantago species

Plantago seeds are widely used as bulk laxatives under the names of psyllium (from *P. psyllium* or *P. indica*) and ispaghula (from *P. ovata*). The possibility that the intestinal absorption of lithium and other drugs may be inhibited should also be considered (534).

Sumatriptan

The 1996 Canadian Product Monograph for sumatriptan (but not the 1998 US package insert) listed the combination of sumatriptan and lithium as contraindicated. However, in a review, there was little evidence of a severe interaction of sumatriptan with lithium (564).

Xanthines

Renal lithium clearance is increased and serum lithium concentrations are reduced by theophylline and aminophylline (496).

Caffeine increases renal lithium clearance (565), and there have been case reports of caffeine withdrawal leading to increased serum lithium concentrations, assumed to be due to reduced renal lithium clearance (565).

Food–Drug Interactions

In 12 healthy men, there was no food-induced change in the systemic availability of a sustained-release lithium formulation that used an acrylic matrix of Eudragit RSPM as a sustaining agent (566).

Other Environmental Interactions

Dietary restriction of sodium causes lithium retention and an increased risk of toxicity. The same would be true of a diet that markedly restricted fluid intake. In brief, dietary extremes should be avoided.

Electroconvulsive therapy

While electroconvulsive therapy (ECT) does not alter serum lithium concentrations, the risk of prolonged confusion after ECT can be increased in the presence of lithium (567). However, there is no universal agreement about this association (568), and there may be circumstances that justify the continuation of lithium during ECT (569,570).

Interference with Diagnostic Tests

Serum lithium measurement

The inadvertent use of lithium heparin as an anticoagulant in the collection tube will lead to a spuriously high serum lithium determination.

- A 33-year-old woman was admitted to an intensive care unit after ingesting unknown quantities of a variety of medications, including lithium. She remained asymptomatic, except for drowsiness, despite serum lithium concentrations of 2.7, 3.1, 3.6, and 5.6 mmol/l. The latter concentration was discovered to be spuriously high when it was realized that blood had been collected in a lithium-heparin anticoagulant tube. When the test was repeated using the proper collection tube, the concentration was 2.2 mmol/l (571).
- A similar problem occurred in a 20-month-old with recurrent convulsions, who had an apparent serum lithium concentration of 3.2 mmol/l. The absence of lithium in the urine prompted further investigation and the source of the lithium was found to be from the use of a lithium-heparin collection tube (572).

Ageing of ion-selective electrodes has been reported to give inaccurately high serum lithium concentration. In one case, a concentration of 0.4 mmol/l was reported in a patient who was not taking lithium (573). The possibility that other substances could interfere with ion-selective electrode lithium analysis has been briefly reviewed (574).

Contamination of lithium heparin blood culture bottles with *Pseudomonas fluorescens* led to an outbreak of pseudobacteremia and the unnecessary treatment of a

© 2006 Elsevier BV All rights reserved.

number of children with antibiotics. Lithium had no direct role in this misadventure (575).

In blood samples from 32 subjects, TSH and free T4 concentrations were no different in collection tubes that contained a lithium heparin anticoagulant compared with dry tubes, but free T3 concentrations were significantly lower (576).

Lithium treatment of adolescents with bipolar disorder and secondary substance abuse improved both conditions (577). It was suggested, however, that lithium-induced polyuria may have diluted urine to the extent that false negative test results were obtained when screening for drugs of abuse (578). While the number of positive urine tests was actually higher (but not significantly so) in those with polyuria (579), there is still a possibility that lithium-induced diabetes insipidus could increase the frequency of false negative urine drug assays, because of urine dilution.

Diagnosis of Adverse Drug Reactions

When a split hair sample from a healthy volunteer was sent to six commercial laboratories in the USA for trace mineral analysis, marked variations in results were found (including lithium concentrations), leading to the conclusion that such analyses were unreliable (580).

Lobeline

General Information

Lobeline is derived from the plant *Lobelia inflata* (Indian tobacco). It is both an agonist and an antagonist at nicotinic receptors, although it is not structurally related to nicotine (1). It inhibits nicotine- and amphetamine-induced dopamine release by interacting with the tetrabenazine-binding site on the monoamine transporter. It also inhibits dopamine re-uptake. It has been used in smoking cessation, but is ineffective (2).

Nausea, vomiting, coughing, tremor, and dizziness have been noted with an average dose of lobeline. It can also cause nausea, sweating, and palpitation when inhaled from a cigarette.

Drug Administration

Drug overdose

Profuse sweating, paresis, tachycardia, hypotension, hypothermia, convulsions, coma, and death can occur in overdosage.

Local anesthetics

General Information

Local anesthetics typically contain a hydrophilic tertiary amine group linked to a lipophilic ester or amide. The most commonly used local anesthetics are either amides or esters, as shown in Table 1. The aminoester anesthetics cause adverse reactions more commonly than local anesthetics in the amide group. The esters are typically metabolized by de-esterification by esterases, such as pseudocholinesterase in the plasma or esterases in the liver. Metabolism occurs rapidly, and so these agents have short durations of action after they reach the systemic circulation. The amides are mainly metabolized in the

© 2006 Elsevier B.V. All rights reserved.

liver, by *N*-dealkylation followed by oxidation by CYP isozymes. Metabolism of these drugs occurs more slowly.

The potency of a local anesthetic depends on its lipophilicity (Table 2) (1); the more lipophilic, the more potent.

Local anesthetics can be classified as follows (2):

(a) low potency, short duration of action (for example procaine);
(b) intermediate potency, intermediate duration of action (for example lidocaine, prilocaine);
(c) high potency, long duration of action (for example ropivacaine).

Local anesthetics have a wide range of effects. They inhibit sodium, potassium, and calcium ion channels, alpha-adrenoceptors, and phosphatidylinositol signalling. They also cause dysrhythmias when injected directly into the brain. Local anesthetics are also mitochondrial poisons and impair oxidative phosphorylation.

The adverse effects of local anesthetics are well established (3,4). The safety advantages claimed for newer agents have to be treated with much reserve. With increasing experience, discovery of optimal doses, and understanding of potency differences, the tolerability of newer agents is often found to be similar to that of substances that have been used for much longer.

The adverse effects of local anesthetics fall broadly into four groups (5):

(a) Effects attributable to the technique itself rather than to the agent used, for example needle damage to a vessel or nerve.
(b) Local and regional effects of the drug, which may be related to its anesthetic activity or a consequence of irritation or allergy.
(c) Systemic effects, most usually seen if the agent is inadvertently injected into a blood vessel in sufficient quantities.
(d) Effects of additives, notably vasoconstrictors to prolong the local effect, hyaluronidase to promote penetration, and preservatives to prevent bacterial contamination or degradation (6).

The possibility must always be anticipated that when a local anesthetic is administered, some of it will reach organs or tissues for which it was not originally destined, either because it has been incorrectly administered or because some anatomical or other idiosyncrasy of the patient has resulted in unexpected diffusion or leakage of the agent beyond its intended location. The main problems that result relate either to effects on the nervous system or adverse effects resulting from unintended entry into the general circulation. Very occasionally, infections are transmitted (SEDA-16, 129).

Systemic toxicity is most likely to occur if a local anesthetic is accidentally injected into a vessel in sufficient quantity (7). Even with appropriate local administration, there is inevitably some diffusion of the local anesthetic into the body from the site at which it is applied, varying with local blood flow and the technique; intercostal block, for example, rapidly produces high plasma concentrations, while subcutaneous infiltration leads to much lower concentrations more slowly. The amount of local anesthetic used is another contributory factor.

Although the effects are usually mild, systemic toxicity related to local anesthesia can be fatal: in one study of 53 deaths after the use of local anesthetics there was no evidence of allergy (SED-11, 217) (8). In preventing systemic complications from local anesthesia, such measures as close monitoring of patients, the administration of intravenous fluids before major regional block, the immediate availability of drugs and equipment to treat systemic toxicity, preoxygenation, injection of a test dose, and incremental dosing are important measures.

Some distinction must be made between the main groups of local anesthetics as to the frequency of complications. Hypersensitivity reactions, for example, are relatively less common with the aminoamides, such as bupivacaine, cinchocaine, etidocaine, lidocaine, mepivacaine, prilocaine, and ropivacaine, than with the aminoesters. However, the systemic toxic effects of individual local anesthetics differ: bupivacaine, cinchocaine, and tetracaine are the most toxic. Furthermore, the individual characteristics of the patient (for example age, sex, body weight, and cardiac, renal, and hepatic function) are important (SEDA-17, 134).

The early recognition of complications can be very difficult if a local anesthetic is administered during

Table 1 Structural groups of some commonly used local anesthetics (durations of action in parentheses)

Amides
Articaine
Bupivacaine (2–8 hours)
Cinchocaine (2–3 hours)
Etidocaine (2–6 hours)
Levobupivacaine
Lidocaine (1–2 hours)
Mepivacaine (1.5–3 hours)
Prilocaine (1–2 hours)
Ropivacaine (4–6 hours)
Esters of benzoic acid
Cocaine
Esters of meta-aminobenzoic acid
Proxymetacaine
Esters of para-aminobenzoic acid
Benzocaine
Chloroprocaine
Oxybuprocaine
Procaine (30–45 minutes)
Propoxycaine
Tetracaine

Table 2 Partition coefficients (*n*-octanol/water) of some local anesthetics

Local anesthetic	Partition coefficient
Benzocaine	1.44
Procaine	2.51
Mepivacaine	2.69
Prilocaine	2.73
Lidocaine	3.40
Bupivacaine	4.05
Etidocaine	4.19
Tetracaine	4.32
Oxybuprocaine	4.38

general anesthesia, to prevent postoperative pain, since unconscious or sedated patients will not recognize the early signs of problems, such as traumatic paresthesia (9).

In a general review of the systemic toxicity of local anesthetics interesting trends were identified (10). The incidence of systemic toxicity has been falling during the last 20 years, most probably due to increased awareness of the potential cardiotoxicity of long-acting aminoamide local anesthetics. Steps to guard against unintentional intravascular injection have been increasingly used. These include aspiration, incremental injection, dose limitation, and the use of test doses. The most studied test dose is adrenaline 15 micrograms, which reliably produces a tachycardia in healthy subjects within 20 seconds of intravascular injection. Specifically, the incidence of cardiotoxicity has also fallen; several case series of systemic toxicity have been published in recent years, reporting only nervous system toxicity but no cases of cardiotoxicity. This contradicts previous estimates of the risk of cardiotoxicity, which suggested an incidence of 10% of all systemic toxicity reactions, reconfirming the impression of increased carefulness of healthcare professionals.

Organs and Systems

Cardiovascular

Cardiovascular complications are not uncommon in the course of local anesthesia; however, most changes are moderate, involving mild peripheral vasodilatation and reduced cardiac output with a change in heart rate.

Local anesthetics reduce myocardial contractility and rate of conduction (11). They also cause direct vasoconstriction or vasodilatation of vascular smooth muscle (12) and central stimulation of the autonomic nervous system (13).

Cardiac arrest and marked myocardial depression, in which hypoxia plays a critical role, have been reported.

Cardiovascular collapse can be severe and refractory to treatment; most fatal cases involve bupivacaine.

The cardiovascular system is more resistant to the toxic effects of local anesthetics than the nervous system. Mild circulatory depression can precede nervous system toxicity, but seizures are more likely to occur before circulatory collapse. The intravenous dose of lidocaine required to produce cardiovascular collapse is seven times that which causes seizures. The safety margin for racemic bupivacaine is much lower. The stereospecific levorotatory isomers levobupivacaine and ropivacaine are less cardiotoxic, and have a higher safety margin than bupivacaine, but not lidocaine; in the case of ropivacaine this may be at the expense of reduced anesthetic potency (14,15). Toxicity from anesthetic combinations is additive.

A comparison of the cardiotoxicity of the two stereoisomers of ropivacaine and bupivacaine on the isolated heart showed that both compounds had negative inotropic and negative chronotropic effects irrespective of the stereoisomer used, but bupivacaine had greater effects compared with ropivacaine at equal concentrations (16). Atrioventricular conduction time showed stereoselectivity for bupivacaine at clinical concentrations; the R(+) isomer had a greater effect in lengthening atrioventricular conduction time, but the less fat-soluble ropivacaine only showed stereoselectivity at concentrations far greater than those used clinically. Similar to the negative inotropic and chronotropic effects, bupivacaine produced greater effects on atrioventricular conduction time than ropivacaine at equal concentrations. This important study has confirmed speculations that not only the stereospecificity of ropivacaine but also its physicochemical properties contribute to its cardiac safety.

Current concepts of resuscitation after local anesthetic cardiotoxicity have been reviewed (17). Vasopressin may be a logical vasopressor in the setting of hypotension, rather than adrenaline, in view of the dysrhythmogenic potential of the latter. Amiodarone is probably of use in the treatment of dysrhythmias. Calcium channel blockers, phenytoin, and bretyllium should be avoided. In terms of new modes of therapy targeted at the specific action of local anesthetics, lipid infusions, propofol, and insulin/glucose/potassium infusions may all have a role, but further research is necessary.

Nervous system

Central nervous system effects of low concentrations of local anesthetics are mainly sedation and confusion; high concentrations are more likely to cause seizures (18).

The first sign of systemic toxicity can be mild sedation or diminished alertness. Dizziness, tinnitus, metallic tastes, muscle twitching, perioral numbness, visual disturbances, disorientation, and light-headedness are the most frequently reported adverse nervous system effects (19).

However, as the blood concentrations achieved are sometimes higher than one would anticipate, toxicity can occasionally prove much more severe than expected, for example frank convulsions, sometimes progressing to respiratory arrest and loss of consciousness. The management of local anesthetic-induced convulsions has been reviewed (20).

Local anesthetic-induced seizures have been reported more often with bupivacaine, particularly in combination with chloroprocaine (SEDA-20, 123). Ropivacaine-induced seizures have also been reported (21,22).

Severe seizures have been reported after topical use of TAC, a combination of tetracaine, adrenaline, and cocaine, in children (23,24).

Endocrine

Local anesthetics generally have only slight endocrine and metabolic adverse effects, without clinical repercussions.

Hematologic

Methemoglobinemia has been reported with benzocaine, Cetacaine (a mixture of benzocaine, butyl aminobenzoate, and tetracaine), cocaine, lidocaine, novocaine, and prilocaine. Acquired methemoglobinemia can result from exposure to chemicals that contain an aniline group, such as benzocaine and procaine, or to those that are transformed to metabolites that contain an aniline group, such as lidocaine and prilocaine. Toxic blood concentrations of local anesthetics, aberrant hemoglobin, and NADH-methemoglobin reductase deficiency are critical

© 2006 Elsevier B.V. All rights reserved.

factors that favor the onset of methemoglobinemia. However, methemoglobinemia can occur even in the absence of such risk factors. Young children are most likely to experience clinical effects, but topical use (for example of Cetacaine) has very occasionally caused severe problems even in adults (25). Intravenous methylthioninium chloride (methylene blue) 1–2 mg/kg and oxygen are usually recommended when methemoglobinemia exceeds 30%.

There have again been several reports of methemoglobinemia following topical anesthesia (26,27). Most have been associated with topical benzocaine, and the patients recovered fully after the administration of methylthioninium chloride.

- A neonate born at 24 weeks had a rectal biopsy under general anesthesia and was intubated with an endotracheal tube that had been lubricated with lidocaine jelly 1 g and after the biopsy a rectal pack soaked in about 1 g of benzocaine lubricant; 30 minutes after surgery she developed cyanosis, with a methemoglobin concentration of 45% (28).

The authors postulated that either local anesthetic could have been responsible, but that the oxidant effects of the two agents may have been additive. They highlighted the need for awareness of seemingly minor uses of medications in neonates.

Liver

Reduced hepatic clearance, as well as relative overdosage, of local anesthetics can lead to systemic toxicity, as illustrated by three patients who underwent topicalization of the oropharynx for transesophageal echocardiography with lidocaine 10% spray or 2% viscous and subsequently became confused and drowsy (SEDA-21, 135).

Immunologic

Systemic hypersensitivity reactions are not a frequent problem in local anesthesia. Systemic toxicity or allergy to additives (hyaluronidase, bisulfate, parabens) has sometimes been mistakenly classified as hypersensitivity to local anesthetics (SEDA-17, 135) (29). Well-documented case reports are very few, relating particularly to the older aminoesters; this appears to be because these agents have the highly antigenic para-aminobenzoic acid as a metabolite (SEDA-l3, 98). The incidence of true allergy is actually very low, probably less than 1% of all the adverse effects attributable to these substances (SEDA-20, 123).

Allergic reactions to aminoamide local anesthetics are unusual, but type I hypersensitivity reactions are described, and life-threatening anaphylaxis can rarely occur (SEDA-21, 136) (SEDA-22, 134). Cross-reaction between amides also occurs, for example articaine, bupivacaine, lidocaine, and prilocaine (SEDA-22, 134).

Type IV delayed hypersensitivity reactions are uncommon, but allergic contact dermatitis and localized erythema and blistering have been reported (SEDA-21, 136).

- A 58-year-old man with a urological stoma used a catheter lubricated with Braum Monodose ointment (30). After almost 2 years, he developed severe pruritus and squamous erythematous plaques in the peristomal skin. Patch tests were positive with the lubricant ointment and one of its constituents, tetracaine.

Both anaphylactoid reactions and bronchospasm have occasionally been reported, although the latter may have been due to sympathetic nervous blockade leading to unopposed parasympathetic effects (SEDA-18, 143) (31).

Contact hypersensitivity also occurs. Benzocaine is a potent skin sensitizer, and several cases of contact dermatitis to lidocaine have been reported. In many cases there is no cross-reactivity between different local anesthetics.

- A 79-year-old man developed a weeping dermatitis of the perianal skin, buttocks, and proximal thighs (32). In the previous 3 weeks, he had used Proctosedyl cream which contains cinchocaine (dibucaine). Patch tests were positive with Proctosedyl cream and 5% cinchocaine in petrolatum, while benzocaine, lidocaine, and clioquinol were negative.
- A 62-year-old woman had a systemic contact dermatitis several days after topical administration of DoloPosterine ointment for hemorrhoids (33). She had erythematous vesicular lesions on her perianal area and an edematous erythematous rash on her upper thighs, elbow flexures, axillae, and face. Patch tests with the ointment and its constituents were positive with DoloPosterine and dibucaine 5% in petrolatum; patch tests with benzocaine and other local anesthetics were negative.
- A 71-year-old Japanese man developed an itchy erythematous papular eruption after using an over-the-counter medicament for skin wounds (Makiron) for 1 month (34). Patch tests with the constituents showed positive reactions to dl-chlorphenamine maleate and cinchocaine hydrochloride (both 1% in petrolatum). Patch tests with lidocaine hydrochloride and mepivacaine hydrochloride showed no cross-sensitization.

However, some sensitized patients do cross-react with various related local anesthetic agents or chemically similar compounds, including some muscle relaxants (SEDA-15, 117). On the other hand, cross-reactivity between aminoesters and aminoamides seems unlikely and does not appear to be on record. Although cross-reactivity between amide local anesthetics is uncommon, it has been reported.

- A 26-year-old woman, 6 months pregnant, developed local redness and itching after exposure to topical agents containing lidocaine, and a further similar reaction to bupivacaine, also with swelling, 8 hours after injection (35). She had a history of anaphylaxis to an unidentified agent, and a patch test was performed using mepivacaine, lidocaine, and ropivacaine; all resulted in strong reactions after 48 hours, while patch testing was negative with chloroprocaine. She subsequently had a cesarean section under spinal anesthesia with chloroprocaine with no adverse reaction.
- A 39-year-old man was investigated for three episodes of facial swelling following dental procedures over 2 years. The swelling always occurred on the same side as the dental procedure and about 12 hours after it, took a couple of days to resolve, did not respond to

© 2006 Elsevier B.V. All rights reserved.

antihistamines, and was not associated with a rash, laryngeal edema, or bronchospasm. He was admitted twice and treated with intravenous antibiotics for cellulitis. He also reported a history of a rash after penicillin but no previous reactions to local anesthetics. All blood tests, including full blood count, C3 and C4 concentrations, and C1 esterase inhibitor activity and function were normal; an antinuclear antibody test was negative, IgE concentrations were not raised, and latex-specific IgE was not detected. Skin prick, intradermal, and subcutaneous tests were carried out with isotonic saline, lidocaine, prilocaine, and procaine; these did not show immediate reactions, but 2 days later a wheal appeared at the lidocaine site. There was a less intense reaction with prilocaine and none with saline or procaine.

The authors concluded that sensitization to lidocaine must have taken place during previous procedures and that cross-reactivity with another amide type local anesthetic, prilocaine, had also occurred.

Contact dermatitis was reported in three hemodialysis patients who used Emla cream repeatedly as analgesia for AV fistula cannulation (SEDA-21, 136).

Twenty patients with a prior history of generalized and/or local skin reactions after local anesthetics were examined with intradermal testing and patch testing; in 10 of them a lymphocyte transformation test was performed to investigate whether they had T cell sensitization to local anesthetics, which might have been responsible for their symptoms (36). Only two had a positive intradermal test, whereas six had a positive patch test and six had a positive lymphocyte transformation test, suggesting that allergic skin symptoms could be mediated by T cells in some patients who do not have evidence of an IgE-mediated reaction.

- A 20-year-old woman, who had had eight previous uneventful exposures to local anesthetics for dental procedures, received an injection of 1% lidocaine for treatment of an in-growing toenail; 12 hours later she developed widespread urticaria lasting a week accompanied by bronchospasm and abdominal discomfort (37). A skin prick test gave a slight positive reaction, and later a positive intradermal injection provided evidence of a true type I hypersensitivity reaction. Following negative skin and intradermal tests with prilocaine, subsequent dental treatment 12 months later was performed using prilocaine with no untoward effects.
- A 70-year-old woman received a peribulbar block using 10 ml of 2% lidocaine, 0.75% bupivacaine (50/50), and hyaluronidase 500 units for cataract extraction; 12 hours later she awoke with a painful, swollen eye (38). There was marked swelling, erythema, tenderness of the eyelids, and a tense orbit, with reduced visual acuity, marked restriction of eye movements, and conjunctival chemosis. There was no hematoma or evidence of infection, but allergy could not be ruled out. Four days later, she received tetracaine eye drops and local infiltration with lidocaine for further suturing and again developed similar symptoms and signs in that eye, with swelling extending to the cheek; follow-up showed persistent ocular dysfunction.

The second patient had had previous exposure to prilocaine, lidocaine, and bupivacaine without problems. The author proposed a diagnosis of lidocaine allergy, although hyaluronidase as the antigen could not be excluded.

- A 23-year-old woman developed an allergic contact dermatitis after applying an over-the-counter proprietary antipruritic jelly containing 0.1% cinchocaine chloride, and a "caine" mixture (5% benzocaine, 1% cinchocaine hydrochloride, 1% procaine hydrochloride) (39). She had positive patch testing to both components.

Allergic reactions attributed to local anesthetics can be due to excipients in the formulation (40).

- A 69-year-old woman developed hypesthesia of all four limbs lasting several hours after three gastroscopies using lidocaine jelly; although the symptom was not typical of an allergic reaction, intradermal tests and nasal provocation tests were performed. The intradermal tests were negative, but the nasal provocation tests were positive for carboxymethylcellulose, a suspending agent used in lidocaine jelly; this caused ipsilateral nasal congestion and dysesthesia of the tongue and the ipsilateral temporal region within 30 minutes. A drug-induced lymphocyte stimulation test was also positive for carboxymethylcellulose.

Hypersensitivity to carboxymethylcellulose may have contributed to this patient's unusual symptoms.

The use of skin testing to identify a causative drug allergen has been repeatedly advocated by several groups, but their advice has not always been followed. Intradermal testing can be helpful in distinguishing between safe and unsafe agents in patients with a history of allergy to local anesthesia.

Various types of immunodepressant effects of local anesthetics can be detected by laboratory testing, although they may have no clinical significance. Lidocaine dose-dependently inhibits EA rosetting by human lymphocytes. In vitro depression of human leukocyte random motility and phagocytosis has also been reported (SED-11, 220) (41).

When injected into the skin, local anesthetics often cause pseudo-allergic reactions, with similar symptoms to immediate type allergy (42). However, true immediate hypersensitivity to local anesthetics is extremely rare.

- A 50-year-old man had local infiltrations a few days after an injection of lidocaine and dexamethasone (43). Prick and intradermal tests were negative after 20 minutes. However, lidocaine produced a positive patch test after 2 days, with erythema and papules.

Second-Generation Effects

Fertility

The use of in vitro fertilization has raised the question of whether the use of local anesthetics during oocyte removal is innocuous or not. Pharmacological concentrations of anesthetic agents are found in follicular fluid (44). No clinical effects have been noted, but knowledge of the behavioral effects of lidocaine on offspring in rats must cause some concern (SEDA-15, 117).

© 2006 Elsevier B.V. All rights reserved.

Pregnancy

It seems most unlikely that local anesthetics have any adverse effect on the fetus when used during pregnancy (45). However, the risks of local anesthetic toxicity may be greater in pregnancy because an increase in the unbound fraction of local anesthetic and physiological changes increase the transfer of local anesthetic into the central nervous system. The authors of a report of systemic symptoms in a pregnant patient suggested the precautionary use of a lower dose of local anesthetic than usual and a longer tourniquet time, to increase the safety of this technique during pregnancy (46).

Susceptibility Factors

Age

Children

Neonates and infants absorb local anesthetics more rapidly after topical application to the airways, and peak plasma concentrations can be reached within 1 minute of application. In the first few months of life they have a larger volume of distribution, reduced hepatic clearance, and lower concentrations of albumin and alpha$_1$-acid glycoprotein (47).

Drug Administration

Drug administration route

Local anesthetics can be given by many different routes, each of which has its own particular adverse effects. In this section the following routes of administration are covered:

- Brachial plexus anesthesia
- Buccal anesthesia
- Caudal anesthesia
- Cervical plexus anesthesia
- Dental anesthesia
- Digital anesthesia
- Epidural anesthesia
- Intercostal nerve anesthesia
- Interpleural anesthesia
- Intra-articular anesthesia
- Intradermal anesthesia
- Intrathecal (spinal) anesthesia
- Intravenous regional anesthesia
- Laryngeal anesthesia
- Lumbar plexus anesthesia
- Nasal anesthesia
- Neck anesthesia
- Obstetric anesthesia
- Ocular anesthesia
- Oropharyngeal anesthesia
- Otic anesthesia
- Paravertebral anesthesia
- Perianal anesthesia
- Peritonsillar anesthesia
- Respiratory anesthesia
- Sciatic nerve anesthesia
- Stellate ganglion anesthesia
- Subcutaneous anesthesia
- Submucosal anesthesia
- Urinary tract anesthesia

Brachial plexus anesthesia

The systemic complications of brachial plexus anesthesia are similar to those seen with others if sufficient drug enters the circulation. Injections outside the axillary sheath result in higher plasma concentrations of local anesthetic than intrasheath injection (SEDA-22, 135). However, several other complications are specific to this route. Local complications include hematoma and infection. Horner's syndrome, temporary phrenic nerve blockade, and peripheral neuropathies have been reported (SEDA-18, 142).

The adverse effects of ropivacaine and bupivacaine have been compared in 104 patients who received 30 ml of either 0.75% ropivacaine or 0.5% bupivacaine for subclavian perivascular brachial plexus block (48). There were similar incidences of nausea (33 and 28%), vomiting (8 and 14%), and Horner's syndrome (8 and 6%), and one patient who received bupivacaine developed a tonic-clonic generalized seizure 8 minutes after injection, suggestive of systemic toxicity.

Patient-controlled interscalene analgesia (PCIA) with ropivacaine 0.2% has been compared with patient-controlled intravenous analgesia (PCIVA) with an opioid in 35 patients after elective major shoulder surgery (49). Although hemidiaphragmatic excursion on the non-operated side was increased in the PCIA group 24 and 48 hours after the initial block, pulmonary function was similar in both groups. Pain was significantly better controlled in the PCIA group at 12 and 24 and the PCIA group had a lower incidence of nausea and vomiting (5.5 versus 60%).

Cardiovascular

Cardiovascular complications can arise from unintended stellate ganglion block (SEDA-21, 131).

- A 67-year-old man had an axillary plexus block for a right palmar fasciectomy with mepivacaine 850 mg and adrenaline 225 micrograms. Twenty minutes later he became agitated and confused and an electrocardiogram showed fast atrial fibrillation. Rapid systemic absorption of the combination of high-dose mepivacaine and adrenaline in a patient who was also taking amiodarone, sotalol, captopril, and amiloride for pre-existing cardiac disease was felt to be responsible (50).

Pulmonary embolism has been attributed to brachial plexus block.

- A 43-year-old man with end-stage renal disease became acutely hypoxic after an interscalene brachial plexus block with 35 ml of 1.5% mepivacaine for primary placement of an arteriovenous fistula in the left arm (51). He had been undergoing hemodialysis for 1 month using subclavian and internal jugular vascular catheters for temporary access. Immediately after an apparently straightforward block, his oxygen saturation fell from 99 to 85%, he complained of chest pain and shortness of breath, and he developed hemoptysis. A CT scan suggested acute pulmonary embolism.

© 2006 Elsevier B.V. All rights reserved.

The authors proposed that manipulations and vasodilatation related to the interscalene block may have facilitated the dislodgement of a pre-existing thrombus in the arm.

Respiratory

Large volumes (30–40 ml) of local anesthetics for interscalene block cause hemidiaphragmatic paresis in nearly all patients. An interscalene brachial plexus block in 11 volunteers using 10 ml of either 0.25% bupivacaine or 0.5% bupivacaine, both with adrenaline 1:200 000, resulted in significant impairment of lung function (forced vital capacity fell by 75% and FEV_1 by 78%) and in hemidiaphragmatic excursion in those given 0.5% bupivacaine, but not 0.25% bupivacaine (52). The authors suggested that 10 ml of 0.25% bupivacaine provides adequate anesthesia, with only occasional interference with respiratory function.

However, reducing the volume of local anesthetic (1.5% mepivacaine) from 40 to 20 ml, and applying proximal digital pressure, did not reduce the incidence or intensity of diaphragmatic paralysis during interscalene block in 20 patients, in whom arterial oxygen saturation fell significantly (53).

- A 55-year-old man with newly diagnosed non-small-cell lung cancer developed difficulty in breathing, cyanosis, agitation, and confusion, 10 minutes after interscalene supplementation of an axillary nerve block with only 3 ml of 2% mepivacaine with adrenaline (54). He was anesthetized, intubated, and ventilated. Surgery proceeded and postoperative radiographic examination of the lungs showed ipsilateral elevation of the diaphragm with reduced respiratory excursion. Phrenic nerve block after the interscalene injection was the postulated cause of the deterioration in respiratory function. He was successfully extubated at the end of the procedure.

Pneumothorax has occasionally been observed (55). The axillary technique is recommended to prevent this complication (56).

Phrenic nerve palsy, resulting in paralysis of the ipsilateral hemidiaphragm, can rarely cause severe respiratory compromise, depending on pre-existing lung dysfunction. In unpremedicated patients who underwent supraclavicular brachial plexus block for upper limb surgery, blocks were performed using a peripheral nerve stimulator and 0.5 ml/kg of bupivacaine 0.375% (57). Spirometric and ultrasonographic assessments of diaphragmatic function were made at intervals. Of 30 patients, 15 had complete paralysis of the hemidiaphragm, 5 had reduced diaphragmatic movement, and 10 had no change. Those with complete paralysis all had significant reductions in pulmonary function and those with reduced or normal movement had minimal changes. Only one of the patients had respiratory symptoms and the oxygen saturation remained unchanged. This may not be the case, however, in patients with significant pre-existing respiratory disease or in obese people; the authors therefore suggested caution in choosing this approach as a safer alternative to general anesthesia in such individuals.

Two cases of respiratory compromise after infraclavicular brachial plexus blockade have been described (58).

- An 84-year-old woman weighing 74 kg had a past history of hypertension, emphysema, and ischemic heart disease. She had an infraclavicular brachial plexus block with 40 ml (400 mg) of prilocaine 1% and 10 ml (75 mg) of ropivacaine 0.75%, and 20 minutes later developed difficulty in breathing and became desaturated. She had received midazolam 2 mg before the block.
- A 47-year-old woman with a history of hypertension, gastric reflux, and obesity was premedicated with oxazepam 10 mg and had an infraclavicular brachial plexus block with the same doses of ropivacaine and prilocaine as in the first case; 10 minutes later she developed dyspnea and became desaturated.

Each patient's symptoms settled with supplementary oxygen, and surgery proceeded uneventfully. In both instances a chest X-ray showed a raised hemidiaphragm on the side of the block, but pneumothorax was excluded. The respiratory compromise was probably caused by paresis of the ipsilateral diaphragm due to blockade of the phrenic nerve, which is likely to occur after an infraclavicular plexus block but is well tolerated in most patients. Dyspnea in these two patients may have resulted from several factors. Both had been lightly sedated with benzodiazepines (although both were alert and cooperative, so this probably had a minimal contribution). The first had emphysema, which may have been an important factor; in such patients diaphragmatic function is important for sufficient gas exchange and a 50% loss of function can result in significant impairment. The second woman was obese, and obesity is associated with a reduction in functional residual capacity and respiratory function, so she may have had reduced respiratory reserve. The authors suggested that in patients with reduced pulmonary reserve, infraclavicular brachial plexus blockade should be avoided and an axillary approach considered. In addition they speculated that a smaller volume of local anesthetic may reduce the risk of phrenic nerve blockade.

Nervous system

Neurological injury after peripheral blockade has an incidence of less than 1%. However, it has been suggested that for axillary nerve blocks, neurological damage is more likely if paresthesia is the endpoint for location of the nerve sheath, in contrast to the transarterial method. This is probably due to the increased likelihood of direct damage from a needle, intraneural injection of local anesthetic, or toxicity of the local anesthetic to the nerve (59). However, published results on this issue remain contradictory (60).

Ropivacaine is less toxic than bupivacaine. However, there have been reports of brachial plexus blockade after ropivacaine, associated with unusual symptoms of nervous system toxicity; none of the patients recalled the events and there were no subsequent sequelae (61).

- A 46-year-old man received an axillary nerve block using 40 ml of 0.5% ropivacaine with 1:200 000 adrenaline and 45 seconds later developed a sinus tachycardia and started screaming, appearing terrified. He struck out violently with all limbs and sat upright, attempting

© 2006 Elsevier B.V. All rights reserved.

to leave the bed. The pulse oximeter reading (SpO_2) fell to 90% and his symptoms were interpreted as a seizure and treated successfully with 100% oxygen, sodium thiopental, and intubation.

- A 60-year-old woman received an interscalene block using 30 ml of 0.5% ropivacaine with 1:200 000 adrenaline. Immediately after the injection, she sat up and began screaming in a loud high-pitched voice, appearing terrified and enraged. She then attempted to get off the stretcher in an uncoordinated manner and became unresponsive to verbal commands. She had a sinus tachycardia and hypotension. Treatment with 100% oxygen and propofol was effective.
- A 76-year-old woman received an interscalene block using 20 ml of 0.75% ropivacaine with 1:400 000 adrenaline. At the end of the injection, she sat up and appeared extremely terrified; she screamed twice, fell back on the stretcher, and began moving the unblocked arm and both legs in clonic movements, remaining unresponsive to verbal command. She had a sinus tachycardia and hypertension (205/70 mmHg). The seizure abated with thiopental.

The authors suggested that these signs of anxiety, vocalization, and agitation may have been due to the administration of ropivacaine formulated exclusively as the *S*(–) enantiomer, which has a spectrum of nervous system and cardiovascular toxicity different from the racemic mixture.

Reverse arterial flow can cause nervous system toxicity, even during peripheral regional blocks with only small volumes of local anesthetic (62).

- A 47-year-old woman received an axillary brachial plexus block with 3 ml of 1% lidocaine after negative aspiration. She became dysphoric 30 seconds later, with muscle twitching in the face and distal arms, became unresponsive, and required ventilation.

During a study of 104 adults to compare the efficacy and safety of 40 ml of 0.75% ropivacaine (300 mg) and 40 ml of 0.5% bupivacaine (200 mg) for axillary plexus block, significantly more patients reported postoperative dizziness in the ropivacaine group (5 versus 0) (63). However, this occurred 4–5 hours after the injection in two patients and the day after in the other three, and was therefore unlikely to have been due to high serum concentrations. One patient developed dizziness, dysarthria, and unconsciousness, with convulsions shortly after an injection of ropivacaine, indicating an intravenous injection.

In some cases adjuvants should be considered as well as the local anesthetic after a toxic reaction (64).

- A 52-year-old woman received an axillary plexus block with 20 ml of 1% ropivacaine, clonidine 70 micrograms, and 15 ml of 1% mepivacaine with 1:400 000 adrenaline. Generalized tonic-clonic seizure activity developed, even though careful incremental aspiration was performed. She was still comatose 90 minutes later, but this was reversed by intravenous naloxone.

The authors suggested that clonidine could have been responsible for the maintenance of her unconscious state.

Axillary blockade using high-dose mepivacaine with adrenaline was performed in 50 patients, each of whom received 850 mg of mepivacaine; two patients had symptoms of toxicity associated with this combination (euphoria, dizziness, and tinnitus) 13 and 15 minutes after the procedure with doses of 14.1 and 16.4 mg/kg of mepivacaine respectively (65). One patient who received 10.9 mg/kg developed hypertension and atrial fibrillation, became agitated, and lost consciousness 12 minutes after the block was performed, and required beta-blockade and midazolam before waking up 15 minutes later. Another received 6.5 mg/kg, became light-headed, agitated, and hypertensive, and reported whole body numbness 18 minutes later, with resolution of symptoms after 10 minutes with beta-blockade. The author thought that adrenaline had probably been responsible for the reaction in the first patient. As high-dose mepivacaine did not greatly improve the quality of the block and can obviously produce serious systemic reactions, it would be prudent to limit the dose to under 10 mg/kg.

Horner's syndrome is a well-recognized complication of interscalene brachial plexus block, stellate ganglion block, and occasionally epidural blockade. It occurs when the local anesthetic reaches the cervical sympathetic trunk and is usually transient. However, persistent Horner's syndrome is a rare complication, and may represent traumatic interruption of the cervical sympathetic chain. Cases of prolonged Horner's syndrome related to prevertebral hematoma formation at the site of continuous interscalene blockade have been described (66).

- A 48-year-old obese woman had a 22G interscalene catheter inserted under local anesthesia via a short-bevel stimulating needle. Anesthesia was achieved using 0.6% ropivacaine 40 ml followed by an infusion of ropivacaine 0.2% for effective analgesia. On day 3, she reported blurred vision and a painful neck swelling. She had developed a hematoma around the catheter insertion site (confirmed by ultrasound) and had an ipsilateral Horner's syndrome including myosis, ptosis, enophthalmos, ipsilateral anhidrosis, and conjunctival hyperemia.
- An interscalene catheter was inserted in an awake 20-year-old woman for analgesia after shoulder surgery. Analgesia was achieved with ropivacaine 0.2% as a 30 ml bolus followed by an infusion of the same solution. One day later she had visual disturbance and neck swelling due to a hematoma between the prevertebral and scalene muscles.

Neither patient was taking NSAIDs, aspirin, or anticoagulants. Catheters were removed immediately on diagnosis of hematoma formation. There was no neurological or sympathetic fiber damage to the upper limb in either patient, as tested by electroneuromyography and sympathetic skin response. Remission in both cases occurred within 1 year. There has been one previous report of prolonged Horner's syndrome in the absence of any obvious technical complication (67). Further studies into the use of interscalene catheters are needed to assess their propensity to cause this rare complication.

In 60 patients receiving patient-controlled interscalene analgesia with either ropivacaine 0.2% or bupivacaine 0.15%, there was a significant reduction in hand motor function and an increased incidence of paresthesia in the bupivacaine group, with no difference in pain scores (68).

© 2006 Elsevier B.V. All rights reserved.

This finding contrasts with that in a comparison of epidural bupivacaine or ropivacaine, in which there was no difference in motor function between the two groups (69).

Inadvertent injection into the subarachnoid space, occasionally causing cerebral or neurological problems, is a life-threatening complication of brachial plexus anesthesia. It can also cause postdural puncture headache (SEDA-21, 131).

Interscalene block can cause paralysis of the arm.

- A 33-year-old woman received combined regional and general anesthesia for a shoulder repair (70). Preoperatively an interscalene catheter was placed uneventfully. The next day, she had almost complete paralysis of the arm with hypesthesia of dermatomes C5–7. The symptoms persisted and 4.5 months later, during surgical exploration of the brachial plexus, electrical stimulation of the three trunks was possible and there were electrophysiological signs of recovery. Despite extensive neurophysiological tests a clear cause could not be established and there was no improvement at 2 years.

Sensory systems

- An intolerable metallic taste appeared and disappeared in a 48-year-old woman within hours of infusion of bupivacaine via an axillary catheter, and its severity changed with the rate of infusion (71). The mechanism was postulated to be through sodium channels or taste bud disturbances.

Psychological, psychiatric

- A 59-year-old woman, grade ASA I, had psychiatric effects associated with local anesthetic toxicity after receiving bupivacaine 50 mg and mepivacaine 75 mg for an axillary plexus block. She complained of dizziness and a "near death experience" (72).

Hematologic

Methemoglobinemia has been reported in a woman who received a combination of local anesthetics (73).

- A 60-year-old woman with medical problems including severe coronary vascular disease and anemia, taking multiple medications, including isosorbide dinitrate, received axillary plexus blockade with bupivacaine 150 mg + 10 ml of 1% lidocaine injected into the operative field; 90 minutes later her SpO_2 fell to 85–89% on oxygen 10 l/minute. She became drowsy, disoriented, and tachypneic, and an arterial blood gas showed a metabolic acidosis and a methemoglobin concentration of 6.4%. Her mental status improved 10 minutes after methylthioninium chloride and sodium bicarbonate; her SpO2 rose to 96% on air, her methemoglobin concentration fell to 1.6%, and her acidosis partly resolved.

The authors assumed that displacement of lidocaine from protein binding by bupivacaine, in combination with metabolic acidosis and treatment with nitrates, had caused methemoglobinemia.

Susceptibility factors

Mepivacaine toxicity has been studied in 10 patients with end-stage chronic renal insufficiency undergoing vascular access surgery (74). These patients represent a high-risk group for general anesthesia, as they often have concomitant coronary artery disease, hypertension, and diabetes. Brachial plexus block is often used: as well as avoiding systemic effects, it enhances regional blood flow. However, high doses of local anesthetic are required, and this block carries one of the highest rates of seizures. In this study, following axillary block with mepivacaine 650 mg, plasma concentrations were greater than the threshold of 6 micrograms/ml, above which signs of nervous system toxicity reportedly occur. The authors suggested that the absence of nervous system signs may have been due to slow systemic absorption of the local anesthetic. Peak concentrations occurred after 60–90 minutes, but were still high at 150 minutes, raising the question of more prolonged monitoring after these blocks.

Buccal anesthesia

Persistent hiccup, paralysis of cranial nerves, and systemic toxicity are the main complications of local anesthesia in the mouth (75–77). Trismus has been seldom reported (78–80).

Caudal anesthesia

In a study in 60 anesthetized children undergoing minor subumbilical surgery caudal blocks, 0.2% ropivacaine, 0.25% racemic bupivacaine, and 0.25% levobupivacaine (all 1 ml/kg) were compared (81). All the blocks were successful in terms of intraoperative and early postoperative analgesia. Ropivacaine, but not levobupivacaine, was associated with less motor block during the first postoperative hour compared with racemic bupivacaine. However, the lower concentration of ropivacaine will have biased this result.

Caudal block with bupivacaine in children provides adequate analgesia in the early postoperative period, but additional analgesia is often required as the block wears off. Two studies have looked at adjuvants to prolong the analgesic effect.

The first was a randomized, controlled trial in 60 boys undergoing unilateral herniorrhaphy (82). They received 0.25% bupivacaine 1 ml/kg or the same dose of bupivacaine plus 1.5 mg/kg tramadol, or tramadol 1.5 mg/kg alone made up to the same volume. Caudal administration of bupivacaine plus tramadol resulted in more effective analgesia, with a longer period without demand for additional analgesia postoperatively without increases in any adverse effects. The second was a study of the addition of midazolam to caudal bupivacaine in 30 children undergoing genitourinary surgery (83). They randomly received 0.25% bupivacaine 0.5 ml/kg or the same dose of bupivacaine plus midazolam 50 micrograms/kg. There were no untoward events in either group. Fewer required additional analgesia in the first 6 hours postoperatively in the bupivacaine plus midazolam group than with bupivacaine alone: 27% compared with 60%. Midazolam prolonged analgesia with no increase in adverse effects.

In 165 children receiving caudal anesthesia with fentanyl 1 mg/kg and bupivacaine 4 mg/kg, there were adverse effects in only six, two of whom required postoperative ventilation. This was felt to be due to their pathology and not the anesthetic. However, there was no comment on the presence or absence of specific local anesthetic adverse effects, and an unusually high dose of

© 2006 Elsevier B.V. All rights reserved.

bupivacaine was used, 4 mg/kg, twice that recommended by the manufacturers and greater than that used by most pediatric anesthetists (2.5–3 mg/kg) (SEDA-20, 124).

Caudal bupivacaine has been successfully combined with clonidine, ketamine, diamorphine, and buprenorphine, with increased duration of anesthesia and a low incidence of adverse effects (SEDA-20, 124) (SEDA-21, 131).

Awake regional anesthesia for inguinal hernia repair in former preterm infants has been suggested, in order to avoid life-threatening respiratory complications that can occur after general anesthesia. Caudal anesthesia is becoming a more popular technique for this purpose. To prolong the duration of anesthesia and to reduce the postoperative need for analgesics in these infants, caudal clonidine has been considered useful.

- A former preterm infant had two awake caudal anesthetics for herniotomy within 3 weeks (84). The first was uneventful with bupivacaine 0.25% at 35 weeks of age. At 38 weeks, the baby had intraoperative and postoperative bouts of apnea after inadvertent administration of bupivacaine 0.125% plus clonidine.

There has been a report of T wave changes on the electrocardiogram during caudal administration of local anesthetics (85).

- A 4.2 kg 2-month-old baby was given a caudal injection under general anesthesia for an inguinal hernia repair. A mixture of 1% lidocaine 2 ml and 0.25% bupivacaine 2 ml was injected. Every 1 ml was preceded by an aspiration test and followed by observation for electrocardiographic changes for 20 seconds. On administration of the third 1 ml dose, there was a significant increase in T wave amplitude. The aspiration test was repeated and was positive for blood. The caudal injection was stopped and the electrocardiogram returned to normal after 35 seconds. The baby remained cardiovascularly stable with no postoperative sequelae.

Previous reports have suggested that an increase in T wave amplitude could result from inadvertent intravascular administration of adrenaline-containing local anesthetics. This is the first case report of local anesthetics alone causing significant T wave changes.

Inadvertent dural puncture is a recognized complication in up to 1% of caudal anesthetics. It can be due to excessive needle insertion or sacral abnormalities. Potentially serious consequences, such as total spinal anesthesia, can result (SEDA-21, 131).

In eight episodes of toxic methemoglobinemia in seven premature infants after the combination of caudal anesthesia (prilocaine 5.4–6.7 mg/kg) and Emla cream (prilocaine 12.5 mg) for herniotomy, the highest methemoglobin concentration 5.5 hours after anesthesia was 31% (86). All the infants were symptomatic, with mottled skin, pallor, cyanosis, and poor peripheral perfusion. The most severe symptoms occurred at 3–8 hours and disappeared within 10–20 hours. The authors stressed the importance of recognizing the poor tolerance of premature infants to methemoglobinemia and that whereas topical prilocaine is relatively safe, caudal administration is not.

Cervical plexus anesthesia

Nervous system

Deep cervical plexus block can cause ipsilateral phrenic nerve palsy. A patient with pre-existing respiratory disease and a contralateral raised hemidiaphragm developed hypoxia and respiratory distress when given 20 ml of plain bupivacaine 0.375% by this route for carotid endarterectomy (87). Local anesthetic spread resulted in presumed stellate ganglion block, which caused nasal congestion and aggravated the respiratory distress. The symptoms resolved without intubation, but the authors advised against deep cervical plexus block in patients with diaphragmatic motion abnormalities or chronic respiratory disease.

Nerve palsies can occur during deep cervical plexus anesthesia.

- A woman complained of being unable to clear secretions effectively from her throat, had a paroxysm of coughing, and developed a large neck hematoma requiring surgical re-exploration (88).
- A 71-year-old man complained of difficulty in breathing and was desaturated on pulse oximetry for 5 minutes after cervical plexus blockade (89). He required tracheal intubation, was ventilated for 110 minutes, and was then successfully extubated. It was thought that the most likely diagnosis was cardiorespiratory failure exacerbated by phrenic nerve blockade.
- A 67-year-old man developed transient hemiparesis and facial nerve palsy before becoming unconscious and apneic 10 minutes after a right cervical plexus block (89). His trachea was intubated without the need for anesthetic drugs and he was ventilated. Hypotension was treated with intravenous ephedrine. He woke up, started breathing, and was extubated 75 minutes later. The authors postulated brainstem anesthesia following accidental injection of local anesthetic into a dural cuff as a cause of loss of consciousness.

Hemidiaphragmatic paralysis can occur with cervical plexus anesthesia and can be particularly risky in cases of pre-existing airways obstruction (90).

Infiltration of even small doses of a local anesthetic in the region of the carotid artery is likely to cause nervous system toxicity if injected intra-arterially (91).

- A 76-year-old man had already received a deep and superficial cervical plexus block for an awake carotid endarterectomy. One hour later, during manipulation of the carotid artery discomfort was treated with infiltration of 1 ml of 0.5% lidocaine in that region. Immediately he became unresponsive, with generalized tonic-clonic seizure activity of the face and arms. He was given 100% oxygen and within 30 seconds the seizure terminated spontaneously with no sequelae.

This demonstrates the requirement for constant vigilance in a patient undergoing awake carotid endarterectomy.

Dental anesthesia

Dental anesthesia is generally safe and effective. However, it can cause adverse effects, ranging from mild to severe, perhaps a reflection of the number of dental anesthesias performed.

© 2006 Elsevier B.V. All rights reserved.

Systemic effects, such as dizziness, tachycardia, agitation, nausea, tremor, syncope, seizures, and bronchospasm, are a definite risk with local anesthesia in a vascular area. A wide range of patients present for dental surgery, and it is important that an adequate medical history be taken and accurate doses calculated on an individual basis. Low concentrations of adrenaline should be used.

Complication rates increase with premedication at home, and pre-existing disease or risk factors, such as pregnancy, cardiovascular disease, and allergies. Articaine and lidocaine with epinephrine 1:200 000 were associated with a low incidence of complications (3.1 and 0%), whilst mepivacaine and articaine with adrenaline 1:100 000 caused the most frequent complications (7.2 and 6.1%) (SEDA-22, 135).

Cardiovascular

Acute hypertension leading to myocardial infarction and pulmonary edema has been described after the use of mepivacaine with levonordefrin (92).

Nervous system

An unexplained case of permanent neurological deficit, consisting of left facial palsy, right sensorineural hearing loss, gait ataxia, and hemisensory loss in the body and face, has been described after inferior alveolar nerve block (93).

Facial paralysis is occasionally reported and is not necessarily due to poor technique; in one case vascular spasm seemed to provide an explanation (SED-12, 252).

- An 8-year-old girl received prilocaine for a dental procedure performed under 70% oxygen/30% nitrous oxide (94). The dose of 288 mg was 2.7 times higher than the recommended safe dose of 6 mg/kg. Toward the end of the procedure, she became unconscious and had a convulsion.

Two reviews have highlighted the fact that the degree and incidence of neurological damage after dental anesthesia is probably underestimated. Some drugs, such as articaine and prilocaine, seem to cause a higher incidence of paresthesia than others (SEDA-20, 124).

In seven subjects articaine with adrenaline caused distortion of lingual nerve function with effects on vowel pronunciation and therefore the potential to impair speech (95).

- A 49-year-old man developed uvular deviation as a result of palatal muscle paralysis following intraoral mandibular block of the inferior alveolar nerve with 1.8 ml of 2% lidocaine with adrenaline 1 in 100 000 (96). A few minutes after injection he had swallowing difficulties and a foreign body sensation in his throat. There was paralysis of the velum palatinum, with deviation of the uvula towards the non-paralysed side opposite the point of anesthetic infiltration. This resolved after the anesthetic had worn off.

The authors suggest that a high inferior alveolar nerve block can easily affect the mandibular nerve if the anesthetic solution diffuses to the internal trunk of the third trigeminal branch and the supply to the tensor veli palatini.

Sensory systems

Adverse ocular effects, such as ptosis, are on record (SEDA-15, 118). Transient dizziness, diplopia, and partial blindness have been reported after the entry of lidocaine with adrenaline into the ophthalmic artery following mandibular block (97). A similar case after posterior alveolar block resulted in dizziness and diplopia for 3 hours when the patient stood up, possibly due to the entry of local anesthetic into the ophthalmic artery (SEDA-22, 135).

Ophthalmological complications after intraoral anesthesia occurred in 14 cases over 15 years (98). The most common symptom was diplopia. Three patients developed Horner's syndrome, with ptosis, enophthalmos, and miosis on the same side as the anesthesia. Three patients developed mydriasis and ptosis. There was complete resolution in all patients. The authors postulated that direct diffusion of anesthetic solution from the pterygomaxillary fossa through the sphenomaxillary cavity to the orbit had caused the ophthalmological effects.

- A 45-year-old man developed temporary monocular blindness, ophthalmoplegia, ptosis, and mydriasis immediately after a mandibular block injection (99). Unidentified intra-arterial injection into the maxillary artery, with backflow of the local anesthetic solution to the middle meningeal artery was the postulated cause.

Additives

Additives in local anesthetic solutions can cause allergic reactions (100).

- A 34-year-old man developed swelling and redness of the face after receiving lidocaine as Lignospan® for dental treatment. Patch testing showed allergic contact dermatitis due to the preservative disodium ethylenediamine tetra-acetic acid (EDTA).

Digital anesthesia

Digital anesthesia with 1% lidocaine plus adrenaline was performed on 23 patients for surgery to finger injuries; 11 patients received adrenaline 1:200 000, and 12 received 1:100 000 (101). A digital tourniquet was also used, but no patient developed ischemic symptoms. The authors discussed the usefulness of adrenaline as an additive to local anesthetic solutions in prolonging regional block, reducing the dose of local anesthetic required. They stated that an extensive search of the literature had revealed no sound clinical evidence to support the widely held opinion that adrenaline contributes to the risk of gangrene when it is used in digital blocks.

Epidural anesthesia

The accidental transformation of epidural to subarachnoid block can be dramatic, and tracheal intubation and ventilatory support may be necessary (102). Severe hypotension can result after inadvertent intrathecal local anesthesia (SEDA-21, 131). In women in labor, fetal bradycardia can occur. Postdural puncture headache can also be a sign of catheter migration.

Long-term epidural catheters can be highly effective in the management of chronic pain of malignant and non-malignant origin, but they can also cause complications. Infection and extravasation of fluid to the paraspinal

© 2006 Elsevier B.V. All rights reserved.

tissue resulting in inadequate analgesia have been described in a patient with non-Hodgkin's lymphoma (103). Another patient with non-Hodgkin's lymphoma had a tunnelled thoracic epidural for analgesia and presented with spinal cord compression. Laminectomy showed a mass consisting of white chalk-like drug-related precipitate around the catheter tip. As the solvent for bupivacaine contains sodium hydroxide and sodium chloride, the authors assumed that the mass was a precipitate of sodium hydroxide (104).

- A 1-year-old boy inadvertently received ropivacaine 6 mg intravenously over 2 hours when his epidural infusion was incorrectly connected to his intravenous cannula (40). He had already received ropivacaine 28 mg via his epidural catheter. He suffered no overt adverse effects.

In a dose-finding study for the combination of 0.2% ropivacaine with fentanyl for thoracic epidural analgesia in 224 patients undergoing major abdominal surgery, each received fentanyl in concentrations of 0, 1, 2, or 4 micrograms/ml; effective pain relief was provided by all the combinations and the degree of motor block was low overall and did not differ significantly among the groups (105). Hypotension was most common during the first postoperative 24 hours and was most frequent in those given fentanyl 4 micrograms/ml. Although the combination with fentanyl 4 micrograms/ml improved the quality of analgesia, there was a higher incidence of adverse effects, such as hypotension, nausea, and pruritus.

Patient-controlled epidural analgesia is increasingly being used, as it reduces the need for adjustment of epidural infusion rates by anesthetic personnel. In a retrospective survey of 1057 patients who received postoperative patient-controlled epidural analgesia using bupivacaine 0.1% plus fentanyl 5 micrograms/ml, on the first postoperative day 93% of the patients had adequate analgesia and 96% reported no nausea; two patients had an episode of respiratory depression and one patient was unrousable (106). Hypotension occurred in 4.3%, but there were no cases of epidural hematoma or abscess. Despite these adverse events, the authors concluded that patient-controlled epidural analgesia was effective and safe on surgical wards. The large amount of fentanyl in the solution they used is most probably the reason for the rare, potentially life-threatening adverse effects.

The amount of bupivacaine with fentanyl used in patient-controlled epidural analgesia was significantly less than with a continuous infusion of the same mixture in a group of 54 patients (mean age 71 years) after total knee arthroplasty (107). However, 10% of the patients were too confused to use the PCEA device. Despite the advantages of analgesic dosage reductions, a constant infusion may prove more appropriate in this age group.

Patient-controlled epidural analgesia (0.05% bupivacaine and fentanyl 4 micrograms/ml) has been studied prospectively in 1030 patients requiring postoperative analgesia (108). Pruritus was the most common adverse effect, with an incidence of 17%, with two susceptibility factors: age (under 58 years) and increased consumption of analgesia (over 9 ml/hour). The incidence of nausea was 15% and of sedation 13%; female sex was a slight risk factor for both. Hypotension had an incidence of 6.8% and motor block of 2%; lumbar placement of the epidural catheter was the strongest risk factor. Respiratory depression occurred in 0.3%.

The effects of single-dose epidural analgesia with lidocaine and morphine have been studied in 60 women undergoing elective cesarean section (109). The patients received morphine sulfate 4 mg and 2% lidocaine 18–20 ml. Four patients proceeded to general anesthesia owing to failure of the epidural block to reach T6, 48% of patients complained of discomfort during surgery, and 23% needed supplementary analgesia. Perioperative adverse effects were hypotension 29%, bradycardia 3.6%, and shivering 5.4%. Postoperative adverse effects were pruritus 45% and nausea and vomiting 35%. Apgar scores at 1 and 5 minutes were 8 or over. At 2 hours and 24 hours, two babies had transient tachypnea and one had mild respiratory distress. Maternal and neonatal venous concentrations of morphine, measured at delivery, were low. The authors recommended this technique for elective cesarean section in uncomplicated obstetric patients. This study had no control group and reported a high incidence of unwanted effects and a high perioperative failure rate. Mean analgesic duration of morphine was reported as 24 hours. However, 75% of patients required additional analgesia after 12 hours. There was no record of the incidence of postoperative maternal respiratory depression.

Comparative studies

After thoracotomy, 106 patients received a thoracic epidural infusion of either 0.1% or 0.2% bupivacaine, both with fentanyl 10 micrograms/ml, compared with epidural fentanyl alone; there was no difference in the number of episodes of postoperative hypotension (systolic pressure below 90 mmHg) or in the number of interventions for postoperative hypotension, but intraoperative vasopressors were used significantly more in the bupivacaine groups (110). In addition, two patients given 0.2% bupivacaine reported slight weakness of both hands and another a right-sided Horner's syndrome and weakness of the right hand. There was a similar incidence of nausea and pruritus in all the groups; however, the incidence of respiratory depression with fentanyl was high (4.2%).

Random allocation of 150 women in labor to either an intermittent epidural bolus, a continuous epidural infusion, or patient-controlled epidural analgesia with 0.125% bupivacaine and sufentanil 0.5 micrograms/ml resulted in significantly more frequent motor blockade with continuous infusion compared with intermittent boluses (22 versus 4%), with similar frequencies of pruritus, hypotension, and high sensory level in each group (111).

In 52 patients who received either epidural bupivacaine (0.10–0.28 mg/kg/hour) or lidocaine (0.44–0.98 mg/kg/hour), both with epidural morphine, there were no significant differences in the times to mobilize, motor function (as measured by the Bromage grade), and the incidence of hypotension (112). Most of the patients had no motor blockade, and the Bromage grade did not help predict which of them could be mobilized.

In 90 parturients who received epidural analgesia during labor with bolus administration of either 10 ml of 0.125% bupivacaine or 0.125% ropivacaine, each with sufentanil 7.5 micrograms, there were comparable onset times and duration of analgesia in the two groups, but

© 2006 Elsevier B.V. All rights reserved.

patients given ropivacaine had significantly less motor blockade after the third and subsequent epidural injections compared with those given bupivacaine: 93% of those given ropivacaine had no motor impairment compared with 66% of those given bupivacaine (113). There were no differences in hemodynamic effects and pruritus.

An epidural infusion of 0.2% ropivacaine plus sufentanil has been compared with 0.175% bupivacaine plus sufentanil in 86 patients postoperatively after major gastrointestinal surgery; there was no statistically significant difference in the incidence of adverse effects (respiratory depression, sedation, nausea, vomiting, pruritus, and motor blockade), but those given ropivacaine mobilized more quickly (114).

In 60 women who underwent elective cesarean section under epidural anesthesia, 0.5% levobupivacaine or 0.5% bupivacaine (30 ml) were equally efficacious in terms of anesthesia (115). The incidence and severity of motor blockade, hypotension, changes in QT interval, nausea, and vomiting were not significantly different, and neither were the neonatal Apgar scores.

Drug combinations are often used in epidural anesthesia to enhance the analgesic effect and minimize adverse effects. Continuous epidural analgesia (0.125% bupivacaine 12.5 mg/hour and morphine 0.25 mg/hour) has been compared with patient-controlled analgesia (morphine) in 60 patients after major abdominal surgery. Analgesia was superior in the epidural group, satisfaction and sedation scores were similar in both groups, whilst episodes of moderate nocturnal postoperative hypoxemia (SaO_2 85–90%) were more frequent in the epidural group (116).

The addition of opioids to local anesthetic to improve the efficacy of epidural analgesia for cesarean section has been advocated (109,117). A test dose of lidocaine 60 mg was given to 24 patients undergoing elective cesarean section, followed by either bupivacaine 45 mg or bupivacaine 45 mg plus fentanyl 50 micrograms (117). Sensory blockade to T6 was achieved in both groups, but pain scores were significantly lower in the fentanyl group. Rescue fentanyl on uterine exteriorization was required in 40% of the control group, but in none in the fentanyl group. There were no significant differences in adverse effects, specifically pruritus, hypotension, nausea and vomiting, maternal respiratory depression, and Apgar scores.

Cardiovascular

Hypotension is a frequent adverse effect of epidural anesthesia. In a comparison of the effects of bupivacaine and ropivacaine in 60 women undergoing cesarean section, 90% had a fall in blood pressure to below 90 mmHg, or by more than 30% of baseline (118).

Abrupt onset of arterial hypotension is also a complication of cervical epidural anesthesia, particularly in elderly patients (119). However, supplementation with adrenaline in this high-risk group is no longer defensible; it is better to be cautious with dosage and to monitor the patient closely.

- Severe hypotension during a lumbar epidural anesthetic in a 61-year-old woman taking amitriptyline was refractory to high doses of ephedrine and other indirect alpha-adrenergic agents (120). It eventually responded to one dose of noradrenaline 200 micrograms, illustrating the importance of the choice of vasopressor for treating hypotension in the presence of chronic tricyclic antidepressant use.
- A 27-year-old woman developed significant myocardial depression and pulmonary edema after administration of 5 ml of bupivacaine 0.5% via an epidural catheter (121). The bupivacaine followed a test dose of 3 ml lidocaine 2%.

Although initial aspiration on the epidural catheter was negative, the most likely explanation must be inadvertent intravascular administration of lidocaine and bupivacaine.

Unusually, a mother and her child died after repeated administration of a local anesthetic for cesarean section; pulmonary edema was believed to have been the cause (122).

Intracardiac conduction disturbances should not be considered as absolute contraindications to epidural anesthesia: there were only nine cases of sinus bradycardia, easily reversed with atropine sulfate, in 66 patients (123). However, rare cases of complete heart block and complete left bundle branch block have occurred (SEDA-21, 132) (124).

Unexpected cardiopulmonary arrest can result from accidental dural puncture during epidural blockade (SEDA-22, 136).

- Asystolic cardiac arrest has been described in a 55-year-old man who underwent partial hepatectomy under combined general and epidural anesthesia (125). During postoperative recovery he developed asystole followed by ventricular fibrillation. Resuscitation was unsuccessful.

The authors concluded that in the absence of any other abnormality the arrest had been the result of an autonomic imbalance due to spreading sympathetic block, although other postoperative causes of death should not be discarded.

Respiratory

Respiratory depression was noted in 0.24% of patients in a Chinese series of 10 978 epidural blocks (SED-12, 254) (126). Direct paralysis of respiration probably plays an important role. Respiratory depression with adverse cardiovascular effects after miscalculated dose requirements or a misplaced catheter has also been described (SEDA-22, 136).

In 15 patients receiving lidocaine 300 mg plus adrenaline by cervical epidural injection, the upper cervical nerve roots C3, 4, and 5 were anesthetized. None of the patients had pre-existing pulmonary disease. Only one had symptoms of impaired pulmonary function at 20 minutes after epidural, and complained of dyspnea, with a reduction in maximum inspiratory pressure, FEV_1, FVC, and SpO_2. Four patients had a bradycardia requiring atropine, eight complained of nausea, and one developed hypotension requiring ephedrine. At 20 minutes after the epidural, all the patients had a maximum reduction in FEV_1 and FVC, ranging from 12 to 16% of preanesthetic measurements. The authors felt that as the maximum inspiratory pressure was virtually unchanged, this

© 2006 Elsevier B.V. All rights reserved.

suggested that the motor function of the phrenic nerve was mostly intact, despite analgesia of the C3, 4, and 5 dermatomes (127).

Nervous system

Peripheral paresthesia, in 1.13% of patients in a Chinese series (SED-12, 254) (126) and 0.16% of patients in a Japanese study of 15 884 epidurals (128), is the most frequent neurological deficit attributed to spinal and epidural analgesia.

High spinal block has previously been reported as a rare complication of epidural anesthesia.

- A 31-year-old woman in labor had an epidural catheter sited at L3/4 (129). A test dose of 0.25% bupivacaine 10 ml was followed 90 minutes later by another 10 ml. After a further 90 minutes she required cesarean section, had a block to T7, and was topped up with 0.75% ropivacaine 10 ml. Within minutes she developed arm weakness, and over the next 15 minutes developed further ascending block requiring intubation. Three hours later the block had regressed to T8 and she had no further complications.

The cause was thought to be subdural injection, although other mechanisms could not be excluded; for example the catheter could have been partly intrathecal and the ultimate distribution of the dose could have been related to the speed of injection or catheter migration before the final dose was given.

Lumbar extradural analgesia with bupivacaine increases intracranial pressure in some patients, apparently those who already have some reduced intracranial compliance, and who may be at risk (130). A sudden increase in intracranial pressure, due to an increased volume in the caudal space, can precipitate respiratory arrest because of direct midbrain stimulation.

- A watershed cerebral infarct with subsequent full recovery occurred in a 70-year-old man 8 hours after a hypotensive event following an incremental bolus of 1% lidocaine 10 ml via an established epidural catheter (131).

A cause-and-effect relation cannot be established in such cases.

Epidural anesthesia can mask a neurological deficit, such as nerve compression of the femoral nerve and lateral femoral cutaneous nerve of the thigh from the lithotomy position (SEDA-22, 137).

- Neurological effects after accidental intravenous injection of a large dose of levobupivacaine (142 mg) have been described during epidural anesthesia (132).
- A 77-year-old woman had epidural anesthesia, following negative aspiration, with a 3 ml test dose of 0.75% levobupivacaine with 1:200 000 adrenaline and then incremental doses up to a total of 17 ml of 0.75% levobupivacaine. During the final 5 ml of injection, she became disoriented and drowsy, with slurred speech, immediately followed by excitation with shouting and writhing about. She was given thiopental for seizure prophylaxis with high-flow oxygen, and the excitatory signs abated. The catheter was withdrawn 1 cm and blood was freely aspirated. The serum levobupivacaine concentration 14 minutes later was 2.7 micrograms/ml.

Transient radicular irritation

Transient radicular irritation has been reported (SEDA-21, 130) (SEDA-22, 137).

- A 38-year-old woman underwent cystoscopy and urethral dilatation in the lithotomy position under continuous epidural anesthesia at the L3–4 interspace with 3 ml of 1.5% lidocaine with adrenaline 1:200 000 as a test dose, followed by a total of 15 ml of 2% lidocaine with adrenaline 1:200 000 in incremental doses (133). The operation was uneventful, but 4 hours later she developed severe bilateral buttock and posterior leg pain, described as "deep, aching, and excruciating," worse when immobile, and better when standing; there were no other symptoms and ibuprofen gave immediate relief.

The authors stressed that transient radicular irritation can occur after epidural administration, despite the lower concentrations of lidocaine in the cerebrospinal fluid.

- Transient neurological symptoms have been reported in two parturients who received lidocaine 45 mg with adrenaline 5 micrograms/ml as a test dose followed by bupivacaine (134). One patient received a single dose of bupivacaine 12.5 mg and the other received a total of 62 mg bupivacaine administered as two 5 ml and one 3 ml bolus of 0.25% bupivacaine followed by an infusion of 0.125% bupivacaine at 5 ml/hour for 4 hours 40 minutes. Both patients later developed reversible burning lower back, buttock pain, and leg pain; there was nothing to suggest intrathecal administration of local anesthetic in either case. Both patients gave birth in the lithotomy position, which may have been contributory.
- Severe burning pain in the buttocks, thighs, and calves has been described in a 5-year-old boy who was given 0.25% bupivacaine and morphine epidurally for perioperative and postoperative analgesia (135).

Two unexplained cases of back and leg pain have been separately described (SEDA-20, 125).

Motor block

Prolonged profound motor block occurred in two patients using patient-controlled epidural analgesia with 0.1% ropivacaine subsequent to spinal bupivacaine for cesarean section (136). One of them developed pressure sores on both heels. The authors hypothesized that epidural ropivacaine may interact with intrathecal bupivacaine to prolong its effects and advised caution when this combination is used, as unexpected motor block can ensue.

The optimal concentration of lumbar epidural ropivacaine in terms of adverse effects and quality of analgesia has been studied in 30 patients using patient-controlled epidural analgesia after lower abdominal surgery (137). Each solution provided comparable analgesia, but motor block was significantly more common and more intense with 0.2% ropivacaine + 4 micrograms/ml fentanyl than with 0.1% ropivacaine + 2 micrograms/ml fentanyl or 0.05% ropivacaine + 1 microgram/ml fentanyl. The amount of ropivacaine used by the 0.1% ropivacaine group was significantly higher than in the other two groups, implying that the concentration rather than the amount of ropivacaine is a primary determinant of motor block with

© 2006 Elsevier B.V. All rights reserved.

patient-controlled epidural analgesia. The authors recommended the use of ropivacaine in concentrations under 0.2% to reduce motor blockade while still providing effective analgesia.

Epidural solutions containing 0.125% levobupivacaine with and without fentanyl 4 micrograms/ml produced a greater degree of motor blockade only in the first 6 hours of patient-controlled epidural analgesia compared with fentanyl alone in groups of 22 patients after total hip or knee arthroplasty (138).

- An 85-year-old woman undergoing elective right total knee replacement had prolonged motor blockade of her left leg when her epidural ropivacaine (0.2% at 8–10 ml/hour) infusion was discontinued on the third postoperative day; normal motor function had returned by the sixth postoperative day (139).

Paraplegia can result, and can be prevented by early recognition, appropriate investigation, and immediate surgical intervention.

- Delayed onset, prolonged coma, and flaccid quadriplegia occurred in a 22-year-old woman 2 hours after an injection of fentanyl 100 micrograms and 10 ml bupivacaine 0.25%, given in divided doses (4, 3, and 3 ml) via an epidural catheter (140). At the time of the initial attempt at insertion she had complained of severe cervico-occipital pain with loss of resistance to air injection. Despite negative aspiration of CSF, the physician suspected intrathecal injection of air and abandoned the attempt at epidural catheter placement at that level. An epidural catheter was successfully inserted one level higher. Within 1 hour of the original epidural injection, she developed hypotension requiring ephedrine, and a surprisingly high sensory block to T6 with profound lower limb motor blockade. This progressed 2 hours later to upper limb weakness, with respiratory failure requiring intubation and ventilation. She remained unconscious for 9 hours after the initial intubating dose of thiopental. She was able to move all of her limbs 26 hours later and was successfully extubated 43 hours later.

In this case the authors felt that although the initial picture looked like the effects of subdural injection of bupivacaine and fentanyl, the prolonged coma with high motor blockade was more reminiscent of total spinal injection. They postulated that delayed total spinal anesthesia had occurred in this patient as a result of the epidural administration of a large quantity of bupivacaine and fentanyl via a hole made in the dura during the first attempt at epidural insertion.

Accidental subdural block can also lead to rapidly developing high block, patchy block, and symptoms such as myoclonus and anxiety (SEDA-20, 125) (SEDA-22, 136).

Total spinal anesthesia

Permanent or temporary deficits of spinal cord function are caused either by cord ischemia after arterial hypotension, or by cord compression due to an epidural or subdural hematoma or infection, or injury to the spinal cord and nerve roots as a consequence of needle puncture, introduction of a catheter, or chemical irritation.

Total spinal anesthesia is a potentially life-threatening complication of epidural anesthesia.

- A 68-year-old man developed total spinal anesthesia after the administration of 20 ml of ropivacaine 1% without a prior test dose via an epidural catheter, which was inadvertently placed intrathecally (83). Initial aspiration of both the Touhy needle and the catheter failed to identify the intrathecal position of the catheter. The patient noted weakness in his right leg immediately after the end of the injection. This was followed by weakness in his right arm, asystole, apnea, and loss of consciousness. Ventricular escape beats were noted and sinus rhythm returned after mask ventilation with 100% oxygen and the administration of atropine 1 mg and ephedrine 50 mg. He was able to open his eyes, but remained apneic and was therefore intubated and ventilated. Cardiovascular stability was maintained with incremental boluses of ephedrine to a total of 60 mg. He regained consciousness and was successfully extubated 145 minutes later. All sensory and motor deficits had resolved within 8 hours and no neurological deficit or transient neurological symptoms were detected 5 days later.

This complication emphasizes the fact that aspiration is not sufficient to identify an intrathecal catheter position and that a large dose of a local anesthetic should never be administered without a prior test dose.

- Total spinal anesthesia was suspected in a 46-year-old man who was found unconscious and apneic with no palpable cardiac output 20 minutes after a high thoracic (T2/3) epidural injection of 3 ml lidocaine 1% and 3 ml bupivacaine 0.125% (141). Following initial cardiopulmonary resuscitation he was admitted to the intensive care unit, where treatment included mechanical lung ventilation, thiamylal infusion, and cooling to a core temperature of 33–34°C. The thiamylal was withdrawn after 17 days and he was warmed and successfully extubated the next day. He was discharged after a further 4 months of rehabilitation with no relevant neurological consequences.

Horner's syndrome

Horner's syndrome (miosis, ptosis, anhidrosis, and vasodilatation, with increased temperature of the affected side) can result from epidural anesthesia. A report of Horner's syndrome due to a thoracic epidural catheter has highlighted the fact that small doses of local anesthetic can block the sympathetic fibers to the face, particularly when the catheter tip is close to T2 (142). The same symptoms have been reported after obstetric epidural anesthesia (143).

Horner's syndrome has been reported after lumbar epidural block in two other patients who were having lumbar epidural anesthesia for chronic pain treatment (144). The authors suggested that this complication had probably occurred through anatomical changes in the epidural space, leading to a high degree of sympathetic blockade.

A left-sided Horner's syndrome has been reported following a lumbar epidural with ropivacaine for cesarean section (145). The symptoms resolved after 5 hours. The

© 2006 Elsevier B.V. All rights reserved.

most likely cause was high sympathetic block, possibly facilitated by left lateral positioning, leading to cephalad spread of the local anesthetic. The authors also wondered whether the physicochemical properties of ropivacaine favor its effect on sympathetic fibers over bupivacaine.

Metabolism

A small reduction in glucose concentrations, rarely leading to hypoglycemic coma, can occur (SEDA-16, 130). This effect is in keeping with the finding that the catabolic stress response to surgery may be suppressed by epidural analgesia (SED-12, 254) (146). However, in one study, thoracic epidural administration produced a degree of hyperglycemia (SED-12, 252) (147).

- Symptomatic hypoglycemia occurred in a healthy 30-year-old primigravida after a second 5 ml bolus of 0.25% bupivacaine administered epidurally during labor (148). She developed an altered mental state, which responded rapidly to 50 ml of 50% dextrose administered intravenously.

Urinary tract

Epidural anesthesia increases the risk of urinary retention (149).

Musculoskeletal

Occasionally orthopedic patients have developed compartment syndrome postoperatively during epidural infusions of bupivacaine/fentanyl mixtures. However, although "aggressive analgesia" was blamed for the resulting disasters, there seems to have been a remarkable lack of adequate pressure area care, correct positioning, and regular review of both patients and splints (SEDA-22, 136).

Infection risk

Contamination of catheters, with subsequent clinical infection, is a potential hazard of epidural analgesia. But not every suspected infection is what it seems; aseptic meningitis has been described after an intradural injection of bupivacaine with methylprednisolone acetate (150).

Death

Inadvertent intravenous administration, due to the accidental placement of an epidural catheter in a vein, is a high-risk complication; deaths have been reported (151).

Pregnancy

Patient-controlled epidural analgesia using either 0.125% ropivacaine with fentanyl 2 micrograms/ml or 0.125% bupivacaine with fentanyl 2 micrograms/ml was studied in 50 patients during labor. Significantly more patients receiving bupivacaine developed motor blockade; 68% of patients in the bupivacaine group developed minimal motor block (Bromage score = 1), while the majority (68%) of patients in the ropivacaine group had no motor blockade. The incidences of adverse effects were similar in both groups. Hypotension occurred in 24% of the ropivacaine group and 16% of the bupivacaine group. Pruritus occurred in 56% of the ropivacaine group and 52% of the bupivacaine group (152).

In 122 women who received 20 ml of either ropivacaine 7.5 mg/ml or bupivacaine 5 mg/ml for epidural anesthesia during elective cesarean section, there were no significant differences in adverse effects, such as the incidence of hypotensive episodes, bradycardia, or nausea and vomiting; however, there was a greater median fall in systolic blood pressure in those given ropivacaine (24 versus 16%) (153). Efficacy and neonatal tolerability were similar in the two groups. This, together with its lesser cardiotoxicity, favors ropivacaine as an alternative to bupivacaine in this setting.

The possibility of increased maternal mortality is a topic of debate. In 1979 there were 150 maternal deaths (0.27 per 1000 births) in Germany, of which 15–25% were apparently related to regional anesthesia, with such complications as hypotension, systemic toxicity, total spinal block, hematoma, catheter rupture, and uterine injury (SED-12, 253) (154). However, obstetric regional anesthesia is regarded as being safer than general anesthesia, whatever the choice of drug, if competently and carefully performed.

Fetotoxicity

Maternal hypotension and excessive placental transfer of local anesthetics and other drugs, for example narcotics or sedatives, given to the mother before or during delivery are the main causes of neonatal death related to the use of these agents in obstetrics. However, deaths are very infrequent (155).

In about 10% of cases, obstetric use of epidural anesthesia will cause some bradycardia in the fetus, but this is not always a clinical problem (SEDA-15, 119). However, accidental intravenous injection of bupivacaine can lead to both maternal convulsions and severe fetal bradycardia (156).

The question of possible neurobehavioral effects in the child as a consequence of obstetric analgesia is still debated; although impairment of visual and neurological performance, reduced alertness, and alterations in walking and muscle tone have all been reported, most authors have found normal Apgar scores and psychomotor development after obstetric anesthesia (SED-12, 253) (157,158), and any functional defects noted at birth are likely to be transient (159).

The effects of low concentrations of epidural bupivacaine on the developing neonatal brain has been studied in infant rhesus monkeys, to decide if there was a detrimental relation between perinatal analgesia with epidural bupivacaine and later infant development (160). The monkeys, whose mothers had been given epidurals at term (but not during labor) were subjected to a battery of neurobehavioral tests for 1 year. The authors concluded that epidural bupivacaine did not cause neonatal abnormalities or specific cognitive defects, but that it may delay the normal course of behavioral development. It is difficult to extrapolate the results of this small study to human obstetrics.

Susceptibility factors

Epidural infusions of bupivacaine are often used in children. However, there are concerns about the increased incidence of adverse effects in infants, owing to reduced hepatic clearance and serum protein binding. In 22 infants

© 2006 Elsevier B.V. All rights reserved.

aged 1–7 months who received a continuous infusion of bupivacaine 0.375 mg/kg/hour for 2 days during and after surgery, the unbound and total serum concentrations of bupivacaine were measured, along with presurgical and postsurgical concentrations of alpha$_1$ acid glycoprotein (161). The concentrations of alpha$_1$ acid glycoprotein increased markedly after surgery. However, because of reduced clearance unbound concentrations of bupivacaine increased to over 0.2 micrograms/ml in two infants younger than 2 months. The authors proposed a maximum dosage rate of 0.25 mg/kg/hour in infants younger than 4 months and 0.3 mg/kg/hour in older infants.

Intercostal nerve anesthesia

High spinal anesthesia after inadvertent injection is a possible complication of intercostal nerve block (SED-12, 252). Pneumothorax is another reported complication (55).

Interpleural anesthesia

Interpleural administration of local anesthetics has been followed by Horner's syndrome and increased skin temperature, apparently pointing to an effect on the sympathetic nervous system (162). Pneumothorax or infection can also result. Interpleural administration of local anesthetics can produce high serum drug concentrations and a risk of systemic toxicity (SEDA-21, 13), possibly increased by the addition of adrenaline (SEDA-20, 126).

Intra-articular anesthesia

Intra-articular anesthesia has been used successfully in many patients, with few adverse effects (SEDA-20, 126). However, it is not always safe; at least one death has occurred from bupivacaine used in this way (163). Intra-articular anesthesia in the knee joint was followed in one case by necrosis of the knee ligament and the skin, apparently due to localized drug-induced embolism (164).

Intradermal anesthesia

Intradermal local anesthetic solutions can cause considerable pain on injection. Additives, such as hyaluronidase, which are used to enhance the analgesic effect of local anesthetics, can often exacerbate this (165). Infiltration from the inside of a wound can be less painful than through intact skin (166).

The order of injection can affect the pain of local anesthetic infiltration with buffered lidocaine; in a sequence of two injections the second injection was consistently reported to be more painful than the first. This finding has important consequences with regard to trial design in this area of research (167). Buffered lidocaine warmed to 37°C was less painful than warmed plain lidocaine, plain lidocaine, and buffered lidocaine in a randomized controlled trial in 26 volunteers (168).

Intrathecal (spinal) anesthesia

Intrathecal anesthesia has been compared with general anesthesia in 33 patients with pre-eclamptic toxemia undergoing cesarean section (169). The complications after general anesthesia were more serious, with a 4.3% mortality, whereas complications after spinal anesthesia were less serious and easily manageable, notably intraoperative hypotension (47%), difficulty in locating the subarachnoid space (29%), and intraoperative vomiting (6%).

Hyperbaric ropivacaine 0.25% has been compared with hyperbaric bupivacaine 0.25% in a crossover study in 18 volunteers who received an intrathecal anesthetic; the doses were 4, 8, or 12 mg (170). More patients had lumbosacral back pain after intrathecal ropivacaine compared with bupivacaine (5 versus 1), although this difference was not significant; the back pain lasted 3–5 days and was mild to moderate in intensity.

Intrathecal isobaric ropivacaine (15 mg) has been compared with intrathecal isobaric bupivacaine (10 mg) in 100 patients having transurethral resection of the bladder or prostate (171). Median cephalad spread of blocks was two segments higher for both pinprick and cold with bupivacaine compared with ropivacaine. Onset time to anesthesia was the same in both groups. Significantly more patients in the ropivacaine group complained of painful sensations at the surgical site (16 versus 0%). There was no difference in anesthetic duration, the incidence, intensity, onset, and duration of motor blockade, or the incidence of hypotension in the two groups. There were no cases of transient neurological symptoms. The authors concluded that ropivacaine 15 mg is less potent than bupivacaine 10 mg for intrathecal analgesia.

Continuous intrathecal anesthesia with 10 ml of 0.25% bupivacaine over 24 hours has been compared with continuous epidural anesthesia with 48 ml of 0.25% bupivacaine over 24 hours during the first 2 days after hip replacement in 102 patients (172). Continuous spinal anesthesia provided better analgesia and more patient satisfaction, but significantly more patients had motor blockade during the day of surgery and the first postoperative day. There was a significantly higher incidence of nausea and vomiting with continuous epidural anesthesia (39 versus 21).

When a pneumatic tourniquet was used in intrathecal anesthesia, pain was twice as frequent with tetracaine (60%) as with bupivacaine (25%) (173). However, using bupivacaine and tetracaine together seems to produce a more prolonged analgesic effect without inducing more hypotension than either agent alone (SEDA-18, 143).

In 80 patients undergoing lower extremity or lower abdominal surgery randomized to receive hyperbaric bupivacaine 10 mg alone or in combination with fentanyl 12.5 micrograms intrathecally, those given fentanyl had significantly longer duration of analgesia with no reported sedation or respiratory depression (174). Pruritus occurred in 20% of patients given fentanyl and shivering occurred significantly more often in those given bupivacaine only (30 versus 12.5%).

The addition of low doses of clonidine and neostigmine to intrathecal bupivacaine + fentanyl in 30 patients in labor significantly increased the duration of analgesia but was associated with significantly more emesis (175).

In a comparison of intrathecal bupivacaine 10 mg and bupivacaine 7.5 mg combined with ketamine 25 mg, in 30 healthy women there was no extension of postoperative analgesia or reduction in postoperative analgesic requirements in those given ketamine (176). Those given ketamine had a shorter duration of motor blockade, but had an increased incidence of adverse effects, and the study was abandoned after 30 patients.

© 2006 Elsevier B.V. All rights reserved.

Intrathecal blockade with 0.5% isobaric bupivacaine 10 mg has been compared with 0.5% isobaric bupivacaine 5 mg combined with fentanyl 25 micrograms (diluted to 2 ml with isotonic saline) in 32 patients undergoing elective cesarean section (177). The bupivacaine + fentanyl combination was associated with significantly less hypotension than bupivacaine alone (31 versus 94%) and a near 10-fold reduction in the mean ephedrine requirement (2.8 versus 23.8 mg). There were also significant differences in the incidence of nausea (31 versus 69%) and the median time to peak block (8 versus 10 minutes) with bupivacaine plus fentanyl. The authors advised further large-scale studies to quantify the minimum dose of bupivacaine plus fentanyl for single-dose spinal anesthesia.

An isobaric solution of sameridine given intrathecally in doses of 15, 20, and 23 mg has been compared with hyperbaric lidocaine 100 mg in 100 volunteers (178). Sameridine has both local anesthetic and opioid analgesic properties. There was one incident of transient paresthesia with sameridine 20 mg and two cases of bradycardia with lidocaine; the incidence of hypotension was more frequent with lidocaine, but pruritus was more common with sameridine.

Cardiovascular

Hypotension is the most frequent adverse effect of spinal anesthesia; in one very large series it occurred in 22% of the subarachnoid group (179), but the actual figures differ with the anesthetic, its concentration, and the definition of hypotension used. For example single-dose spinal anesthesia causes significantly more hypotension and bradycardia than continuous spinal anesthesia (180). Hypotension may be more of a problem with tetracaine or lidocaine than with bupivacaine in equivalent doses (SEDA-12, 35), and the incidence is less when the patient is in the lateral rather than the sitting position. However, using bupivacaine and tetracaine together seems to produce a more prolonged analgesic effect without inducing more hypotension than either agent alone (SEDA-18, 143). Hypotension is also reported with intrathecal opioids and opioid/local anesthetic combinations; sufentanil appears to predominate in these reports (SEDA-21, 132) (SEDA-22, 137).

Hypotension can be prevented or treated with vasopressors and/or fluids (SED-12, 254) (SEDA-18, 143) (181–183). A comparison of these approaches showed that ephedrine alone is less effective than ephedrine and colloid (184), and metaraminol, with or without colloid, is better than colloid alone (185).

The effect of baricity on the hemodynamic effects of intrathecal 0.5% bupivacaine has been measured by recording invasive systolic blood pressure and central venous pressure in 36 men given plain bupivacaine 0.5%, heavy bupivacaine 0.5% (in dextrose 8%), or a mixture of the two (in dextrose 4%) (186). Heavy bupivacaine caused more rapid falls in central venous pressure and systolic blood pressure than plain bupivacaine. However, it was subsequently remarked that both 4 and 8% dextrose are significantly hyperbaric relative to adult cerebrospinal fluid, implying that the 4% solution should have behaved more like the 8% solution (187).

In 191 women who had had cesarean sections under spinal anesthesia using hyperbaric bupivacaine 12–15 mg and morphine 0.25 mg, who were transferred to the recovery room on a stretcher with the upper body either flexed 30° or supine during transport 10% of each group had a greater than 20% fall in systolic blood pressure unaffected by position (188). The authors recommended routine monitoring of the blood pressure and pulse after transfer to the stretcher, and suggested that raising the head for the comfort of the mother during transport does not increase the risk of hypotension.

Isobaric bupivacaine 4 mg combined with fentanyl 20 micrograms has been compared with isobaric bupivacaine 10 mg alone in 20 patients over the age of 70 undergoing surgery for fractured neck of femur (114). Hypotension was defined as a systolic blood pressure less than 90 mmHg or a fall in mean arterial pressure of more than 25%. Significantly more patients given bupivacaine only had hypotension (90 versus 10%). The mean dosage requirement of ephedrine was higher with bupivacaine only (32 versus 0.5 mg) and two patients in this group required phenylephrine, while no patient given bupivacaine plus fentanyl did. No patient in either group complained of perioperative pain or required supplementary analgesia intraoperatively.

In young infants similar problems with blood pressure occur, and some changes in heart rate may be found, but tend to be transient (SEDA-12, 154) (189).

Intrathecal blockade for cesarean section using 0.5% hyperbaric bupivacaine at three different doses of 7.5 mg, 8.75 mg, and 10 mg has been studied in a double-blind comparison in 60 patients (190). There was no significant difference in maximum block height, but more of the patients who were given the two lower doses had moderate visceral pain requiring rescue ketamine. Bupivacaine 10 mg was associated with significantly more bradycardia, and 7.5 and 8.75 mg with significantly more hypotension. Motor block lasted significantly longer with 10 mg. The outcome was good in all the infants, although one baby whose mother had received bupivacaine 10 mg had an Apgar score below 10 at 5 minutes. The authors concluded that the use of bupivacaine 7.5 mg avoids hypotension, bradycardia, and prolonged block.

Bradycardia occurs in some 3% of spinal anesthetics in adults. Bradycardia can lead to cardiac arrest, either by direct block of the sympathetic innervation of the heart (in unintended high block) or as a consequence of insufficient venous return. In 900 cases of major anesthetic mishaps giving rise to compensation claims, there were 14 cases of cardiac arrest under spinal anesthesia, of which six were fatal (191). Myocardial infarction and cardiac arrest preceded by atrioventricular block have also been described.

- A 68-year-old man was given 0.5% bupivacaine 4 ml or spinal anesthesia, and 5 minutes later complained of nausea and developed hypotension, loss of consciousness, and a tonic-clonic seizure. He had first-degree heart block 4 minutes after subarachnoid injection, followed 1 minute later by third-degree heart block, and then asystole. He was successfully resuscitated. Proposed theories included a reflex bradycardia resulting from reduced venous return and/or unopposed

© 2006 Elsevier B.V. All rights reserved.

vagal tone due to thoracic sympathectomy induced by spinal anesthesia (192).

Bradycardia has been reported to follow spinal anesthesia in association with urinary retention (193).

- A receding spinal block to level L1–2 gave rise to acute bradycardia (34–40/minute) and transient loss of consciousness in a 31-year-old man 5 hours after spinal anesthesia; on waking he complained of severe low back pain, and although he had no symptoms of urinary retention, urinary catheterization yielded 900 ml of urine with immediate relief of symptoms.

Slow injection of hyperbaric bupivacaine 8 mg has been compared with hyperbaric bupivacaine 15 mg used to achieve bilateral block in 30 patients of ASA grades I–II (194). There was significantly greater cardiovascular stability in the patients who had a unilateral spinal block.

Respiratory

Respiratory arrest is one of the most serious potential adverse effects of spinal anesthesia, either due to brainstem depression in high block or rostral spread of opioids after the use of combined techniques (SEDA-21, 132) (SEDA-22, 137).

Immediate respiratory arrest has been reported after the administration of intrathecal bupivacaine and fentanyl (195).

- A 26-year-old woman in labor was given an epidural for analgesia. After 2 hours and total doses of bupivacaine 77.5 mg and fentanyl 190 micrograms, the epidural was removed owing to failure. A subsequent intrathecal injection of bupivacaine 2.5 mg plus fentanyl 10 micrograms was followed 4 minutes later by apnea and loss of consciousness. She was rapidly intubated and regained consciousness after 15 minutes, at which time her sensory level was T8 to pinprick. She was extubated after 30 minutes.

The authors concluded that the respiratory depression had been due to excessive cephalad spread of fentanyl, possibly facilitated by the volume of bupivacaine that had previously been injected epidurally.

Bronchospasm has been reported in two obstetric patients, possibly due to thoracic sympathetic blockade in one and hypersensitivity in the other (SEDA-21, 132).

There is a potential risk that spinal anesthesia will cause apnea in premature infants. However, spinal anesthesia with a sound technique has been used safely in high-risk infants. Tetracaine was used in 142 such cases; only two infants had serious adverse effects, one with unexplained but treatable apnea and one in whom too high a block resulted in respiratory arrest (196).

Two former preterm infants (postconceptual age 38 weeks) both received spinal anesthetics for inguinal herniorrhaphy (block level T4–6) (197). No other medications were given. Both infants had frequent episodes of perioperative apnea and associated bradycardia. One had a 20-second bout of apnea, with an oxygen saturation of 70% and a heart rate of 80/minute, the other a 30-second bout of apnea, with a saturation of 70% and a heart rate of 60/minute. These episodes persisted for 8 hours into the postoperative period in one of the infants.

- A patient who was receiving modified-release morphine for malignant pain had a respiratory arrest after intrathecal bupivacaine 12.5 mg. She recovered after treatment with naloxone. Another patient who was taking modified-release morphine was given intrathecal morphine 10 mg and bupivacaine 7.5 mg. He had respiratory distress and became comatose. Morphine-induced respiratory depression was not diagnosed and the patient subsequently died. In both cases, respiratory distress and sedation was probably due to opioid action in the absence of the stimulating effect of pain on respiration, due to the intrathecal bupivacaine (198).
- A 20-year-old woman who received a combined spinal epidural for labor had a respiratory arrest 23 minutes after the administration of sufentanil 10 micrograms and bupivacaine 2.5 mg (199).

Nervous system

- A 40-year-old woman developed acute aphasia and a change in mental status 15 minutes after the intrathecal administration of sufentanil 10 micrograms and isobaric bupivacaine 2.5 mg as part of a combined spinal epidural anesthetic for analgesia during labor (200). She appeared to be in a dissociated state, had apparent difficulty swallowing, and was aphasic, but able to follow simple commands. She had sensory block to T6 on the right and T8 on the left, with no motor block. The neurological picture resolved about 100 minutes after the anesthetic; an exact etiology could not be established.
- A similar case has been reported 20 minutes after the intrathecal administration of 0.5% hyperbaric bupivacaine 2 ml for cesarean section (201). She became unresponsive then apneic for a short time. There were no changes in heart rate or blood pressure and no loss of airway protection. She slowly regained consciousness over the next hour without any consequences.

The authors were unclear about the cause and suggested subdural injection, as the slow onset, stable hemodynamics, and rapid recovery were suggestive of this complication. However, other causes, including a psychogenic response, are possibilities.

- New onset, severe lightning pain after repeated subarachnoid blockade occurred in a 48-year-old man with pre-existing neuropathic pain after incomplete spinal cord injury, similar to previous reports in patients with phantom limb pain (202).

Postural headache is a common complication of spinal anesthesia (so-called postdural puncture headache). It is caused by CSF leakage through the puncture site. The incidence has been greatly reduced by the use of smaller-gauge and pencil-point spinal needles. However, headache (or psychosis) can be the presenting sign of subdural hematoma, which has twice been observed in women given spinal anesthesia for childbirth (SEDA-18, 143).

- A 30-year-old patient developed aseptic meningitis 24 hours after spinal anesthesia with bupivacaine plus fentanyl; it resolved without sequelae within 48 hours (203).

Conus medullaris syndrome has been reported after consecutive intrathecal injections of hyperbaric 1%

© 2006 Elsevier B.V. All rights reserved.

tetracaine, followed by hyperbaric 5% lidocaine with adrenaline, in a patient with diabetic neuropathy (SEDA-21, 130).

Less frequent neurological complications are bladder dysfunction or sphincter paresis (204), intracranial hypertension, and convulsions, the latter reflecting systemic toxicity.

- A 36-year-old man had two generalized tonic-clonic convulsions after receiving intrathecal tetracaine 8 mg to supplement inadequate block established by intrathecal administration of tetracaine 10 mg (205). His seizures were controlled with intravenous thiamylal sodium. He regained consciousness, but complained of dizziness and blurred vision. He had a sensory block to T4–5.

The authors excluded total spinal anesthesia as a cause of the seizures, on the basis of the sensory level and the lack of hypotension.

Cauda equina syndrome

Cauda equina syndrome is the triad of bilateral paraparesis or paraplegia of the muscles of the legs and buttocks, saddle anesthesia plus sensory deficits below the groin, and incompetence of bladder and rectal sphincters, causing incontinence of urine and feces.

Cauda equina syndrome has been reported after the use of microcatheters for continuous intrathecal anesthesia. The concern was sufficient reason for the FDA to withdraw microcatheters from the US market after 11 cases of cauda equina in 1992 (SEDA-21, 129) (206). It has now become obvious that a confounding factor was the use of hyperbaric solutions pooling around lumbosacral nerve roots, aggravated by the poor mechanics of microcatheters and the use of inappropriate amounts; the authors of one study argued that the problem was not evident with the use of low concentrations of isobaric local anesthetics administered via microcatheters (207).

Six cases of the syndrome have also been reported after "single-shot" spinal anesthesia at the L3–4 interspace with 5% hyperbaric lidocaine (208).

- A 55-year-old man was given 5% hyperbaric lidocaine 100 mg intrathecally in the sitting position for transurethral resection of the prostate in the lithotomy position, with no complications. However, the next day he complained of persistent numbness of the perianal, scrotal, penile, and sacral regions, and both legs. He also had difficulty in defecation and weakness of both quadriceps muscles. Despite normal MRI scanning, electromyography, and electroneurography, he had no neurological improvement, even 1.5 years after the operation.
- A 59-year-old woman received 5% hyperbaric lidocaine 60 mg for an operation on a toe. That evening she complained of urinary and bowel incontinence; 5 months later she had urinary stress incontinence and bowel incontinence, with absent anal reflexes. There was also reduced sensation over the medial side of the foot.
- A 48-year-old woman had spinal anesthesia for hallux valgus surgery and had pain radiating to the left buttock during insertion of the needle. Hyperbaric 5% lidocaine 100 mg was injected, with no associated paresthesia. One month later, she complained of persistent numbness of the perianal and sacral regions and had sensory loss in these regions, which failed to improve over 6 months.
- A 31-year-old man had spinal anesthesia with 5% hyperbaric lidocaine 100 mg for fasciotomy. His systolic blood pressure briefly fell to 90 mmHg and he was given ephedrine. He later complained of persistent numbness of the entire right leg, right scrotum, right side of the penis, and right buttock, and had difficulty in micturition; there was no improvement one month later, and he had reduced pain and temperature sensation in the right leg, intact touch sensation, and weakness of right hip extension. His neurological state did not improve over a year.
- A 37-year-old woman had varicose vein surgery under spinal anesthesia with 5% hyperbaric lidocaine 120 mg in two injections followed by a general anesthesia, because the spinal block was inadequate. Postoperatively she complained of persistent numbness in the right buttock, difficulty in micturition, and bowel incontinence. She had reduced sensation in the perianal region and both labia majora, with a large residual urine volume. An MRI scan was normal, but electromyography, electroneurography, and cystometry 4 months later showed denervation of the pelvic muscles, partial denervation of the detrusor muscle, and signs of reinnervation. After 5 months her condition remained much the same.
- A 59-year-old man had spinal anesthesia for hallux valgus surgery with 5% hyperbaric lidocaine 75 mg. The next day he had persistent perianal numbness, difficulty in micturition, and a large residual urine volume. An MRI scan was normal and he had reduced perianal and scrotal sensation, difficulty in defecation, and erectile impotence. He was no better 5 months later.

The authors stated that at least some of the cases had probably resulted from neurotoxicity of hyperbaric lidocaine, most often in the absence of obvious maldistribution. They recommended that hyperbaric lidocaine should be used in concentrations not exceeding 2% and in a total dose no greater than 60 mg.

- A 75-year-old woman with a history of lumbar laminectomy, but no neurological deficit, received an intrathecal injection of 4 ml of 0.5% bupivacaine with preservatives at the L4–5 level using a 22-gauge spinal needle for a total knee replacement (209). Intraoperatively she complained of severe low back pain, which improved 8 hours later. In parallel, she developed persistent sensory loss to L1 and flaccid paralysis of both legs. An MRI scan was normal, but myelography showed inflammation of the cauda equina; 2 months later she developed hydrocephalus and had adhesive arachnoiditis of the thoracolumbar region. Her neurological condition did not improve over 2 years.

A retrospective review of 603 continuous spinal anesthetics (127 had microcatheters) showed three patients with postoperative paresthesia, one of whom was from

© 2006 Elsevier B.V. All rights reserved.

the microcatheter group (210). One patient, who had received anesthesia via a macrocatheter with 5% lidocaine, developed sensory cauda equina syndrome.

- A 57-year-old man with pre-existing severe vascular disease was given bupivacaine 12.5 mg with 1:1000 adrenaline 0.2 ml for incision and drainage of a thigh abscess (211). After 2–3 minutes he complained of "severely painful warmth" on the anterior of both thighs. The pain resolved with onset of the block, but the next morning he had symptoms of cauda equina syndrome. Some perineal sensation returned over the next few days.

The authors suggested that the neurological deficit had been due to anterior spinal artery insufficiency secondary to intrathecal bupivacaine and adrenaline. They questioned the use of adrenaline in patients with multi-organ vascular disease.

- A man with severe vascular disease was given general and epidural anesthesia with 2% isobaric lidocaine plus adrenaline for a popliteal distal vein bypass graft (212). The epidural inadvertently became a total spinal, which was discovered at the end of the operation. He developed cauda equina syndrome, confirmed by electromyography. He was unable to turn or sit up by himself for a month and at 12 months was walking with a cane and needed self-catheterization and medication for neuropathic pain.

The cauda has a tenuous blood supply, and in this patient with pre-existing vascular disease, perioperative hypotension and the use of intrathecal adrenaline may have precipitated ischemia in an area with very poor reserve. To follow this with an accidental large dose of lidocaine, which is neurotoxic in animals when directly applied and theorized to cause interruption of nerve blood supply, would add insult to injury. The authors questioned the wisdom of performing continuous epidural anesthesia in such patients, when frequent neurological assessments cannot be performed.

Bupivacaine has recently been implicated in two cases of cauda equina syndrome (213). One patient was given 3.6 ml of a hyperbaric 0.5% solution, and the other, 3.5 ml of plain bupivacaine. Spinal stenosis was felt to have contributed to the first case, while the cause of the second was unclear.

- Cauda equina syndrome occurred in a 55-year-old woman who underwent spinal anesthesia with a 22 G needle in the L4–5 interspace (214). On needle insertion, she felt radiating pain in her right leg. The needle was immediately withdrawn and repositioned. Pain-free intrathecal injection of 2.0 ml of hyperbaric cinchocaine 0.24% with adrenaline 66 micrograms resulted in block to L1. Surgery was carried out in the supine position. Three days postoperatively, she had enuresis and reduced perineal sensation, without bowel dysfunction or lower limb symptoms. There was sensory loss at S2–5. The symptoms persisted, required self-catheterization and systemic steroids, and disappeared on the 19th postoperative day.

The cause of this transient neurological deficit was unclear, but the authors suggested that the following factors may have contributed:

- direct nerve damage;
- local anesthetic toxicity;
- adrenaline effects.

Transient radicular irritation

Neurological sequelae of intrathecal anesthesia are rare and usually minor. However, transient radicular irritation can occur with the use of both isobaric and hyperbaric solutions of local anesthetics. Hyperbaric 5% lidocaine is such a persistent offender that there is little to recommend its use in neuraxial blockade (SEDA-20, 125) (SEDA-21, 129) (SEDA-22, 138). However, others have suggested that lidocaine can be used for intrathecal anesthesia if a short-acting anesthetic is desired (215). There have also been reports with most other local anesthetics, including tetracaine and mepivacaine. High concentrations of hyperbaric 4% mepivacaine are likely to cause transient radicular irritation of the same order of magnitude as 5% lidocaine (216). A randomized study with isobaric mepivacaine 2% administered intrathecally to patients undergoing surgery in the supine position showed an incidence of 7.5% compared with 2.5% with isobaric lidocaine 2% (217). There is a low incidence of transient radicular irritation after intrathecal bupivacaine, but a few cases have been reported (SEDA-20, 125). Bupivacaine and tetracaine have toxic effects on chick neuron cultures in vitro (218).

Since the cause of transient radicular irritation after lidocaine intrathecal anesthesia has not been elucidated, and although non-neurotoxic mechanisms must be considered, it has been recommended that the lowest effective doses and concentrations for intrathecal injection should be used (219).

Presentation Transient radicular irritation causes transient pain in the back, buttocks, and lower extremities, without formal neurological signs or symptoms. It can follow single-dose intrathecal anesthesia. Lidocaine has been reported as the predominant culprit. However, transient radicular irritation has also been reported with bupivacaine, mepivacaine, tetracaine, and prilocaine. Osmolarity, the addition of dextrose, and speed of injection do not contribute, and even reducing the concentration of lidocaine does not alter the incidence (220,221).

Cases involving lidocaine (222–224) and mepivacaine (225,226) have been reported.

- A 50-year-old woman had a right knee arthroscopy under spinal anesthesia with 1% lidocaine 4 ml. The anesthetic and procedure were uncomplicated. At 4 hours she complained of a mild cramp in her buttocks and went home at 6 hours. By the next morning the buttock pain was severe, cramp-like in nature, and radiated down the fronts of both thighs. Walking alleviated it, simple analgesics were ineffective, and lying down made the pain worse. Neurological examination was unremarkable and the pain was gone after 36 hours.
- A 74-year-old man who had a cystoscopy performed in the lithotomy position, reported dull pain in the hips, buttocks, and legs, radiating to the toes after a spinal anesthetic with 5% hyperbaric lidocaine 75 mg. The pain occurred 30 hours after the dural puncture and

© 2006 Elsevier B.V. All rights reserved.

disappeared after 18 hours. Three months before he had had a similar anesthetic for a transurethral resection of the prostate and complained of similar but more severe symptoms of transient radicular irritation.

- A 66-year-old woman with unrecognized spinal stenosis had six spinal anesthetics over 3 years. The first five were with lidocaine 2%. After 24–48 hours, she developed pain in the back, hips, buttocks, and thighs, which lasted for 2–3 days. On the sixth occasion she had a spinal anesthetic with 1.5% mepivacaine 4 ml and the next day again had severe back pain radiating bilaterally to the hips and thighs.
- Three patients undergoing minor surgical procedures in the lithotomy position were given a spinal anesthetic with 2% mepivacaine 3 ml. From 6 to 10 hours postoperatively they complained of burning pain in both buttocks radiating to both thighs and calves. Neurological examination in all cases was normal and all symptoms had resolved by 3–5 days postoperatively.
- A 30-year-old man had a left spermatic vein ligature performed in the supine position. He had uncomplicated unilateral spinal anesthesia with 1% hyperbaric bupivacaine 8 mg. Three days later he reported an area of hypesthesia in the L3–4 dermatomes of the left leg. Sensation returned to normal after 2 weeks.

Incidence The incidence of transient radicular irritation varies depending on the local anesthetic used, its baricity, and its concentration. It has been reported to be as high as 37% in patients who receive 5% lidocaine. In a prospective study of 303 parturients undergoing intrathecal anesthesia using 0.75% hyperbaric bupivacaine or 5% lidocaine there were no cases of transient radicular irritation after lidocaine (227). This is remarkable, as significantly more procedures were performed in the lithotomy position in the lidocaine group; the authors wondered if such a low incidence of transient radicular irritation could have been explained by their use of a 1:1 dilution of lidocaine with cerebrospinal fluid.

Transient neurological symptoms have been studied in patients given intrathecal lidocaine 2% or intrathecal prilocaine 2%. In one study of 70 patients transient neurological symptoms occurred in 20% of patients given lidocaine, with no cases in those given prilocaine (228). In another study in 70 patients given intrathecal procaine or lidocaine in a 2:1 dose ratio there were significantly more transient neurological symptoms with lidocaine than with procaine (31 versus 6%) (229). However, in a similar study of 100 patients there was no significant difference in the incidence of transient neurological symptoms, although the trend suggested a lower incidence with prilocaine (4 versus 14.3%) (230).

In 110 patients presenting for knee arthroscopy who were randomized to receive either 1% hypobaric lidocaine 50 mg or 1% hypobaric lidocaine 20 mg + fentanyl 25 micrograms complaints of transient neurological symptoms were nearly ten times more frequent in those given lidocaine 50 mg (33 versus 3.6%) (231). Patients given lidocaine 50 mg also had a greater fall in systolic blood pressure and a greater need for ephedrine.

In a prospective study of 1045 patients receiving spinal anesthesia with 3% hyperbaric lidocaine for anorectal surgery in the prone position, 4 (0.4%) complained of aching, hypesthesia, numbness, and dull pain in both buttocks and legs on the third postoperative day. In three cases the symptoms resolved by day 5 and in one by day 7 (232).

In a retrospective audit of 363 patients receiving spinal anesthesia, of whom 322 received hyperbaric 5% lidocaine 75–100 mg and 41 hyperbaric 0.5% bupivacaine 12.5–15 mg, six patients given lidocaine reported back pain at 24 hours; five of them had undergone arthroscopy. One patient given bupivacaine, who underwent arthroscopy, complained of backache (233).

Over 14 months, 1863 patients received spinal anesthesia, of whom 40% were given bupivacaine, 47% lidocaine, and 13% tetracaine (234). Patients given lidocaine had a significantly higher risk of transient radicular irritation (relative risks 5.1 compared with bupivacaine and 3.2 compared with tetracaine). They were more likely to be men, have outpatient surgery, and have surgery in the lithotomy position. For those who were given lidocaine, the relative risk of transient radicular irritation was 2.6, for those in the lithotomy position 3.6, and for ambulatory surgery 1.6. Most of the patients had resolution of symptoms by 72 hours and all by 6 months.

The incidence of transient radicular irritation with two different local anesthetics used for single-dose spinal anesthesia has been studied in 60 ambulatory patients given spinal anesthesia for knee arthroscopy (235). None of those who were given 1.5% mepivacaine 45 mg developed transient radicular irritation. Six of those given 2% lidocaine 60 mg developed transient radicular irritation, but all symptoms resolved by 1–5 days. The difference between the two groups was significant.

Of 90 patients who received intrathecal hyperbaric lidocaine 5%, mepivacaine 4%, or bupivacaine 0.5%, none in the bupivacaine group developed transient radicular irritation, but 20% in the lidocaine group and 37% in the mepivacaine group complained of a mixture of back and leg pain, classified as transient radicular irritation (216).

When 90 patients received spinal anesthesia for gynecological procedures with 2% lidocaine, 2% prilocaine, or 0.5% bupivacaine (all 2.5 ml in 7.5% glucose), nine of the 30 patients who received lidocaine had transient radicular irritation, defined as pain or dysesthesia in the legs or buttocks, compared with none of the 30 patients who received bupivacaine (236). The symptoms resolved within 48 hours. One of the 30 patients who received prilocaine had transient radicular irritation that lasted for 4 days.

In 200 patients given hyperbaric 5% lidocaine or hyperbaric 5% prilocaine, four developed transient radicular irritation after lidocaine (the patients were supine or prone) compared with one after prilocaine (this patient had a knee arthroscopy) (237). There were no significant differences between the two groups.

When procaine 5% or procaine 5% with fentanyl 20 micrograms was given to 106 patients for spinal anesthesia, the incidence of transient radicular irritation was 0.9% (238). There was nausea and vomiting in 17% of men and 32% of women.

Procaine has been suggested as an alternative to lidocaine for intrathecal use in ambulatory surgery, as it also

© 2006 Elsevier B.V. All rights reserved.

has a short duration of action. In a randomized, double-blind comparison of procaine 10% or lidocaine 5% in glucose 7.5% for spinal anesthesia, transient radicular irritation occurred in 27% of the lidocaine group compared with none of the patients in the procaine group (239). However, the failure rate in the procaine group was 14%. This was perhaps a reflection of the fact that the procaine was glucose-free.

Intrathecal hyperbaric lidocaine 1.5% has been compared with hyperbaric bupivacaine 0.75% for outpatient transvaginal oocyte retrieval (240). The time to voiding of urine and the time to discharge were significantly longer in the bupivacaine group, despite the fact that there were no differences in the time to recovery of sensory and motor function. The incidence of transient radicular irritation in the lidocaine group was 5%, compared with none of the women in the bupivacaine group. The authors concluded that bupivacaine was a useful alternative to lidocaine in outpatient spinal anesthesia.

There have been two studies of transient radicular irritation in the obstetric population. One was a randomized, double-blind comparison of intrathecal hyperbaric lidocaine 5% or bupivacaine 0.75% for postpartum tubal ligation (241). All the patients were supine for surgery. The incidence of transient radicular irritation was 3% with lidocaine and 7% with bupivacaine. The other was a prospective follow-up study of patients who had cesarean sections under spinal anesthesia using hyperbaric 0.5% bupivacaine; the incidence of transient radicular irritation was 8.8% (242).

In a careful meta-analysis, 29 randomized, controlled studies of the incidence of transient radicular irritation were identified (243). Lidocaine and mepivacaine were identified as the two local anesthetics that most commonly cause transient radicular irritation, while prilocaine, bupivacaine, and ropivacaine had the lowest incidences. Owing to insufficient data, definitive statements could not be made about the effects of the baricity of the local anesthetic, the concentration, and the effect of vasoconstrictors, although all these factors seemed not to be relevant. With regard to intrathecal ropivacaine, the incidence in the formal studies was zero. However, there has been one previous report after intrathecal administration, and one report of transient radicular irritation following epidural anesthesia with ropivacaine; the symptoms resolved within 24 hours (244).

Mechanism The cause of transient radicular irritation is unclear but probably multifactorial. Several factors have been implicated (SEDA-21, 130) (220,245):

(a) high concentrations of local anesthetic producing neurological injury;
(b) possibly the high osmolarity and density of some solutions;
(c) the addition of vasopressors that compromise neural blood flow;
(d) pooling of anesthetic around nerve roots;
(e) the patient's position, with a significantly higher incidence in patients positioned for knee arthroscopy and the lithotomy position (stretching lumbosacral nerve roots);
(f) co-existing disease subarachnoid lidocaine;
(g) ambulatory surgery;
(h) stretching of nerve roots.

With the introduction of 25 gauge and 27 gauge spinal needles, it was suggested that slow injection may be an additional factor predisposing to transient radicular irritation, since layering of the hyperbaric fluid in the dependent portion may lead to areas of highly concentrated local anesthetic (246).

The high baricity of the local anesthetic solutions was thought to be chiefly responsible for transient radicular irritation. However, isobaric local anesthetics have also been implicated; commonly the concentrations are 2% or greater. From comparisons of 2 and 5% hyperbaric and isobaric lidocaine and hyperbaric 0.5% bupivacaine, it seems more likely that high concentrations of local anesthetic solutions are responsible for transient radicular irritation rather than the osmolarity of the solutions (247–249). That the concentration of lidocaine is not a contributory factor to transient radicular irritation has been shown in 109 patients who received hyperbaric spinal lidocaine 50 mg, as a 2, 1, or 0.5% solution (250). The incidence of transient radicular irritation did not differ (16, 22, and 17% respectively).

The importance of the patient's position has been illustrated by a study in which transient neurological symptoms occurred in five of 12 volunteers who were given 5% lidocaine 50 mg intrathecally and then placed in the low lithotomy position (251). No consistent abnormalities were detected by prespinal and postspinal electromyography, nerve conduction studies, or somatosensory evoked potentials. This is in line with the current opinion that transient neurological symptoms constitute neither a true neurological syndrome nor an expression of the neurotoxicity of local anesthetics.

In 70 patients undergoing surgery in the supine position, there were transient neurological symptoms in 26% of patients after intrathecal lidocaine, compared with 3% after intrathecal bupivacaine (252). The incidence of transient neurological symptoms after intrathecal lidocaine 5% in patients undergoing surgery in the supine position is therefore similar to the previously reported incidence in the lithotomy position.

Animal studies have highlighted the potential toxic effects of adding adrenaline to local anesthetics for intrathecal injection. In one study the effects of adding 0.01% adrenaline to intrathecal tetracaine 1% and 2% was investigated in rabbits (253). Although adrenaline had no neurotoxic effects when given alone, there was worsening of neurotoxicity when it was given in combination with tetracaine. The same group had previously shown an increase in glutamate concentrations in the CSF and dose-dependent neurotoxicity with tetracaine injected intrathecally in rabbits (254). In another study they looked at the effects of intrathecal lidocaine 5% with and without adrenaline 0.02% on the spinal cord and nerve roots of rats (254). They showed that lidocaine 5% caused persistent sensory impairment and histological damage that was significantly exacerbated by the addition of adrenaline.

Several explanations for the increased neurotoxicity of vasoconstrictors, such as adrenaline and phenylephrine, in combination with local anesthetics have been offered:

© 2006 Elsevier B.V. All rights reserved.

(a) vasoconstrictors may reduce the absorption of local anesthetics and thereby increase anesthetic exposure intrathecally;
(b) a reduction in blood flow caused by vasoconstrictors may cause ischemia in the spinal cord;
(c) bisulfite, used as a preservative in adrenaline formulations, which may have a role, although that would not explain the lack of toxicity seen with adrenaline alone.

A randomized study in 64 patients undergoing urological, gynecological, or lower limb surgery showed no significant difference in the incidence of transient neurological symptoms between hyperbaric tetracaine 0.5% with and without phenylephrine 0.025% (255). In fact, the neurological symptoms that were described (in 6.7% of the patients) occurred in the group without phenylephrine and could possibly have been explained by the patient's position or by the effects of plaster-cast compression postoperatively.

Early ambulation has previously been implicated in transient radicular irritation. However, in a randomized trial there was no difference between early and late mobilization in patients who received intrathecal lidocaine 2% for inguinal hernia repair; the incidence was 23% in both groups (256).

In a prospective audit of 100 patients having intrathecal anesthesia with 5% hyperbaric lidocaine in a mean dose of 73 mg, there was an unusually low incidence of 4% (257). All the patients recovered completely, which led the authors to conclude that 5% hyperbaric lidocaine is acceptable for intrathecal anesthesia in patients in whom rapid recovery from the block is desired. The low incidence in this study might have been due to the fact that the patients were placed in the supine or lateral position, as patient position has previously been reported to be a risk factor for the development of transient radicular irritation, the lithotomy position and knee arthroscopy having a higher incidence, possibly owing to excessive stretching of the nerve roots, leading to ischemic damage.

This impression has been confirmed by three recent reports of patients who developed transient radicular irritation after intrathecal anesthesia, as all these patients had surgery in positions that could have caused excessive stretching of nerve roots.

- A 44-year-old man developed transient pain in the buttocks and thighs 4 hours after 4% hyperbaric mepivacaine had been used to provide anesthesia for knee arthroscopy (258). The symptoms resolved after 2 days.
- A 46-year-old woman had an epidural placed at L4/5 (259). As there was insufficient block 20 minutes after injection of 300 mg mepivacaine, the epidural catheter was removed and an intrathecal injection of 0.5% tetracaine 2 ml dissolved in 5% glucose was performed. She was then placed in the lithotomy position for 30 minutes. One day postoperatively she developed pain and numbness in her left leg, and the numbness spread to the lower back, buttocks, and thighs. The symptoms disappeared after 4 days.
- A 50-year-old man had an intrathecal injection of 2% lidocaine 40 mg diluted to 1% with sterile water, while in the prone jack-knife position for excision of a pilonidal cyst (260). About 7 hours after the start of the block he developed acute sharp lower back pain radiating to the right buttock. There were no accompanying neurological signs. The pain settled with ketorolac and was gone after 5 days.

The last case is the first report of transient radicular irritation after the use of hypobaric lidocaine, but it again suggests the importance of sciatic stretching.

A high concentration of tetracaine given intrathecally in rabbits caused neuronal injury and glutamate release in the CSF (254). The authors postulated that this might give some insight into the mechanisms of neurotoxicity of intrathecal local anesthetics.

An animal study of the histological and physiological effects of intrathecal lidocaine at varying concentrations from 3 to 20% showed the presence of lesions in the posterior roots and columns characterized by axonal degeneration (261). The lesions were severe at higher concentrations, but even at the lower concentration of 7.5% there were mild lesions that did not correlate with the presence of neurofunctional deficit.

In a study of the effect of clinically relevant concentrations of lidocaine, bupivacaine, mepivacaine, and ropivacaine on cultured neurons, the local anesthetics caused destruction of the growth cones, implying that they have a toxic effect on the growth and regeneration of neuronal tissue (262). Lidocaine had the most marked effect and mepivacaine the least. While this might not be of direct relevance to the etiology of transient radicular irritation, the authors pointed out the potential risks of using local anesthetics in very young children, taking into consideration the difficulties of extrapolating from in vitro studies to in vivo use.

Sensory systems

Hearing

In some series, transient hearing loss after anesthesia with bupivacaine was found with intrathecal but not epidural administration (SEDA-13, 99) (SEDA-16, 129)(263). It has been suggested that the cause could be a reduction in CSF pressure transmitted through the cochlear aqueduct (264), a hypothesis that has been both supported and criticized (SEDA-16, 129). Sensorineural hearing loss after spinal anesthesia with bupivacaine has been thought to be due to the entry of bupivacaine into the inner ear, resulting in a direct effect on its functional apparatus (265).

When 44 patients undergoing inguinal hernia repair were given intrathecal anesthesia with 2% prilocaine 6 ml or 0.5% bupivacaine 3 ml, those given prilocaine had an average hearing loss of about 10 dB and 1–3 days postoperatively and those given bupivacaine had an average hearing loss of about 15 dB (266). However, 10 of 22 in those given prilocaine developed hearing loss, compared with four of the 22 given bupivacaine.

Gastrointestinal

Dysphagia has been reported from the cephalad spread of a spinal anesthetic (267).

- A 26-year-old woman underwent cesarean section with an intrathecal injection of 12 mg of 0.75% hyperbaric

© 2006 Elsevier B.V. All rights reserved.

bupivacaine, fentanyl 25 micrograms, and morphine 0.2 mg. After 4 minutes she developed hypotension, which was treated with ephedrine. Another 4 minutes later she became agitated and complained of difficulty in swallowing. At this stage she had a block to T4 with no dyspnea, her facial sensation was normal, and phonation was intact; the dysphagia resolved within 30 minutes.

Urinary tract

Urinary retention as a true transient neurological symptom developed after accidental total spinal anesthesia with mepivacaine, which is often considered to be the best agent for intrathecal anesthesia, owing to its low incidence of transient radicular irritation (268).

- A 71-year-old man received an intrathecal anesthetic with 2 ml of 0.3% hyperbaric mepivacaine using a 25-gauge Quincke needle at the L3–4 interspace, before which he had slight hypesthesia in the L5–S1 dermatomes in the right leg, reportedly having originated from the use of local anesthetic in the lumbar spine 16 years before to treat severe lumbago (269). When he was turned supine he started to complain of severe lightning pain in the region of his hypesthetic segments, which completely resolved 4 hours later.

Musculoskeletal

Profound musculoligamental relaxation by high doses of local anesthetics may contribute to the development of postoperative musculoskeletal pain. Of 60 patients who received either spinal anesthesia with hyperbaric 5% lidocaine (85–100 mg) or balanced general anesthesia with neuromuscular blockade, there was transient radicular irritation in eight patients who received spinal anesthesia and in one who received general anesthesia, a significant difference (270). However, there was non-radiating back pain in ten of the patients who received spinal anesthesia and in six of those who received general anesthesia.

Sexual function

For reasons that are not understood, intraoperative penile erection is sometimes observed with neuraxial blockade; it can be followed by prolonged priapism (SEDA-14, 110).

A long-standing belief that intrathecal anesthesia in young men reduces sexual potency was not confirmed in a retrospective study (SEDA-17, 139).

Intravenous regional anesthesia

Systemic toxic reactions are the most common complications of intravenous regional anesthesia, and they occur soon after the tourniquet is released. In cases of early accidental tourniquet release or rupture, deaths have resulted; prilocaine seems to be the safest agent for this technique (271).

- A 74-year-old woman was given prilocaine 400 mg for carpal tunnel surgery. Within 3 minutes, she developed signs of central nervous system toxicity, sweating, and tachycardia. Twenty minutes later, her symptoms had resolved and the cause was found to be a leak in the tourniquet.

The authors used this case to stress the importance of adequately functioning equipment and the relative safety of prilocaine (272).

Methods of reducing the dose of lidocaine used in intravenous regional anesthesia by adding fentanyl 0.05 mg, pancuronium bromide 0.5 mg, or both, have been evaluated in 60 patients undergoing elective forearm, wrist, and hand surgery; the dose of lidocaine used was 100 mg (273). None of the patients had signs of drug toxicity on release of the tourniquet; those who were given all three agents had better anesthesia and muscle relaxation. A separate group of volunteers, in whom the tourniquet was released immediately after injection of the lidocaine/fentanyl/pancuronium mixture, complained of minor adverse effects including mild dizziness and transient visual disturbances and one case of vomiting and moderate hypotension.

A study of lidocaine toxicity in intravenous regional anesthesia showed that two of 24 patients who were given 0.5% lidocaine 40 ml for carpal tunnel decompression had serum lidocaine concentrations above the target range 2 minutes before and 2, 5, and 10 minutes after distal tourniquet deflation (274). However, no patients had signs of central nervous system or cardiovascular toxicity.

Cardiovascular

Chloroprocaine, because of its rapid onset and ester hydrolysis, should be the ideal agent for intravenous regional anesthesia. However, there are reports that it can cause endothelial damage and dysrhythmias after tourniquet deflation (275).

- Phlebitis seems to have been triggered by intravenous regional anesthesia in a 32-year-old smoker who was also taking oral contraceptives (276).

Nervous system

In 15 volunteers, ropivacaine 1.2 and 1.8 mg/kg produced intravenous regional anesthesia as quickly as a conventional dose of lidocaine (3 mg/kg), but with more prolonged anesthesia (55 minutes before loss of pinprick analgesia) and motor block (120 minutes before return of hand grip strength) at the higher dose, suggesting that ropivacaine can provide a greater degree of residual analgesia (277). All the volunteers given lidocaine and only one patient receiving high-dose ropivacaine developed light-headedness and a hearing disturbance when the tourniquet was released after 30 minutes, but with individual peak arterial plasma ropivacaine concentrations lower than the mean values for the group. The authors pointed out the limitations of this study in terms of a small sample size and their inability to determine the safety of ropivacaine for intravenous regional anesthesia.

- A 56-year-old man developed unexplained acute aphasia when the tourniquet was released 20 minutes after the infusion of 0.75% lidocaine 20 ml for wrist surgery (278). He also had light-headedness, but no circumoral numbness or visual or auditory disturbances. He made a spontaneous recovery 20 hours later with no sequelae.

The correlation of nervous system adverse effects with plasma concentrations after the intravenous

© 2006 Elsevier B.V. All rights reserved.

administration of 40 ml of lidocaine 0.5% plus ropivacaine 0.2% for regional anesthesia has been examined in 10 volunteers (279). The double-cuffed tourniquet was inflated for as long as it could be tolerated. The incidence, duration, and intensity of nervous system adverse effects were recorded at 3, 10, and 30 minutes after tourniquet release and correlated with venous samples. There was a lower incidence and shorter duration of nervous system adverse effects with ropivacaine than with lidocaine; however, the dose of ropivacaine was much lower than that of lidocaine and therefore no clear conclusions can be drawn. In view of the availability of safer and effective alternatives for intravenous regional anesthesia, such as prilocaine and lidocaine, the reasons for using ropivacaine are hard to comprehend.

Sensory systems

Ears

It has been suggested that ropivacaine is a good choice for intravenous regional anesthesia because of its longer duration of action and lower risk of toxicity. In 20 patients scheduled for upper limb surgery who received 40 ml of either ropivacaine 0.2% or lidocaine 0.5% for intravenous regional anesthesia, both agents provided same onset and quality of surgical anesthesia, but ropivacaine gave longer-lasting analgesia in the immediate postoperative period (279). Additionally, one patient in the lidocaine group had tinnitus on release of the tourniquet, while there were no adverse effects in the ropivacaine group.

Taste

When 20 patients each received 40 ml of 0.5% chloroprocaine or 0.5% lidocaine for intravenous regional anesthesia, chloroprocaine caused a significantly higher incidence of a metallic taste (22 versus 0%) than lidocaine; when the study was repeated using alkalinized instead of plain chloroprocaine, there was no significant difference between the groups (280).

Skin

When 20 patients each received 40 ml of 0.5% chloroprocaine or 0.5% lidocaine for intravenous regional anesthesia, chloroprocaine caused a significantly higher incidence of urticaria (28 versus 0%) than lidocaine; when the study was repeated using alkalinized instead of plain chloroprocaine, there was no significant difference between the groups (280).

Laryngeal anesthesia

Local anesthesia to the larynx, for example with 4% lidocaine, is generally safe. Laryngeal edema has been reported in a few cases, perhaps due to the propellant rather than to lidocaine itself (281). An unusual complication is mydriasis if part of the spray is accidentally directed to the eye (SEDA-18, 144).

- A 22-year-old man had a generalized tonic-clonic convulsion and loss of consciousness after an attempted superior laryngeal nerve block using 2% lidocaine 2 ml (282). The seizure was not terminated by intravenous diazepam 10 mg and he was intubated after intravenous thiopental and suxamethonium. He required two boluses of ephedrine 10 mg to maintain his blood pressure. Surgery proceeded uneventfully and he recovered without any sequelae.

The authors postulated vertebral artery injection of local anesthetic as the cause of the seizure and loss of consciousness.

Local anesthesia administered directly into a fracture hematoma can cause systemic absorption and toxicity (SED-12, 252) (283).

Lumbar plexus anesthesia

The combination of lumbar plexus and posterior sciatic nerve block represents an alternative to a neuraxial technique.

- An 80-year-old 41 kg woman was given a combination of a posterior lumbar plexus block and a posterior sciatic nerve block for dynamic hip screw repair of a fractured right neck of femur (284). The lumbar plexus block was technically difficult, requiring three attempts, and 25 ml of ropivacaine 0.75% (187.5 mg), adrenaline (1 in 400 000), and clonidine 50 micrograms was slowly injected, aspirating after every 3 ml. The sciatic nerve block was straightforward, and 20 ml of a solution containing mepivacaine 1.5% (300 mg), adrenaline 1 in 400 000, and clonidine 50 micrograms was injected slowly. She had seizures and dysrhythmias 20 minutes after completion of the block. Cardiopulmonary resuscitation was successful, surgery proceeded under general anesthesia, and she made a full recovery. Blood samples taken 5 minutes after the seizures contained ropivacaine 1.9 micrograms/ml and mepivacaine 3.7 micrograms/ml.

The authors suggested that the timing of events (the neurological signs preceded cardiac toxicity) suggested a toxic reaction to one of the local anesthetics or an overdose from their combination.

Nasal anesthesia

Intranasal 4% lidocaine has been used for migraine and cluster headaches with success and few serious adverse effects: a bitter taste was common and some patients complained of nasal burning and oropharyngeal numbness

Unilateral mydriasis (anisocoria), suggesting serious neurological injury, has been attributed to topical cocaine (285).

- A 51-year-old man developed mydriasis in one eye, with loss of the accommodation reflex, immediately after endoscopic sinus surgery, before which 4% cocaine had been applied to the nasal mucosa on cotton pledglets. There were no surgical or anatomical complications.

The authors suggested a diagnosis of local anesthetic blockade of the nasociliary nerve.

Acute angle closure glaucoma has been attributed to local cocaine (286).

- A 46-year-old woman developed acute angle closure glaucoma 24 hours after the application of topical intranasal 25% cocaine (about 200 mg) for an elective antral washout under general anesthesia. She developed a severe headache around the right eye, with halos and blurring of vision on the same side and associated

© 2006 Elsevier B.V. All rights reserved.

nausea and vomiting. The next day, when she awoke, she had completely lost the vision in that eye.

Neck anesthesia

With regional anesthesia in the neck there is a risk of inadvertent intra-arterial injection; this could explain one report of convulsions in an elderly woman (287). There is also a risk of subarachnoid injection and pneumothorax.

Obstetric anesthesia

When a local anesthetic is used for episiotomy, there is a risk that the needle will enter the child's scalp; in two cases involving prilocaine, this resulted in cyanosis, methemoglobinemia, and hemolytic anemia (288).

Retroperitoneal hematoma has been reported as a complication of pudendal block, probably due to pudendal artery perforation (SEDA-21, 134).

Prilocaine 3% + felypressin 0.03 IU/ml has been compared with lidocaine 2% + adrenaline 12.5 micrograms/ml in 300 women having large-loop excision of the cervical transformation zone (289). Those who received lidocaine had significantly less blood loss, but were more likely to have adverse effects, including shaking and feeling faint.

Ocular anesthesia

A cluster of 25 cases of transient or permanent diplopia occurred after 13 retrobulbar blocks, 10 peribulbar blocks, and two unknown techniques, possibly related to the non-availability of hyaluronidase, highlighting the likely importance of hyaluronidase in preventing anesthetic-related myopathy in the extraocular muscles (290). Other reports of 21 cases of persistent postoperative diplopia following the peribulbar technique (291) and 4 cases following the retrobulbar technique during the period of non-availability of hyaluronidase support this theory (292). Bupivacaine and lidocaine may be contraindicated for peribulbar or retrobulbar injections without hyaluronidase.

Severe sneezing after ocular local anesthetic injection during intravenous sedation has been linked to photic sneezing. However, in 557 patients there was no relation between the two (293). Severe involuntary sneezing occurred after ocular blockade under thiopental sedation overall in 5.2% and only in 7.6% of those with a history of photic sneezing; peribulbar block had a significantly higher incidence of involuntary sneezing compared with retrobulbar block (24 versus 4.5%). Sneezing can occur with many hypnotics and after injections inside the muscle cone and outside the orbit, without pupillary dilatation or lid elevation (294). Awareness of this phenomenon can facilitate recognition and prompt needle withdrawal to avoid serious problems from sudden head movements during injection.

Ocular explosion occurred in seven cases after periocular anesthetic injections (295). To minimize the incidence of ocular explosion, the authors recommended the following:

(a) use a blunt needle and a 12 ml syringe;
(b) aspirate the plunger and wiggle the syringe before injection;
(c) discontinue the injection if corneal edema or resistance to injection is noted;
(d) inspect the globe for evidence of intraocular injection before ocular massage or placement of a Honan balloon.

Retrobulbar anesthesia

Retrobulbar anesthesia, competently administered, is a safe procedure. In 13 000 patients in whom a curved needle technique was used, the only serious complication was a single case of postoperative ischemic neuropathy (296). However, other centers have experienced recurrent problems with chemosis (up to 30%), sub-conjunctival hemorrhage, and lid hemorrhage before perfecting their technique (SEDA-18, 144).

Inadvertent injection into the subarachnoid space surrounding the optic nerve has on various occasions led to bilateral impairment of vision and ophthalmoplegia, with varying degrees of nervous system and respiratory effects, ranging from pulmonary edema (297) to respiratory arrest (SED-12, 254) (SEDA-21, 133) (298). Similar adverse effects result from diffusion of the local anesthetic toward the cerebrospinal fluid (SEDA-14, 110). Several groups have shown that such complications can occur, especially with higher concentrations, independently of any fault in technique (SED-12, 254) (299). Patients must therefore be closely monitored during ocular anesthesia and surgery. Particular care should be taken in patients with orbital roof defects, as there is potential for local anesthetics to move rapidly into the nervous system, with severe toxic effects (SEDA-20, 126).

On the other hand, headache after bupivacaine-induced block has been traced to the use of a vasoconstrictor additive, and is more likely to occur with noradrenaline than adrenaline (300). Unwanted effects on the eye muscles, occurring in some 1% of retrobulbar blocks, extend to ptosis, horizontal rectus muscle palsy, and lagophthalmos; all recover spontaneously within a matter of weeks (301). It has been postulated that local anesthetics can be myotoxic, causing contracture and subsequent diplopia (302). Tissue pressure, causing ischemia, can also lead to muscle damage and subsequent contracture and strabismus (SEDA-22, 139).

Two cases of vitreous hemorrhage have been observed after retrobulbar block in patients with severe diabetic retinopathy (303).

- A retrobulbar injection in a 45-year-old woman with high myopia was complicated by globe perforation with vitreous and submacular hemorrhage (304).
- In another case, retrobulbar hemorrhage and raised intraocular pressure developed after subtenon block with lidocaine (305).

Retinal vascular occlusion is rare, but it can occur in patients with severe vascular disease, without retrobulbar or optic nerve sheath hemorrhage; the mechanism is unclear (SED-12, 254) (306).

There is a risk of traumatic optic nerve injury with retrobulbar block (SEDA-21, 134).

Complications from retrobulbar block can arise from accidental scleral perforation and intraocular injection of local anesthetic.

© 2006 Elsevier B.V. All rights reserved.

- An 86-year-old man scheduled for cataract surgery sustained an inadvertent occult single perforating needle injury with an intraocular injection of 0.5% plain bupivacaine during a retrobulbar block using a long (38 mm) needle (307). He had pain on injection and a raised intraocular pressure, with corneal edema, poor iris detail, and a reduced red reflex. Paracentesis lowered the intraocular pressure and surgery proceeded uneventfully. At 6 weeks, he had a reduction in visual acuity, and a scan identified a vitreous hemorrhage and retinal detachment. Prompt vitreoretinal surgery was performed with reasonable success.

The authors added that retinal toxicity of the local anesthetic agent did not affect the visual outcome in this patient. Scleral perforation is a well-known complication of eye blocks for ophthalmic surgery. The incidence with retrobulbar techniques is 0.075% and with peribulbar blocks 0.0002%. When recognized, ocular perforation usually requires a vitreoretinal procedure and is associated with a poor visual outcome. Risk factors include an anxious or oversedated patient, long sharp needles, superior injection, incorrect angle of needle insertion, and myopic eyes. If the intraocular pressure is increased, paracentesis may acutely reduce it, preventing retinal and optic nerve ischemia and possible permanent visual loss.

Retrobulbar anesthesia can lead to serious systemic toxicity. However, in animal studies accidental intravitreous spread of lidocaine, bupivacaine, or a mixture of the two did not cause long-term retinal damage (308).

Possible techniques to reduce complications include avoiding Atkinson's position, the classical position for retrobulbar block (309), during injection, limiting the volume of solution injected, and the use of shorter needles (310,311).

Retrobulbar anesthesia can be complicated by brainstem anesthesia (312).

- A 79-year-old man received retrobulbar anesthesia using a 1:1 mixture of 2% lidocaine and 0.5% bupivacaine plus hyaluronidase, which was complicated by brainstem anesthesia presenting as dysarthria. Initially there was some resistance to injection and the syringe was withdrawn slightly before injection of 4 ml of solution; 5 minutes later he complained of a strange sensation in his throat, which progressed to difficulty in swallowing and not being able to speak above a whisper. His blood pressure rose to 210/118 and his pulse to 120/minute; he also had signs of involvement of cranial nerves III, VI, and XII. He received glyceryl trinitrate for the hypertension and by 24 hours all the cranial nerve symptoms and signs had resolved.

Two cases of cardiopulmonary arrest after retrobulbar block for corrective squint surgery have been described (313). Both the patients were fit, healthy young men and they received a retrobulbar block with 2% lidocaine 2 ml via a 23G 1.5" needle after negative aspiration. Three minutes later both complained of breathlessness and rapidly became apneic and unresponsive, with unrecordable pulse and blood pressure. Both were resuscitated and became fully alert within 40 minutes. Possible reasons suggested were an allergic reaction, a direct toxic effect, a vasovagal attack, intra-arterial injection, or injection directly into the optic nerve sheath with spread of the local anesthetic into the CSF. The latter seemed to be the most likely in these cases. Since then the authors have altered their technique, including changing the position of gaze and using a short blunt needle. These cases illustrate the need for careful monitoring, knowledge of potential complications, and the ready availability of resuscitation facilities (including appropriately trained personnel familiar with the equipment), even when performing what many regard as minor local anesthetic blocks.

Peribulbar anesthesia

Peribulbar anesthesia is generally considered safer than retrobulbar anesthesia, with a lower incidence of adverse effects. It avoids deep penetration of the orbit and therefore inadvertent subarachnoid injection. It also seems to be safer with regard to the risk of bulb perforation (314).

Cardiovascular

In addition to complications arising from the local anesthetic used during ocular anesthesia, complications can arise as a direct result of the injection. An arteriovenous fistula has been reported (315).

- An arteriovenous fistula of the supraorbital vessels developed in a 75-year-old man after peribulbar anesthesia with a supplementary supranasal injection. He elected to have conservative management and the lesion remained asymptomatic and static in size over 10 months follow-up.

Respiratory

Pulmonary edema has been attributed to lidocaine (316).

- A 74-year-old woman had peribulbar blockade with 4 ml of 2% lidocaine at the inferotemporal approach and then 3 ml at the medial approach. She had a history of mitral stenosis, occasional angina, and possibly myocardial infarction, but denied breathlessness on exertion, nocturnal dyspnea, or orthopnea. She had breathlessness and sweating 10 minutes after the medial injection. She then developed hypoxia and a few minutes later began to cough up pink frothy secretions, required intubation, and developed a sinus tachycardia without acute electrocardiographic or cardiac enzyme changes.

The authors assumed that she had developed neurogenic pulmonary edema, probably worsened by the co-existing myocardial disease.

Sensory systems

Nine patients developed prolonged symptomatic diplopia (predominantly vertical) after peribulbar anesthesia with ropivacaine 1% plus hyalase 750 units (317). The mean time to resolution of the diplopia was 24 hours. The authors stressed the importance of warning patients undergoing peribulbar blockade with ropivacaine of the possibility of prolonged diplopia and queried its future use in routine cataract surgery.

Six cases of global perforation have occurred during routine cataract surgery (SEDA-21, 134). It has incidentally led to contralateral mydriasis, hemiplegic coma, and damage to the infra-orbital nerve (SEDA-18, 144). The contralateral

© 2006 Elsevier B.V. All rights reserved.

eye may exhibit oculomotor weakness (SEDA-16, 130). Three other reports have highlighted problems.

- A 76-year-old man undergoing trabeculectomy developed bilateral amaurosis after a peribulbar block with 6 ml of a mixture of 2% lidocaine, 0.5% bupivacaine, and hyaluronidase (318). The authors thought it unlikely that the optic nerve sheath had been penetrated and suggested that local spread to the optic nerves via the subarachnoid or subdural space had been responsible.
- A 49-year-old woman had a tonic-clonic seizure about 15 minutes after a peribulbar block for left trabeculectomy (319). She recovered and surgery continued uneventfully. However, she had severe permanent visual loss in that eye, and an MRI scan at 4 weeks showed swelling of the left optic nerve. The authors suggested that some prilocaine had been injected into the nerve sheath, causing the convulsions, local optic nerve swelling, and subsequent optic nerve atrophy.

In 60 patients, peribulbar blockade was performed with either 8 ml of 0.75% ropivacaine or a 1:1 mixture of 2% lidocaine and 0.5% bupivacaine (320). Surgical block was achieved after a similar period of time in each group, but ropivacaine provided a better quality of postoperative analgesia, with no pain reported at 24 hours in 26 (87%) compared with 18 (60%) in the lidocaine + bupivacaine group. One patient given ropivacaine reported unbearable pain due to a high intraocular pressure, and the incidence of postoperative nausea and vomiting was under 7% in both groups.

In 54 patients who received peribulbar anesthesia with either 1% ropivacaine or a mixture of 0.75% bupivacaine + 2% lidocaine there was no significant difference in akinesia scores or adverse effects reported the following day, notably headache, dizziness, nausea, scalp anesthesia, and diplopia, the latter occurring in 26% and 30% respectively (321).

Peribulbar anesthesia with 1% etidocaine, 0.5% bupivacaine, and hyaluronidase has been evaluated in 300 patients (322). The mean volume administered was 17 ml. There was adequate analgesia in 85% of cases, and the other 15% required supplementation with a subtenon block. Akinesia occurred in 82% of cases. Two patients developed generalized seizures, and four developed severe hypotension.

- A rare case of hyphema after peribulbar block with 1% lidocaine 8 ml occurred in a 38-year-old woman with a history of Fuchs' heterochromic iridocyclitis (323).

Postoperative strabismus and diplopia occurred in two of 200 patients undergoing cataract extraction under peribulbar anesthesia; the symptoms resolved spontaneously by 6 months (324).

Hematologic

- A 27-year-old woman with diabetes mellitus, complicated by diabetic retinopathy and chronic renal insufficiency with anemia, developed methemoglobinemia (11%) after peribulbar blockade with prilocaine 80 mg, bupivacaine 30 mg, hyaluronidase, and naphazoline (325). She recovered uneventfully after methylthioninium chloride 1.5 mg/kg.

The authors concluded that she may have been at increased risk of methemoglobinemia as a result of the metabolic acidosis associated with renal insufficiency, since impaired protein binding of prilocaine could have increased the concentrations of ionized prilocaine. Furthermore, the patient was also taking isosorbide dinitrate, which may have predisposed her to methemoglobinemia.

Topical anesthesia

Topical anesthesia in the eye is relatively safe in controlled circumstances, when administered correctly (SEDA-20, 127). There does not seem to be any benefit in warming topical local anesthetic solutions before use (326).

Topical anesthetic abuse, mostly unintentional, remains a persistent cause of keratitis and epithelial defects, leading to continuing ocular pain, visual impairment, and at worst enucleation (SEDA-21, 134) (SEDA-22, 140) (327). Mechanisms include direct toxicity of the local anesthetic or preservative and immunological causes.

In 14 patients, 0.5% proxymetacaine had similar efficacy to 0.4% oxybuprocaine and 0.5% tetracaine but was significantly better tolerated (328).

There have been reports of topical ocular anesthetic abuse.

- A 49-year-old woman developed repeated episodes of severe keratitis after radial keratotomy for myopia (329). After 18 months of repeated hospital admissions, several operations, and considerably reduced visual acuity, it eventually transpired that she had been self-medicating with 1% proparacaine mixed with artificial tears to control pain after her surgery.

Abuse of these medications often results in irreversible corneal damage and visual loss (330). Two patients continued to instil their topical 0.5% tetracaine eye-drops, despite medical advice. The result was bilateral corneal perforation in the first case and a large unilateral descemetocele in the second. Surgery was required to correct the perforations, but the long-term anatomical and functional results were poor. A third patient had obtained 0.5% tetracaine hydrochloride drops over the counter to relieve discomfort in his eye after colleagues at work had attempted to remove a foreign body from his eye. He had developed chronic toxic keratitis and was persuaded to discontinue the eye-drops. With appropriate treatment the cornea returned to normal.

Lidocaine gel 2% has been compared with 0.5% tetracaine drops for topical anesthesia in cataract surgery in 25 patients (331). There were no corneal epithelial or ocular surface complications, demonstrating the safety of the gel, which may provide a more practical and efficient method of anesthesia, because it needs to be applied only once as opposed to three applications of the drops.

Differences in the manufacture of unpreserved lidocaine formulations have been postulated as a cause of transient corneal clouding in patients who were given intraocular unpreserved lidocaine 1% as an adjunct to topical anesthesia (332). Independent analysis of the lidocaine solution associated with corneal clouding found it to be hypotonic and not buffered with bicarbonate compared with the solution that did not cause corneal clouding.

© 2006 Elsevier B.V. All rights reserved.

Intracameral anesthesia

Non-preserved intracameral lidocaine 1% is a useful adjunct to topical anesthesia for cataract surgery. In 631 patients, topical anesthesia alone was compared with combined topical and intracameral anesthesia (333) The combination had greater efficacy—only 1% of those given combined anesthesia needing to be converted to general anesthesia compared with 40% of those given topical anesthesia alone. The authors suggest that the key difference between the two methods is reduced sensitivity to the microscope light. Another prospective study in 93 patients showed that intracameral non-preserved lidocaine was both safe and efficacious; four patients reported discomfort and none had measurable endothelial cellular changes (334).

The endothelial toxicity of local anesthetics has been assessed in pigs, as this might be relevant to the safety of agents given by intracameral injection (335). Lidocaine, mepivacaine, and prilocaine were safe, while bupivacaine in clinically effective concentrations resulted in significant cell reduction.

Sub-tenon anesthesia

Sub-tenon infiltration of local anesthesia has recently become increasingly popular for cataract and vitreoretinal surgery; presumed advantages are its safety, speed of onset, and patient compliance. Three cases of persistent diplopia following sub-tenon local anesthesia have been reported (336). Two of the patients were given injections of 4 ml of a mixture of lidocaine 1% or 2% with adrenaline 1 in 100 000 and hyaluronidase 1500 units, and the third was given 4 ml of 0.75% bupivacaine with lidocaine. All had vertical diplopia, consistent with restriction of the inferior rectus muscle, which persisted for 2–9 months. The authors suggested possible mechanisms, including direct trauma to the muscle, inflammation and adhesions, infection, and myotoxicity of local anesthetics. They have since modified their technique, reducing the rate and force of infiltration.

An infectious complication of sub-tenon anesthesia has been reported (337).

- A 63-year-old woman underwent phacoemulsification and lens implantation under sub-tenon block. After the local anesthetic was injected, the eye was prepared with an aqueous solution of povidone iodine and the surgery proceeded uneventfully. At the end, gentamicin and betamethasone were injected subconjunctivally. Over the next few days she developed orbital cellulitis, requiring intravenous antibiotics.

The authors concluded that bacterial contamination of the episcleral space from the ocular surface or skin flora had occurred during or after the sub-tenon injection. They recommended applying topical povidone iodine before the episcleral space is opened, in order to reduce this risk.

Eyelid and conjunctival anesthesia

Local infiltration with prilocaine 2% was significantly more comfortable than lidocaine 2% in a prospective randomized study in 125 patients undergoing minor eyelid procedures (338).

Two cases of transient blindness after subconjunctival injection of 2% mepivacaine 2 ml were reported in patients with advanced refractory glaucoma undergoing diode laser cyclophotocoagulation (339). The authors hypothesized that in patients with advanced optic neuropathy, even subconjunctival anesthesia can result in optic nerve block.

Oropharyngeal anesthesia

Reduced hepatic clearance, as well as relative overdosage, of local anesthetics can lead to systemic toxicity, as illustrated by three patients who underwent topical anesthesia of the oropharynx for transesophageal echocardiography and subsequently became confused and drowsy (SEDA-21, 135).

- Acute bilateral parotid swelling occurred after upper gastrointestinal endoscopy in a 53-year-old woman who had gargled 2% lidocaine solution beforehand; the swelling was associated with difficulty in swallowing and resolved after treatment with intravenous glucocorticoids for 4 days (340).
- A 21-year-old developed seizures, respiratory distress requiring tracheal intubation, severe hypotension, and then bradycardia culminating in asystole and death while gargling with 4% lidocaine 20 ml (800 mg) (341).

The authors strongly advised against exceeding the maximum recommended dose of lidocaine (200 mg), even when using it topically.

Otic anesthesia

Transient vestibular irritation without hearing loss after infiltration of the auditory canal has been incidentally attributed to diffusion of the local anesthetic from the site of injection (342).

Paravertebral anesthesia

Postural headache after thoracic paravertebral nerve anesthesia, and probably reflecting dural entry, has been reported (343). Nerve root damage is another possible complication. Hematuria due to injury to the kidney or ureter is an unusual complication of lumbar paravertebral sympathetic block (344).

An epidural abscess and paraplegia occurred after paravertebral lidocaine infiltration for back pain (SEDA-21, 133).

Among 44 women who received a single paravertebral block with 0.3 ml/kg of 0.5% bupivacaine at the level of T4 for breast surgery, there was one incident of epidural spread of the block with paraparesis for 280 minutes accompanied by unilateral Horner's syndrome for 170 minutes (345).

Post-thoracotomy pain can be treated with thoracic epidural or thoracic paravertebral blockade. In 100 adult patients allocated to receive one of these treatments with preoperative bolus doses of bupivacaine followed by a continuous infusion there was less postoperative respiratory morbidity and significantly better arterial oxygenation in the paravertebral group; nausea (10 versus 2), vomiting (7 versus 2), and hypotension (7 versus 0) were more problematic in the epidural group (346).

© 2006 Elsevier B.V. All rights reserved.

Perianal anesthesia

Local anesthetic ointments are widely used to relieve the symptoms of hemorrhoids and anal fissures. Absorption through the mucosa can be considerable; a case of convulsions as a suspected consequence of such treatment has been cited (SED-12, 253) (347).

Peritonsillar anesthesia

A stroke occurred after infiltration of the tonsillar bed with bupivacaine subsequent to tonsillectomy (348).

- A 16-year-old girl undergoing adenotonsillectomy had cardiac asystole for 10 seconds after injection of her adenoid bed with 0.5% bupivacaine 1 ml with adrenaline 5 micrograms/ml. She had already been given an unstated quantity of bupivacaine with adrenaline 5 micrograms/ml injected into her tonsillar fossae. Her cardiac output returned spontaneously, but she had a central medullopontine infarction, confirmed on MRI and CT brain scans. Magnetic resonance angiography showed an abnormal circle of Willis, with absence of both posterior communicating vessels. The authors were unclear as to the exact cause of the cardiac event and stroke, which resulted in a persistent neurological deficit.

Two cases of medullary injury after injections of local anesthetics intraoperatively have been reported (349).

- A 4-year-old child received injections of lidocaine plus adrenaline into the anterior tonsillar pillars and nasopharynx during adenotonsillectomy. After the procedure, he became agitated and dysarthric, vomited, and had abnormal eye movements. He was unable to stand and walk, owing to ataxia. An MRI scan showed a cavity in the right paramedian medulla.
- A 7-year-old boy underwent tonsillectomy, with an injection of lidocaine plus adrenaline into the operative field. After surgery he was lethargic, and during the next 24 hours he developed respiratory distress requiring mechanical ventilation. He was pyrexial (41.8°C) and had cardiomegaly and a left hemiparesis. A cranial MRI scan showed a hemorrhagic lesion in the right paramedian medulla.

Both patients had lesions in the medial medulla supplied by branches of the anterior spinal and vertebral arteries, and although such cases are rare it seems wise, in the light of these reports, to avoid the routine use of adrenaline as an adjunct to local anesthesia for adenotonsillectomy.

Excessive volumes of local anesthetic in a confined space can lead to life-threatening upper airway obstruction. When glossopharyngeal nerve blocks are used for tonsillectomy, children under 15 kg should be given 1 ml or less of 0.25% bupivacaine per tonsil (350).

Respiratory anesthesia

Topical anesthesia of the airways is commonly used to facilitate endoscopy and sometimes manipulation of the airways. This can result in an increase in airway flow resistance, possibly due to laryngeal dysfunction (351). Lidocaine spray 10%, used for upper airways anesthesia for fiber optic intubation in a grossly obese patient, caused acute airway obstruction. The patient went on to have a percutaneous tracheotomy, and it was postulated that the local anesthetic had abolished laryngeal receptors responsible for airway maintenance, or that laryngospasm and reduced muscle tone due to the lidocaine might have been the cause (SEDA-22, 140).

- Unilateral bronchospasm has been described in a 19-year-old woman after the administration of lidocaine 4% 5 ml into the larynx via a Laryngojet injector (352).

Lidocaine gel is not recommended for lubrication of laryngeal masks. It confers no benefits and increases the incidence of adverse effects such as intraoperative hiccups, postoperative hoarseness, nausea, vomiting, and tongue paresthesia (353).

- A patient due to have a bronchoscopy was given an overdose of lidocaine to anesthetize the airway by an inexperienced health worker. He was then left unobserved and subsequently developed convulsions and cardiopulmonary arrest (354). He survived with severe cerebral damage. His lidocaine concentration was 24 micrograms/ml about 1 hour after initial administration (a blood concentration over 6 micrograms/ml is considered to be toxic).
- A 19-year-old healthy volunteer undergoing bronchoscopy was given about 1200 mg of lidocaine to anesthetize the airway and was sent home after the procedure, despite complaining of chest pain. Shortly afterwards she had a tonic-clonic seizure and cardiopulmonary arrest and died 2 days later. The research protocol had failed to specify an upper dose limit for lidocaine (355).

Sciatic nerve anesthesia

Sciatic nerve anesthesia can cause cardiovascular depression (356).

- A 74-year-old man was to receive a combined sciatic nerve and psoas compartment block for a total hip arthroplasty; the classic Labat's approach was used and 30 ml of 0.75% ropivacaine was injected over 1.5 minutes, after which he suddenly became unresponsive and developed tonic–clonic movements. Propofol was administered and the seizure resolved, but he developed sinus bradycardia with progressive lengthening of the QRS interval, which converted to nodal bradycardia. A ventricular escape rhythm at 20/minute with T wave inversion was treated with ephedrine 10 mg and adrenaline 0.1 mg, resulting in supraventricular tachycardia with transient atrial fibrillation.

The authors pointed out that an equipotent dose of bupivacaine would have resulted in worse cardiovascular depression with less chance of successful resuscitation.

Stellate ganglion anesthesia

Inadvertent spinal anesthesia and subsequent nervous system toxicity, for example with transient paralysis or apnea, are the main complications of stellate ganglion block (SEDA-22, 140). It has been suggested that ultrasound guidance when performing the block might improve safety (357). The use of very small test doses and an anterior approach to the stellate ganglion are recommended preventive measures.

Brachial plexus paresis has been reported (358). Accidental block of the recurrent laryngeal nerve can cause hoarseness and occasionally aspiration of saliva (359).

© 2006 Elsevier B.V. All rights reserved.

In two women with Raynaud's syndrome, the symptoms were aggravated contralaterally after stellate ganglion block (SEDA-18, 145).

Severe hypertension has been reported after a left-sided block, possibly due to vagal nerve block and unopposed sympathetic output (SEDA-21, 134).

Convulsions are a recognized complication of inadvertent intra-arterial injection during stellate ganglion block; two such cases have been described (360).

- A 28-year-old 75 kg woman underwent stellate ganglion block for symptomatic treatment of Raynaud's syndrome. An anterolateral approach was used, guarding the carotid artery and jugular vein. After an aspiration test was negative in two planes, 5 ml of 1% lidocaine was injected over 2–3 seconds using a 20 G needle. However, a second aspiration test was positive for blood, the needle was pulled back, and on reinjection the patient immediately had a severe generalized tonic-clonic seizure. The patient made a rapid recovery with no further treatment and was fully conscious after 2 minutes.
- A 31-year-old 72 kg man with diabetes, who had had a below-knee amputation in the past, developed Buerger's disease affecting his hands, particularly on the right. He underwent his third stellate ganglion block for symptomatic treatment. An anterior paratracheal approach was used with a 20 G 3.5 cm needle; after an aspiration test was negative in two planes, 1 ml of 1% lidocaine was injected every 2–3 seconds. After one injection, he had an abrupt seizure which was treated with diazepam 10 mg. He made a full recovery and later completed his course of stellate ganglion blocks uneventfully.

It was thought that inadvertent vertebral arterial injection had occurred, with subsequent rapid elimination due to high cerebral blood flow. The authors suggested several precautions to minimize this risk, including using a large-diameter needle and using less than the calculated minimum arterial toxic dose of lidocaine (16.8 mg) as the initial test dose; for subsequent doses they suggested 5 mg.

Subcutaneous anesthesia

When infiltrating local anesthetics into the skin there is always a risk of intravascular injection (SEDA-17, 140), but it can be avoided by back-aspiration of the syringe or continuous advancement of the needle during injection.

Skin infiltration with local anesthetics can cause pain. The pain experienced during skin infiltration of lidocaine, chloroprocaine, and buffered solutions of both has been studied in 22 volunteers in a double-blind, randomized study (361). The pH of the solutions was unrelated to the pain score, but both formulations of chloroprocaine were significantly less painful than lidocaine.

A weak solution of lidocaine has sometimes been injected into excess fat before liposuction, so that the procedure can be carried out without general anesthesia. The technique is generally regarded as safe (362). However, deaths are reported, associated with local anesthetic toxicity or drug interactions (363).

Of 30 volunteers who had subcutaneous slow infusion tumescent anesthesia at 250 ml/hour with three solutions containing lidocaine 2 mg/ml, ropivacaine 0.5 mg/ml mixed with lidocaine 1 mg/ml, and ropivacaine 1 mg/ml alone, all containing adrenaline 1:1 000 000, one had a tingling sensation in the tongue after lidocaine and another went into vasovagal shock (364). In the same paper, 5020 surgical procedures were reported in 3270 patients using different strengths of ropivacaine alone (0.05–0.2%) with a maximum dose of 300 mg, or with a mixture of ropivacaine and prilocaine (0.08–0.3%) with a maximum ropivacaine dose of 160 mg and a maximum prilocaine dose of 300 mg. There was no methemoglobinemia and there were no minor or major adverse effects related to the local anesthetic. The maximum plasma concentrations were low, suggesting that higher maximum doses may be possible, provided adrenaline is added.

- Ventricular tachycardia, severe hypertension, and pulmonary edema developed in a 53-year-old woman soon after she had a skin flap infiltrated with 4 ml of 0.5% lidocaine and 0.0005% adrenaline (20 micrograms) (365).

This has been previously described during general anesthesia but not with a local anesthetic alone, and the author emphasized the risk of severe cardiovascular compromise, even with a small dose of adrenaline.

Five patients with complex regional pain syndrome received a subcutaneous infusion of 10% lidocaine, with successful alleviation of many of their symptoms; initially 200 mg/kg was infused but symptoms of vertigo and slurred speech each occurred in four of them and stuttering in three, so the rate was adjusted to 100–190 mg/hour and serum lidocaine concentrations of 0.1–8.1 micrograms/ml (average 3.7 micrograms/ml); other symptoms, such as aphasia, nausea, fatigue, metallic taste, lightheadedness, and perioral numbness, each occurred in over half of the patients (366).

An iatrogenic tension pneumothorax was the result of breast infiltration with lidocaine and adrenaline before an augmentation procedure (SEDA-20, 127).

Infiltration anesthesia has reportedly caused transient paralysis.

- Transient paraplegia occurred after wound site infiltration with bupivacaine in a 35-year-old woman during removal of a lumboperitoneal shunt that had been inserted 2 years previously for benign intracranial hypertension (367). Under general anesthesia with the patient in the left lateral position, a small incision was made over the right flank and the drain was easily removed. The site was infiltrated with 7.5 ml of 0.5% bupivacaine with adrenaline 1 in 200 000. During recovery, she was anxious and moderately hypotensive and had a flaccid paralysis from T4 down. An MRI scan was normal. She gradually recovered motor function, sensation, and pain at the wound site.

The authors concluded that the local anesthetic may have passed down a fistulous track into the subarachnoid space, producing spinal block.

Submucosal anesthesia

Complications noted at various times with submucosal use include allergic reactions to the parabens present in lidocaine, systemic effects due to general diffusion (which

© 2006 Elsevier B.V. All rights reserved.

readily occurs), or necrosis (when adrenaline is included in the formulation) (SEDA-16, 131).

Urinary tract anesthesia

Urethral instillation of anesthetics is most likely to be needed in the elderly, in whom there may be marked absorption from the mucosa, especially if it is diseased or damaged. Seizures after instillation of lidocaine jelly (for example 20 ml of a 2% formulation) have been reported as a consequence of this (368).

Local anesthetic gels and creams used liberally on traumatized epithelium can be rapidly absorbed, resulting in systemic effects, such as convulsions, particularly if excessive quantities are used.

- A 40-year-old woman developed seizures after lidocaine gel 40 ml was injected into the ureter during an attempt to remove a stone (369).

Drug–Drug Interactions

Neuromuscular blockers

The effects of non-depolarizing neuromuscular blocking drugs can be potentiated and their actions prolonged by large doses of local anesthetics, because of depression of nerve conduction, inhibition of acetylcholine formation, mobilization, and release, reduced postsynaptic receptor channel opening times, and reduced muscle contraction (370).

Opioids

Opioids potentiate the analgesic effect of neuraxial local anesthetics, with minimal adverse effects (SEDA-18, 141) (SEDA-20, 121) (SEDA-22, 135), as shown in several studies with clonidine, fentanyl, morphine, or pethidine as the systemic or neuraxial analgesic, and bupivacaine, lidocaine, and ropivacaine as the local anesthetic. The benefits have been shown in relief of long-term pain and postoperative pain, in adults and children (SEDA-18, 141) (SEDA-18, 146).

Sulfones/sulfonamides

Local anesthetics, sulfones, and sulfonamides are all aniline derivatives, exposure to which, particularly to two or three concurrently, can predispose patients to methemoglobinemia (5,371,372).

Lofepramine

See also Tricyclic antidepressants

General Information

Lofepramine is an imipramine analogue whose animal pharmacology suggests low toxicity (1). Its clinical efficacy is similar to that of imipramine and amitriptyline. Patients on lofepramine report less dryness of the mouth, fewer disturbances of accommodation, and less drowsiness, but a greater incidence of tremor (2).

Lofepramine has apparently not been compared with desipramine, to which it is mainly metabolized. The claim that lofepramine has fewer adverse effects than

© 2006 Elsevier B.V. All rights reserved.

traditional tricyclic compounds must be viewed with skepticism (SEDA-11, 14). However, lofepramine is safer than conventional tricyclic antidepressants in overdose.

Loganiaceae

See also Herbal medicines

General Information

The genera in the family of Loganiaceae (Table 1) include strychnos and trumpet flower.

Strychnos nux-vomica

The dried ripe seeds of *Strychnos nux-vomica* (nux vomica) contain the alkaloids strychnine and brucine, together with traces of other alkaloids.

Adverse effects

Strychnine is a powerful convulsant, which can cause serious and even lethal poisoning (1).

Maqianzi, the dried ripe seed of *S. nux-vomica* contains 1.0–1.4% each of strychnine and brucine. It has been used as a herbal remedy for rheumatism, musculoskeletal injuries, and limb paralysis.

- A 42-year-old woman with neck pain took 15 g of maqianzi in two doses 7 hours apart (recommended dose 0.3–0.6 g) (2). One hour after she took the second dose she suddenly developed tonic contractions of all her limbs and carpopedal spasm lasting 5 minutes, difficulty in breathing, chest discomfort, and perioral numbness. She complained of muscle pain and tiredness and had hyperventilation and weakness of all four limbs. All her symptoms gradually subsided over the next few hours.

Table 1 The genera of Loganiaceae

Fagraea
Gelsemium (trumpet flower)
Labordia (labordia)
Mitreola (hornpod)
Spigelia (pinkroot)
Strychnos (strychnos)

Lomefloxacin

See also Fluoroquinolones

General Information

Lomefloxacin is a fluoroquinolone antibacterial drug with actions and uses similar to those of ciprofloxacin.

Organs and Systems

Gastrointestinal

In a multicenter, prospective, randomized study of oral lomefloxacin 400 mg/day in 182 patients with chronic bacterial prostatitis, the most frequent adverse events were gastrointestinal disorders (1).

Skin

Photosensitivity was found in 44 (1.03%) of 4276 patients treated with lomefloxacin in Japan. Most cases were not severe and improved after withdrawal. Risk factors for a sensitivity reaction were age over 60 years with concomitant diseases and complications, total amount of lomefloxacin over 20 g, treatment for longer than 30 days, and previous treatment with a quinolone (2).

In eight patients (mean age 69 years) with eczematous or acute sunburn-like lesions in photo-exposed areas, who took lomefloxacin for 1 week to several months, phototoxicity appeared to be the main mechanism of photosensitivity, particularly in older patients with concomitant diseases and long-term use of the drug (3).

Lonazolac

See also Non-steroidal anti-inflammatory drugs

General Information

Lonazolac, an arylacetic acid derivative, causes adverse effects like those of other NSAIDs. Gastrointestinal disturbances are followed in frequency by nervous system and skin reactions. The extent of gastrointestinal blood loss is similar to that with diclofenac (1). Cholestatic hepatitis has also been reported (SEDA-8, 106).

Reference

1. Uthgenannt H, Arent H. Uber den Einfluss von 3-(4-Chlorphenyl-) 1-phenyl-1H-pyrazol-4-Essigsäure (Lonazolac-Ca), Diclofenac-Na und Indometacin auf die gastrointestinale Blutausscheidung. [Effect of 3-(4-chlorphenyl-) 1-phenyl-1H-pyrazole-4-acetic acid (lonazolac-Ca), diclofenac-Na and indomethacin on the gastrointestinal blood loss.] Wien Klin Wochenschr 1982;94(13):345–9.

Loperamide

General Information

Loperamide is an opioid whose action is almost completely restricted to the gut. Recognition of its consequent safety, if it is appropriately used, has led to its being released in many countries for sale without prescription. It nevertheless has some central activity, and nausea, dizziness, dry mouth, abdominal pain, ileus, and lethargy all occur in a minority of users, with occasional reports of more serious central reactions, such as a possible association with delirium in a child (1).

The effectiveness of loperamide 4, 8, and 12 mg in reducing symptoms of lactose intolerance has been investigated in an open study in 19 subjects (2). Loperamide 8 mg significantly improved symptom scores to a similar extent as lactase tablets. Four subjects complained of delayed constipation and abdominal cramps related to loperamide.

Organs and Systems

Gastrointestinal

Some cases of necrotizing enterocolitis have been reported in infants with paralytic ileus after treatment for mild diarrhea (3). This is only one of the good reasons to avoid the drug in young children; the most important is that diarrhea in infants should not be suppressed pharmacologically (4).

Second-Generation Effects

Teratogenicity

To determine whether loperamide in pregnancy is associated with an increased risk of birth malformations, birth outcomes in 105 women who had taken loperamide during pregnancy (89 during the first trimester) were compared with the outcomes in women matched for age, smoking, alcohol, and other exposures (5). There were no differences in the frequencies of birth malformations between the two groups. However, 21 of the women had babies that were 200 g smaller than babies in the control group.

Lopinavir and ritonavir

See also Protease inhibitors

General Information

Lopinavir and ritonavir are nucleoside analogue reverse transcriptase inhibitors that are used in combination in the treatment of AIDS.

The pharmacology, clinical pharmacology, uses, adverse effects, and interactions of lopinavir + ritonavir have been reviewed (1).

Observational studies

In studies of combining ritonavir with fluconazole (2) and ritonavir with mefloquine (3) there were no significant effects, and dosage adjustment is not warranted.

Placebo-controlled studies

In a randomized, double-blind study in 70 patients taking a regimen containing protease inhibitors, lopinavir + ritonavir 400/100 mg or 400/200 mg bd was substituted (4). On day 15 nevirapine 200 mg bd was added and NRTIs were changed to include at least one NRTI not previously taken. Despite a more than four-fold reduction in phenotypic susceptibility to the pre-entry protease inhibitor in 63% of the patients, mean plasma HIV-1 RNA concentrations fell by 1.14 log copies/ml after 2 weeks. At week 48, 86% had plasma HIV-1 RNA concentrations of

© 2006 Elsevier B.V. All rights reserved.

under 400 copies/ml, and 76% under 50 HIV-1 RNA copies/ml. Mean CD4 cell counts increased by 125 cells/μl. The most common adverse events were diarrhea ($n = 16$) and weakness ($n = 4$). There were rises in gamma-glutamyltransferase activity ($n = 18$), total cholesterol ($n = 17$), and triglycerides ($n = 17$), and transient rises in transaminase activities ($n = 11$). Three patients discontinued therapy because of drug-related adverse events.

General adverse effects

In early monotherapy studies, including 62 and 87 patients (5,6), in which the potent antiretroviral effect of ritonavir was first demonstrated, the most common adverse events were nausea, diarrhea, headache, circumoral paresthesia, and altered taste sensation. Nausea, vomiting, and diarrhea are common during the start of therapy and usually disappear over the first few weeks of treatment. These adverse effects can be markedly reduced by using a step-up approach, increasing to the full dose over six days. General weakness, circumoral paresthesia, and taste disturbance occur in 5–10% of patients and are seldom dose-limiting.

Ritonavir does not have a broad therapeutic margin, and patients with higher ritonavir concentrations are at a higher risk of neurological or gastrointestinal adverse effects. It is feasible to individualize the dosage regimen with the aid of plasma concentration measurement and close observation of adverse effects, and there is a close relation between the two; this may enable one to increase substantially the percentage of patients who tolerate ritonavir without risking underdosage (7).

An important consideration in the use of all HIV-1 protease inhibitors, but of ritonavir in particular, is their potential for drug interactions through their effects on cytochrome P450 isozymes. The various interactions of ritonavir with other anti-HIV drugs have recently been reviewed (8).

Organs and Systems

Cardiovascular

Two of 16 patients taking lopinavir + ritonavir developed so-called inflammatory edema, which resolved on withdrawal and recurred after rechallenge (9). In three of eight patients inflammatory edema occurred 1–4 weeks after they started to take regimens that contained lopinavir + ritonavir (10). The edema affected the feet, ankles, and calves and was associated in one case with fever and in another with a transient rash; in one case the left shoulder and groin were also affected. All three recovered completely within 1–4 weeks despite continued drug treatment, but 7 months later one had a relapse that required withdrawal of lopinavir + ritonavir.

From a case in which there was positive dechallenge and rechallenge it has been concluded that edema of the lower limbs can be an adverse effect of ritonavir in some HIV-positive patients (11). The authors suspected a relation to the drug's vasodilatory activity. However, it should also be borne in mind that ritonavir has caused reversible renal insufficiency, which should be looked for in any patient who develops edematous changes.

Nervous system

Myasthenia has been attributed to ritonavir (12).

- A 71-year-old man with an 8-year history of HIV infection developed slurred speech, difficulty in climbing stairs, bilateral ptosis, and lateral rectus weakness 3 weeks after having started to take ritonavir (1200 mg/day). All his signs worsened with prolonged testing, and edrophonium produced improvement in ptosis and speech. Specific electromyographic testing confirmed myasthenia gravis. Computed tomography of the chest was normal. After withdrawal of ritonavir the signs and symptoms partly resolved by 3 months.

A definite causal link with ritonavir could not be established, but the authors speculated that ritonavir may have unmasked myasthenia gravis in this patient.

Sensory systems

Ototoxicity has been attributed to lopinavir + ritonavir (13).

- A 46-year-old man took a regimen containing lopinavir + ritonavir, and 4 weeks later complained of reduced auditory acuity accompanied by lancinating pain. Audiology showed mild to moderate bilateral sensorineural hearing loss. On withdrawal and use of efavirenz his hearing recovered.

Based on the time-course and the effect of withdrawal, lopinavir/ritonavir appears to have been the causative agent in this case.

Gastrointestinal

In a prospective, randomized trial in 100 patients, the most common adverse effects of lopinavir + ritonavir included abnormal stools, diarrhea, and nausea (14).

Urinary tract

In a retrospective analysis of 87 HIV-positive patients taking ritonavir in combination with two nucleoside analogues, serum creatinine increased in 12 cases by 66 (5–242)% from 66 (range 46–102) μmol/l, with a median glomerular filtration rate (GFR) of 116 ml/minute (60–202). Ten of the 12 patients had other risk factors for nephrotoxicity, such as dehydration or use of nephrotoxic drugs (15). It is prudent to monitor renal function in patients receiving ritonavir, particularly in the presence of other risk factors for renal dysfunction.

Three patients developed reversible renal insufficiency 10–12 days after starting treatment including ritonavir (16).

Reproductive system

Four women taking ritonavir developed hypermenorrhea, strongly suggesting that this can occur as a complication of ritonavir treatment (17).

Immunologic

Subcutaneous non-tuberculous granulomatous lesions developed in a 48-year-old HIV-positive man when he was given ritonavir (18).

© 2006 Elsevier B.V. All rights reserved.

Susceptibility Factors

Age

The adverse effects commonly observed with ritonavir in adults are reportedly similar in children (19). Of 51 children aged 6 months to 18 years who took escalating doses of a liquid formulation of ritonavir (from 250 up to 400 mg/m^2 every 12 hours), seven withdrew because of gastrointestinal toxicity and four because of grade three hepatic transaminase rises. Both serum triglyceride and cholesterol concentrations increased significantly from baseline within 12 weeks of treatment.

Drug–Drug Interactions

Carbamazepine

Ritonavir can interact with carbamazepine (20).

- A 49-year-old woman with a long history of HIV infection developed worsening ataxia leading to two falls. Four days before admission she had had her antiretroviral drugs changed from zidovudine, lamivudine, and indinavir to ritonavir, saquinavir, and efavirenz. She was also taking carbamazepine to control generalized seizures resulting from a previous right thalamic infarction. The change in antiretroviral therapy resulted in an increase in serum carbamazepine concentration from 6.9 to 20 μg/ml. Serum concentrations in the usual target range were eventually achieved by a sixth of the dose of carbamazepine that had been required before starting ritonavir.

As saquinavir is only a mild inhibitor of CYP3A4 and efavirenz is an inducer, this effect was attributed to the potent inhibitor ritonavir.

Coumarin anticoagulants

Ritonavir can dangerously increase warfarin concentrations (21).

In contrast, ritonavir has been reported to reduce the effect of acenocoumarol (22).

- A 46-year-old man with prosthetic cardiac valves took acenocoumarol and later started to take stavudine, lamivudine, and ritonavir 600 mg bd. His INR fell markedly. Although the dose of acenocoumarol was progressively increased to three times the original dose, it was impossible to achieve the previous INR, and ritonavir was withdrawn.

Ecstasy

Ritonavir can interact with methylenedioxymetamfetamine (MDMA, ecstasy) (23).

- A 32-year old HIV-positive man who added ritonavir 600 mg bd to his existing antiretroviral regimen of zidovudine and lamivudine became unwell within hours after having ingested two and a half tablets of ecstasy, estimated to contain 180 mg of methylenedioxymetamfetamine. He was hypertonic, sweating profusely, tachypneic, tachycardic, and cyanosed. Shortly after, he had a tonic-clonic seizure and cardiorespiratory arrest. Attempts at resuscitation were unsuccessful. Blood concentrations obtained postmortem showed an concentration of 4.56 μg/ml, in the range of that reported in a patient with a life-threatening illness and symptoms similar to this patient after an overdose of 18 tablets of MDMA.

Ritonavir inhibits CYP2D6, which is the principal pathway by which MDMA is metabolized.

Ergot alkaloids

Ergot alkaloids are among the many medications that are contraindicated in patients taking ritonavir. One patient developed severe ergotism after taking ritonavir and ergotamine for 13 days (24), and other cases of ischemia of the lower limbs or elsewhere in the periphery have been reported in patients taking both ritonavir and ergotamine (25–27).

Fentanyl

By inhibiting CYP3A4, ritonavir can significantly inhibit the metabolism of fentanyl, and considerable caution is needed (28).

Ketoconazole

In 12 patients taking ritonavir and saquinavir for HIV infection, ketoconazole significantly increased the AUC, the plasma concentration at 12 hours, and the half-life of ritonavir by 29, 62 and 31% respectively (29). Similar increases of 37, 94, and 38% were recorded for saquinavir. CSF concentrations of ritonavir were raised by 178% by ketoconazole, but there was no significant change in CSF concentrations of saquinavir.

Methadone

Withdrawal symptoms, and the need to increase the dose of methadone, in a 51-year-old man previously stable on a maintenance dosage, have been attributed to ritonavir (30).

Rifamycins

In a pilot, non-randomized study, HIV-infected patients with tuberculosis were treated with regimens containing rifampicin and ritonavir (31). Despite the effects on CYP3A4, there was no significant interaction; plasma ritonavir concentrations remained sufficiently high and rifampicin concentrations did not rise to the toxic range.

Statins

An interaction of ritonavir with simvastatin reportedly resulted in rhabdomyolysis (32).

- A 51-year-old woman taking zidovudine, lamivudine, indinavir, and simvastatin started to take ritonavir and after 1 week developed diffuse muscle weakness and body aches. Creatine kinase (total and the MB isozyme), lactate dehydrogenase, and transaminases were all raised. There were crystals and hemoglobin in the urine.

Presumably this interaction occurred through inhibition of CYP3A4 by ritonavir.

Loratadine

See also Antihistamines

General Information

Loratadine is a second-generation antihistamine (SEDA-18, 182) (SEDA-19, 174) (SEDA-22, 178).

Organs and Systems

Cardiovascular

In contrast to astemizole and terfenadine, loratadine is generally believed to be free of adverse cardiac effects. However, there is some evidence that it could be associated

© 2006 Elsevier B.V. All rights reserved.

with atrial dysrhythmias. In human atrial myocytes loratadine rate-dependently inhibited the transient outward potassium current at therapeutic concentrations, possibly providing a basis for supraventricular dysrhythmias (1). However, during prolonged exposure (3 months) of healthy adult men to four times the recommended daily dose (40 mg/day) there was no change in the electrocardiogram that would suggest QT_c prolongation or any evidence of cardiac dysrhythmias (2).

Prolonged QT interval and symptomatic ventricular tachycardia has been described in a patient who took loratadine plus quinidine, but is most likely to have been attributable to the quinidine and the patient's cardiac condition (SEDA-19, 174).

The pharmacokinetics, electrocardiographic effects, and tolerability of loratadine syrup have been studied in 161 children aged 2–5 years (3). A single-dose open study was performed to characterize the pharmacokinetic profiles of loratadine and its metabolite desloratadine, and a randomized, double-blind, placebo-controlled, parallel-group study was performed to assess the tolerability of loratadine syrup 5 mg after multiple doses. Electrocardiographic parameters were not altered by loratadine compared with placebo. There were no clinically important changes in other tolerability assessments.

In healthy adults loratadine 10 mg/day had no effects on the electrocardiogram when co-administered for 10 days with therapeutic doses of ketoconazole or cimetidine (4).

Liver

Two cases of severe hepatotoxicity in patients using loratadine have been reported (5).

Skin

Loratadine caused erythematous, edematous, pruriginous skin eruptions in a 19-year-old woman who complained of at least three episodes of eruptions located at the same sites each time (6). An oral challenge with loratadine was positive, and cetirizine and ebastine caused no cutaneous reaction. Histopathology suggested a fixed drug eruption.

Drug–Drug Interactions

Nefazodone

Nefazodone is a phenylpiperazine antidepressant that is predominantly metabolized by CYP3A. In a randomized, double-blind, double-dummy, parallel-group, multiple-dose study in healthy men and women who were given loratadine 20 mg od or nefazodone 300 mg every 12 hours, the plasma loratadine concentrations were significantly increased by co-administration of nefazodone (7). The mean QT_c interval was unchanged by loratadine alone, but was markedly prolonged with co-administration of nefazodone, and the extent of prolongation correlated with the plasma loratadine concentration.

Lorazepam

See also Benzodiazepines

General Information

Lorazepam is a benzodiazepine with CNS, depressant, anxiolytic, and sedative properties, used as a hypnotic, sedative, and anxiolytic drug.

Comparative studies

In a multicenter, randomized, double-blind comparison of diazepam (0.15 mg/kg followed by phenytoin 18 mg/kg), lorazepam (0.1 mg/kg), phenobarbital (15 mg/kg), and phenytoin (18 mg/kg) in 518 patients with generalized convulsive status epilepticus, lorazepam was more effective than phenytoin and at least as effective as phenobarbital or diazepam plus phenytoin (1). Drug-related adverse effects did not differ significantly among the treatments and included hypoventilation (up to 17%), hypotension (up to 59%), and cardiac rhythm disturbances (up to 9%).

Intramuscular lorazepam 4 mg has been compared with the combination of intramuscular haloperidol 10 mg + promethazine 50 mg in 200 emergency psychiatric patients with agitation, aggression, or violence (2). The treatments were comparably effective and well tolerated overall, but two patients who took lorazepam had moderate adverse effects: one had worse bronchial asthma and one had nausea and dizziness.

Placebo-controlled studies

The use of intravenous benzodiazepines administered by paramedics for the treatment of out-of-hospital status epilepticus has been evaluated in a double-blind, randomized trial in 205 adults (3). The patients presented either with seizures lasting 5 minutes or more or with repetitive generalized convulsive seizures and were randomized to receive intravenous diazepam 5 mg, lorazepam 2 mg, or

© 2006 Elsevier B.V. All rights reserved.

placebo. Status epilepticus was controlled on arrival at the hospital in significantly more patients taking benzodiazepines than placebo (lorazepam 59%, diazepam 43%, placebo 21%). The rates of respiratory or circulatory complications related to drug treatment were 11% with lorazepam, 10% with diazepam, and 23% with placebo, but these differences were not significant.

Organs and Systems

Respiratory

Patients receiving intravenous benzodiazepines must be monitored for respiratory depression, which may demand artificial ventilation during intensive treatment. Lorazepam may cause less respiratory depression than diazepam at equieffective dosages (SEDA-20, 59).

Psychological, psychiatric

Lorazepam causes some rare adverse effects, including a manic-like reaction on withdrawal, delirium, and paradoxical precipitation of tonic seizures or myoclonus in children (SEDA-19, 35). It can both relieve and worsen behavioral disturbances in demented elderly patients (SEDA-20, 32).

The effects of lorazepam on three neuropsychiatric measures of attention and psychomotor performance have been investigated in 40 patients, 20 of whom were given placebo, 10 were given lorazepam 1 mg, and 10 were given lorazepam 2.5 mg (4). Performance on digit cancellation, digit-symbol substitution, and the Paced Auditory Serial Addition Task was significantly impaired by lorazepam (2.5 mg) and this was significantly worse in the middle-aged subjects compared with the younger. These results suggest that older people are more susceptible to these adverse effects.

Lorazepam disinhibits aggression more than its chemically and kinetically similar analogue oxazepam (5).

Cognition

The psychomotor and amnesic effects of single oral doses of lorazepam 2 mg were studied in 48 healthy subjects in a double-blind, placebo-controlled, randomized, parallel-group study (6). The effects were assessed by a battery of subjective and objective tests that explored mood and vigilance, attention, psychomotor performance, and memory. Vigilance, psychomotor performance, and free recall were significantly impaired by lorazepam.

Lorazepam shares with other benzodiazepines the ability to impair explicit memory, but has a distinct further effect on implicit memory as well (7). However, it impairs memory more than its chemically and kinetically similar analogue, oxazepam (8). The effects of lorazepam 2.5 mg and diazepam 0.3 mg/kg on explicit and implicit memory tasks have been examined in 24 men and 24 women randomly allocated to lorazepam, diazepam, or placebo (7). An implicit word-stem completion task and explicit memory tasks of immediate and delayed word recall and word recognition were administered 90 minutes after drug administration. Both diazepam and lorazepam significantly impaired performance on explicit memory measures. Only lorazepam significantly impaired performance on the implicit memory task.

In a separate study, pharmacokinetic–pharmacodynamic modeling of the psychomotor and amnesic effects of a single oral dose of lorazepam 2 mg was investigated in 12 healthy volunteers in a randomized, double-blind, placebo-controlled, two-way, crossover study using the following tasks: choice reaction time, immediate and delayed cued recall of paired words, and immediate and delayed free recall and recognition of pictures (9). The delayed recall trials were more impaired than the immediate recall trials; similar observations were made with the recognition versus recall tasks.

The effects of lorazepam and diazepam on false memories and related states of awareness have been investigated in 36 healthy volunteers, randomly assigned to one of three groups (placebo, diazepam 0.3 mg/kg, lorazepam 0.038 mg/kg) (10). The results suggested that diazepam and lorazepam cause impaired conscious recollection, associated with true, but not false, memories.

Metabolism

Metabolic acidosis and hyperlactatemia have been attributed to lorazepam (11).

- A 34-year-old woman with a history of renal insufficiency induced by long-term use of cocaine developed respiratory failure and was intubated and sedated with intravenous lorazepam (65 mg, 313 mg, and 305 mg on 3 consecutive days). After 2 days she had a metabolic acidosis, with hyperlactatemia and hyperosmolality. Propylene glycol, a component of the lorazepam intravenous formulation, was considered as a potential source of the acidosis, as she had received more than 40 times the recommended amount over 72 hours. Withdrawal of lorazepam produced major improvements in lactic acid and serum osmolality.

Long-Term Effects

Drug withdrawal

Lorazepam has considerable abuse potential, and poses particular difficulties in withdrawal (12). On the other hand, a sizeable sample ($n = 97$) of chronic users who wanted to discontinue were generally able to use stable or decreasing doses on an as-needed basis (13).

The Omnibus Budget Reconciliation Act of 1987 (OBRA '87) regulations (www.elderlibrary.org) specify when antipsychotic drugs can and cannot be used to treat behavioral disturbances in nursing home residents in the USA. Accordingly, antipsychotic drugs can be used in patients with delirium or dementia only if there are psychotic or agitated features that present a danger to the patient or others. Preventable causes of agitation must be excluded and the nature and frequency of these behaviors must be documented. Non-dangerous agitation, uncooperativeness, wandering, restlessness, insomnia, and impaired memory are insufficient in isolation to justify the use of antipsychotic drugs. With this in mind, the effects of withdrawing haloperidol, thioridazine, and lorazepam have been examined in a double-blind, crossover study in 58 nursing home residents (43 women and 15 men, mean age 86 years), half of whom continued to take the psychotropic drugs that had been prescribed,

© 2006 Elsevier B.V. All rights reserved.

while the other half were tapered to placebo (14). After 6 weeks, the drugs were tapered to the reverse schedule for another 6 weeks. There were no differences between drug and placebo in functioning, adverse effects, and clinical global impression. Cognitive functioning improved during placebo. The authors concluded that gradual dosage reductions of psychoactive medications must be attempted, unless clinically contraindicated, in an effort to withdraw these drugs. Similar conclusions have been reached in other studies (SEDA-22, 54).

Drug Administration

Drug administration route

The pharmacokinetics of intranasal lorazepam compared with oral administration have been evaluated in 11 volunteers in a randomized, crossover study (15). Lorazepam had favorable pharmacokinetics for intranasal administration compared with standard methods. Intranasal delivery could provide an alternative non-invasive delivery route for lorazepam.

Drug–Drug Interactions

Caffeine

Caffeine aggravates, rather than attenuates, lorazepam-induced impairment in learning and performance (16). This contradicts popular wisdom that stimulants are useful in perking up patients taking benzodiazepines, and invites research into what may be a very dangerous practice in benzodiazepine users, that of taking caffeine before driving or operating machinery (see also General Introduction in the monograph on Benzodiazepines).

Clozapine

Caution has been recommended when starting clozapine in patients taking benzodiazepines (SEDA-19, 55). Three cases of delirium associated with clozapine and benzodiazepines (17) have been reported. There have been several reports of synergistic reactions, resulting in increased sedation and ataxia, when lorazepam was begun in patients already taking clozapine (18).

Haloperidol

A thorough review of the pharmacokinetics of haloperidol, with special emphasis on interactions, has been published (19). The interactions include one with lorazepam.

Moxonidine

When co-administered with lorazepam 0.4 mg, moxonidine increased impairment of attentional tasks (choice, simple reaction time and digit vigilance performance, memory tasks, immediate word recall, delayed word recall accuracy, and visual tracking). These effects should be considered when moxonidine is coadministered with lorazepam, although they were smaller than would have been produced by a single dose of lorazepam 2 mg alone (20).

Lorcainide

See also Antidysrhythmic drugs

General Information

The clinical pharmacology, clinical use, efficacy, and adverse effects of lorcainide have been reviewed (1–3).

Organs and Systems

Cardiovascular

Cardiovascular effects of lorcainide are reportedly uncommon (under 1% of cases) and have mostly been associated with intravenous administration. They include hypotension (1) and heart block. Pre-existing sinoatrial disease and heart block are contraindications to the use of lorcainide (4).

Nervous system

Nervous system effects account for most adverse reactions to lorcainide after both intravenous and oral administration. During intravenous treatment patients may complain of vertigo, feeling hot, numbness of the feet (5), dizziness, blurred vision, muscle tremor (6), and tingling sensations in the fingers or tongue (7). All of these effects are transient.

During long-term oral therapy the most frequent adverse effect is sleep disturbance of one kind or another, the frequency being up to 45% (6,8–13). The main types of disturbance are difficulty in falling asleep, nightmares, and lively dreams. In about half of the patients affected there is also excessive sweating (10,11). These effects become less severe after a week or two of therapy, and during that time benzodiazepines may give symptomatic relief (14). In contrast, these patients do not suffer drowsiness or other central nervous system effects during the day.

Seizures and hallucinations have been reported rarely (14).

Endocrine

Lorcainide has been reported to cause hyponatremia, attributed to inappropriate secretion of ADH (15).

Gastrointestinal

Nausea occurs in about 5% of patients during long-term oral therapy. It is probably of central nervous origin (14).

Skin

There have been a few reports of mild allergic skin reactions (14).

Susceptibility Factors

The adverse effects of lorcainide may be partly caused by its active metabolite, norlorcainide, which accumulates during treatment (15).

Drug Administration

Drug overdose

- Lorcainide 2500 mg produced bradycardia, convulsions, and coma in a 15-year-old girl who took a deliberate overdose and died rapidly (16).

Lorenzo's oil

General Information

Lorenzo's oil is a 4:1 mixture of glyceryl trioleate and glyceryl trierucate. It is used in patients with adrenoleukodystrophy. The dyslipidemia in patients with adrenoleukodystrophy consists of increased blood concentrations of very-long-chain saturated fatty acids, particularly hexacosaenoic acid (C26:0). Treatment with Lorenzo's oil has tended to normalize the abnormality in the blood while the patient deteriorates. Neurological changes are unrelated to the fatty acid changes in the blood, and, moreover, erucic acid does not seem to enter the brain. Owing to lack of controlled trials, it is not known whether it works.

Registration of adverse effects with Lorenzo's oil has been hampered by the absence of controlled trials. In 22 patients treated for at least 12 months, although Lorenzo's oil did not seem to be beneficial, there were possible adverse effects, such as mild increases in liver enzymes (55%), thrombocytopenia (55%), gastrointestinal complaints (14%), and gingivitis (14%). Furthermore, there were falls in hemoglobin concentration and leukocyte count, and an increase in the plasma alkaline phosphatase concentration; the reduction in platelet count did not result in hemorrhage (1). Whether some of the adverse effects of Lorenzo's oil are due to low concentrations of essential fatty acids or caused by reduced dietary fat intake is not known.

Organs and Systems

Hematologic

Lorenzo's oil affected blood platelet counts in 39 patients followed for 1 year (2). Blood platelet aggregation studies in those patients were normal and there were no platelet-associated immunoglobulins. It has been suggested that the thrombocytopenia might be due to platelet activation, resulting from an increase in the concentration of erucic acid in the platelet membrane (1).

Lormetazepam

See also Benzodiazepines

General Information

Lormetazepam is a short-acting benzodiazepine with effects similar to those of diazepam.

Organs and Systems

Psychological, psychiatric

Auditory hallucinations have been attributed to lormetazepam (1).

- A 45-year-old woman with moderate depression and anxiety took lormetazepam 4 mg/day. After a few days, she noticed musical auditory hallucinations like children's songs. There were no neurological, otological, or psychiatric causes for the hallucinations. When the dose of lormetazepam was reduced to 2 mg the auditory experience changed to "classic tinnitus." The lormetazepam was eventually withdrawn, but a slight degree of tinnitus persisted.

Lornoxicam

See also Non-steroidal anti-inflammatory drugs

General Information

Data are insufficient to indicate whether the oxicam NSAID lornoxicam is safer for the gastrointestinal tract than other oxicam derivatives (SEDA-16, 113). Headache, dizziness, and gastrointestinal symptoms are the most frequent adverse effects; clinically significant gastrointestinal events include upper gastrointestinal ulceration, with or without hemorrhage or perforation (SEDA-20, 94) (SEDA-21, 107). The profile of drug interactions is similar to the profiles of other NSAIDs (SEDA-21, 108).

Drug–Drug Interactions

Phenprocoumon

Lornoxicam altered the pharmacokinetics of the more potent *S*-isomer of phenprocoumon and to a lesser extent *R*-phenprocoumon, with a reduction in factor II and VII activity (1). In contrast, at the upper limit of the recommended doses lornoxicam did not alter the pharmacokinetics of *R*-acenocoumarol or the anticoagulant activity of acenocoumarol (2).

Warfarin

Lornoxicam increased the mean serum concentration of racemic warfarin and correspondingly increased its anticoagulant effect (3).

Losartan

See also Angiotensin II receptor antagonists

General Information

Losartan is a non-peptide, selective angiotensin type 1 (AT_1) receptor antagonist. Because it has been suggested that there is a local renin–angiotensin system in the eye, losartan may be useful in treating glaucoma. In a small, well-designed, placebo-controlled, crossover study in four groups of subjects—controls, hypertensive patients with normal intraocular pressure, and patients with primary open-angle glaucoma with and without hypertension—a single oral dose of losartan 50 mg produced a drop in intraocular pressure in all subjects within 2–6 hours after drug intake, proportional to baseline eye pressure (1). Blood pressure fell only in the hypertensive subjects. Thus, the fall in intraocular pressure was independent of the systemic effect on blood pressure. Beyond the potential for using losartan as a therapy for glaucoma, ophthalmologists should take into account concomitant therapy with losartan (and possibly other angiotensin receptor antagonists) when measuring intraocular pressure.

Using the method of prescription event monitoring (PEM), the incidence densities of adverse effects per 1000 patient-months of exposure have been measured in 14 522 patients (2). Most were hypertensive (63%). During treatment months 2–6, the commonest adverse effects were cough (17%), malaise and lassitude (15%), dizziness (15%), headache or migraine (11%), nausea and vomiting (6.0%), rash (5.0%), dyspnea (4.9%), edema (4.8%), dyspepsia (4.2%), and diarrhea (3.7%). These were also the most common reasons for drug withdrawal. The seemingly high incidence of cough may have been due to carry over from previous use of ACE inhibitors. In 1378 patients with mild to moderate hypertension valsartan 80 mg/day has been compared with losartan 50 mg/day and placebo for 8 weeks (3). This study confirmed the excellent tolerance profile, not different from placebo, of both angiotensin II receptor antagonists.

An extensive review of the use of losartan, with special focus on elderly patients, has included an update on the tolerability profile, mainly in clinical trials, but with no significant new information (4).

Organs and Systems

Nervous system

An isolated case of migraine occurring after a single dose of losartan was reported (5). The temporal association during challenge and rechallenge, although in unblinded conditions, argues for a possible causal relation.

Sensory systems

There have been reports of taste disturbance in patients taking ACE inhibitors, tentatively attributed to chelation of metal ions. However, no mechanism for taste loss due to angiotensin-II receptor blockers has been proposed. Reversible loss of taste discrimination has been reported with losartan (6). In two cases dysgeusia occurred some time after switching from an ACE inhibitor to losartan (1 week in one case and 3 months in the other). In both cases the dysgeusia disappeared after withdrawal of losartan (timing not reported in one case, 1 week after in the other) (7). The authors referred to previously reported cases, one with losartan (8) and one with valsartan (9), and to a personal communication from the manufacturer of 12 other cases within a large safety monitoring program.

Hematologic

Anemia in hemodialysis (10) and mainly in renal transplant patients has been reported (11–13). The suggested mechanism is by an action on erythropoietin, similar to that of ACE inhibitors, which produce the same adverse effect. However, in a small uncontrolled but prospective study, losartan given for 3 months to 15 patients on chronic hemodialysis with anemia, neither altered plasma erythropoietin concentrations nor aggravated the anemia (14). In those taking losartan there was no need for higher doses of co-administered r-Hu Epo in order to correct anemia, in contrast to controls.

Liver

Hepatic injury due to losartan is a recognized rare adverse effect (15).

- A 52-year-old woman developed jaundice, right upper abdominal discomfort, and weakness. She had had a similar problem previously, after taking losartan

© 2006 Elsevier B.V. All rights reserved.

50 mg/day for 5 months for hypertension. At that time she was jaundiced with increased serum transaminase activities. The losartan was withdrawn and during the following 3 weeks she improved. Losartan was then reintroduced, and 2 weeks later her symptoms recurred. She was jaundiced, with raised transaminase, alkaline phosphatase, and lactic dehydrogenase activities; tests for viral hepatitis were negative. A liver biopsy showed chronic hepatitis with moderate to severe inflammation and mild fibrosis. Losartan was withdrawn and the laboratory tests returned to normal over a period of 4 months. She was healthy with normal laboratory tests 2 years later.

The authors made a strong case for a causal relation, based on the absence of other causes, the return to normality after withdrawal of losartan, and re-occurrence on rechallenge. A literature search revealed four previous reports of losartan-induced liver damage.

Pancreas

Pancreatitis can occur with losartan (16).

- A 42-year-old woman with insulin-dependent diabetes and chronic renal insufficiency developed pancreatitis 5 days after taking enalapril 2.5 mg and recovered after drug withdrawal. The pancreatitis relapsed one week after her general practitioner had prescribed losartan 50 mg/day, with full recovery after withdrawal. A rechallenge test with losartan was fully positive.

The case was well documented and causality seems to have been very convincingly established. No mechanistic speculation was given by the authors.

Urinary tract

Renal insufficiency has been reported with losartan (17).

- A 69-year-old man with hypertension and heart failure took losartan 25 mg/day, increasing to 50 mg/day after 2 weeks. He also took spironolactone 50 mg/day, furosemide 40 mg/day, digoxin 0.25 mg/day, acenocoumarol, and allopurinol. Two weeks later he developed acute renal insufficiency with a plasma creatinine concentration of 725 μmol/l (previously 115 μmol/l). Within 24 hours after losartan withdrawal (it was not stated whether spironolactone was also stopped) and hemodialysis, he recovered renal function (plasma creatinine 124 mg/l). He was later found to have bilateral renal artery stenosis, which is a contraindication to angiotensin II receptor antagonists.

The authors did not discuss the possible aggravating role of spironolactone.

- Anuric renal insufficiency occurred with losartan in a 70-year-old man with a solitary kidney (18). An interesting feature was that the patient's blood pressure could be controlled with captopril without the development of anuria.

This is in line with a study in dogs, in which there was a greater deterioration in glomerular filtration with angiotensin II receptor inhibition than with ACE inhibition, for the same effect on blood pressure (19).

Skin

Two cases of atypical cutaneous lymphoid hyperplasia have been reported (20). Both occurred after 2 weeks of treatment with losartan 50 mg/day.

Immunologic

Angioedema has been reported with angiotensin II receptor antagonists (21,22).

- An African-American developed swelling of the lips and shortness of breath within 24 hours of starting losartan. However, similar reactions had been noted before, while the patient was taking captopril. It was therefore unclear whether the reaction was related to losartan or was a carry-over reaction to captopril.
- A 45-year-old white man, who had taken losartan, hydrochlorothiazide, allopurinol, and colchicine for 9 months, developed facial urticaria, eyelid swelling, shortness of breath, and upper chest tightness, which resolved quickly with famotidine, methylprednisolone, and adrenaline. He had a recurrence 7 hours later, not having taken another dose of losartan. The patient had no history of allergy and was well after losartan withdrawal.

The late onset and recurrence of symptoms after initial resolution are the unique original features of this case report. Patients with such reactions should be kept under observation after the resolution of initial symptoms.

Second-Generation Effects

Teratogenicity

In the study of 14 522 patients mentioned in the introduction to this monograph (2) three mothers were exposed to losartan during the first trimester of pregnancy. One pregnancy terminated in a spontaneous abortion. The two others were both complicated by hypertension. One baby died with extreme prematurity and growth retardation, and the second survived after having been born prematurely. A woman who took losartan from 17 to 31 weeks of gestation developed oligohydramnios and delivered a stillborn fetus with deformities of the extremities and face (23).

Susceptibility Factors

Renal disease

Losartan was evaluated in 406 patients with end-stage renal insufficiency undergoing hemodialysis (24). Only 15 patients discontinued losartan because of adverse effects. In seven the adverse reaction was hypotension. Two patients reported a possible anaphylactoid reaction on treatment with AN69 dialysis membranes. However, nine patients with a history of previous anaphylactoid reactions on treatment with AN69 have not shown this complication with losartan and AN69.

Drug Administration

Drug overdose

In a case of accidental overdose in an 80-year-old patient, who was taking 200 mg/day for 2 months, no ill effects were observed (2).

Drug–Drug Interactions

Erythromycin

Because losartan is metabolized by CYP2C9 and CYP3A4 to an active metabolite, E3174, which has greater antihypertensive activity than the parent compound, the effects of co-administration of losartan 50 mg/day and erythromycin, a moderate inhibitor of CYP3A4, have been investigated in a well-designed study in healthy volunteers. There was no significant effect of erythromycin.

Fluconazole

The pharmacokinetic interaction of fluconazole 200 mg/day with losartan 100 mg/day has been investigated in 32 healthy subjects (25). Fluconazole significantly increased the steady-state concentration of losartan by 66% and inhibited the formation of the active metabolite EXP-3174 by 34%.

Another very similar study investigated interactions with itraconazole, an inhibitor of CYP3A4, and fluconazole, which is more specific for CYP2C9 (26). Fluconazole reduced the mean peak plasma concentrations of losartan and E3174 to 30% and 47% of their control concentrations respectively. The half-life of losartan was prolonged by 67%. Itraconazole had no significant effect. The possibility of a reduced effect of losartan when co-administered with fluconazole should be expected.

Grapefruit juice

Administration of grapefruit juice (which inhibits both cytochrome P450 and P glycoprotein) to healthy volunteers resulted in an increased serum concentration ratio of losartan to its active metabolite E3174 (27). As both losartan and its metabolite contribute to the therapeutic effects, the absence of pharmacodynamic measurements in this study obviated conclusions about the clinical implications of this interaction.

Indometacin

Indometacin 50 mg bd for one week did not interfere with the antihypertensive efficacy of losartan 50–100 mg/day in patients with essential hypertension, despite the fact that indometacin caused significant increases in weight and extracellular fluid volume (28). Glomerular filtration rate remained unchanged. Indometacin did not adversely influence peripheral hemodynamics. This is in contrast to the reported effects of indometacin during ACE inhibition, leading to an increase in blood pressure. It suggests that prostaglandins in part mediate vasodilatation during ACE inhibition, a mechanism that is not shared by angiotensin II antagonists. However, the result of this study is in contrast with those of several similar interaction studies with other antihypertensive agents, in which prostaglandin inhibition for 1–4 weeks caused an increase in weight combined with an increase in blood pressure. If indometacin had been given with losartan for more than 1 week, it may have produced a similar increase in blood pressure. Thus, the results of this study should not be taken as an argument against the recommendation that non-steroidal anti-inflammatory drugs should not be combined with angiotensin II antagonists, a recommendation that should be re-emphasized.

Lithium

An interaction of losartan with lithium has been reported (29).

- A 77-year-old woman who had been taken lithium carbonate 625 mg/day with a stable lithium concentration of around 0.6 mmol/l started to take losartan for hypertension. Within 4 weeks she developed ataxia, dysarthria, and confusion, and her serum lithium concentration was 2.0 mmol/l. Her symptoms resolved on withdrawal of losartan.

The authors proposed that this effect had occurred by reduced aldosterone secretion, an effect which is greater with ACE inhibitors than with angiotensin II receptor antagonists. In healthy volunteers losartan did not alter the fractional secretion of lithium (30), so presumably this patient had some susceptibility that caused the interaction.

Rifampicin

A study in 10 healthy volunteers has suggested that rifampicin interacts with losartan (31). The AUCs of both losartan and its active metabolite were markedly reduced (about 30 and 40% respectively) when rifampicin 300 mg bd was given for 1 week.

Because losartan is metabolized by CYP2C9 and CYP3A4 to an active metabolite, E3174, which has greater antihypertensive activity than the parent compound, the effects of co-administration of losartan 50 mg/day and the potent enzyme inducer rifampicin have been investigated in a well-designed study in healthy volunteers. Rifampicin produced 35 and 40% reductions in the AUCs of losartan and E3174 respectively. Losartan oral clearance increased by 44% and the half-lives of both compounds were shortened by 50% (32). Given the magnitude of the effect, this interaction is likely to be of clinical relevance.

Lovastatin

See also HMG Co-A reductase inhibitors

General Information

The adverse events profile of lovastatin in 8245 patients with moderate hypercholesterolemia has been evaluated in a double-blind, diet- and placebo-controlled trial (1). The difference between lovastatin and placebo in the incidence of adverse events that required discontinuation was small, ranging from 1.2% at 20 mg bd to 1.9% at 80 mg/day. Among a variety of symptoms, only constipation differed significantly between drug and placebo, with a slightly higher frequency in the treated group. The treated patients also gained on average 0.4 kg more weight than controls. Deaths were few. Lovastatin-induced rhabdomyolysis can occur (2), even in the absence of other drug therapy (SEDA-12, 1101) (3).

Organs and Systems

Psychological, psychiatric

In a double-blind study, 209 healthy adults were randomized to placebo or lovastatin 20 mg/day for 6 months (4). Placebo-treated subjects improved between baseline and post-treatment periods on neuropsychological tests in all performance domains (neuropsychological performance, depression, hostility, and quality of life), consistent with the effects of practice on test performance, whereas those treated with lovastatin improved only on tests of memory recall. Comparisons of the changes in performance between placebo and lovastatin showed small but significant differences for tests of attention and psychomotor speed, and were consistent with greater improvement with placebo. Psychological well-being was not affected by lovastatin. The authors concluded that treatment of hypercholesterolemia with lovastatin did not cause psychological distress or substantially alter cognitive function. However, treatment did result in slight impairment of performance in neuropsychological tests of attention and psychomotor speed, the clinical importance of which is uncertain.

© 2006 Elsevier B.V. All rights reserved.

Skin

Ichthyosiform eruptions on the abdomen and back occurred in a Korean patient after 3 months of lovastatin therapy; they disappeared on withdrawal (5). Similar lesions occurred in a 54-year-old Chinese man (6).

Reproductive system

Hypospermia has been reported in a patient taking lovastatin (7).

Immunologic

There were 25 serious hypersensitivity reactions (such as arthralgia and thrombocytopenia) among the first million patients taking lovastatin; at least some of these were considered to be due to the drug (8).

Body temperature

Severe hyperthermia has been attributed to lovastatin (9).

Drug–Drug Interactions

Diuretics

Potassium-depleting diuretics, except indapamide, can attenuate the effect of lovastatin on blood lipid concentrations (10).

Erythromycin

Rhabdomyolysis due to a short course of erythromycin in a 73-year-old man who had taken lovastatin for 7 years was accompanied by signs of multiple organ toxicity so severe as to mimic sepsis (11).

Gemfibrozil

Lovastatin in combination with gemfibrozil caused a rise in creatine kinase activity 234 000 U/l, with complete remission after both drugs had been withdrawn (12).

Quetiapine

Lovastatin caused prolongation of the QT interval in a patient taking quetiapine.

- A 46-year-old African-American woman with schizophrenia, taking quetiapine 800 mg/day and sertraline 100 mg/day, was given lovastatin 10 mg/day for dyslipidemia (13). Although 2 months later her lipid concentrations had improved, a routine electrocardiogram showed prolongation of the QT_c interval to 569 milliseconds; it had been 416 milliseconds 6 months before. There were no electrolyte abnormalities and no history of cardiac conduction abnormalities. The dose of lovastatin was reduced to 5 mg/day and an electrocardiogram the next day showed a normal QT_c interval (424 milliseconds). Later she switched from lovastatin to niacin and subsequent electrocardiograms were all normal.

Probably lovastatin caused an increase in plasma quetiapine concentrations through competitive inhibition of CYP3A4.

Loxapine

See also Neuroleptic drugs

General Information

Loxapine is a dibenzoxazepine neuroleptic drug.

Organs and Systems

Hematologic

Three cases of leukocytosis attributed to loxapine have been reported; all resolved when loxapine was withdrawn (1).

© 2006 Elsevier B.V. All rights reserved.

Drug Administration

Drug overdose

A review of acute loxapine overdosage suggested that it has a high potential for causing serious neurological problems and cardiotoxicity (2).

In a study of overdosages of different neuroleptic drugs, loxapine had the highest fatality index (the number of deaths divided by the number of prescriptions) (3).

Loxoprofen

See also Non-steroidal anti-inflammatory drugs

General Information

Data on the safety of loxoprofen are based on an open, multicenter trial of about 4000 elderly patients in Japan (SEDA-17, 112). Adverse effects were mainly gastrointestinal, but other adverse effects, common to every NSAID, included edema, dizziness, skin rashes, pruritus, and a case of eosinophilic pneumonia and liver dysfunction (SEDA-17, 112).

Organs and Systems

Respiratory

A fatal asthmatic attack occurred in a young man with a history of asthma and nasal polyps who took loxoprofen (SEDA-18, 105).

Gastrointestinal

In a retrospective study of NSAID-induced colonic ulceration related to NSAID therapy, five of 14 patients were taking loxoprofen (1). However, this finding does not prove that loxoprofen is more ulcerogenic than other NSAIDs.

Liver

The Japanese Health Authority has tightened the hepatic warnings for loxoprofen after eight reports of serious hepatic adverse events since 1997, including two deaths (2).

Immunologic

Three cases of a type-I hypersensitivity reaction to loxoprofen, characterized by generalized urticarial rash and dyspnea, have been reported (3,4).

Drug–Drug Interactions

ACE inihibitors

Loss of consciousness due to marked bradycardia caused by severe hyperkalemia has been described in an 85-year-old woman who took loxoprofen for several days and long-term imidapril, an ACE inhibitor. The combination of an NSAID with an ACE inhibitor can produce serious adverse effects in high-risk patients (5).

Lumefantrine

General Information

Lumefantrine is a synthetic aminoalcohol fluorene derivative, related to halofantrine and mefloquine (1). It was highly effective in uncomplicated chloroquine-resistant malaria tropica in an open, non-comparative trial in 102 patients in China when given in four oral doses over 48 hours (2). No significant adverse effects have been reported. It has also been marketed in a combination of artemether (20 mg) plus lumefantrine (120 mg).

In 60 children in the Gambia with uncomplicated malaria tropica, lumefantrine was safe and effective. No neurological, cardiac, or other adverse effects were reported (3).

Lumefantrine was inferior to artesunate + mefloquine in an open, randomized comparison in 617 patients in Thailand with uncomplicated multidrug-resistant malaria tropica, but produced two to four times fewer adverse effects, such as nausea, vomiting, dizziness, sleep disorders, or other neurological symptoms (4).

In another study in Thailand, lumefantrine was less efficacious than mefloquine in a double-blinded, randomized trial in 252 adults (5). The lower efficacy of

© 2006 Elsevier B.V. All rights reserved.

lumefantrine in Thailand may be due to poorer absorption and more resistant parasites in these areas, and the manufacturers have recommended higher doses than were used in these studies (6).

In an open, randomized trial in 260 Tanzanian children, lumefantrine was superior to chloroquine and did not produce major adverse effects (7).

Lycopodiaceae

See also Herbal medicines

General Information

The family of Lycopodiaceae contains three genera of clubmoss, *Huperzia*, *Lycopodium*, and *Lycopodiella*.

Lycopodium serratum

Lycopodium serratum (clubmoss, Jin bu huan) has been used in Chinese medicine for more than 1000 years. It contains the alkaloid serratidine and triterpenoids, such as oxolycoclavinol, oxoserratenetriol, tohogeninol, and tohogenol.

Adverse effects

Jin bu huan can cause liver damage (1).

- A 49-year-old man developed signs of hepatitis after taking three tablets of Jin bu huan per day for 2 months for insomnia. No other potential causes for the liver damage could be identified. A liver biopsy showed chronic hepatitis with moderate portal and parenchymal lymphocytic inflammation and focal necrosis. The patient stopped taking the herbal remedy and his liver function normalized.

There have been other reports of hepatotoxic effects of Jin bu huan (2).

Overdosage of Jin bu huan can cause central nervous system and respiratory depression with rapid life-threatening bradycardia (3,4).

Lyme disease vaccine

See also Vaccines

General Information

Lyme disease is a tick-borne, spirochetal zoonosis, characterized by a distinctive skin lesion, systemic symptoms, and neurological, rheumatological, and cardiac involvement, occurring in varying combinations over a period of months to years. *Borrelia burgdorferi* is the causative agent in North America, whereas in Europe three genomic groups (named *Borrelia burgdorferi sensu stricto*, *Borrelia garinii*, and *Borrelia afzelii*) have been identified. Endemic foci have been found in North America, Europe, the former USSR, Japan, and China. In many of these areas, Lyme disease is now the most common vector-borne disease. Because of this epidemiological problem and the severity of the disease, a vaccine was developed. High titers of antibody to outer surface protein A (OspA) of the spirochete prevented *B. burgdorferi* infection in mice and subsequently in immunized hamsters, dogs, and monkeys.

In December 1998, based on many prelicensure clinical trials, the first Lyme disease vaccine (LYMErix, manufactured by the then SmithKline Beecham) was licensed by the Food and Drug Administration (FDA) for individuals aged 15–70 years old (1) and subsequently became commercially available in the USA. In 1999, the Advisory Committee on Immunization Practices (ACIP) made recommendations for Lyme disease vaccine (2), including data on efficacy and safety (SEDA-23, 338). No convincing evidence was found that the vaccine caused serious problems, but discussion about its safety continued and

© 2006 Elsevier B.V. All rights reserved.

the demand for the vaccine did not reach a sustainable level. Therefore, in February 2002 the vaccine was withdrawn by the manufacturers.

In two overviews the results of various clinical and efficacy trials were summarized (3,4) and the safety, immunogenicity, and efficacy of the vaccine were underlined. The authors considered that the intravector mode of action of the vaccine was unique and opened the door to a new method of preventing insect-borne illnesses in humans.

Dr Neal Halsey, head of the Institute for Vaccine Safety at John Hopkins University, explained that the poor sales had resulted from "public misperception and the promotion of false concerns" (5). Lyme disease researchers consider the Lyme vaccine story in the USA to have been a setback in Lyme disease prevention. Vaccines meeting the specific epidemiological situation in Europe are under development. Lyme disease prevention and prophylaxis has been reviewed (6).

Observational studies

LYMErix safety data reported to the Vaccine Adverse Event Reporting System (VAERS) from 21 December 1998 to 31 October 2000 mentioned reports of adverse events associated with Lyme vaccine in prelicensure trials, including injection site reactions, transient arthralgia and myalgia within 30 days of vaccination, fever, and a flu-like illness (7). Allergic reactions were reported to the VAERS and some could have plausibly been linked to the vaccine because of the short latency between vaccination and reaction onset. No clear patterns in age, sex, time to onset, or vaccine dose were identified, although the unexpected predominance of reports of arthrosis in men might warrant further consideration.

Placebo-controlled studies

The results of two efficacy and safety trials using Lyme disease vaccine with or without adjuvant have been reported. In a double-blind trial, 10 305 subjects at least 18 years old, recruited at 14 sites in areas of the USA where Lyme disease was endemic, were randomly assigned to receive either placebo ($n = 5149$) or OspA vaccine ($n = 5156$) (8). The first two injections were given 1 month apart and 7515 subjects also received a booster dose at 12 months. The efficacy of the vaccine was 68% in the first year of the study in the entire population and 92% in the second year among the 3745 subjects who received a third injection. The vaccine was well tolerated. There was a higher incidence of mild, self-limiting, local and systemic reactions in the vaccine group, but only during the 7 days after vaccination (Table 1). There was no significant increase in the frequency of arthritis or neurological events in vaccine recipients. The authors concluded that OspA vaccine was safe and effective in the prevention of Lyme disease.

In another randomized, double-blind trial in 10 936 subjects in areas of the USA in which Lyme disease is endemic, either recombinant *B. burgdorferi* OspA with adjuvant or placebo was given initially and at 1 and 12 months (9). After two injections, 22 subjects given vaccine and 43 given placebo contracted definite Lyme disease; vaccine efficacy was 49% (95% CI = 15, 69%). In the second year, after the third injection, 16 vaccine recipients and 66 placebo recipients contracted definite Lyme disease; vaccine efficacy was 76% (CI = 58, 86%). The efficacy of the vaccine in preventing asymptomatic infection was 83% in the first year and 100% in the second year. Injection of the vaccine was associated with mild to moderate local or systemic reactions lasting a median of 3 days (Table 2).

Table 1 Percentage incidences of adverse effects within 7 days after injection

Adverse effect	Vaccine	Placebo
First injection		
Number of subjects	5156	5149
Any adverse effect	9.8	4.1
Musculoskeletal	6.4	1.3
Myalgia	5.5	0.6
General	1.8	0.9
Pain at injection site	0.3	0.04
Second injection		
Number of subjects	5050	5034
Any adverse effect	6.1	3.1
Musculoskeletal	3.3	1.1
Myalgia	2.5	0.4
General	1.7	0.8
Pain at injection site	0.8	0.1
Third injection		
Number of subjects	3745	3770
Any adverse effect	11.2	5.5
General	7.3	2.6
Tenderness	2.3	0.2
Pain at injection site	1.5	0.2
Unspecified pain	1.0	0.1
Reaction at injection site	0.8	0.2
Swelling	0.6	0.1
Pain in limb	0.5	0.02
Edema at injection site	0.5	0
Rigors	0.2	0
Skin or subcutaneous tissue	2.1	0.2
Erythematous rash	1.9	0.1

Organs and Systems

Musculoskeletal

Suspicions were expressed in the Mealey Publication's Drug and Medical Device Report that the Lyme disease vaccine LYMErix could cause an incurable form of autoimmune arthritis. It was hypothesized that blood concentrations of OspA after three doses of vaccine place vaccinees classified by genetic type HLA-DR4+ at risk of developing treatment-resistant Lyme arthritis. The premarket trials for the vaccine were assessed by an independent advisory committee, which found no link between Lyme disease immunization and autoimmune arthritis (10). However, the committee stressed the need for long-term surveillance and further studies in those over 70 years and in children, and the effect of the vaccine in patients with chronic arthritis; the possible development of autoimmunity deserves further study (11). After licensing of the vaccine, more than 1 million Americans received it and no unusual adverse effects were reported to the manufacturer (10).

Unrelated to vaccination			
Early (<30 days)	27.1	27.9	0.37
Late (>30 days)	53.3	52.6	0.48

[*] Totals include all early or late related or possibly related systemic events, not just those with a frequency of at least 1%.

However, subsequently the FDA received some reports of arthritis and Lyme disease after the use of the vaccine (12). Therefore, on 31 January 2001, the FDA's Vaccines and Related Biological Products Advisory Committee held a meeting to evaluate safety data of LYMErix. Among other information, the experts considered a manufacturer's briefing document as well as safety data reported to the VAERS. The Associated Press Report from 31 January 2001 on the FDA meeting on Lyme vaccine read (in part) as follows: "Vaccine Safety experts found no proof that the LYMErix vaccine is dangerous—the rare cases of arthritis and other symptoms could be coincidence. Many reports are of minor complaints or are not believed to have been caused by the vaccine, but the FDA is studying 133 reports of severe arthritis-like symptoms. That's because of a theory that the vaccine might set off an autoimmune reaction where the body attacks its own tissues, particularly in people who carry a certain gene called HLA-4." The panel said that ultimately "no convincing evidence exists that the vaccine causes serious problems", but the experts urged the FDA and the manufacturer to expedite new safety studies and demanded that the Government should act to ensure that patients are told about the possible risks before inoculation. They also urged that the CDC should aggressively distribute a patient-friendly safety fact sheet about LYMErix (13).

A postmarketing assessment cohort study using automated record linkage was initiated at Harvard Pilgrim Health Care (HPHC) in order to address the theoretical concern that immunization with a vaccine containing OspA might cause an autoimmune arthritis and to evaluate whether exposure to the vaccine is a risk factor for Lyme disease, treatment-resistant Lyme disease, rheumatoid arthritis, certain neurological diseases, allergic events, hospitalization, and death (SEDA-24, 367) [http://www.fda.gov/ohrms/dockets/ac/01/slides/3680s2-05_platt.pdf]. The study involves 25 000 HPHC members who are expected to receive the vaccine and 75 000 non-immunized controls. For the most recent report, matched data were available for 2568 vaccinees and 7497 controls. At this stage, the available results do not suggest that the outcomes of interest were more frequent among vaccinees than among non-vaccinees. Having recognized that enrolment into the database is at a slower rate than anticipated, two additional Health Maintenance Organizations in countries where Lyme disease is endemic have been identified and will contribute.

On 30 November 2000, 1.4 million doses of vaccine had been distributed. From January 1999 to the time of the database query, there was no evidence that the incidence of these arthritic conditions was higher than reported in the general population or that they were associated with an autoimmune process (7).

To address further the question of a possible link between Lyme vaccine and arthritis, the FDA is conducting a telephone survey of individuals who have reported arthritic conditions to the VAERS after receiving the vaccine (7). This survey is a census of available and willing individuals who submitted reports that have been coded as arthritis, arthrosis, rheumatoid arthritis, joint disease, and arthralgia. The goals of the survey are to describe the characteristics of these adverse events, to identify concomitant factors that might influence the characteristics of these events, and to describe the relation of the events to immunization. After this survey phase is complete, the VAERS will identify cases of arthritis and will conduct a case-control study to examine the hypothesis that Lyme vaccine causes arthritis. It is planned to compare people who report arthritis after Lyme disease vaccine with two control groups: people who report arthritis to the VAERS after other vaccines and people who report adverse events to the VAERS other than arthritis after Lyme vaccine. All cases will be age-, sex-, and race-matched with controls. All three groups will be tested for DR HLA haplotypes at the allele level and for peripheral blood lymphocyte responses to OspA and leukocyte function-associated antigen-1 (LFA-1). This is an attempt to determine if people who report arthritis after Lyme vaccine have a higher prevalence of certain HLA alleles that are known to be associated with rheumatoid arthritis and have the same third common hypervariable region, while simultaneously having greater peripheral T cell reactivity to OspA and LFA-1. Given the relatively small number of arthritis cases reported after Lyme vaccine, probably only a very high risk will be detectable.

Four cases of arthritis associated with the administration of Lyme vaccine have been reported (14).

- 15 weeks after a third dose of Lyme vaccine a 9-year-old boy developed arthritis, including both knees, the right elbow, the left hip, the right ankle, and the right thumb; he was probably in an asymptomatic phase of natural Lyme infection.

© 2006 Elsevier B.V. All rights reserved.

- About 3 months after a third dose of Lyme vaccine a 16-year-old boy developed arthritis of both knees.
- 24 hours after a second dose of Lyme vaccine a 53-year-old man developed flu-like symptoms and arthralgia; he later developed swelling of the finger joints and toe joints.
- 24 hours after a second dose of Lyme vaccine a 43-year-old man developed multiple synovitis.

In all cases the disease was self-limiting and to the knowledge of the authors inconsequential in the long term. They considered that the findings supported post-infectious and mimicry models, by showing that OspA, an outer surface protein of the causative organism of Lyme disease, *B. burgdorferi*, could cause acute arthritis, the possibility that it was associated with a more protracted form of arthritis, and that it perhaps had a modulating effect in individuals with concurrent Lyme infection.

Susceptibility Factors

Genetic factors

From reports containing information on HLA types, clinical descriptions of adverse events in those given Lyme disease vaccine are similar in people with DR4 and non-DR4 HLA haplotypes and do not suggest more inflammatory arthritis in people of DR4 haplotype (15) [http://www.fda.gov/ohrms/dockets/ac/01/briefing/3680b2-06.pdf]. The characteristics of adverse events in people with a self-reported history of Lyme disease do not differ substantially from all adverse events after Lyme vaccine.

Drug Administration

Drug dosage regimens

In a randomized study in 956 volunteers aged 17–72 years a shortened immunization schedule of injections at 0, 1, and 2 months were compared with a schedule of injections at 0, 1, and 12 months (16). Adverse events were transient and mild to moderate. Soreness was the most frequently reported local symptom (82%), whereas fatigue (20–22%) was the most frequently reported general symptom. Two volunteers had more serious adverse events: severe chills and shaking in one and an episode of syncope (lasting a few minutes with complete recovery) on the day of the first dose in another. The authors concluded that doses at 0, 1, and 2 months would provide protection during a typical tick-transmission season.

Lysergide

General Information

Lysergic acid diethylamide (LSD) is a hallucinogen that is usually taken orally. Its initial effects, anticholinergic and sympathomimetic in type, occur within about half an hour and include tachycardia, hyperthermia, mydriasis, piloerection, hypertension, and occasionally nausea and vomiting. The more important psychoactive effects develop 1–2 hours later and can last 24–48 hours. They are principally

© 2006 Elsevier B.V. All rights reserved.

changes in perception, mood, and behavior, leading in many cases to acute panic, hallucinations, delusions, and in some cases a classical psychosis. Perception may be strikingly heightened and distorted, and initial perceptions may mask and overshadow later sensory perception. Users often grossly exaggerate their mental and emotional capacities, attributing to themselves extraordinary powers. Visual hallucinations, loss of appreciation of time and space, and instability of mood are common. Meaningfulness and a sense of universal union often predominate. A significant problem in street purchase is the uncertain quality and likely impurity of the material obtained. Doses of 25 mg and more are sufficient to cause its psychophysiological effects, which are generally dose-related up to 500 mg. The half-life is about 3 hours, but the effects last considerably longer (1).

Acute panic attacks and hallucinogen-induced psychotic disorder often occur when people with preexisting personality disorder or pre-psychotic personalities use hallucinogens. Suicide and self-injury have been reported. Prolonged psychotic disorders can occur, but psychiatric opinion is divided as to whether these occur only in people with pre-existing disorders or in healthy individuals as well. "Flashbacks" occur particularly when there has been prolonged heavy use, but eventually disappear (SED-11, 83) (1,2). Self-injury and suicide can result (3).

Hypersensitivity reactions are exceedingly rare and no reports have been validated. Tumor-inducing effects are possible, as a consequence of various reports from animal and human studies that chromosomal abnormalities may be associated with exposure to LSD. However, its mutagenic effects in practice are questionable, and no useful evidence for or against its potential for carcinogenicity has been produced (4).

Organs and Systems

Cardiovascular

Vasoconstriction, affecting both cerebral and peripheral circulations, has been associated with LSD (5), but it is not usually significant at ordinary doses in people with a normal circulatory system.

Nervous system

Hallucinogen-induced mood disorder is associated with changes in affect, varying from euphoria to manic-like symptoms, panic/fear, and depression, often occurring within minutes and often varying in the same individual on different occasions. Changes in sensory perception, with a loss of ability to distinguish temporal or spatial reality and sensory hallucinations, particularly visual and tactile, are frequent, with a tendency to assume godlike attributes. These features often merge in a psychosis, particularly with repeated use. Whether chronic psychosis after LSD is the result of the drug or of a combination of the drug and predisposing factors is currently unanswerable (6–8).

The repeated use of LSD is associated not only with psychoses, but also with more specific neurological signs and symptoms, including ataxia, incoordination, dysphasia, paresthesia, and tremor. Convulsions have been reported. "Flashback," or the return of hallucinogenic effects, occurs in almost a quarter of those who have used LSD, particularly if they have also used other CNS stimulants, such as alcohol or marijuana (2,9). They can experience distortions of perception of objects, space, or time, which intrude without warning into reality, resulting in delusions, panic, and unusual images. A "trailing phenomenon" has also been reported, in which the visual perception of objects is reduced to a series of interrupted pictures rather than a constant view (10). The frequency of these events may slowly abate over several years, but in a significant number their incidence later increases (1,3).

Sensory systems

Apart from visual hallucinations (discussed under the section Nervous system in this monograph), diplopia, blurred vision, mydriasis, and other visual disturbances occur (11). Pupillary dilatation, combined with altered sensory appreciation, has led to a number of instances of retinal damage after continued direct exposure to the sun (12).

Hematologic

The only hematological effect reported has been an increased rate of blood clotting associated with severe hyperthermia (13).

Gastrointestinal

Retroperitoneal fibrosis has been reported, not unexpectedly, in view of the structural similarity between LSD and methysergide (3).

Body temperature

Hyperthermia can occur but does so very seldom with usual doses (14). It has been produced experimentally with high doses.

Second-Generation Effects

Teratogenicity

Animal studies have not shown that LSD is teratogenic. Various publications have referred to a high incidence of abortions and congenital abnormalities associated with LSD. However, none of these has shown any consistent pattern of abnormality, and neither has there been an acceptable control group (4).

Susceptibility Factors

People who are predisposed to psychosis, schizophrenia, or a family history thereof, may be at considerable risk of developing LSD psychosis (3,8). People with epilepsy may be more prone to convulsions, with a reduction in convulsant threshold.

© 2006 Elsevier B.V. All rights reserved.

Drug–Drug Interactions

Monoamine oxidase inhibitors

Chronic administration of a monoamine oxidase inhibitor causes a subjective reduction in the effects of LSD, perhaps due to differential changes in central serotonin and dopamine receptor systems (15).

Phenothiazines and butyrophenones

Phenothiazines and butyrophenones can counteract the psychoactive effects of LSD and benzodiazepines can depress their effects (16).

Reserpine

Reserpine can accentuate the effects of LSD (17).

Interference with Diagnostic Tests

Ambroxol

A urine sample from a patient with a severe head injury tested positive for LSD (18). The test was carried out using a homogeneous immunoassay CEDIA DAU LSD (Boehringer, Mannheim). Although LSD has a half-life of 3 hours, the patient's urine tested positive for several days. Analysis of the same urine samples using high-performance liquid chromatography (HPLC) failed to detect LSD. LSD screening was then performed in urine samples obtained from ten other patients in the same ward. All samples tested positive for LSD by the CEDIA DAU LSD assay but negative using HPLC. All of the patients were taking ambroxol. Ambroxol was detected in the urine by HPLC. In a volunteer, LSD was not detected in a fasting urine sample. After a dose of ambroxol 15 mg a urine sample obtained 90 minutes later tested positive for LSD. The addition of 50 µl of Mucosolvan juice (which contains ambroxol) to the negative fasting urine sample resulted in a positive test for LSD. The authors concluded that ambroxol should be excluded when LSD screening is performed using the CEDIA DAU LSD test.

Lysine acetylsalicylate

General Information

Lysine acetylsalicylate is a soluble form of salicylate developed for intravenous administration in acute pain. Its mode of action and scope of adverse effects are similar to those of aspirin (1), although it has a faster onset of action (2) and causes less gastrointestinal bleeding (3).

Macrolide antibiotics

General Information

The basic structure of the macrolide antibiotics is characterized by a lactonic cycle with two osidic chains, and they are classified according to the number of carbon atoms in the cycle: 14-membered macrolides (for example clarithromycin, dirithromycin, erythromycin, roxithromycin, troleandomycin), 15-membered macrolides (for example azithromycin), and 16-membered macrolides (for example josamycin, midecamycin, spiramycin).

The following macrolides are covered in separate monographs: azithromycin, clarithromycin, dirithromycin, erythromycin, josamycin, midecamycin, rokitamycin, roxithromycin, spiramycin, and troleandomycin (all rINNs).

The antibacterial activity of the macrolides is based on interference with protein synthesis by combining with a subunit of bacterial ribosomes. This generally results in a bacteriostatic effect. They cover a broad range of pathogens. Most are active against Gram-positive cocci and some Gram-negative bacteria, including *Campylobacter* and *Haemophilus*, but not most *Enterobacteriaceae*. However, they are very active against *Mycoplasma*, *Ureaplasma*, *Chlamydia*, *Legionella*, and *Coxiella*. Their activity against *Mycobacterium avium* complex, *Cryptosporidia*, and *Toxoplasma* is variable (1). The macrolide antibiotics have established themselves in the treatment of community-acquired infections. In addition, some have found new indications in the treatment of opportunistic infections in HIV-infected patients (1).

Actions and uses in non-infective conditions

Erythromycin is a motilin receptor agonist (2–4). Azithromycin also produced a significant increase in postprandial antral motility (5). Clarithromycin is also prokinetic, as shown in 16 patients with functional dyspepsia and *Helicobacter pylori* gastritis (6). For this reason, the macrolides have been used to treat gastroparesis (7).

Azithromycin may be useful in reducing ciclosporin-induced gingival hyperplasia in renal transplant recipients (8).

A beneficial effect of low doses of clarithromycin on sputum rheology has been reported in patients with chronic pulmonary diseases, such as chronic bronchitis (9).

In a murine model of virus-induced lung injury, erythromycin significantly improved survival rate (10). This may be explained by inhibition of inflammatory-cell responses and suppression of nitric oxide overproduction in the lungs of the virus-infected mice.

In 202 patients with unstable angina pectoris, roxithromycin prevented death and re-infarction for at least 6 months after initial treatment (11). However, these findings could not be confirmed in another study in 302 patients with coronary heart disease and a seropositive reaction to *Chlamydia pneumoniae* who were treated with azithromycin. While global tests of markers of inflammation improved, there were no differences in antibody titers and clinical events (12).

General adverse effects

Macrolides are in general well tolerated and are used over wide dosage ranges. The rates of adverse reactions are dose-related, as exemplified by the rate of adverse reactions to clarithromycin, which was higher with 2000 or 4000 mg in two doses per day than with 500 or 1000 mg/day (1). Severe toxicity is very rarely observed with macrolides. Most adverse reactions are rated as either mild or moderate, regardless of the macrolide used. Among 245 patients who were hospitalized because of toxic epidermal necrolysis or Stevens–Johnson syndrome, 6 patients had had exposure to macrolides within the week before the onset of the illness (13). The following antibiotics were used: erythromycin, roxithromycin (14), and spiramycin (14). The results of a case-control study suggest that macrolides do not pose an excess risk of this toxic complication (13). Anaphylactic reactions to macrolides are exceedingly uncommon, but anaphylaxis and acute respiratory distress have been reported (15,16). Skin tests with erythromycin were positive for the immediate and/or delayed types of hypersensitivity (17). Tumor-inducing effects have not been reported.

Table 1 and Table 2 summarize the frequencies of adverse reactions and premature withdrawal of the most widely used macrolides.

Pharmacoeconomics

The pharmacoeconomic impact of adverse effects of antimicrobial drugs is enormous. Antibacterial drug reactions account for about 25% of adverse drug reactions. The adverse effects profile of an antimicrobial agent can

Table 1 Frequencies of adverse reactions to macrolide antibiotics

Drug (number of patients)	Adverse reactions (%)	Premature withdrawal (%)	Reference
Erythromycin (112)	33	18.7	(18)
Clarithromycin (4291)	19.6	3.5*	(19)
Roxithromycin (2917)	4.1	0.9	(20)
Azithromycin (3995)	12	0.7	(21)
Dirithromycin (2825)	33.1	3.1	(22)

*at high doses (2000 mg/day) withdrawal rate 22%.

Table 2 Adverse effects of macrolide antibiotics

Drug	Gastro-intestinal (%)	Nervous system (%)	Skin (%)	Reference
Erythromycin (n = 112)	27	4	1	(18)
Clarithromycin (n = 96)	6	2	0	(19)
Roxithromycin (n = 2917)	3.9	0.4	0.7	(20)
Azithromycin (n = 3995)	9.6	1.3	0.6	(21)
Dirithromycin (n = 4263)	5.6	4.5	0.4	(22)

© 2006 Elsevier B.V. All rights reserved.

contribute significantly to its overall direct costs (monitoring costs, prolonged hospitalization due to complications or treatment failures) and indirect costs (quality of life, loss of productivity, time spent by families and patients receiving medical care). In one study an adverse event in a hospitalized patient was associated on average with an excess of 1.9 days in the length of stay, extra costs of $US2262 (1990–3 values), and an almost two-fold increase in the risk of death. In the outpatient setting, adverse drug reactions result in 2–6% of hospitalizations, and most of them were thought to be avoidable if appropriate interventions had been taken. In a review, economic aspects of antibacterial therapy with macrolides have been summarized and critically evaluated (23).

Organs and Systems

Cardiovascular

Cardiovascular reactions are rare if macrolide antibiotics are used in the absence of susceptibility factors, which include drug interactions, increasing age, female sex, concomitant diseases, and co-morbidity (24).

Respiratory

In an animal model, acute lung injury was inhibited by pretreatment with clarithromycin or roxithromycin, which significantly ameliorated bleomycin-induced increases in the total cell and neutrophil counts in bronchoalveolar lavage fluids and wet lung weight (25). Pretreatment with clarithromycin or roxithromycin also suppressed inflammatory cell infiltration and interstitial lung edema. Pretreatment with azithromycin was much less effective.

Nervous system

Table 2 lists the rates of adverse events affecting the nervous system attributed to erythromycin and newer macrolides.

Sensory systems

Eyes

Bilateral ischemic optic neuropathy can develop secondary to macrolides (26).

Ears

The cochlear toxicity of systemic macrolides, azithromycin, clarithromycin, and erythromycin, has been investigated in guinea pigs by measuring transiently evoked otoacoustic emissions (27). A single intravenous dose of erythromycin 125 mg/kg caused no change in evoked otoacoustic emissions, whereas oral azithromycin 45 mg/kg and intravenous clarithromycin 75 mg/kg reversibly reduced the emission response. This could have been caused by transient dysfunction of the outer hair cells.

Psychological, psychiatric

Although there is no evidence that neuropsychiatric complications of macrolides develop more readily in uremic patients, several factors may predispose toward these adverse effects, such as reduced drug clearance, altered plasma protein binding, different penetration of drug across the blood–brain barrier, and an increased propensity for drug interactions.

Two women, aged 49 and 50 years, developed altered mental status a few days after starting to take clarithromycin for eradication of *H. pylori* (28). There was incoherent speech with perseveration, inability to sustain attention, impaired ability to comprehend, coprolalia, euphoria, restlessness, visual hallucinations, anxiety, and inappropriate affect. Similarly, in three cases, a 46-year-old man, a 39-year-old woman, and a 4-year-old boy, treatment with clarithromycin was followed by nervous system and psychiatric symptoms that included euphoria, insomnia, aggressive behavior, hyperactivity, and emotional lability (29).

Hematologic

Clarithromycin and roxithromycin slightly inhibited the down-regulation of L-selectin expression on neutrophils induced by interleukin-8 stimulation (30). Furthermore, clarithromycin strongly inhibited the interleukin-8-induced up-regulation of the expression of Mac-1, an adhesion molecule, on neutrophils.

Hematological changes with macrolides are very rare. Isolated instances of neutropenia are occasionally reported (31).

Gastrointestinal

The gastrointestinal adverse effects are the most common untoward effects of the macrolides (Table 2). Nausea and vomiting associated with abdominal pain and occasionally diarrhea can be minor and transitory or, in a small percentage of patients, become severe enough to result in premature withdrawal. The rate of these adverse effects varies among the different antibiotics. In general, newer macrolides, such as azithromycin, clarithromycin, or roxithromycin, are better tolerated and cause fewer adverse effects than erythromycin.

Erythromycin is a motilin receptor agonist (2–4). This mechanism may be at least partly responsible for the gastrointestinal adverse effects of macrolides.

Based on observations in dogs and rabbits, clarithromycin is significantly less potent than azithromycin and erythromycin as an agonist for stimulation of smooth muscle contraction (32). A lower rate of gastrointestinal adverse events would therefore be expected with clarithromycin than with azithromycin (Table 2). Since most of these data were compiled from several studies, and since most have not been obtained by direct comparison of the various macrolides in single studies, the rates should be interpreted with caution. They most probably provide only an approximate indication of the rate of adverse events. Small differences in rates between individual macrolides will in most cases not be clinically useful indicators of the true risk for the occurrence of adverse events.

In contrast to the macrolides mentioned above, macrolides with a 16-membered lactone ring (acetylspiramycin, josamycin, leucomycin, midecamycin, rokitamycin, spiramycin, tylocin) have little if any motor-stimulating effects (33,34).

Drug-induced esophagitis is rare, accounting for about 1% of all cases of esophagitis. An incidence of 3.9 in 100 000 has been reported. After the first description, there have been more than 250 observations, with more than 50 different drugs. Among those, the principal antibiotics included

© 2006 Elsevier B.V. All rights reserved.

tetracyclines (doxycycline, metacycline, minocycline, oxytetracycline, and tetracycline), penicillins (amoxicillin, cloxacillin, penicillin V, and pivmecillinam), clindamycin, co-trimoxazole, erythromycin, lincomycin, spiramycin, and tinidazole. Doxycycline alone was involved in one-third of all cases. Risk factors included prolonged esophageal passage, due to motility disorders, stenosis, cardiomegaly, the formulation, supine position during drug ingestion, and failure to use liquid to wash down the tablet. Direct toxic effects of the drug (pH, accumulation in epithelial cells, non-uniform dispersion) also seem to contribute to the development of drug-induced esophagitis (35).

Liver

Erythromycin can cause two different types of liver damage (36,37), benign increases in serum transaminases, which may or may not recur on rechallenge, and cholestatic hepatitis. Reports of intrahepatic cholestasis with azithromycin (38), clarithromycin (39,40), and josamycin (41) suggest that the newer macrolides are not free of this adverse effect, although the relative risks compared with erythromycin are unclear. Similar involvement of the liver has been seen with the ester of triacetyloleandomycin, but not with the unesterified antibiotic.

Macrolides such as josamycin, midecamycin, and spiramycin, which do not form stable complexes with cytochrome P450, rarely if ever cause cholestatic hepatitis.

Urinary tract

- A 77-year-old man taking regular captopril, furosemide, salbutamol inhaler, vitamin C, and nasal beclomethasone dipropionate took clarithromycin 250 mg bd for sinusitis and bronchitis and 5 days later developed abdominal pain and intermittent fever (42). Laboratory findings included raised serum creatinine and blood urea nitrogen, aspartate transaminase, amylase, lactate dehydrogenase, and creatine kinase (not of the MB isoenzyme). The cause of the non-oliguric renal insufficiency was diagnosed by renal biopsy as interstitial nephritis with eosinophilic infiltrates. During the course of illness he also developed thrombocytopenia.

Skin

Skin rashes and fixed drug eruptions can occur during treatment with various macrolides but are rare (under 1%) (17).

Immunologic

Immunomodulatory effects of macrolides have been repeatedly reported; for example suppression of the release of chemotactic mediators may be important for the clinical effect of roxithromycin in patients with chronic lower respiratory tract infections (43). Both clarithromycin and azithromycin altered cytokine production in human monocytes in vitro (44).

The suppressive activity of macrolide antibiotics on pro-inflammatory cytokine production has also been shown in human peripheral blood monocytes, in which roxithromycin inhibited the in vitro production of interleukin-1 beta and tumor necrosis factor alpha (45). It also suppressed cytokine production after a prolonged pretreatment period in mice. In another mouse model both roxithromycin and clarithromycin inhibited angiogenesis and enhanced the antitumor activity of some cytotoxic agents, suggesting a beneficial effect when combined with such drugs against solid tumors (46,47). Furthermore, growth suppression of human fibroblasts by roxithromycin has been demonstrated both in vitro and in vivo (48).

Azithromycin has been associated with Churg–Strauss syndrome in a patient with atopy (49).

- A 46-year-old man with asthma was treated with oral roxithromycin 300 mg/day for 5 days for purulent rhinitis and 2 weeks later developed arthritis, mononeuritis multiplex, eosinophilia (64%), eosinophilic infiltrations in the bone marrow, raised IgE concentrations, and transient pulmonary infiltrates. Churg–Strauss syndrome was diagnosed.

A similar course of disease had occurred 1 year before, after the administration of azithromycin (50).

Leukocytoclastic vasculitis associated with clarithromycin has been reported in an 83-year-old woman who was treated for pneumonia. All her symptoms resolved after withdrawal and a short course of glucocorticoids (51).

- Henoch–Schönlein purpura developed in an 84-year-old Indian woman 10 days after she started to take clarithromycin (250 mg bd) for pneumonia (52). She was otherwise healthy and taking no regular medications. Histology confirmed a leukocytoclastic vasculitis of superficial vessels, with extravasation of erythrocytes, and direct immunofluorescence showed immunoglobulin A in superficial dermal vessels. Treatment with prednisone (1 mg/kg/day) was required. Most of the symptoms and signs resolved within a few days, but renal function remained impaired.

The authors identified two previous case reports of clarithromycin-induced leukocytoclastic vasculitis.

- A 39-year-old man developed acute angioedema and urticaria 6 hours after taking erythromycin base 500 mg in enteric-coated pellets for acute sinusitis (53). He remembered having taken erythromycin once before without any problem. He had no known allergies and was taking no regular medications, but he had had chemotherapy for non-Hodgkin's lymphoma several years earlier.

The authors identified five previous reports of erythromycin-associated urticarial reactions. However, it was not possible to exclude a reaction to the ingredients of the coated pellets.

Long-Term Effects

Drug tolerance

An area of increasing concern and clinical importance is the increasing macrolide resistance that has been reported over the last several years with some of the common pathogens, particularly *Streptococcus pneumoniae*, group A streptococci, and *Haemophilus influenzae*, and may result in failure of therapy of pneumonia, pharyngitis, and skin infections (54). High rates of resistance of several groups of streptococci to macrolides have been reported from all parts of the world (55–64).

© 2006 Elsevier B.V. All rights reserved.

Resistance to erythromycin can develop rapidly and is usually associated with bacterial cross-resistance to the other macrolide antibiotics, and also to the chemically unrelated lincomycins. Resistance has been detected in strains of staphylococci, Group A hemolytic streptococci, viridans streptococci, *Streptococcus pyogenes*, *Neisseria gonorrhoeae*, *Bacteroides fragilis*, and *Clostridium difficile* (65,66). It has tended to occur in hospitals, where either erythromycin or the lincosamides were used extensively, but can also result from multiple drug resistance when other antibiotics are used. Subinhibitory concentrations of erythromycin can cause resistance in staphylococci.

In combination with proton pump inhibitors and other antibiotics, macrolides are still successfully used for the eradication of *H. pylori* infection (67,68). However, resistance of *H. pylori* to macrolides has emerged in a number of countries. The first case of *H. pylori* resistance to clarithromycin has now also been documented in Denmark and follows increased use of this macrolide in eradication regimens (69).

Clinical isolates of *N. gonorrhoeae* with reduced susceptibility to azithromycin are commonly found in Uruguay, and one of the mechanisms involved included mutations in the mtrR gene (70).

Resistance of *H. pylori* to clarithromycin appears to have increased in proportion to clarithromycin use. Clarithromycin resistance arises through mutations that lead to base changes in 23S ribosomal RNA subunits. A rapid PCR hybridization assay with a sensitivity of 97% for the detection of clarithromycin resistance of strains of *H. pylori* has been described (71). Resistance to clarithromycin has a serious impact on the efficiency of eradicating regimens that include clarithromycin (72–74). The reported incidences of primary resistance of *H. pylori* to clarithromycin are 6.1% in the USA, 8% in Austria, 8.7% in Bulgaria, 9.5% in Japan, 10% in Spain, 11% in France, 13% in Nigeria, and 23% in Italy (75–82).

Among strains of *Enterococcus faecium*, resistance against tylosin was mainly detected in strains from poultry, but also in some strains from pork. Among strains of *E. faecium* and *Enterococcus faecalis* isolated from pigs and poultry in Denmark, resistance to tylosin was often observed among isolates from places in which these antimicrobials had been widely used, but rarely among isolates from places in which their use had been limited (83).

Second-Generation Effects

Teratogenicity

In a large case-control surveillance study from Hungary in 38 151 pregnant women, oral erythromycin during pregnancy did not present a detectable teratogenic risk to the fetus (84).

Susceptibility Factors

Allergic reactions to antimicrobials are frequent in patients with Sjögren's syndrome. They are especially susceptible to reactions to penicillins, cephalosporins, and sulfonamides, but reactions to macrolides and tetracyclines also seem to be over-represented in these patients (85).

Drug–Drug Interactions

Alfentanil

The metabolism of alfentanil, a potent short-acting narcotic, is inhibited by macrolide antibiotics, resulting in significant changes in half-life and clearance (86).

Antihistamines

Toxic effects of terfenadine and astemizole have been reported in patients taking concomitant macrolides, especially clarithromycin (87–89,116), typically resulting in prolongation of the QT interval and cardiac dysrhythmias (torsade de pointes) (111). The potential interaction of azithromycin with terfenadine has been evaluated in a randomized, placebo-controlled study in 24 patients who took terfenadine plus azithromycin or terfenadine plus placebo (90). However, azithromycin did not alter the pharmacokinetics of the active carboxylate metabolite of terfenadine or the effect of terfenadine on the QT_c interval.

Only a modest increase in QT_c interval has been observed with concomitant use of erythromycin and the antihistamine ebastine (91).

Clarithromycin (500 mg bd for 10 days) significantly increased the steady-state maximum plasma concentration and the steady-state AUC of loratadine (10 mg/day for 10 days) (92). In contrast, the addition of loratadine did not affect the steady-state pharmacokinetics of clarithromycin or its active metabolite, 14(R)-hydroxyclarithromycin. No QT_c interval exceeded 439 ms in any subject.

Benzodiazepines

Interactions of macrolides with triazolam and midazolam are clinically important. Increased serum concentration, AUC, and half-life, and reduced clearance have been documented (93,94,118). These changes can result in clinical effects, such as prolonged psychomotor impairment, amnesia, or loss of consciousness (95). No interactions between ciprofloxacin and diazepam have been reported (96).

Carbamazepine

Significant increases in serum carbamazepine concentrations due to reduced clearance (97) and prolonged half-life (98,122,123) can result in confusion, somnolence, ataxia, vertigo, nausea, and vomiting in patients taking macrolides (100,124,125). Toxicity can occur rapidly after addition of the macrolide and abate quickly on withdrawal (126). However, a retrospective analysis of 3995 patients treated with azithromycin did not show any pharmacokinetic interaction in patients who were also taking carbamazepine (127,128).

- Carbamazepine toxicity, with dizziness, lethargy, and nystagmus, developed in a 17-year-old boy two days after he started to take clarithromycin 500 mg/day (129). His serum carbamazepine concentration (previously acceptable) rose, but returned to within the target range after withdrawal of clarithromycin.

Ciclosporin

The pharmacokinetics of ciclosporin can be altered by macrolides. Commonly observed changes include increases

© 2006 Elsevier B.V. All rights reserved.

in ciclosporin AUC and peak plasma concentration and reductions in the time to peak and clearance (102,104,130,131). Ciclosporin concentrations should therefore be monitored, to minimize the risk of toxicity in patients taking certain macrolides. When azithromycin is used concomitantly with ciclosporin, blood ciclosporin concentrations need to be monitored (132).

Cytochrome P450

The frequency and pattern of drug interactions with macrolides is influenced by the chemical structure of the individual macrolide. The most important mechanism determining many drug interactions is the effect of macrolides on the hepatic cytochrome P450, which oxidizes macrolides after binding of the drug to oxidized (Fe_3) cytochrome P450 (126). Binding of the macrolide to group IIIA cytochrome P450 can have one of several consequences: oxidation can result in the formation of a stable iron-metabolite complex, causing either induction of cytochrome P450 and increased metabolism of the antibiotic, or inactivation of cytochrome P450 and inhibition of drug metabolism (126).

Structural properties of the macrolides determine whether the drug metabolizing enzyme is induced or inactivated. Macrolides with a 14-membered lactone ring have a greater potential to inhibit cytochrome P450 than bulkier macrolides with 15-membered or 16-membered lactone rings. It is therefore useful to group the macrolides according to their molecular structure and their potential for drug interactions via cytochrome P450 (Table 3).

The differences in interactions of different macrolides with cytochrome P450 are marked. Troleandomycin is a more potent inhibitor of microsomal drug metabolism than erythromycin, while josamycin, midecamycin, and spiramycin have not so far been incriminated (133,134). Azithromycin does not induce or inhibit cytochrome P450 in rats (135).

The occurrence of an interaction in a particular patient is difficult to predict. Hepatic concentrations of CYP3A4, the activity of which can be estimated by an erythromycin breath test (133), vary at least ten-fold among patients (136,137).

Table 3 Molecular structures of macrolides and the extent of their interactions with cytochrome P450

Degree of interaction	Number of carbon atoms in macrolide ring		
	14	15	16
High	Troleandomycin Erythromycin		
Low	Flurithromycin Clarithromycin Roxithromycin		Josamycin Midecamycin Miocamycin
Not incriminated	Dirithromycin	Azithromycin	Rokitamycin Spiramycin

The variability is compounded by the fact that, in addition to the liver, mucosal cells of the small intestine commonly express CYP3A4, where it is responsible for significant first-pass metabolism of orally administered substrates (137).

Drugs that participate in major CYP3A4 interactions with macrolides are listed in Table 4. Other drugs that may be affected include alprazolam (138), the water-soluble artemisinin analogue artelinic acid (139), gallopamil (140), lovastatin (141), nefazodone (142), and risperidone (143). Pharmacokinetic interactions with clarithromycin, erythromycin, and troleandomycin have been reviewed (144).

Digoxin

The interaction between macrolides and digoxin is not a consequence of altered cytochrome P450 activity. Digoxin is metabolized in the gastrointestinal tract by *Eubacterium lentum* in the bowel flora of about 10% of patients (106). The direct antibacterial effect of macrolides reduces digoxin metabolism and increases its systemic availability (134). The resultant increased digoxin plasma concentrations are associated with severe nausea, vomiting, and dysrhythmias (105,145,146).

Table 4 Summary of major interactions with macrolides

Interacting drug	Azithromycin	Clarithromycin	Erythromycin	Roxithromycin	Reference

A concomitant clarithromycin-associated interaction with digoxin and warfarin has been reported (147).

- A 72-year-old man was taking regular digoxin (0.25 mg/day) and warfarin (22.5 mg/week) for chronic atrial fibrillation; other medications included furosemide, enalapril, glyceryl trinitrate paste, and a beclomethasone inhaler. He developed signs of digoxin intoxication after taking clarithromycin (500 mg tds) for 12 days and a raised serum digoxin concentration was confirmed. In addition, the INR was well above the target range (7.3 instead of 2.0–3.0).

An interaction with CYP450 enzymes was thought to be involved in the interaction with warfarin, and alteration of gut flora may have been involved in digoxin intoxication. Inhibition of P-glycoprotein by clarithromycin may also have contributed to the interaction with digoxin (148).

Azithromycin

- In a 31-month-old boy with Down's syndrome and Fallot's tetralogy during a 5-day course of azithromycin 5 mg/kg/day the serum digoxin concentration rose and the child had anorexia, diarrhea, and second-degree atrioventricular block with junctional extra beats (149).

The mechanism was not investigated, but it is likely that azithromycin affects *Eubacterium lentum*. When azithromycin is used concomitantly with digoxin, serum digoxin concentrations need to be monitored (132).

Clarithromycin

- In a 72-year-old woman taking digoxin 0.25 mg/day, the addition of clarithromycin caused a rise in the serum digoxin concentration to 4.6 ng/ml (147).

In two other cases in which clarithromycin increased serum digoxin concentrations there was an associated reduction in the rate of renal digoxin clearance, which may be another mechanism for this interaction (150). The authors hypothesized that clarithromycin inhibited P glycoprotein. This was supported by the observation of a concentration-dependent effect of clarithromycin on in vitro transcellular transport of digoxin.

There is anecdotal evidence that this interaction may be clinically important. Digoxin toxicity occurred in a patient taking clarithromycin (151).

Erythromycin

- Digoxin toxicity occurred in a neonate who was also given erythromycin (152). She had bradycardia and coupled extra beats. Digoxin and erythromycin were withdrawn and she was given antidigoxin antibodies. Her plasma digoxin concentration, which had previously been 1.8 ng/ml, had risen to 8.0 ng/ml.

Disopyramide

Severe cardiac dysrhythmias and major hypoglycemia have occurred in patients taking disopyramide with some macrolide antibiotics, especially erythromycin and clarithromycin (153).

Clarithromycin

- In a 76-year old woman, severe prolongation of the QT_c interval and self-terminating torsade de pointes were induced by the combined use of clarithromycin and disopyramide; concomitant hypokalemia may have contributed to the cardiac dysrhythmia (154).
- Symptomatic hypoglycemia developed in a 59-year-old man treated with a combination of disopyramide (50 mg/day) and clarithromycin (600 mg/day) (155).

Additional investigations in the second case suggested enhanced insulin secretion induced by toxic disopyramide concentrations as the probable mechanism.

Erythromycin

Disopyramide alters the protein binding of erythromycin, and this results in increased plasma concentrations in vitro (156). The interaction between erythromycin and disopyramide was potentially fatal in two cases (107).

Roxithromycin

Disopyramide alters the protein binding of roxithromycin, and this results in increased plasma concentrations in vitro (156). However, this effect has not been observed with roxithromycin in vivo.

Glucocorticoids

Some macrolides have a dose- and time-related effect on methylprednisolone elimination, resulting in a prolonged half-life and reduced clearance (157). These changes were considered advantageous (steroid sparing) in patients with asthma (158,159). However, a retrospective analysis of 3995 patients treated with azithromycin did not show any pharmacokinetic interaction in patients who were also taking methylprednisolone (127,128).

In an open study in six adults with mild to moderate asthma, clarithromycin significantly reduced methylprednisolone clearance, thereby increasing the risk of steroid-induced adverse effects (160). In contrast, prednisolone clearance and mean prednisolone plasma concentrations were unaffected. Frank psychosis due to combined therapy with prednisone and clarithromycin has been reported (161).

Lincomycins

Antagonism in vitro has been described between macrolides and lincomycins (162). Competition for similar binding sites at bacterial ribosomes probably underlies this phenomenon.

Oral contraceptives

Most reports associating cholestatic jaundice with the concomitant use of oral contraceptives and macrolides have implicated troleandomycin (163–166). The exact mechanism of this interaction has not been established. Troleandomycin possibly inhibits the metabolism of estrogens and progestogens (133). In most patients jaundice persisted for more than a month after the antibiotic was withdrawn.

In a non-blinded study in 20 healthy women using Ortho Novum 7/7/7–28, oral dirithromycin 500 mg/day

© 2006 Elsevier B.V. All rights reserved.

for 14 days produced a small (7.6%) but statistically significant reduction in the mean ethinylestradiol 24-hour AUC and an increase in apparent oral clearance (167). No woman ovulated or had compromised effectiveness of the oral contraceptive in this small series, so the clinical importance of this interaction may be negligible.

Risperidone

Drugs that inhibit CYP3A, such as the macrolides, can significantly alter risperidone concentrations, especially in patients with CYP2D6 deficiency (143).

SSRIs

- A 12-year-old boy developed the serotonin syndrome, which is normally associated with the interaction of two or more serotonergic agents, after the co-administration of erythromycin and sertraline.

This could have been due to erythromycin-induced inhibition of sertraline metabolism by CYP3A (168).

Statins

Macrolide antibiotics inhibit the metabolism of statins that are metabolized by CYP3A4 (atorvastatin, cerivastatin, lovastatin, simvastatin) (169). This interaction can cause myopathy and rhabdomyolysis, particularly in patients with renal insufficiency or in those who are concurrently taking medications associated with myopathy. Rhabdomyolysis is a rare disorder that mostly results from adverse drug effects. Hydroxymethylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors (statins) are among the most important drugs causing this disorder, and the risk is increased when gemfibrozil or macrolide antibiotics are concurrently administered. The interaction usually develops within 2 weeks of combination therapy with macrolide antibiotics. Treatment includes drug withdrawal, intravenous fluids, urine alkalinization, and in severe cases dialysis.

Atorvastatin

In 12 healthy volunteers, erythromycin increased both the maximal plasma concentration and AUC of co-administered atorvastatin (170).

Lovastatin

Based on case reports or small studies, the potential for drug interactions between macrolides and lovastatin should be considered (171).

- Rhabdomyolysis, acute renal insufficiency, pancreatitis, ileus, livedo reticularis, and raised transaminase activities developed in a patient who had taken lovastatin for 7 years and took erythromycin before a dental procedure.
- Rhabdomyolysis requiring short-term dialysis occurred in a 57-year-old man with chronic renal insufficiency treated with lovastatin 40 mg/day, gemfibrozil 600 mg bd, and clarithromycin 500 mg tds (172).

In a review of the literature, three other reported instances of erythromycin and lovastatin interaction presenting with rhabdomyolysis, raised transaminase activities, and acute renal insufficiency were identified (173).

Simvastatin

Erythromycin interacts with simvastatin, probably by inhibiting its metabolism by CYP3A4. In a randomized, double-blind crossover study in 12 healthy volunteers, erythromycin significantly increased mean peak serum concentration and AUC for both unchanged simvastatin and its active metabolite simvastatin acid. However, there was extensive interindividual variability in the extent of this interaction (174).

- A 64-year-old African-American man developed rhabdomyolysis resulting from concomitant use of clarithromycin and simvastatin (175).

Theophylline and other xanthines

The most frequent effects of macrolides on theophylline pharmacokinetics are increased half-life and serum theophylline concentration and reduced clearance (133). The interaction with theophylline is mainly seen with higher doses of macrolides and can result in theophylline toxicity (108).

The effect of macrolides on serum theophylline concentration and clearance has been investigated in 53 patients with moderate asthma treated with theophylline (400 mg/day) in a randomized trial reference. Erythromycin (500 mg bd) and roxithromycin (150 mg bd), but not clarithromycin (250 mg bd) or azithromycin (250 mg bd), caused increased serum theophylline concentrations and reduced clearance.

However, a retrospective analysis of 3995 patients treated with azithromycin did not show any pharmacokinetic interaction in patients who were also taking theophylline (127,128). Furthermore, in two double-blind, placebo-controlled, randomized studies azithromycin did not inhibit the metabolism of theophylline (176,177). However, there has been a report of reduced theophylline concentrations after withdrawal of azithromycin (178). The authors concluded that the mechanism of interaction was best explained by concomitant induction and inhibition of theophylline metabolism by azithromycin, followed by increased availability of unbound enzyme sites as azithromycin was cleared from the system.

Clarithromycin increases the serum concentration of theophylline by inhibiting CYP450 enzymes.

- In a 72-year-old man, the administration of clarithromycin (400 mg/day) plus modified-release theophylline (200 mg/day) resulted in acute rhabdomyolysis with renal insufficiency requiring hemodialysis after 5 days of combined treatment (179).

Verapamil

- A 77-year-old woman taking verapamil and propranolol for hypertrophic cardiomyopathy and paroxysmal atrial fibrillation developed symptomatic bradycardia on two separate occasions within days of taking either erythromycin or clarithromycin. The proposed mechanism of the interaction was inhibition of cytochrome P450, since verapamil is a substrate of an isoenzyme that is inhibited by some macrolides (180,181).

© 2006 Elsevier B.V. All rights reserved.

Severe hypotension and bradycardia after combined therapy with verapamil and clarithromycin has been reported in another case (182).

Warfarin

Azithromycin can increase the effect of warfarin (183), perhaps by inhibiting its metabolism. Despite only modest effects of macrolides on serum warfarin concentrations and increases in prothrombin time (119), morbidity caused by hemorrhage may be significant, as illustrated by several case reports (184–188). It is likely that this interaction is potentiated by other factors, such as old age or dietary restrictions (119). However, a retrospective analysis of 3995 patients treated with azithromycin did not show any pharmacokinetic interaction in patients who were also taking warfarin (127).

- A 71-year old woman, who was taking maintenance warfarin for a prosthetic heart valve, took a 5-day course of azithromycin, and 6 days later her INR rose from 2.5 to 3.5–15 (189).

A concomitant clarithromycin-associated interaction with digoxin and warfarin has been reported (147).

- A 72-year-old man was taking regular digoxin (0.25 mg/day) and warfarin (22.5 mg/week) for chronic atrial fibrillation; other medications included furosemide, enalapril, glyceryl trinitrate paste, and a beclomethasone inhaler. He developed signs of digoxin intoxication after taking clarithromycin (500 mg tds) for 12 days and a raised serum digoxin concentration was confirmed. In addition, the INR was well above the target range (7.3 instead of 2.0–3.0).

An interaction with CYP450 enzymes was thought to be involved in the interaction with warfarin, and alteration of gut flora may have been involved in digoxin intoxication. Inhibition of P-glycoprotein by clarithromycin may also have contributed to the interaction with digoxin (148).

Zafirlukast

Although zafirlukast inhibits CYP3A, it did not have any significant pharmacokinetic effect on single doses of azithromycin or clarithromycin in 12 healthy volunteers (190).

Macrophage colony-stimulating factor (M-CSF)

See also Myeloid colony stimulating factors

General Information

Macrophage colony-stimulating factor (M-CSF) stimulates the growth and differentiation of the monocyte lineage, and promotes the survival, proliferation, and functions of mature monocytes/macrophages (1). It also enhances myelopoiesis through the amplified production of G-CSF and GM-CSF by monocytes, and has antitumor activity. Purified human urinary M-CSF and recombinant human M-CSF are under investigation in humans.

The safety of human M-CSF (hM-CSF) in allogeneic and syngeneic bone marrow transplantation was evaluated in a randomized, double-blind, placebo-controlled trial in 119 patients (2). There was mild transient fever in 6.7% of patients and there were no significant adverse effects on the platelet count. The incidence of graft-versus-host disease or graft rejection and the leukemic relapse rate were not affected compared with placebo. There was a similar safety profile in patients with autologous bone marrow transplants (3).

Glycosylated mammalian-derived recombinant human M-CSF (rhM-CSF) has been used in several trials. Constitutional symptoms (malaise, fatigue, insomnia, headache, nausea, fever, and chills) sometimes occurred. There was no evidence of long-term toxicity during follow-up of patients who received rhM-CSF after allogeneic bone marrow transplantation (4).

Organs and Systems

Sensory systems

Subclinical conjunctival injection occurred in 50% of patients in one series, with moderate but symptomatic episcleritis and blurred vision in one patient (SEDA-19, 345). Asymptomatic retinal or perilimbal hemorrhages were sometimes noted, but there was no clear correlation with platelet count. Subjective ophthalmological symptoms, ocular inflammation, iridocyclitis, or malaise have also occurred as dose- or treatment-limiting adverse effects in other studies (5,6).

Hematologic

The most significant adverse effect of glycosylated mammalian-derived rhM-CSF is a transient, dose- and schedule-related severe thrombocytopenia, which correlates with monocytosis and typically occurs after 7–10 days of treatment (7). Thrombocytopenia sometimes resolves despite continued administration of rhM-CSF and has usually not been sufficiently severe to cause bleeding. In other cases, a 50% reduction in the dose of rhM-CSF should be considered to allow treatment to be continued. The mechanism of rhM-CSF-induced thrombocytopenia does not involve suppression of hemopoiesis, but rather increased activity of the monocyte/macrophage system in the liver and spleen (8).

© 2006 Elsevier B.V. All rights reserved.

Urinary tract

Acute nephrotic syndrome has been reported in a patient with a previous history of mild proteinuria (SEDA-20, 339), but the origin of the M-CSF (recombinant or human) was not stated.

Skin

Mild local toxicity sometimes occurs after subcutaneous injection of M-CSF (SED-13, 1118) (7). In one patient, multiple subcutaneous nodules consistent with a panniculitis occurred after each administration (SEDA-19, 345).

In one study, severe erythroderma and a dramatic proliferation of blast cells after each dose of hM-CSF were the only significant severe adverse effects, reported in one patient each (SEDA-19, 345).

Mafenide

General Information

Mafenide is a topical sulfonamide that has been used for the treatment of burns but is now obsolete. Its adverse effects include hyperchloremic metabolic acidosis and (possibly) methemoglobinemia (1). Pulmonary insufficiency has been ascribed to mafenide acetate cream (SEDA-8, 160).

Magnesium salts

General Information

Magnesium is a bright, silver-white alkaline earth metallic element (symbol Mg; atomic no. 12). It is widely found as different salts in minerals such as boracite (borate), ankerite and dolomite (carbonates), carnallite (chloride), brucite (hydroxide), periclase (oxide), lazulite (phosphate), amphibole, cummingtonite, enstatite, garnierite, hornblende, humite, hypersthenite, iolite, jade, melilite, monticellite, olivine, Pennine, saponite, sapphire, serpentine, talc, and tremolite (silicates), and epsomite, kainite, kieserite, and polyhalite (sulfates).

Uses

Magnesium salts are used in the following ways:

- as antacids (magnesium trisilicate, magnesium hydroxide) usually in combination with an aluminium salt; the combination of magnesium hydroxide and aluminium hydroxide is called co-magaldrox
- as laxatives (magnesium oxide)
- in the treatment of eclampsia (magnesium sulfate)
- to treat cardiac dysrhythmias (magnesium sulfate)
- in urological irrigation solutions, used for dissolution of urinary calculi (magnesium citrate).

General adverse effects

Acute toxicity can arise from overdosage or intestinal or renal disease. The main symptoms of magnesium toxicity are neuromuscular (paralysis) and cardiac (electrocardiographic changes, hypotension, bradycardia, heart block). In more severe cases there will be nervous system or respiratory depression, hypomotility of the bowel, muscle paralysis, and hyporeflexia.

Magnesium sulfate in bolus doses of 2–4 g over up to 5 minutes causes feelings of warmth, flushing, and sometimes sweating (1–3). Transient nausea has also been reported (2,3).

Organs and Systems

Cardiovascular

Circulatory collapse can occur as a symptom of severe hypermagnesemia if magnesium-containing products are taken in large amounts in high-risk patients (4).

Respiratory

Magnesium can be absorbed via the renal pelvis, at least when it is inflamed (5), and it has been suggested that absorption of magnesium through inflamed pelvic mucosa results in hypermagnesemia. Respiratory paralysis is a terminal event in severe hypermagnesemia, and iatrogenic hypermagnesemia with respiratory depression has been reported in patients who received hemiacidrin, a magnesium-containing irrigation fluid, through a ureteric catheter, together with magnesium citrate orally (6). Intravenous calcium directly antagonizes respiratory depression due to magnesium, possibly by displacement by calcium of magnesium from cell membranes (7).

Electrolyte balance

Severe hyperkalemia has been reported in pregnant intravenous drug abusers during prolonged parenteral magnesium sulfate therapy for treatment of toxemia (8). Hypermagnesemia was thought to be responsible.

Some patients develop mild transient hypotension after the administration of bolus doses of intravenous magnesium sulfate (2,3). In patients with suspected myocardial infarction who received magnesium sulphate infusions there was an increased incidence of atrioventricular conduction disturbances (9).

Gastrointestinal

Magnesium salts, given alone or in combination with other antacids, commonly cause diarrhea of osmotic origin (10).

In infants of low birth weight, the use of magnesium-containing antacids has caused hypermagnesemia and intestinal perforation (SEDA-16, 417).

Urinary tract

A Japanese patient taking magnesium silicate developed urolithiasis, the stone consisting of 98% silicate (11); some 15 cases of silica stones have been reported in Japan, but it is not clear how many of these patients had used magnesium silicate.

Skin

A fixed drug eruption during magnesium trisilicate treatment has been reported (SEDA-11, 321).

Susceptibility Factors

Renal disease

In severe renal insufficiency there can be accumulation of magnesium due to reduced excretion, with inhibition of parathyroid function and consequent calcium and phosphorus abnormalities (12).

Drug Administration

Drug administration route

Enema treatment with magnesium salts can cause severe hypermagnesemia (13).

Drug overdose

Magnesium overdose is usually inadvertent, due to high intake of magnesium-containing antacids or laxatives.

- A 42-year-old Hispanic woman with normal renal function took magnesium hydroxide (as milk of magnesia) 30 ml each night with Maalox 30 ml tds for about 5 days for abdominal pain and constipation (14). She developed confusion, vomiting, hypothermia, hypotension, and abdominal distension. Additional medications included lithium carbonate, chlorpromazine, benzatropine, and docusate sodium. Her serum magnesium concentration was 4.5 mmol/l (reference range 0.7–1.0). She was treated with intravenous calcium gluconate and fluids. At surgery for abdominal distension she was found to have adhesions from a previous oophorectomy. On the second postoperative day she developed a cardiac dysrhythmia and died in asystole.
- A 3-week-old girl who was treated with magnesium oxide as a laxative developed severe hypermagnesemia as a result. Treatment was with a combination of hyperhydration, forced diuresis and natriuresis, and administration of intravenous calcium and insulin (15).

Magnesium was administered in high doses to a child as part of an alternative regimen of megavitamin/megamineral therapy (16). The treatment was prescribed by an alternative nutritionist without the knowledge of the pediatrician in charge. The child died of hypermagnesemia.

Malaria vaccine

General Information

For centuries, attempts have been made to find a vaccine against malaria, especially malaria tropica (1). Most of these attempts have been disappointing (SEDA-13, 822) (SEDA-21, 298). However, the results of a number of field studies have been reported.

SPf66 vaccine is a synthetic polypeptide based on preerythrocyte and asexual blood stage proteins of *Plasmodium falciparum*. A trial in Tanzania, in an area in which malaria is not only endemic, but the parasite load heavy, showed an estimated efficacy of 30% (95% CI = 0, 52%). The vaccine was immunogenic. There was also a difference in mortality between the groups, with one death among the vaccinated children and five in the control group. Adverse effects were in general mild and similar to those in earlier work (2,3).

In Colombia, the vaccine brought about an immune response, and adverse effects were minimal. The first randomized, double-blind, controlled trial in Colombia, in which 1548 volunteers participated, showed an overall efficacy of 39%. In a small, selected group of volunteer soldiers there was a protective effect of 60–80%. In 96% of cases there were no adverse effects and the adverse effects in the remainder were mainly localized erythema, discomfort, and sometimes induration (4,5).

A study in Ecuador showed 67% mean prophylactic efficacy against *P. falciparum*, but the 95% CI were very wide (2.7, 89%). The vaccine was administered in three doses, at zero time and after 30 and 180 days. Adverse effects (local pain, erythema, and local induration) occurred after the first dose in 6.2%, after the second dose in 19%, and after the third dose in 14%. The placebo group had similar adverse effects, but in a lower proportion of subjects and with fewer cases of induration. There was no protection against *Plasmodium vivax* infections (6).

In a Venezuelan study (7), 1442 villagers were vaccinated and vaccination was completed with the three doses in 976 subjects, with a comparison group of 938 subjects from the same area. Antibodies were produced against the vaccine. The adverse effects were as in earlier work, but there was also some contralateral induration, mainly after the third dose of vaccine, which was given alternately into the left and right arms. Five women had generalized pruritus. Bronchospasm was observed in one case.

A new recombinant vaccine has shown promise in vitro and in rabbits. It combines segments of 21 different immunogenic peptides from *P. falciparum* into a single recombinant protein, eliciting a multilayered immune response, including B cell and T cell responses (1).

Organs and Systems

Immunologic

Immediate-type hypersensitivity reactions (acute, systemic urticaria after the third immunization) occurred in two of 39 volunteers immunized with a synthetic multiantigen peptide vaccine (PfCS-MAP1NYU) against *P. falciparum* sporozoites, with detection of serum IgE MAP antibody (8). Immediate pain at the injection site was associated with the adjuvant QS-21, and delayed local inflammatory reactions were associated with high titers of circulating IgG anti-MAP antibody. Skin tests using intradermal injections of diluted MAP vaccine, to identify those who were sensitized to the vaccine, were negative in seven volunteers tested 27 days after the first vaccination, but six of these developed positive wheal and flare reactions when tested 14 or 83 days after the second vaccination; IgE MAP antibody was detected in only one of them. Skin tests may help in identifying individuals who have been sensitized to malaria peptides and who are at risk of developing systemic allergic reactions after revaccination.

On the other hand, delayed-type hypersensitivity testing has been used to test T cell functional activity in 27 volunteers immunized with a synthetic multi-antigen peptide vaccine (MAP) (PfCS-MAP1NYU) against *P. falciparum* sporozoites (9). Intradermal inoculations (0.02 ml) of several concentrations of the MAP vaccine and adjuvant control solutions were applied and induration measured 2 days after. Nine of 14 vaccinees with high serum titers of anti-MAP antibody developed positive skin tests (at least 5 mm induration), which first appeared by 29 days after immunization and persisted for at least 3–6 months after one or two more immunizations. In contrast, skin tests were negative in all of eight vaccinees with no or low antibody titers, and in all of five non-immunized volunteers. Biopsies of positive skin test sites were histologically compatible with a delayed hypersensitivity reaction. The authors concluded that the presence of T cell functional activity is reflected by a positive skin test response to the MAP antigen and may serve as another marker for vaccine immunogenicity.

Malathion

General Information

Malathion is used for the treatment of lice, a single application of 0.5% in a solution being customary. Used in this way, it is generally safe, although the same compound has caused fatal poisoning when used as a pesticide in the environment.

Four children developed malathion intoxication after hair-washing with a solution containing malathion (50% in xylene) for the purpose of louse control (1). Hyperglycemia and glycosuria were found in all cases. One child, described in detail, was in coma and did not respond to pain stimuli; other symptoms included severe dyspnea, extensive, moist coarse crackles in both lung fields, voluminous frothy saliva, and mucus filling the nose, mouth and pharynx, pinpoint pupils not responding to light, excess lacrimation and fasciculation in the upper eye lids, and flaccid limbs and absent tendon reflexes.

Malvaceae

See also Herbal medicines

General Information

The genera in the family of Malvaceae (Table 1) include cotton, okra, and various types of mallow.

Gossypium species

Gossypol occurs in certain species of *Gossypium* (cotton), mostly in the seeds and root bark. Clinical studies have confirmed its efficacy as a male contraceptive agent (1).

Gossypol is a racemic mixture of (+)-gossypol and (−)-gossypol. When tested separately in male rats in a dosage of 30 mg/kg orally for 14 days, only the latter enantiomer had a clear anti-fertility effect. Furthermore, (+)-gossypol has less acute toxicity than (−)-gossypol after intraperitoneal administration to mice. In a human study, the enantiomers showed pharmacokinetic differences in half-life; less than 5 hours for (−)-gossypol compared with 133 hours for the (+)-enantiomer.

Adverse effects

The reported adverse effects of gossypol include fatigue, changes in appetite, transient rises in alanine transaminase, and hypokalemia.

Because of the adverse effects of gossypol, The Special Program of Research, Development and Research Training in Human Reproduction (HRP) at the World Health Organization (WHO) decided that gossypol is not acceptable as an antifertility drug (2).

Electrolyte balance

Gossypol causes potassium loss, perhaps by a direct toxic effect on the renal tubules (3), which can cause renal tubular acidosis (4). Hypokalemic paralysis (5) has been reported in about 1% of 8806 volunteers and in China was more common in areas of low dietary potassium intake, such as Nanjing (6); muscular weakness and severe fatigue are prodromal signs (7). Neither potassium supplementation nor triamterene prevented potassium loss in patients taking gossypol (8).

Fertility

Of 151 men from Brazil, Nigeria, Kenya, and China who received gossypol 15 mg/day for 12 or 16 weeks and were then randomized to either 7.5 or 10 mg/day for 40 weeks,

Manganese

General Information

Manganese is a hard but brittle grayish-white metallic element (symbol Mn; atomic no. 25) that occurs in nature chiefly in the form of its oxides, but is also found as a sulfide (for example in alabandite), carbonate (ankerite, dialogite, and rhodochrosite), niobate and tantalate (columbite), silicate (piedmontite, rhodonite, spessartite, and tephroite), arsenate (synadelphite), and tungstate (wolframite).

Uses

The inorganic manganese salt potassium permanganate is used as a local anti-infective, an astringent, and a powerful deodorant and cleanser.

Manganese is often present in mineral supplements, in hemopoietic formulations, and in some solutions for parenteral nutrition. Trace elements are required in patients receiving long-term parenteral nutrition (1), and the use of manganese has been reviewed (2).

Mangafodipir trisodium (Mn DPDP; Teslascan, Nycomed, Oslo) is a chelate complex containing manganese (II) ion bound to fodipir, used as a hepatobiliary contrast agent (SEDA-22, 246). After injection, mangafodipir trisodium undergoes net transmetalation with endogenous zinc (II) ion and removal of the two phosphate groups to give two metabolites, manganese dipyridoxal ethyldiamine diacetate and zinc dipyridoxal ethylenediamine diacetate. The transmetalation with zinc is associated with a transient reduction in serum zinc concentrations, which normalize within about 24 hours after injection. About 14–20% of the manganese

© 2006 Elsevier B.V. All rights reserved.

is excreted in the urine and 52–61% is excreted in the feces over 4 days. About 92% of fodipir is eliminated within 24 hours. Mangafodipir trisodium is mainly indicated to enhance the MRI T1-weighted images that are used in the detection, localization, and characterization of hepatic lesions. Normal liver parenchyma takes up the manganese and becomes bright, resulting in clear demarcation of abnormal parenchymal lesions.

LumenHance (Bracco Diagnostics Inc, Princeton, NJ) is a gastrointestinal MRI contrast agent based on manganese chloride.

Finally, as with other metallic elements, non-medical exposure to manganese can occur, particularly in occupational settings, and can cause neurotoxicity (3).

General adverse effects

The toxic effects of manganese in dogs (SEDA-21, 239) and humans (4) tend to involve the heart, liver, and nervous system, but some endocrine effects can occur. The general toxicity of manganese (5) and its neurotoxicity (6) have been reviewed.

Two cases of manganese intoxication during intermittent parenteral nutrition have been reported (2). In one case, manganese had been given once or twice a week for 4 years and in the other case twice a month for 5 years. Both patients had mild headache and dizziness. One had mild hepatic dysfunction. After withdrawal of manganese the symptoms all disappeared. Patients should be carefully monitored when receiving long-term parenteral nutrition including manganese, even when the manganese dose is small and administration infrequent.

The best way to monitor excessive exposure to manganese includes serum manganese concentration measurement in combination with brain MRI scanning and perhaps a battery of neurofunctional tests (7). Studies have concentrated on manganese in patients on parenteral nutrition (8) and occupational exposure (9).

In a phase III study 546 patients with suspected or known focal liver lesions received intravenous mangafodipir trisodium 5 μmol/kg before MRI examination (10). There were 195 adverse effects in 123 (23%) patients; only 72 were considered to be related to the contrast medium. Most common were nausea (7%), headache (4%), vomiting and abdominal pain (2% each), chest pain and palpitation (1% each), and hypertension, flushing, vasodilatation, and hypotension (under 1% each). Injection-associated reactions included heat (49%) and flushing (39%). Most of the adverse events (65%) were moderate and 7% were severe. Changes in laboratory values (full blood count, electrolytes, serum creatinine, and liver function tests) and vital signs (pulse, blood pressure) were generally transient, not clinically significant, and did not require treatment. The authors concluded that exposure to mangafodipir trisodium is not associated with short-term risks.

Organs and Systems

Nervous system

Workers who have been exposed to manganese, patients with hepatic disease, and patients undergoing total parenteral nutrition with excessive amounts of manganese (11,12) can accumulate manganese selectively in the globus pallidus of the basal ganglia without immediate neurological effects. Because of its paramagnetic properties manganese can be visualized by MRI, and produces high-intensity, bilateral, symmetrical signals, visible in T1-weighted images. Two indicators of exposure and hyperintensity should be considered: the concentration of manganese in total blood and the pallidal index.

Following occupational exposure, neurobehavioral effects resembling parkinsonism have been observed in a series of manganese workers at exposures well below current occupational standards (13); higher levels of exposure can cause dystonic rigidity and proximal tremor. The late effects of currently asymptomatic exposure are uncertain; however, in Chilean workers with past exposure in manganese mines, hand tremor was detectable (14).

Two cases of manganese intoxication have been reported during total parenteral nutrition including manganese (15).

- A 68-year-old woman developed psychiatric symptoms and gait disturbance. She had received total parenteral nutrition for 3 months for ulcerative colitis, and essential trace elements (Elemenmic), including manganese (20 μmol/day), had been added. She was markedly confused and had parkinsonism, with dysarthria, marked rigidity, hypokinesia with a mask-like facies, and a supranuclear vertical gaze palsy. Her manganese concentrations were raised in both serum (4.2 ng/ml, normal 0.4–2.0 ng/ml) and urine (9.0 ng/ml; normal under 2.0 ng/ml). Serum concentrations of other trace elements (zinc, copper, iron) were normal. An MRI scan showed symmetrical high intensity T1 weighted images in the basal ganglia, especially the globus pallidus. Trace element supplementation was discontinued, levodopa was given, and her psychiatric symptoms and parkinsonism gradually abated. Calcium EDTA 1 g/day for 5 days produced marked urinary secretion of manganese. The high intensity basal ganglia MRI lesions regressed after supplementation had stopped.
- A 70-year-old man was given total parenteral nutrition for 4 months, with essential trace elements (Mineralin), including manganese (20 μmol/day). After 2 months he had progressive gait disturbance and confusion. His manganese was raised (5.1 ng/ml in serum, and 1 ng/ml in the urine). He was markedly confused and had parkinsonism, with marked rigidity, a mask-like facies, hypokinesia, and a slight resting finger tremor. An MRI scan showed symmetrical high intensity signals on T1 weighted images of the basal ganglia, especially the globus pallidus, and T2 weighted images showed multiple high intensity spots in the cerebral white matter, suggesting multiple lacunar infarcts. Trace element supplementation was discontinued, levodopa was given, and his parkinsonism gradually improved. Calcium EDTA daily for 5 days produced marked urinary secretion of manganese. The high-intensity basal ganglia lesions regressed after supplementation had stopped.

It is difficult to distinguish parkinsonism due to manganese from idiopathic parkinsonism by clinical signs only, but positron emission tomography can be helpful in discriminating them.

© 2006 Elsevier B.V. All rights reserved.

- In a 48-year-old welder with parkinsonism an MRI scan showed symmetrical high signal intensities in the globus pallidus (16). The intensities disappeared almost completely 6 months after the last exposure to manganese. Positron emission tomography showed reduced uptake of ^{18}F-dopa in the left putamen, findings that occur in idiopathic parkinsonism.

Another study reports positron emission tomography discriminated between idiopathic parkinsonism and parkinsonism due to manganese in three cases (17).

- A 51-year-old man had a mask-like face, marked postural tremor of the hands, dystonia of the neck and arms, severe retropulsion, and lateropulsion, typical of chronic manganese intoxication. An ^{18}F-dopa scan was normal.
- Two other patients, a 46-year-old man and a 47-year-old man with tremor at rest, rigidity predominantly on the right side, bradykinesia, stooped posture, and postural instability, all of which were typical of Parkinson's disease, had reduced uptake of ^{18}F-dopa in the striatum, particularly in the posterior putamen, predominantly on the left side.

The first patient had pure manganism, while the other two had Parkinson's disease, because loss of nigrostriatal fibers was obvious, with asymmetry in the putamen.

Endocrine

In a series of workers exposed to manganese dust for more than 14 years in a ferroalloy-producing plant, the correlation between prolactin and manganese in blood and in urine was studied (18). In the manganese-exposed workers there was an increase in serum prolactin, which correlated with manganese in both the blood and urine, suggesting impairment of tonic inhibition by tuberoinfundibular dopaminergic neurons.

Gastrointestinal

A phase 3 multicenter study of LumenHance has been reported (19). At a concentration of 40 μg/ml of Mn^{2+} the agent causes the lumen to have high-signal intensity on T1 weighted images and low signal intensity on T2 weighted images. The contrast agent was reconstituted with water and given in three 300 ml doses, 45 minutes, 30 minutes, and immediately before imaging in 226 patients, of whom 48 complained of one or more adverse effects, mainly related to the gastrointestinal tract (nausea was the most common). There were no serious adverse effects and no changes in vital signs or laboratory parameters. Reported adverse effects were not statistically different from placebo, and the authors concluded that LumenHance is a safe and efficacious oral gastrointestinal MRI contrast agent.

Of 30 patients undergoing contrast enhanced MRI scanning for focal liver lesions only two complained of slight nausea during the injection of mangafodipir (20). In all other cases the contrast agent was well tolerated.

Liver

In a series of neonates on total long-term parenteral nutrition, cholestatic disorders were associated with high manganese concentrations (over 360 nmol/1) (21).

Susceptibility Factors

Hepatic disease

Chronic hepatic cirrhosis is associated with manganese overload (not as a rule of medicinal origin), and manganese deposition in the brain may be responsible for hyperintensity of the T1-weighted magnetic resonance imaging (MRI) signal that is consistently seen in the globus pallidus of patients with cirrhosis (22).

- A 14-year-old boy presented with progressive hepatic myelopathy caused by cryptogenic micronodular cirrhosis, associated with persistent polycythemia and large increases in whole blood manganese concentration (23). An MRI scan showed manganese deposition in the basal ganglia and other regions of the brain. The liver manganese concentration was raised. Environmental exposure to manganese was investigated and excluded.

Apparently the liver disorder initiated altered manganese metabolism. However, the patient developed neither liver failure nor parkinsonism.

Other features of the patient

In patients on home parenteral nutrition, hypermanganesemia can be facilitated through (1) cholestatic liver disease and thereby reduced manganese biliary excretion, (2) high nutritional requirements (responsible for increased manganese supply), and/or (3) altered manganese metabolism or body distribution (12).

Manidipine

See also Calcium channel blockers

General Information

Manidipine is a dihydropyridine calcium channel blocker that can be given once a day for hypertension. In a comparison of manidipine 10 mg/day and amlodipine 5 mg/day in a multicenter, randomized, double-blind study in 530 patients with mild-to-moderate hypertension, the two drugs had comparable antihypertensive effects, but manidipine was associated with a significantly lower incidence of ankle edema (1). Nevertheless, adverse events caused withdrawal from treatment in a similar number of patients, 23 with manidipine and 26 with amlodipine.

Mannitol

General Information

Mannitol is an osmotic diuretic that has been used in acute oliguric renal insufficiency, acute cerebral edema, and the short-term management of glaucoma, especially to reduce intraocular pressure before ophthalmic surgery. Other indications include promotion of the excretion of toxic substances by forced diuresis, bladder irrigation during transurethral resection of the prostate, and oral administration as an osmotic laxative for bowel preparation. Mannitol is used as a diluent and excipient in pharmaceutical formulations and as a bulk sweetener.

Large doses of mannitol used in treating cerebral edema can alter extracellular fluid volume, osmolality, and composition and can lead under some circumstances to acute renal insufficiency, cardiac decompensation, and other complications (1). The patient's body habitus, age, total body water content relative to body weight, pretreatment plasma sodium concentration and plasma osmolality, and the presence of edema or ascites can influence the degree of extracellular fluid change and the rate of mannitol excretion to a significant degree.

Mannitol is excreted unchanged through the kidneys, and when renal function is impaired it accumulates and the movement of water into the intravascular space results in cellular dehydration. Two patients have been reported who suffered reversible acute oliguric renal insufficiency after mannitol infusion given as treatment for intracranial hypertension (2). Both had nausea and vomiting and became increasingly lethargic with the development of generalized edema. Congestive cardiac

© 2006 Elsevier B.V. All rights reserved.

failure occurred. Laboratory tests showed severe dilutional hyponatremia with hyperosmolality.

The commonly recognized complications of osmotic agents used in patients with acute closed-angle glaucoma are mild headache, neck pain, nausea, and vomiting.

Organs and Systems

Nervous system

Rebound intracranial hypertension can develop as a result of mannitol administration in neurological patients and is associated with an increase in CSF mannitol and osmolality after intravenous administration (3,4). The reported incidence of rebound intracranial hypertension with mannitol varies widely. There is no agreement that osmotic gradients and their reversal are the respective mechanisms of intracranial pressure reduction and rebound after mannitol. Another explanation is that mannitol reduces intracranial pressure by reducing viscosity and compensatory vasoconstriction, thus reducing cerebral blood volume and thereby reducing intracranial pressure. Rebound can then be explained by the delayed increase in viscosity after mannitol-induced diuresis and elimination of mannitol. It is unlikely that this provides a comprehensive explanation for the effects of mannitol. It may be that passage of mannitol across the blood–brain barrier is significantly influenced by the presence and nature of neurological disease. There may be patient subsets, such as those with diffusely increased blood–brain barrier permeability or those with focally increased blood–brain barrier permeability but diffuse distribution of mannitol throughout the cerebrospinal fluid. Such patients might be especially susceptible. These observations need to be regarded as speculative for the time being, but the idea of identifying subsets of patients who are at special risk is challenging.

Psychological, psychiatric

Acute mania has been reported in a patient who was given intravenous mannitol (5).

- A previously well 75-year-old woman without a personal or family history of mental disorders developed severe major depression and was given nortriptyline 50 mg/day. After 10 days a diagnosis of bilateral acute angle-closure glaucoma was made and she was given a continuous intravenous infusion of mannitol 20%, oral acetazolamide 500 mg, and topical pilocarpine 2%, timolol 0.5%, and dexamethasone 0.1% (each 1 drop every 15 minutes). She became euphoric 30 minutes later and remained overactive, overly affectionate, and talkative, telling jokes, with pressured speech and flight of ideas. Her manic state remitted 1 hour after the end of the mannitol infusion and her severe depression recurred dramatically.

Mannitol can cause both acute expansion of extracellular fluid volume and a rapid reduction of intracellular fluid volume with retention of brain electrolytes; these may have been the mechanisms in this case.

Gastrointestinal

Oral mannitol can raise intracolonic hydrogen concentrations sufficiently to cause explosions at diathermy (6).

Urinary tract

Four cases of acute renal insufficiency have been described in men aged 20–42 years who received mannitol 1172 (sd 439) g over 58 (sd 28) hours (7). The onset of acute renal insufficiency was detected 48 (sd 22) hours after the start of infusion. All the patients had dilutional hyponatremia (average 120 mmol/l) and serum hyperosmolarity (osmolar gap 70 mosm/kg water). In the three anuric cases, in which hemodialysis was performed, there was immediate recovery of diuresis. This emphasizes the risk of renal insufficiency with mannitol and stresses the importance of early hemodialysis. Mannitol is dialysable and once its suppressive effect on renal perfusion is eliminated functional recovery is prompt.

Maprotiline

See also Antidepressants, second-generation

General Information

Maprotiline has a tetracyclic structure, in which the tricyclic nucleus adjoins a fourth ring formed by an ethylene bridge vertical to the major plane of the molecule (SEDA-5, 34). It has a strong inhibitory effect on noradrenaline uptake across cell membranes, and relatively weak effects on serotonergic mechanisms. The half-life averages 43 hours (1), allowing once-daily dosing.

After the release of maprotiline in Britain, information was collected from 10 000 patients treated in general practice during 9 months (2). Patients were given 75 mg/day, preferably at night, and were followed for 3 weeks. By the end of that time 1343 patients had dropped out owing to adverse effects, of which drowsiness was the most common, followed by dizziness and headache. Skin rashes reached a constant peak incidence of about 3%

© 2006 Elsevier B.V. All rights reserved.

after 2 weeks; rashes were reported in some earlier clinical trials (SEDA-2, 12).

Blood concentrations were measured in two trials in general practice (3). On both regimens (single and divided doses), a steady state was reached after 1 week, but there was considerable individual variability (up to ten-fold) in plasma concentrations. In a multicenter study of over 2000 records from more than 500 general practitioners (4) the onset of action usually occurred within the first week of treatment and the effect was complete after 3–4 weeks; roughly half of the total improvement occurred by the end of the first week.

There have been several comparisons of maprotiline with other antidepressants. There was no significant difference in adverse effects compared with doxepin (5), amitriptyline (6), or imipramine (7).

Organs and Systems

Cardiovascular

Maprotiline is among the antidepressants with the lowest reported incidence of tachycardia and postural hypotension.

Respiratory

Exercise-induced bronchospasm has been reported (8).

Nervous system

Information released by the UK Committee on Safety of Medicines showed that maprotiline was associated with a disproportionate risk of seizures (9). Among 186 patients taking antidepressants who were admitted to a medical center during one year only one of 45 patients taking tricyclic compounds and none of the 109 patients not taking antidepressants had a seizure; in contrast, five of 32 patients taking maprotiline had seizures, a significant difference (10). The patients who had seizures were aged 20–66 years and none had a previous history. Dosages of maprotiline were 75–300 mg/day, and each patient had undergone a dosage increase in the week before the seizure. A report based on experience in one hospital, in addition to a review of 87 cases reported to the manufacturer, showed that seizures tended to occur at high doses (regardless of dose escalation or plasma concentrations), and that seizures presented after patients had been taking maprotiline for several weeks (11). Post-marketing surveillance has also shown a higher seizure risk with maprotiline than with tricyclic antidepressants, but since the maximum dose of maprotiline was reduced from 300 to 225 mg, few seizures have been reported (SEDA-17, 22).

So-called speech blockage has been reported with other antidepressants.

- A 54-year-old man developed a stammer and speech blockage while taking maprotiline 75 mg/day (12). It responded to a reduction in dose to 50 mg/day, reappeared with another challenge of 75 mg/day, and did not respond to physostigmine intramuscularly on two occasions. It did not occur when he took desipramine 50 mg/day.

Myoclonus due to maprotiline has been reported (13). Further neuromuscular symptoms that have been reported with maprotiline include cerebellar ataxia in a 54-year-old man with a history of unipolar depression and chronic alcohol abuse who was taking maprotiline 200 mg/day (14). The question of whether his history of alcohol abuse contributed by sensitizing his cerebellum to maprotiline-induced ataxia was unresolved.

Non-convulsive status epilepticus occurred in a 27-year-old woman shortly after starting treatment with clomipramine and maprotiline (15). On withdrawal of medication she gradually improved.

Endocrine

Galactorrhea occurred in a 23-year-old woman 2 weeks after she started to take maprotiline 50 mg/day (increased to 75 mg after 10 days) and resolved after withdrawal (16).

Metabolism

An often troublesome adverse effect of antidepressant medication is weight gain. Two cases of this adverse effect have been reported in patients taking low doses of maprotiline (17).

Hematologic

Neutropenia has been reported in a 51-year-old woman who took 150 mg/day for several months and developed myeloid hyperplasia with a virtual absence of mature granulocytes; she recovered fully with conservative management (18).

Liver

As noted previously (SEDA-10, 21), hepatotoxicity has been described with maprotiline, and two further reports have been published. In one of these, hepatotoxicity was observed in a 54-year-old man treated with maprotiline for chronic head and neck pain (19). The other report described a patient who developed a marked increase in liver enzymes and symptoms during therapy with maprotiline and opipramol; after withdrawal the patient recovered completely (20).

Skin

Ichthyosiform desquamation of the skin and alopecia have been reported (SEDA-17, 22).

Drug Administration

Drug overdose

Reports of overdose with maprotiline relate to doses of 750–3200 mg (21,22). The symptoms included impaired consciousness, convulsions, confusion, disorientation, visual hallucinations, and electrocardiographic changes similar to those seen with tricyclic compounds. Among 41 patients who had taken overdoses of maprotiline cardiotoxicity was equal to or greater than that of tricyclic drugs (23). Mania occurred in one case of maprotiline overdose (SEDA-17, 22).

Fatal overdose has been reported in detail in a 13-year-old girl who took 3000 mg of maprotiline and developed lactic

© 2006 Elsevier B.V. All rights reserved.

acidosis, which the authors believed was responsible for her death (24). Another death due to maprotiline was reported in the USA in a 23-year-old woman who took 4.5–6.0 g (25).

Drug–Drug Interactions

Risperidone

In three patients, plasma concentrations of maprotiline were increased by concomitant treatment with the atypical antipsychotic drug, risperidone (26). The data suggest that risperidone is a modest inhibitor of CYP2D6 and should therefore be used with caution in combination with drugs such as maprotiline, where increased plasma concentrations have the potential to cause serious toxicity.

Mazindol

See also Anorectic drugs

General Information

Mazindol is a tricyclic compound with central nervous system stimulant properties similar to those of amphetamine. It releases and blocks reuptake of dopamine and noradrenaline (1), and the actions of these catecholamines, not serotonin, are responsible for its anorectic activity. With fairly high doses (6 mg/day) central nervous system effects were reported in 30% of 23 patients (2). Euphoria does not occur at therapeutic doses, but can occur at higher doses. It has a much lower addiction potential than the amphetamines and practically no cases have been reported of a physical withdrawal syndrome.

The most frequent adverse effects in a multicenter open study in 274 subjects in Ireland were dry mouth, nausea, insomnia, constipation, headache, and dizziness. Restlessness and drowsiness were each reported by four patients. The incidence of adverse effects was higher at the beginning of the study, but dropped progressively throughout the 12-week treatment period (SEDA-1, 6).

In a double-blind 12-week study of 50 obese patients, adverse effects consisted of dry mouth and a tendency to constipation, except for one case of angioedema and another of peripheral edema and vomiting (SEDA-1, 6).

In another double-blind study over 12 weeks in 60 obese patients taking mazindol there were minimal adverse effects; in this instance, the complaints were insomnia and nausea (3).

In a double-blind study in 40 obese subjects with stabilized controlled diabetes mellitus and no history of emotional instability, drug dependence, or cardiovascular

© 2006 Elsevier B.V. All rights reserved.

disease, there were single cases of mild dry mouth and vertigo (4).

Organs and Systems

Cardiovascular

In another study, an increase in heart rate, probably due to an amphetamine-like stimulatory effect, was ascribed to mazindol (5).

Nervous system

Impaired concentration, but not mood elevation, was noted in healthy subjects who had taken mazindol for 3 weeks (6). Other reported adverse effects were considered to be more peripheral than central. There was no effect on standing blood pressure and pulse.

Urinary tract

There have been two reports of young adult patients with a "semen-like" urethral discharge during micturition and testicular pain attributed to mazindol (7). The composition of the discharge was not identified. Voiding of the discharge did not recur after mazindol was withdrawn, and rechallenge was not performed.

Susceptibility Factors

Adverse effects of mazindol occur with higher frequency and intensity in patients treated for longer periods of time and when it is combined with a low calorie diet (8).

Measles vaccine

Live measles vaccine

Live measles virus vaccine is available in monovalent (measles only) form and in combinations: measles–rubella (MR) and measles–mumps–rubella (MMR) vaccines. Measles vaccines based on further attenuated strains (beyond the level of the original strain, for example the Edmonston B strain or Schwarz strain) produces a mild or subclinical and non-communicable infection.

Inactivated measles vaccine

Inactivated measles vaccine was not distributed after 1967 (owing to lack of efficacy). Reports of the atypical measles syndrome that can occur after immunization with this vaccine type have been reviewed (SED-11, 679) (SEDA-8, 299) (SEDA-11, 291).

High-titer Edmonston–Zagreb measles vaccine

High-titer Edmonston–Zagreb measles vaccine is more immunogenic in young infants than measles vaccine based on other strains. It was hoped that the use of such vaccines could help to reduce the incidence of measles in infancy in developing countries. However, little was known about the long-term effects of high-titer measles vaccine given early in life. Subsequently, experience gained in Senegal, Guinea-Bissau, and other developing countries showed that child mortality after immunization was significantly higher in those who received high-titer Edmonston–Zagreb vaccine than in those given standard vaccine. The higher risk of death remained significant in multivariate analyses (1,2). There is a reason for concern about the long-term safety of high-titer measles vaccine. The World Health Organization has suspended the use of high-titer measles vaccine. Additionally, the mortality data in all West African trials have been analysed. All children were followed up to at least 3 years of age. Mortality in the high-titer group was significantly higher than in those given the standard vaccine. These results support the decision of the WHO that high-titer measles vaccines should no longer be used (3).

General adverse effects

About 5–15% of vaccinees develop a temperature of >39°C (beginning about the sixth day after immunization and lasting up to 5 days). Transient rashes have been reported in about 5% of vaccinees. Allergic reactions very rarely follow the immunization. Most of these reactions are considered minor and consist of wheal and flare or urticaria at the injection site. Very few cases of immediate allergic reactions in children who had histories of anaphylactoid reactions to egg ingestion have been reported, but these reactions could potentially have been life-threatening (4). This risk of egg allergy is excluded in modern vaccines, in which the virus is propagated in chicken or human fibroblast cell cultures.

In Japan, three further attenuated live measles vaccines are licensed for general use:

1. AIK-Cvaccine
2. Biken-CAM vaccine
3. Schwarz-FFB vaccine.

No significant differences have been reported between the three vaccines regarding either immunogenicity or adverse reactions (5).

Data on adverse effects after measles immunization reported in the framework of the US Monitoring System on Adverse Events Following Immunization to the Centers for Disease Control have been published (SEDA-13, 274). Case reports on suspected encephalitis (including two cases with hearing loss) and convulsions have been reviewed (SEDA-8, 299) (SEDA-9, 284) (SEDA-11, 291) (SEDA-12, 283) (SEDA-16, 388); very rare individual case reports on cerebellar ataxia, diffuse retinopathy, optic neuritis, regional lymphadenitis, thrombocytopenic purpura (70% of cases of thrombocytopenic purpura occur following viral diseases; purpura has been reported also following the receipt of measles vaccine), paroxysmal cold hemoglobinuria, parkinsonism, pityriasis lichenoides et varioliformis acuta, nephrosis, and depression of the tuberculin skin test reaction were cited (SED-11, 679) (SED-12, 811) (SEDA-12, 283) (SEDA-16, 389) (SEDA-17, 376).

A review of the data generated in the last 4 years has amply described the continued efforts of the scientific community to monitor and understand true measles vaccine-associated adverse events (6). The rapidity and clarity of this same community's debunking of the spurious associations with Crohn's disease and autism suggests that those charged with vaccination programs have learned from past mistakes.

The immunogenicity and safety of two live attenuated measles vaccine strains (Schwarz strain and AIK-C strain) have been compared in 9-month-old Taiwanese infants in order to find a candidate for an effective measles immunization in the first year of life (7). Because of persisting maternal measles antibody, the commercially available measles vaccines do not produce a sufficient antibody response when given during the first year of life. However, early protection is particularly required in developing countries with high measles morbidity and mortality in infants. Attempts to find suitable candidates for early immunization, including the use of the high-titer Edmonston–Zagreb measles vaccine strain, failed (SED-14, 1078). The Japanese AIK-C measles vaccine strain (derived from the Edmonston strain) has been given to 67 infants and a measles vaccine based on the Schwarz strain was given to 68 infants. The AIK-C strain vaccine caused seroconversion in 65 infants (97%), whereas only 65 infants (70%) seroconverted with the Schwarz strain vaccine. Adverse effects of the two vaccines were comparable: fever 8.8% (Schwarz strain) versus 19% (AIK-C strain); skin rash 13 versus 13%; rhinorrhea 8.8 versus 12%; cough 7.4 versus 6%; diarrhea 2.9 versus 4.5%; poor appetite 2.9 versus 1.5%; irritability 2.9 versus 6%.

Mumps vaccine

Live mumps virus vaccine is available in monovalent (mumps only) form and in combination with measles (MM vaccine) and with measles and rubella (MMR vaccine). Vaccines based on the following mumps vaccine strains are in use:

- The Jeryl Lynn strain is used mainly in vaccines prepared in the USA. The virus was isolated from a female patient in 1963. Vaccines based on Jeryl Lynn strain are mostly used worldwide.
- The Urabe Am9 strain was attenuated in Japan and has been used for the preparation of MMR and other mumps-containing vaccines in Japan and Europe.
- The Rubini strain was isolated in Switzerland and was attenuated by passage in human diploid cells for use in vaccine production.
- The L-3 (Leningrad) strain was derived by combining five isolates of mumps virus from sick children. The attenuated strain is used for vaccine production, especially in Russia.
- The L-3 strain was further attenuated in Zagreb, Croatia, by adaptation and passage in SPF chick embryo fibroblast cell cultures (mumps vaccine strain L-Zagreb).

The most commonly used vaccines have been based on the Urabe Am9 strain and the Jeryl Lynn strain. However, in September 1992 health authorities worldwide were informed by Smith Kline Beecham Biologicals that the company had decided to suspend the distribution of vaccines containing the Urabe Am9 strain, since alternative vaccines were available to maintain the immunization programs established in the various countries.

General adverse effects

Various authors have investigated the immunogenicity and reactogenicity of different mumps vaccine strains. Among adverse reaction reports, episodes of parotitis and low-grade fever have been most prominent. Rash, pruritus, purpura, and other allergic reactions are uncommon, usually mild, and of brief duration (8). Data on adverse effects after immunization with mumps-containing vaccines collected in the framework of MSAEFI have been published (SEDA-13, 274). There have been reports of febrile convulsions, meningitis, orchitis, parotitis, swollen lymph nodes, and thrombocytopenia (SED-12, 813) (SEDA-16, 389) (SEDA-17, 377).

Rubella vaccine

Rubella vaccine is a live attenuated virus vaccine. Most of the vaccines currently manufactured outside Japan are produced in human diploid cells and are based either on the RA 27/3 strain (the most widely used) or the Cendehill strain. In Japan, five different vaccine strains (for example TO 336 and MEQ 11) are produced in two different non-human substrates. In China, another vaccine strain (BRD-2) has been developed and produced in human diploid cells. Its antigenicity and reactogenicity are comparable to those of the RA 27/3 strain.

General adverse effects

Subcutaneous injection is commonly followed by local soreness and induration. Children sometimes develop

low grade fever, rash, and lymphadenopathy after immunization. Acute arthritis/arthralgia sometimes occurs.

Measles–mumps–rubella vaccine

In most industrialized countries, measles–mumps–rubella (MMR) vaccine has replaced the former use of single antigen vaccines against measles, mumps, and rubella in childhood immunization programs. Single antigen rubella vaccines are still used in postchildhood rubella prevention. Comparisons of the efficacy and safety of different MMR vaccines and monovalent versus bivalent or trivalent vaccines have been made in various clinical trials (SEDA-14, 285). Minor symptoms (fever, rash, malaise) occurred usually after 5–14 days and lasting for 2–3 days. Occasionally, febrile convulsions have been recorded within 3 weeks of immunization, and mild parotitis occurred rarely in the third week after immunization. On average, the seroconversion rates were between 95 and 99% for measles and rubella, and less for mumps.

In a crossover study among 581 twin pairs aged between 14 months and 6 years only 0.5–4% had adverse reactions to MMR vaccine. The difference between the reaction rate reported in the immunized members of the twin pairs and those reported in the placebo-injected twin sisters or brothers showed that most of the reactions were temporally and not causally related to immunization. Respiratory symptoms, nausea, and vomiting were more frequent in the placebo-injected group than in the MMR-immunized group (9).

General adverse effects

A Vaccine Safety Datalink project has been used to compare adverse events after MMR immunization either at 4–5 years or at 10–12 years (10). Information on events that are plausibly associated with MMR immunization (seizures, pyrexia, malaise/fatigue, musculoskeletal symptoms, rash, edema, induration, lymphadenopathy, thrombocytopenia, aseptic meningitis, joint pain) has been collected from 8514 children who received the vaccine at preschool age and from 18 036 schoolchildren. The results suggested that the risk of events is greater in those aged 10–12 years.

When the MMR immunization program was launched in Finland in 1982, a countrywide surveillance system, including all hospitals and health centers, was established to monitor serious adverse events after immunization. From 1982 to 1996 almost 3 million doses of MMR vaccine were distributed to 1.8 million individuals, mostly children. Most of the reported adverse events were minor or self-limiting events among 437 vaccinees, for example fever, rash, headache, fatigue, nausea, vomiting, transient arthralgia, and swelling of the parotid glands. In all, 173 potentially serious adverse events were evaluated in detail. The assessment of causality is shown in Table 1.

- One 13-month-old boy died 8 days after immunization. Autopsy showed that the cause of death was aspiration of vomit. The most commonly reported neurological adverse events were febrile seizures. Epilepsy was diagnosed in three children; symptoms manifested for the first time 1, 10, and 21 days after immunization. One child was later diagnosed as having severe Lennox–Gastaut syndrome; medical records subsequent to the acute phase were not available for the other two.

In the four cases of encephalitis, a causal relation with MMR vaccine could not be excluded, because no other specific cause was detected. One child with acute

lymphoblastic leukemia (diagnosed after immunization but with symptoms leading to the diagnosis already present at the time of immunization) developed, during immunosuppressive treatment, measles encephalopathy 54 days after immunization and interstitial pneumonia a few days later; 14 years later the leukemia had not relapsed, but she had developed severe epilepsy. The fourth child had *Herpes simplex* encephalitis, with a temporal association between MMR immunization and encephalitis (11). Idiopathic thrombocytopenic purpura was excluded from the analysis, because it has been analysed before (12).

Organs and Systems

Respiratory

Measles

Measles giant-cell pneumonia after measles immunization has been described in a 21-year-old man with AIDS (13).

- A 21-year-old man developed AIDS followed by *Pneumocystis jiroveci* pneumonia. About a year after a booster immunization with MMR vaccine, he developed measles giant-cell pneumonia, confirmed by transbronchial and thoracoscopic lung biopsies. The entire genome of the isolated strain and that of the currently used vaccine strain Moraten were subsequently sequenced and were almost identical.

Taking into consideration the long interval between measles immunization and pneumonia, the causal relation in this case was doubtful.

Nervous system

Measles

The long debate on the degree of risk to the nervous system presented by measles vaccine, especially encephalitis and encephalopathy, is not completely resolved (14). The problem has been analysed by the CDC, Atlanta, Georgia (4,15,16), the Ministry of Health and Welfare, Japan (5), the National Childhood Encephalopathy Study in the United Kingdom (SEDA-11, 285), and investigators in the Northwest Thames region of England (17). However, most investigators, having critically analysed the studies, have concluded that the incidence of suspected cases of encephalitis/encephalopathy after immunization is still much lower than that of natural infection, suggesting that some or most of the reported neurological disorders may be only temporally and not causally related to measles immunization.

Encephalopathy

Claims that cases of encephalopathy followed by permanent brain injury or death were due to measles immunization, submitted to the US National Vaccine Injury Compensation Program, have been reviewed (SED-13, 920) (18). A total of 403 claims of encephalopathy and/or seizure disorders after measles, measles–rubella, measles–mumps–rubella, mumps, or rubella immunization were identified during the period 1970–93. The medical records of these cases were reviewed by physicians in the compensation program to determine, if possible, the cause of injury and the classification of the findings. The inclusion criteria established by the compensation program were met by 48 claims by patients with acute encephalopathy of undetermined cause 2–15 days after immunization with attenuated measles virus. The clustering and peak onset of encephalopathy occurred in 17 patients on days 8 and 9, and the encephalopathy was followed by permanent brain impairment or death. The patients ranged in age from 10 months to 49 months, with a median age of 15 months. There were no cases of encephalopathy of undetermined cause within 15 days after the administration of mumps or rubella vaccine. Table 2 shows the clinical findings and sequelae among the 48 cases. The authors concluded that manifestations of acute encephalopathy among these 48 children were similar to the clinical features of acute encephalopathy described after natural measles. Vaccine-associated measles encephalopathy may be a rare complication of measles immunization. From 1970 to 1993 in the USA, about 75 million children received measles vaccine by age 4 years. The 48 cases of encephalopathy after measles immunization probably represented under-reporting to this passive compensation system. However, given the generous compensation offered in this program, it is reasonable to conclude that most serious cases temporally related to an immunization have been captured. The incidence of 48 cases of encephalopathy possibly caused by 75 million doses of vaccine can reasonably be described as low.

The clinical features of acute and chronic encephalopathy or death in these 48 patients were classified into three groups based on the initial findings of ataxia in 6, behavioral changes in 8, and seizures in 34. The onset of neurological findings varied in severity from ataxia or behavioral changes to prolonged seizures or coma. Fever preceded the onset of acute encephalopathy by several hours to several days in 43 of 48 children. There was a measles-like rash with a post-vaccination onset from day 6 to day 15 in 13 children.

The 1994 report of the Institute of Medicine concluded that the evidence was inadequate to accept or reject a causal relation between MMR and encephalopathy, and it is known that the incidence of encephalitis after measles immunization of healthy children tends to be lower than the observed incidence of encephalitis of unknown cause. Two large studies have been negative. In a study analogous to the British Childhood Encephalopathy Study there were no increased risks of either encephalopathy or neurological sequelae after measles immunization (19). A retrospective case-control study through the CDC Vaccine Safety Datalink assessing the risk for 300 000 doses of MMR found not a single case of encephalitis/encephalopathy within 30 days of the administration of MMR (20). In contrast, the review mentioned above (18) reported an association between measles vaccine and encephalopathy. However, the conclusion of the report of the Institute of Medicine is still valid, namely that evidence is still inadequate to accept or reject a causal relation between measles vaccine and these diseases.

After the publication of the Institute of Medicine report, a literature search for adverse events after measles immunization, limited to publications published in 1994–98, unearthed a considerable amount of data that strengthened the rare association of measles-containing vaccines with postinfectious encephalomyelitis (6). The report has also been criticized as an attempt to establish an adverse event of a vaccine, without a specific laboratory

Table 2 Clinical effects of acute encephalopathy in 48 patients 2–15 days after the first dose of measles, measles–rubella, or measles–mumps–rubella vaccine, and sequelae, 1970–93

Clinical onset	Number	Acute illness	Number	Neurological sequelae	Number
With initial ataxia ($n = 6$)					
Irritability	6	Ataxia	6	Ataxia (chronic)	4
Fever	5	Changed behavior	4	Mental retardation	3
Measles-like rash	3	Mental regression	3	Seizure disorder	1
		Hospitalization		Hearing loss	1
With initial behavioral changes ($n = 8$)					
Lethargy	3	Mental regression	8	Mental retardation	6
Irritability	2	Coma	5	Spastic paresis	5
Confusion	2	Hospitalization	6	Seizure disorder	1
Coma	1	Death	2	Choreoathetosis	1
Fever	6			Death (later)	1
Measles-like rash	1				
With initial seizures ($n = 34$)					
Fever	32	Hospitalization	33	Mental retardation	31
Status epilepticus	17	Mental regression	31	Seizure disorder	23
Generalized	14	Coma	29	Spastic paresis	10
Focal	3	Behavioral changes	5	Death (later)	3
Measles-like rash	9	Death	2		

finding, without a specific syndrome, without comparable data for non-immunized children, and by ignoring or minimizing years of descriptive epidemiology on reactions (21). In reply, the original authors reminded their critic that the US Congress had set up the Vaccine Injury Table to avoid disagreements over causation by making temporal association an important eligibility element for listed conditions (22). Although biologic plausibility is an important standard for assessing causation in medicine, it is less important in law. In the case of the National Vaccine Injury Compensation Program, the statute provided for a legal presumption of causation, if encephalopathy began 5–15 days after measles immunization.

Seizures

As with the administration of other agents that can produce fever, some children develop febrile seizures after receiving measles vaccine. Most of these convulsions are simple febrile seizures and do not in themselves increase the probability of subsequent epilepsy or other neurological disorders. There may be an increased risk of convulsions among children with a prior history of convulsions or those with a history of convulsions in siblings or parents. After analysing data on the increased risk of such children, both the US Immunization Practices Advisory Committee (ACIP) and the Committee on Infectious Diseases of the American Academy of Pediatrics have recommended that children with a history of convulsions should be vaccinated because the benefits of immunization outweigh the risks. According to the ACIP, children at risk could receive antipyretics, starting before the expected onset of fever and continuing for 5–7 days. The Committee on Infectious Diseases was reluctant to recommend prevention with antipyretics, though after the onset of fever these are likely to be effective (16,23).

Epilepsy has been attributed to measles vaccine (24).

- A 23-month-old boy developed Lennox–Gastaut syndrome (an epileptic syndrome caused by an acquired organic brain insult) 14 days after measles immunization with Japanese FL-vaccine, based on AIK-C live attenuated measles vaccine strain. The child's prenatal and perinatal histories and his development until 23 months of life were uneventful. His monozygotic twin brother had no epileptic seizures, but it is not clear from the original paper whether or not the twin received the same vaccine.

Subacute sclerosing panencephalitis

Subacute sclerosing panencephalitis (SSPE) can occur after immunization with live attenuated measles vaccine, but the possible role of measles virus vaccine in the pathogenesis of SSPE has been neither proved nor disproved. However, the frequency seems to be lower than after natural measles. A fall in the reported incidence of SSPE in the USA accompanied the reduction in the reported incidence of measles and following it by about 7 years (25). Similar experience has been reported from Israel (26), Japan (27,28), and the eastern part of Germany (29). There is no evidence of an increased risk of SSPE on revaccination. A different note is sounded from Romania, where epidemiological investigation of SSPE indicated a yearly incidence of 5–6 cases per million inhabitants without any change due to a measles immunization program implemented about 10 years earlier (30).

Using RNA-templated sequencing, vaccine-strain measles virus has been implicated as the cause of death in three immunocompromised children with inclusion body encephalitis (6). The authors referred to a case of measles vaccine virus-associated giant cell pneumonia in a patient with advanced HIV infection.

Mumps

Meningitis

The risk of aseptic meningitis is increased after the administration of the Urabe mumps vaccine strain in mumps vaccine or MMR vaccine. Since 1992, most

© 2006 Elsevier B.V. All rights reserved.

vaccine manufacturers have decided to suspend the distribution of vaccines containing the Urabe strain, provided that alternative vaccines were available to maintain the immunization programs established in the various countries. In 1997, a mass immunization campaign with an Urabe vaccine strain-containing MMR vaccine was carried out in the city of Salvador, in North-East Brazil (31). There was an increased risk of aseptic meningitis 3 weeks after mass immunization. The estimated risk of aseptic meningitis was 1 in 14 000 doses of MMR vaccine.

To assess the risk of mumps vaccine-associated meningitis, pediatricians were asked to report to the British Paediatric Surveillance Unit (BPSU) all confirmed and suspected cases during 1990–91. The risk based on confirmed cases was estimated to be 1 per 250 000 doses distributed (32). However, data from one district, based on two confirmed cases and one suspected case identified by the Nottingham Public Health Laboratory, suggested a much higher risk, about 1 in 4000 doses (33). To investigate whether the risk observed in Nottingham was atypical or indicative of substantial under-reporting elsewhere, additional studies were initiated. A laboratory study including four independent laboratories identified 13 cases of vaccine-associated meningitis after immunization with Urabe strain vaccines; in one-third of instances, mumps virus characterized as a vaccine-like virus was isolated. The risk estimate of 1 per 11 000 doses distributed was lower than in the Nottingham study but much higher than in the BPSU surveillance. Furthermore, children with a discharge diagnosis of viral meningitis were identified in the Oxford region and their immunization status ascertained. The estimated risk was 4.7 per 100 000 doses. Because there have been no cases of proven vaccine-associated mumps meningitis with isolation of the Jeryl Lynn vaccine virus in the UK, the decision was taken to change to Jeryl Lynn-containing vaccines (32).

Eight cases of mumps vaccine-associated meningitis have occurred in Canada. Mumps viruses have been isolated and characterized by nucleotide sequencing as Urabe Am9-like strains. Urabe mumps vaccine virus-containing vaccines are no longer licensed for sale in Canada (34).

Forsey and colleagues have examined over 80 mumps viruses from around the world; they included 20 isolates found in the cerebrospinal fluid of children with vaccine-associated meningitis in the UK and Ireland and isolates from parotitis and meningitis following mumps immunization from Australia, Belgium, Canada, France, Germany, and Japan (35). They were characterized by PCR and dideoxynucleotide sequencing for the differentiation of wild from attenuated mumps viruses. The isolates were characterized as Urabe Am9-like vaccine strains. The Jeryl Lynn mumps vaccine strain was found in one vaccinee from Germany, but no virus of this type was isolated from a patient with meningitis. Although one cannot conclude from this that Jeryl Lynn is free of such adverse effects, all the evidence points toward a considerable difference between the mumps vaccine strains in the degree of risk. Virological heterogeneity provides a clue for further investigation (36). Commercial mumps vaccine of the Jeryl Lynn strain contains at least two distinct mumps viruses; it has been suggested that this factor contributes significantly to the safety and efficacy of this vaccine (23).

The Global Advisory Committee on Vaccine Safety has considered a comprehensive review of the world literature on the safety of mumps immunization, with special attention to vaccine-associated meningitis. They found no cases of virologically proven aseptic meningitis after mumps immunization based on the Jeryl Lynn vaccine strain. If mumps vaccines based on vaccine strains such as Urabe Am9, Leningrad-3, or Leningrad–Zagreb are being used in mass immunization campaigns, the committee recommends that the potential for clustering of aseptic meningitis cases after the campaign should be taken into consideration. The available data are insufficient to distinguish between the safety profiles of the Urabe Am9, Leningrad-3, and Leningrad–Zagreb strains with regard to vaccine-associated meningitis (37).

Rubella

Adverse effects on the nervous system that have at least temporally been associated with rubella vaccination include myelitis, myeloradiculitis (SEDA-2, 268) (SEDA-20, 292), meningomyelitis (SEDA-10, 291), encephalitis (SEDA-5, 308), peripheral neuropathy (SEDA-12, 284), facial or peripheral paresthesia (SEDA-11, 295) (SEDA-12, 284), and carpal tunnel syndrome (SEDA-12, 284). In many of these cases the causal relation was doubtful. The authors of the report of the Institute of Medicine, National Academy of Sciences, Washington, DC (1991) entitled "Adverse Effects of Pertussis and Rubella Vaccines" (38) considered that there was insufficient evidence to indicate either the presence or absence of a causal relation between RA 27/3 rubella vaccine and radiculoneuritis and other neuropathies.

- Acute disseminated encephalomyelitis occurred in a 14-year-old boy 22 days after rubella immunization (39). The authors suggested that live rubella vaccine can occasionally trigger immunologically mediated demyelination within the nervous system.

It has been suggested that there is insufficient evidence to indicate either the presence or absence of a causal relation between RA 27/3 rubella vaccine and radiculoneuritis and other neuropathies (38), although cases have been reported.

- A 23-year-old woman developed a mild distal demyelination neuropathy 4 weeks after rubella immunization (40). Immunological studies showed the presence of antibodies to the rubella virus proteins and to the myelin basic protein.

The authors suspected that a virus-induced immune response caused an auto-aggressive reaction responsible for demyelination.

Measles–mumps–rubella

A cranial nerve palsy has been attributed to MMR (41).

- A 13-month-old girl developed a recurrent sixth nerve palsy 1 week after MMR immunization. This resolved completely over 8 weeks and recurred 15 weeks after initial onset. Other causes for the sixth nerve palsy were excluded.

Meningitis

Vaccine-associated meningitis is a well-known adverse effect of mumps (or MMR) immunization. Until 1991 the reported incidence was low, but in that year Japanese researchers published the result of a nationwide survey, started in 1989, in which the incidence of vaccine-associated mumps meningitis varied from less than 1 case per 7000 to 1 per 405 from prefecture to prefecture. Meningitis was generally mild and there were no sequelae from the illness. The vaccine used contained the Urabe Am9 strain (42,43). In April 1993, the Ministry of Health and Welfare in Japan decided to interrupt the use of MMR vaccine (44).

A retrospective study was carried out to determine the incidence of vaccine-associated meningitis in Japan after the administration of different locally produced MMR vaccines (MHW MMR vaccine, Takeda MMR vaccine, Biken MMR vaccine, and Kitasato MMR vaccine) (45). Among the three MMR vaccines (Biken vaccine excepted) the incidence of meningitis was about 1 in 500–900 vaccinees. The criteria for inclusion of a case of meningitis were symptoms of meningitis and pleocytosis in the cerebrospinal fluid. In a complementary nationwide comparison of four MMR vaccines conducted in Japan by 1255 pediatricians the total number of vaccinees was 38 203 (46). All were arbitrarily given one of the MMR vaccines produced by three manufacturers (Biken, Kitasato, and Takeda) or the standard MMR vaccine made of designated strains (Biken's mumps Urabe Am9 strain, Kitasato's measles AIK-C strain, and Takeda's rubella To336 strain). The rates of virologically confirmed aseptic meningitis per 10 000 recipients were 16.6, 11.6, 3.2, and 0 for the standard MMR, Takeda MMR, Kitasato MMR, and Biken MMR vaccines respectively. The incidence of convulsions was the highest with the standard MMR vaccine, and the incidence of fever associated with vomiting at 15–35 days (symptoms relevant to aseptic meningitis) were also the highest with the standard MMR vaccine. The incidence of parotitis was the lowest with Takeda MMR vaccine.

The finding that the incidences of aseptic meningitis differed after administration of the standard MMR vaccine or Biken MMR vaccine has inevitably raised questions about the consistency of manufacture of the Urabe Am9 mumps virus vaccines. The National Institute of Health found that the biological characteristics of the Urabe Am9 mumps virus contained in the standard MMR vaccine and in the Biken MMR vaccine were different. The Biken Company reported that the mumps vaccine in the standard MMR vaccine was a mixture of two Urabe Am9 mumps vaccine bulks, one identical to that contained in the Biken MMR vaccine and the other produced by a different manufacturing process.

In 1995, a somewhat different note was sounded from France, where all mumps vaccines produced and marketed at that time contained the Urabe vaccine strain. The incidence of vaccine-associated meningitis was estimated using two different data sources: the national network of hospital virology laboratories and the manufacturer's pharmacovigilance department (47). The risk of vaccine-associated meningitis was assessed at one case per 28 400 doses distributed when using the laboratory network data or one case per 13 000–67 200 doses distributed when using the pharmacovigilance data. The French vaccination committee recommended that the vaccine continue to be used whilst awaiting vaccine containing the Jeryl Lynn strain.

Cases of aseptic meningitis occurring 14–26 days after MMR immunization have been reviewed (48). All the patients had been immunized with the L-Zagreb mumps strain, Edmonston–Zagreb measles strain, and the RA 27/3 rubella strain. The incidence of vaccine-associated meningitis was 9 per 10 000 doses. This finding was similar to that reported for the same mumps vaccine strain by Cizman (49), 10 per 10 000 (SEDA-12, 815), but higher than that found by Kraigher (48).

Transmission of Urabe mumps vaccine strain between siblings has been reported (44). A girl developed parotitis after immunization with Urabe mumps strain; 19 days later her older sister developed mumps. The strain isolated showed molecular biological characteristics typical for the Urabe strain.

The reason for the high incidence of vaccine-associated mumps meningitis has been investigated by a comparison of the nucleotide sequence of the hemagglutinin-neuraminidase gene from vaccine virus with the genes of viruses isolated from patients with vaccine-associated meningitis (50). The analysis showed that the Urabe AM9 vaccine strain is a mixture of viruses that differ at nucleotide 1081: a wild type-like variant A and a variant G. Vaccinees who developed vaccine-associated meningitis or parotitis had predominantly variant A (98–100%), indicating strong selection of the wild type-like variant of the mumps virus.

The incidence of aseptic meningitis after immunization with MMR containing the Jeryl Lynn mumps vaccine strain has been assessed in a Vaccine Safety Datalink project (20). The overall rate of confirmed cases in the study population (children aged 1–2 years) was 172 cases per million children, very close to the background rate of 162 naturally occurring cases per million children aged 1–4 years in Olmsted County, MN. The authors concluded that there is no increased risk of aseptic meningitis after vaccination with MMR including the Jeryl Lynn mumps vaccine strain.

Gait disturbance

An analysis of 41 reports of gait disturbance in 15-month-old children in temporal relation with the first MMR immunization, collected in the framework of the Danish surveillance system for adverse events after immunization, has been reported (51). About 533 000 doses of MMR vaccine were administered to 15-month-old children in Denmark during the 10 years from 1987 to 1996. The number of reported cases of gait disturbance corresponded to a frequency of eight per 100 000 doses of MMR vaccine. The authors considered that the symptoms were characteristic of cerebellar ataxia. The high frequency and mainly mild course of gait disturbances might indicate a mumps-related reaction. The symptoms mainly occurred at 7–14 days after immunization, and the duration was on average 1–2 weeks (range 1 day to over 4 months). Most cases were mild and short-lasting and a longer duration of symptoms seems to be predictive of late sequelae. In

© 2006 Elsevier B.V. All rights reserved.

the same period about the same number of doses were used for the second MMR immunization without similar reactions. Disturbance of gait has rarely been reported, and the authors listed in their paper two reports from Sweden and Germany in which symptoms were so mild that no invasive investigations were carried out.

Guillain–Barré syndrome

To test the hypothesis that MMR vaccine can cause Guillain–Barré syndrome, a retrospective study has been carried out in Finland, based on linkage of individual immunization records with nation-wide hospital discharge registers (52). MMR vaccine did not cause any increase in the incidence of Guillain–Barré syndrome over background and there was no clustering of cases at any time after the administration of the vaccine. The authors concluded that there is no causal association between MMR immunization and Guillain–Barré syndrome.

Sensory systems

Rubella

Bilateral optic neuritis (53) and retinal vasculitis (SEDA-20, 292) have been attributed to rubella immunization.

Psychological, psychiatric

Measles–mumps–rubella

The suggestion that measles/MMR immunization can cause autism has not been confirmed. Autism is characterized by absorption in self-centered subjective mental activities (such as day-dreams, fantasies, hallucinations), especially when accompanied by marked withdrawal from reality.

History

The scientific and public response to the 1998 publication of Wakefield and colleagues (54), and Wakefield's subsequent press conference, in which he suggested that immunization with MMR might be associated with Crohn's disease and autism was enormous and controversial. For example, Black and colleagues (55) stated that the publicity generated by this paper was out of proportion to the strength of the evidence it contained; Beale (56) suggested that the Lancet would bear a heavy responsibility for acting against the public health interest that the journal usually aims to promote; O'Brien and colleagues (57) considered that the substantial amount of evidence that contradicts the findings of Wakefield and colleagues did not achieve the same prominence in the popular press.

In replying to these letters, Wakefield (58) defended the clinician's duty to his patients and the researcher's obligation to test hypotheses. For his part, the editor of the Lancet pointed out that the paper had been presented with a commissioned commentary in the same issue; peer review had confirmed that the paper merited publication, with suitable revisions and editing, as an early report; finally, he considered that the press had presented the information in a balanced way (59). However, it was subsequently discovered that the work had been sponsored by a pharmaceutical company which had not been declared at the time (60). Furthermore, the children who were included in the study had been selected other than at random. Subsequently, 10 of Wakefield's colleagues withdrew the findings that they had initially reported and one other could not be traced; only Wakefield did not retract (61).

The Lancet then reviewed the developments in the discussion (62), with emphasis on evidence that contradicts the alleged association and new data presented by Wakefield. The last part of the editorial read as follows:

In a new twist, Wakefield's crusade fuelled further anxiety among parents when he and John O'Leary, director of pathology at Coombe Women's Hospital, Dublin, Ireland, presented unpublished data to the US Senate's congressional oversight committee in Washington on April 6 [2000]. The hearing was called by the chairman, Dan Burton, an Indiana Republican, whose grandson has autism and visited the Royal Free Hospital in November last year. At the hearing, six parents of children with autism gave moving testimonies of their children's illness. ... Scientific evidence was presented by six chosen 'experts'. According to Wakefield's testimony, he has now studied more than 150 children with 'autistic enterocolitis'—an unproven association had become a disease—and a detailed analysis of the first 60 cases is to be published in the American Journal of Gastroenterology later this year.

Wakefield presented uninterpretable fragments of results only and concentrated on refuting studies that had contradicted his findings. His conclusions were surprisingly non-committal: 'the virological data indicate that this may be measles virus in some children'; he added that it would be imprudent to interpret the temporal relationship with MMR as a chance finding, in the absence of thorough investigation. O'Leary explained that gut-biopsy material from 24 of 25 children with autism was positive for measles virus compared with one of 15 controls, and that this material was presented to him by Wakefield using 'blinded protocols'. Since the controls are not further described and the details of these findings remain unpublished, this evidence raises far more questions than it answers.

"Autism is a poorly understood neurodevelopmental-disease spectrum with a heart-breaking personal story behind every case. But parents of such children have not been served well by these latest claims made well beyond the publically [sic] available evidence. A congressional hearing, like a press conference, is no place to make controversial scientific assessments. And if scientists question the safety of vaccines without making their evidence fully transparent, harm will be done to many more children than they purport to protect."

Wakefield and Montgomery subsequently raised doubts about the adequacy of the evidence that secured the license for MMR vaccine (63). Particularly in view of the immunosuppressive properties of the measles virus, they suggested that there is a potential for adverse interactions between the component live viruses. They therefore proposed that spaced monovalent measles, mumps, and rubella immunization should replace the use of the combined MMR vaccine. The continuing publications of Wakefield led to reduced MMR coverage in some parts of the UK and to well-publicized concerns about the potential for measles outbreaks among primary school entrants. In an editorial in the British Medical Journal, Elliman and Bedford replied to Wakefield's paper (64). They

© 2006 Elsevier B.V. All rights reserved.

considered that the current concerns were idiosyncratic and presented reviews confirming the vaccine's safety. The Medicines Control Agency and the Department of Health in the UK rejected any suggestion by Wakefield and colleagues that combined MMR vaccines were licensed prematurely. A review of the licensing of MMR vaccines led to the assurance that the licensing procedure was normal and was based on robust studies (65). This position was shared by the Committee on Safety of Medicines and the Joint Committee on Vaccination and Immunisation. At the end of November 2001, Wakefield left his post at the Royal Free and University College Medical School in London. The college said: "Dr Wakefield's research was no longer in line with the Department of Medicine's research strategy and he left the university by mutual agreement" (66). The WHO strongly endorsed the use of MMR vaccine. The combination vaccine was recommended rather than monovalent presentations. There was no evidence to suggest impaired safety of MMR (67).

In April 2001, the Institute of Medicine's Immunization Safety Review Committee released its report "MMR vaccine and autism". Although scientists generally agreed that most cases of autism result from events that occur in the prenatal period or shortly after birth, there was concern because the symptoms of autism typically do not emerge until the child's second year, and this is the same time at which MMR vaccine is first administered in most developed countries. The committee took also into consideration the papers published by Wakefield and other groups and scientists suggesting evidence of a link between MMR vaccine and Crohn's disease and autism. Following review of the numerous research efforts on the MMR–autism hypothesis the committee concluded in its report "that the evidence favors rejection of a causal relationship at the population level between MMR vaccine and autistic spectrum disorders". Epidemiological evidence showed no association between MMR vaccine and autism, and the committee did not find a proven biological mechanism that would explain such a relation. Therefore, the committee did not recommend a policy review at this time of the licensure of MMR vaccine or of the current schedules and recommendations for MMR administration (68).

A conference of the American Academy of Pediatrics on "new challenges in childhood immunizations" was convened in Oak Brook, IL, on 12–13 June 2000 and reviewed data on what is known about the pathogenesis, epidemiology, and genetics of autism and the available data on hypothesized associations with Crohn's disease, measles, and MMR vaccine. The participants concluded that the available evidence did not support the hypothesis that MMR vaccine causes either Crohn's disease or autism or associated disorders. They recommended continued scientific efforts directed to the identification of the causes of autism (69).

The response to a newly published adverse event due to immunization must be rapid. If the reported association is correct, urgent re-evaluation of the immunization program is necessary. Otherwise, if the reported association is false, a credible counter-message is necessary to minimize the negative impact on the immunization program (6). The rapidity of response to the 1998 publication of Wakefield and colleagues, including the convening of an independent review panel in the UK, was very useful.

Evidence

Two studies suggested a link between measles/MMR immunization and autism. Fudenberg reported that 15 of 40 patients with infantile autism developed symptoms within a week after MMR immunization (70). Wakefield and colleagues evaluated 12 children with chronic enterocolitis and regressive developmental disorders (54). The onset of behavioral symptoms was associated with MMR immunization in eight cases, as reported by the parents. Both reports were non-comparative and anecdotal. By chance alone some cases of autism will occur shortly after immunization, and most children in developed countries receive their first measles or MMR vaccination in the second year of life, when autism typically manifests. The imprecision of the interval between immunization and the onset of behavioral symptoms in the study by Wakefield and colleagues made these data suspect, even before their retraction.

Inaccuracies in the study of Fudenberg, for example referring to hepatitis B vaccine as a live vaccine, cast some doubts on the carefulness of the entire report. Developmental delay is likely to be detected by a gradual awareness over a period of time, not on a particular day. Epidemiological studies in various countries (UK, Sweden, Finland), comparing the introduction and use of vaccines and the incidence of autism, have not supported a relation between measles/MMR vaccine and autism (71–74). Wing reviewed 16 studies in Europe, North America, and Japan and found no increase in autism with increasing use of measles or MMR vaccines (75). An analysis of two large European datasets produced similar results (76). In early 1998, experts in various medical disciplines reviewed the work of the Inflammatory Disease Study Group of the Royal Free Hospital in detail and concluded that there is no evidence for a link between measles/MMR vaccine and either Crohn's disease or autism (77).

Data from an earlier study have been reanalysed to test the hypothesis that MMR vaccine might cause autism but that the induction interval needs to be short (78). Evidence for an increased incidence was sought using the case-series method. The study used data on all MMR vaccines, including booster doses. The results of this study, combined with results obtained earlier by the same authors, provided powerful evidence against the hypothesis that MMR vaccine causes autism at any time after immunization.

Metabolism

Measles–mumps–rubella

A total of 20 cases of type I diabetes mellitus suspected to be induced by MMR immunization have been reported to Behringwerke, Marburg, Germany, probably due to the mumps component (79). The earliest case occurred 3 days after receiving the vaccine and the latest 7 months after immunization. Twelve cases were diagnosed within 30 days of immunization. The investigators considered the cases of diabetes mellitus to have a temporal relation to the immunization. For every 5 million children immunized against mumps 50 spontaneous cases of diabetes mellitus are to be expected by random coincidence within

© 2006 Elsevier B.V. All rights reserved.

a period of 30 days after immunization. In fact, only 12 cases were reported within 30 days after immunization. Mainly based on this analysis the Deutsche Vereinigung zur Bekämpfung der Viruskrankheiten (DVV) could not confirm the relation between mumps immunization and diabetes mellitus (80).

Hematologic

Measles

Anemia has been reported after measles immunization (81). The vaccine can cause a significant fall in hemoglobin that can persist for 14–30 days and can be difficult to distinguish from iron deficiency.

Rubella

Thrombocytopenic purpura has been attributed to rubella (82). However, the authors of the report of the Institute of Medicine, National Academy of Sciences, Washington, DC (1991) entitled "Adverse Effects of Pertussis and Rubella Vaccines" (38) considered that there was insufficient evidence to indicate either the presence or absence of a causal relation between RA 27/3 rubella vaccine and thrombocytopenic purpura.

Measles–mumps–rubella

There is a relation between MMR vaccination and thrombocytopenic purpura, but not with the measles component itself (18). Thrombocytopenic purpura after MMR has been reviewed, with discussion of pathogenesis and the vaccines and infections associated with this problem (83). Rubella vaccine is one of the most frequently reported causes of thrombocytopenia in Denmark (84). In France, a retrospective epidemiological survey (1984–92) showed that the rates of thrombocytopenic purpura per 100 000 vaccinees were 0.23 for measles vaccine, 0.17 for rubella vaccine, 0.87 for combination MR vaccine, and 0.95 for MMR vaccine (85). Thrombocytopenia was severe and always associated with purpura. Cases of recurrent thrombocytopenic purpura after repeated MMR immunization have been reported (86,87). The Advisory Committee on Immunization Practices (ACIP) of the Centers for Disease Control and Prevention (CDC) has recommended avoiding subsequent doses of MMR when a previous episode of thrombocytopenia occurred in close temporal proximity to the previous immunization, that is within 6 weeks (88,89).

The causal relation between MMR vaccine and idiopathic thrombocytopenic purpura has been confirmed using linkage of immunization records and hospital admission records; the absolute risk within 6 weeks of immunization was 1 per 22 300 doses (90).

Gastrointestinal

Measles–mumps–rubella

The suggestion that measles/MMR immunization can cause Crohn's disease has not been confirmed.

Inflammatory bowel disease (ulcerative colitis and Crohn's disease) is a general term for a group of chronic inflammatory disorders of unknown cause involving the gastrointestinal tract. Despite many attempts to confirm an infectious agent as the cause of disease, no bacterial, viral, or fungal agents have so far been isolated. There is strong evidence for a genetic predisposition.

In 1993 and 1994, researchers in the UK and Sweden suggested that Crohn's disease might be a late result of measles infection at a critical time during early childhood (91,92). In a study of the outcome of maternal measles infection in 25 Swedish babies, three of four children exposed to measles in utero subsequently developed Crohn's disease (93). Whereas wild measles virus was initially implicated, a controversial debate was initiated in 1995, when Thompson and colleagues suggested that attenuated measles vaccine virus might also cause inflammatory bowel disease, having found an increased risk of inflammatory bowel disease in about 3000 immunized individuals compared with about 11 000 non-immunized controls (94). Furthermore, the Inflammatory Bowel Disease Study Group of the Royal Free Hospital, London (Wakefield and colleagues), suggested that measles virus is present in the bowel of patients with Crohn's disease (with evidence from transmission electron microscopy, immunohistochemistry, in situ hybridization, and immunogold electron microscopy) (92,95,96).

Wakefield and colleagues then made two suggestions in a paper in the Lancet (54): that autism is linked to a form of inflammatory bowel disease and that this new syndrome is associated with MMR immunization. Their hypothesis was that MMR vaccine causes non-specific gut injury, allowing the absorption of normally non-permeable peptides, which in turn cause serious developmental disorders. The authors stated that they had not proved an association between measles, mumps, and rubella vaccines and either autism or inflammatory bowel disease. However, there were enough references in the text to lead the reader to the assumption that there is sufficient evidence provided by the study, and by other scientific publications, that there is a link. This paper of Wakefield and colleagues, publicized by a subsequent press conference, resulted in a heated debate and a huge number of letters to the editor of the Lancet, in turn severely criticizing both the article and its implications for immunization programs, blaming the editor for publishing the article, and defending the obligation of clinical researchers to publish provocative findings. Considerable evidence, mainly microbiological and epidemiological, has been collected by others to suggest that the association with MMR does not exist.

The alleged association of measles vaccination with Crohn's disease and autism has also been criticized as being based on poor science and as having been largely refuted by a large volume of stronger work, three types of evidence against the hypothesis (biological, microbiological, and epidemiological) being considered in detail (6).

Several groups have found no evidence of persistence of measles virus in the tissues of patients with Crohn's disease with a very sensitive test (polymerase chain reaction) (97–100). Furthermore, no viral genomic sequences of measles, mumps, and rubella viruses were found in intestinal specimens (100). The results of Iizuka and colleagues (98,101) were particularly interesting—they used the same monoclonal antibody in their immunohistochemical studies that Wakefield and colleagues had used. The antigen recognized could be a measles virus protein, but they

© 2006 Elsevier B.V. All rights reserved.

considered it much more likely that the previous immunochemical observations were accounted for by antigen mimicry between measles virus and a host protein found in the intestinal tissue of patients with Crohn's disease. Serological studies have also shown lower measles complement fixation titers in patients with Crohn's disease than in controls, not supporting an association of measles vaccine with Crohn's disease (102,103).

The major weaknesses of the epidemiological studies reported by the Inflammatory Bowel Disease Study Group have been discussed in a number of letters to the editor (104,105) and editorials (105). On behalf of the World Health Organization's Expanded Program on Immunization, Lee and colleagues (71) questioned the conclusion that there was a temporal association between immunization and the onset of symptoms, because the study of Wakefield and colleagues had provided data on the interval between immunization and the onset of symptoms in only five of their 12 cases of so-called autism-bowel syndrome, and the age at which the vaccine was given was mentioned in only three. Furthermore, Lee and colleagues criticized the study on the grounds that no patient selection had been made by Wakefield and colleagues, other than the 12 patients referred to them; there were no controls and no blinding of the investigators (71). Payne and Mason (106) made the same comment, that the cases reported by Wakefield and colleagues were highly selected and that the underlying population was unclear.

Several epidemiological studies have failed to confirm an association between measles/measles vaccine and Crohn's disease. For example:

- *Copenhagen*: In a study of 25 mothers with measles during pregnancy there were no cases of Crohn's disease in their children (107).
- *Finland*: Peltola and colleagues (108) reported on over a decade's effort to detect all severe adverse events associated with MMR vaccine distributed in Finland. There was no evidence to support the hypothesis that the vaccine could cause pervasive developmental disorders or inflammatory bowel disease. Comparing the incidence of Crohn's disease and the Finnish data for measles and measles immunization, Pebody and colleagues (109) came to the same conclusion, namely that there is no association between Crohn's disease and measles vaccine.
- *Japan*: A nationwide survey of inflammatory bowel disease was carried out in 1979–93 in children under 16 years of age. From 1979 to 1992 the number of cases of inflammatory bowel disease was almost the same (ulcerative colitis rates 0.08–0.12 per 100 000, Crohn's disease 0.04–0.06 per 100 000). In 1992, the incidence of Crohn's disease rose to 0.10 and in 1993 to 0.12 per 100 000; the incidence rate of ulcerative colitis increased in 1993 to 0.18 per 100 000. Measles immunization (implemented in 1968) was 68% until 1993, and during the 1980s and early 1990s was relatively constant at about 70% (110).
- *UK*: In close to 7 million children who received MR vaccine in a catch-up campaign there was no increase in the number of new cases or exacerbation of existing cases of Crohn's disease (111).
- In an international case-control study of 499 patients with chronic inflammatory bowel disease and 998 control patients from nine countries, there was no difference in the risk of inflammatory bowel disease in association with either natural measles or measles immunization (112).

Pancreas

Mumps

Acute pancreatitis after mumps immunization is very rare and has been reported only sporadically in adolescents.

- A 13-month-old boy presented with an acute abdomen and surgery was performed for a suspected perforated appendicitis (113). The appendix was normal but the pancreas was enlarged, edematous, and covered with fibrin, with areas of superficial necrosis. The serum amylase activity was 528 IU (normal under 200 IU).

Unfortunately the authors reported no data on the vaccine used or the interval between immunization and disease onset.

Measles–mumps–rubella

- A 19-year-old woman who received MMR vaccine developed pancreatitis 11 days later (114). Other causes of pancreatitis could not be implicated.

Skin

Measles

- An 11-month-old boy developed hypertrichosis at the injection site (2.5 × 3 cm) 1 month after measles immunization (115). The hypertrichosis and induration persisted during the follow-up period of 3 months.

Measles–mumps–rubella

Gianotti–Crosti syndrome has been reported in a child immunized with MMR (116).

- Three days after MMR immunization a 15-month-old boy developed a rash, initially on the arms but later involving the legs. Six weeks later he had an extensive, symmetrical, non-follicular, papular eruption on his face, arms, and legs, with striking sparing of his trunk. This was labeled Gianotti–Crosti syndrome, a self-healing non-recurrent erythematous or skin-colored papular eruption with symmetrical distribution on the face, buttocks, and extremities in children.

A wide spectrum of infectious diseases has been associated with this syndrome, and preceding immunization against influenza, diphtheria, pertussis, and poliomyelitis has been reported.

- A 13-year-old girl developed toxic epidermal necrolysis 7 days after being immunized with live attenuated MMR vaccine (117).

Musculoskeletal

Rubella

Acute arthritis/arthralgia due to rubella vaccine occurs more often and tends to be more severe in susceptible women than in children, usually involving the small peripheral joints. Joint symptoms generally begin 3–25 days

© 2006 Elsevier B.V. All rights reserved.

after immunization, persist for 1–11 days and rarely recur. Incidence rates are estimated to average 13–25% (118) among adult women after RA 27/3 immunization with much lower rates among children, adolescents, and adult men. The incidence of acute joint symptoms increases with increasing dose. There is also an analogous but chronic complication: in small studies of adult female vaccinees in Canada the incidence of persistent or recurrent arthritis was as high as 5–11%.

Radiological bone changes have also been reported after rubella immunization (118).

The committee responsible for the report of the Institute of Medicine, National Academy of Sciences, Washington, DC (1991) entitled "Adverse Effects of Pertussis and Rubella Vaccines" (38) found that the evidence indicates a causal relation between RA 27/3 rubella vaccine and acute arthritis and the available evidence was weaker but still consistent with a causal relation between RA 27/3 rubella vaccine and chronic arthritis. The section on rubella immunization and chronic arthritis included in the report has been reviewed critically (119). In the authors' opinion it is not justified to conclude on the basis of very limited experience that the evidence is consistent with a causal relation between the RA 27/3 rubella vaccine strain and chronic arthritis in adult women.

Other evidence comes from compensation claims. An analysis of 124 claims to the US National Vaccine Injury Compensation Program relating to chronic arthropathy showed that the onset of symptoms occurred at 1–6 weeks after rubella vaccination in 72 individuals (group 1) and at less than 1 week or more than 6 weeks after vaccination in 52 individuals (group 2). Various conditions developed in the two groups after immunization: unspecified arthritis (29 in group 1, one in group 2), specified arthritis (11 and 19), arthralgia (24 and 7), fibromyalgia (4 and 11), and multiple symptoms with minimal arthralgia or myalgia (4 and 14). The Program and the US Court of Federal Claims accepted that there is a causal relation between rubella vaccine and cases of chronic arthropathy that start at 1–6 weeks after vaccine administration (120).

There have also been reviews of this complication (121). Polyarthropathy associated with rubella vaccine predominantly affects the fingers and knees and usually resolves within 2–4 months. However, the duration of symptoms exceeded 18 months in about 5% of cases. Rubella virus RNA has been identified in the peripheral monocytes of such patients 8–10 months after vaccination. The association between adverse musculoskeletal and neurological events and rubella immunization has also been investigated prospectively in 546 healthy postpartum rubella-seronegative women, who received either monovalent rubella vaccine ($n = 270$) or saline placebo ($n = 276$). There was a significantly higher incidence of acute joint manifestations with rubella vaccine (30%) than with placebo (20%). The frequency of chronic or recurrent arthralgia or arthritis was only marginally significant (SEDA-22, 353).

Data from the VAERS on arthritic reactions (arthralgia, arthrosis, arthritis, and joint disease) after rubella immunization during 1991–98 have been analysed (Table 3) (122). Hepatitis A vaccine-associated arthritic reactions reported to VAERS during 1997–98 were used as controls. The analysis confirmed that rubella vaccine is associated with a large number of arthritic reactions. Among the female subjects given rubella vaccine, these reactions occurred primarily in the adult women. The incidence of arthritic reactions was 126 per million rubella immunizations, whereas the hepatitis A vaccine adult control group had an incidence rate of 3.2 per million immunizations.

Immunologic

Measles

It has been suggested that hydrolysed gelatin, rather than egg protein, is responsible for most episodes of anaphylaxis after measles immunization (6). Egg allergy should no longer be a contraindication to measles immunization. However, a previous anaphylactic reaction to measles or MMR vaccine remains a contraindication.

Toxic shock syndrome was reported to have developed within 3 hours of measles immunization in four children, three of whom died. It was initially seen in women who were using tampons in the presence of vaginal colonization and/or infection with toxin-producing strains of *Staphylococcus aureus*. The hallmarks of toxic shock syndrome are high fever, diarrhea, vomiting, tachycardia, hypertension, mucocutaneous ulceration, rash, conjunctival injection, red palms and soles, and a bleeding diathesis. There was some evidence that a used vial of measles vaccine had been kept in cold water and had thereby become contaminated (123). Similar events from various developing countries have been reported to the World Health Organization. Careful investigation pointed clearly to secondary bacterial contamination as the cause of disease and death (124).

Rubella

It has been suggested that RA 27/3 rubella strain could play a role in the etiology of chronic fatigue syndrome (125). Patients with chronic fatigue syndrome have raised IgG serum antibodies to multiple common viruses. Only IgG rubella antibodies correlate positively with the intensity of symptoms and reach titers that are significantly higher than in healthy controls.

Table 3 Rubella immunization and arthritic reactions reported to the VAERS database

Arthritis reaction type	Number of reports	Women	Men	Mean onset (days)	Mean age (years)	Incidence per million immunizations
Arthralgia	191	170	17	11	40	78
Arthrosis	58	51	4	12	43	24
Arthritis	46	41	2	11	38	19
Joint disease	13	13	0	12	39	5

Measles–mumps–rubella

There is a controversy about the safety of MMR vaccine in children with adverse reactions to egg. Investigating the vaccine produced by Merck Sharpe & Dohme (virus grown in chicken fibroblasts), some did not detect egg protein (126). However, using a competitive ELISA others detected 74 pg of ovalbumin per ml of the MMR vaccine produced by MSD (127). This extremely low amount of ovalbumin appears to be unlikely to provoke allergic reactions. The results of a study carried out in 15 children with egg-positive skin results confirmed the view that the MMR vaccine does not contain enough egg protein to cause reactions (128).

- Moraten vaccine, Berna (virus grown in human fibroblast cultures and therefore certainly ovalbumin-free) was given to a 2-year-old boy with atopic dermatitis (129). The skin tests were positive to cow's milk and egg. Within a few minutes after the receipt of the vaccine, the child developed severe dyspnea, rhinoconjunctivitis, and lip cyanosis; he was successfully treated for an acute anaphylactic reaction. The case seems to demonstrate that the very rare allergic reactions after the administration of measles and MMR vaccines could be due to causes other than egg protein.
- A 17-year-old woman who had an anaphylactic reaction to MMR vaccine was allergic to gelatin; after eating gelatin she developed ear and throat pruritus and tongue swelling (130). Prick skin tests were positive for MMR vaccine and gelatin. Immunoblotting confirmed the presence of IgE antibodies to multiple gelatin components from a variety of animal sources.

MMR vaccine contains gelatin as a stabilizer. The authors concluded that the anaphylaxis was caused by the gelatin component of the vaccine.

- In 24 of 26 children aged 1–4 years who developed anaphylactic reactions within minutes after the administration of MMR vaccine there were IgE antibodies against gelatin (131).
- In 135 children with suspected or documented systemic allergy (atopic eczema, asthma, cow milk's allergy, severe systemic reactions after previous doses of different vaccines), who were prick-tested with undiluted MMR vaccine before immunization, 122 of 126 prick-test-negative children received the MMR vaccine. No untoward reactions developed, except for mild generalized urticaria or fever in two vaccinees. The author concluded that allergic diseases should not be considered as contraindications to MMR immunization (132).

In a brief review of allergy and MMR vaccine the author concluded that anaphylactic reactions are very rare but potentially life-threatening (133). Immunization personnel must therefore be aware of this possibility and trained in its management. Most severe reactions occur within a few minutes after injection and it is extremely unlikely that a child who appears completely well after immunization will subsequently develop a severe reaction.

Second-Generation Effects

Pregnancy

Measles

Live measles vaccine should not be given to pregnant women. This precaution is based on the purely theoretical risk of fetal infection (134).

Rubella

The risks of rubella infection to the unborn child are well known, and necessarily the question has arisen as to whether rubella vaccine is safer. Based on careful analyses by the CDC since 1979 and evaluation of reports from Germany and the UK showing that infants born to susceptible mothers did not develop the congenital rubella syndrome, the Immunization Practices Advisory Committee (135) has concluded that:

- pregnancy remains as a contraindication to rubella immunization because of the theoretical, albeit small, risk of congenital rubella syndrome
- reasonable precautions should be taken to preclude immunization of pregnant women
- rubella immunization of pregnant women should not ordinarily be a reason to consider interruption of pregnancy.

Continued surveillance in the USA (data collected through the Vaccine in Pregnancy Registry) has not shown evidence that RA 27/3 rubella vaccine, administered during pregnancy, can cause the congenital rubella syndrome (136).

Susceptibility Factors

Measles

Persons who have experienced anaphylactic reactions to measles vaccine or neomycin (measles vaccine contains a small amount of neomycin) should not be immunized (137).

Replication of the measles vaccine virus may be potentiated in patients with immune deficiencies and by the suppressed immune responses that occur with leukemia, lymphoma or generalized malignancy, or during therapy with corticosteroids, alkylating drugs, antimetabolites or radiation; such patients should not be immunized (4).

Of 176 high-risk children with pre-existing damage to the central nervous system who were immunized to protect them against measles during an outbreak, only four developed adverse effects after immunization (convulsions, transient electroencephalographic changes) (138). Comparing the risks of immunization and of natural disease, the authors recommended measles immunization of neurologically high-risk children when an epidemic occurs.

Originally, the Committee on Infectious Diseases of the American Academy of Pediatrics and the Advisory Committee on Immunization Practices (ACIP) recommended that severely immunocompromised patients with HIV infection should not receive measles vaccine (139). However, in 1988, recognizing the severity of measles in immunodeficient individuals, it revised its measles immunization guidelines and recommended that

© 2006 Elsevier B.V. All rights reserved.

children with asymptomatic HIV infection should be immunized and that immunization should be considered for symptomatic HIV-infected children (140). Health authorities in many countries have made similar recommendations. Since then, many HIV-infected children have been safely immunized, and the ACIP recommendation has been expanded to all age groups of HIV-infected persons.

Measles–mumps–rubella

Immunocompromise is a contraindication to the use of live virus vaccines, such as measles, mumps, rubella, and oral poliomyelitis vaccine. It is recommended that rubella or MMR vaccine should not be given to persons who are immunosuppressed because of AIDS or other clinical manifestations of HIV infection. The vaccine can be given to asymptomatic infected people (139).

Drug Administration

Drug additives

There has been a report of an allergic reaction after MMR vaccine (141). The author concluded that gelatin seems to be far more often the cause of allergic reactions to MMR vaccine than egg allergy. In vaccinees who receive DTaP vaccine (some brands contain gelatin) before MMR vaccine, the prior injection of gelatin-containing DTaP may be the cause of sensitization to gelatin and the subsequent reaction to other gelatin-containing vaccines.

Mebendazole and flubendazole

See also Benzimidazoles

General Information

Mebendazole, a benzimidazole, is poorly absorbed from the gut, although it dependably enters cyst fluid; it is therefore most useful for treating intestinal infections and cyst-forming infestations. It is essentially an antihelminthic drug, being effective against hookworm, ascariasis, enterobiasis, and trichuriasis. Mebendazole is effective against enteric *Strongyloides* but since it is not absorbed it is ineffective against tissue forms (1). However, it is also effective against *Giardia lamblia*, while *Trichomonas vaginalis* is susceptible in vitro. Mebendazole does not interfere with the normal intestinal flora.

Mebendazole has been assessed in a range of doses and durations of treatment. The most usual dose is 100 mg bd for 3 days; absorption is minimal, but there is considerable variation in plasma concentrations; the half-life is 2–9 hours. Much higher doses, up to 60 mg/kg/day, have been used in inoperable cases of cystic echinococcosis infestation, and then unwanted effects are more common.

Flubendazole is an analogue of mebendazole used in intestinal helminthiasis and hydatid disease. In trials of two-dose oral treatment for intestinal helminthiasis, reactions were mild and uncommon. They consisted of nausea, abdominal pain, dyspepsia, and sleepiness (SEDA-6, 281). Subsequent field experience has not suggested that flubendazole differs appreciably from other members of the class as regards adverse effects.

Comparative studies

Echinococcosis

The use of albendazole and mebendazole in patients with hydatidosis has been evaluated in 448 patients with *Echinococcus granulosis* hydatid cysts who received continuous treatment with albendazole 10–12 mg/kg/day for 3–6 months daily orally in a total dose of (323 patients) twice or mebendazole 50 mg/kg/day (2). At the end of treatment, 82% of the cysts treated with albendazole and 56% of the cysts treated with mebendazole showed degenerative changes. During long-term follow-up 25% of these cysts showed relapse, which took place within 2 years in 78% of cases. Further treatment with albendazole induced degenerative changes in over 90% of the relapsed cysts, without induction of more frequent or more severe adverse effects, as observed during the first treatment period. Adverse effects during the first treatment period consisted of raised transaminases with albendazole (67 of 323 patients) and mebendazole (16 of 125 patients), and abdominal pain in 12 and 11% respectively. With both drugs, occasional patients experienced headache, abdominal distension, vertigo, urticaria, jaundice, thrombocytopenia, fever, or dyspepsia, but most of these are known manifestations of echinococcus infection. Six of 323 patients taking albendazole withdrew because of adverse effects compared with eight of 125 patients taking mebendazole. It appears that albendazole is more effective than mebendazole in the treatment of hydatid cysts caused by *E. granulosis* and that both the intensity and the frequency of the usually mild adverse effects are comparable.

In 78 patients with hydatid disease there was a low recurrence rate of hydatid disease (below 3%) after a postoperative prophylactic course of mebendazole 20 mg/kg/day in three divided doses for 3 months (3). The only adverse effect of mebendazole was excessive loss of hair in two women. The unusual low recurrence rate of hydatid disease after treatment with mebendazole in this study was subsequently questioned and attributed to meticulously careful surgical procedures, with avoidance of spillage of hydatid fluid and complete removal of parasitic components (4).

General adverse effects

With normal doses (100 mg bd for 3 days) very slight headache, dizziness, and nausea or diarrhea are common; in principle allergy can occur. Mild and reversible rises in transaminases can occur and need to be followed, but even in high doses withdrawal is justified in only a few patients (5). Neutropenia has been noted and can be severe and persistent. High doses (up to 50–60 mg/kg) can also cause alopecia and cough. Mebendazole has been associated with extra-intestinal migration of *Ascaris* in heavily infected patients. Apart from the poor therapeutic response obtained in some 25% of cases, drug toxicity (especially at high prolonged dosage) has led to withdrawal in a small proportion of patients. Adverse effects severe enough to lead to withdrawal have included worsening of pre-existing hyperlipidemia (type IV), progressive uremia, and a marked rise in liver enzymes (6). One individual developed a rash accompanied by a striking rise in serum transaminases, which recurred on subsequent re-exposure (7). Experience in the treatment of *Echinococcus multilocularis* infection is similar. One patient with fatal agranulocytosis also had severe, probably unrelated, liver disease (SEDA-8, 292). Some 3–4% develop fever, which can be persistent and accompanied by respiratory symptoms and eosinophilia. Other adverse effects include pain over the site of the cyst, allergic reactions, alopecia, glomerulonephritis, and rashes.

Various authors have reported spontaneous rupture of hydatid cysts with mebendazole, and this is probably more frequent than in untreated individuals. Pleural and peritoneal cysts are more likely to rupture.

Evidence of teratogenicity in rats has not been accompanied by reports that it causes harm in human pregnancy, but the WHO recommends avoidance during the first trimester. It is not known if mebendazole enters the breast milk; no adverse effects have been reported but the issue has not been specifically studied.

Organs and Systems

Liver

All benzimidazoles can cause mild and reversible rises in transaminases, but even in high doses withdrawal is justified in only a few patients (5).

Granulomatous hepatitis with eosinophilia has been attributed with mebendazole (8).

- A 52-year-old man with ascariasis took two 3-day cycles of mebendazole 100 mg bd with a 2-week interval. Within 48 hours of the second course he developed fever (39°C), diarrhea, anorexia, and prostration. Ten days later he had tender hepatomegaly. His liver function tests were abnormal (aspartate transaminase 466 IU/l, alanine transaminase 458 IU/l). The serum alkaline phosphatase and bilirubin were normal and the gamma-glutamyl transferase mildly raised. The white blood cell count was 12.7×10^9/l with 18% eosinophils. Coagulation was normal. Tests for Hepatitis A, B, and C, cytomegalovirus, and Epstein–Barr virus were all negative. Serum ACE was not raised. Antimitochondrial antibodies were negative but antinuclear antibodies (1:60) and antibodies against smooth muscle (1:160) were positive. Extensive tests to exclude other causes of granulomatous hepatitis were all negative. A liver biopsy showed multiple granulomata consisting of epithelioid cells, multinucleated giant cells, plasma cells, and lymphocytes. There was slight fibrosis around the granulomata. There was no evidence of cholestasis. No helminthic ova were found. Ziehl-Nielsen and periodic acid Schiff stains were both negative. After 2 days the fever had subsided without treatment and he felt better. The serum transaminases returned to normal over the next 10 weeks and the eosinophilia disappeared.

Liver damage has been described after treatment with most benzimidazoles, but it is usually cholestatic. The liver damage described in this case was granulomatous. Liver damage after mebendazole in the low dose used in this case is rare, probably because of its poor absorption.

© 2006 Elsevier B.V. All rights reserved.

It is more frequent, although still rare, in the higher doses used in the treatment of human echinococcosis.

Urinary tract

Glomerulonephritis has been observed in five patients from Kenya (9).

Skin

Two cases of exfoliative dermatitis occurred in a total of 131 patients treated (9). In one Indian case, a fixed drug eruption was attributed to the drug (10) and other forms of rash have been seen.

An outbreak of Stevens–Johnson syndrome has been reported in 52 Filipino overseas contract workers (aged 20–30 years, 50 women) working in China who used mebendazole for helminthic prophylaxis (11). All took mebendazole at least once after the appearance of rashes and fever. Three women eventually died, primarily due to septicemia.

Susceptibility Factors

Age

Children aged under 2 years who are infected with helminths are currently excluded from treatment with mebendazole and other antihelminthic drugs on the basis of the manufacturer's instructions. In a double-blind, randomized trial in Tanzania 212 children aged under 2 years were given a total of 653 antihelminthic treatments (317 mebendazole 500 mg; 336 placebo) (12). There were no significant differences in adverse events in the two groups. In the light of the potential nutritional benefit achieved by regular deworming in this age group, the policy that excludes children aged under 2 years from treatment should probably be reconsidered.

Mebeverine

General Information

Mebeverine is an antispasmodic drug that is claimed to act directly on the colonic muscle and is virtually free of systemic adverse reactions. It has been used to treat irritable bowel syndrome, but its therapeutic effect is poor.

The effectiveness and safety of two formulations of mebeverine hydrochloride (200 mg capsules bd and 135 mg tablets tds) in 213 patients with irritable bowel syndrome have been studied in a randomized, double-blind, general practice study lasting 8 weeks (1). The two formulations were equally effective in relieving abdominal pain. The frequencies of reported adverse events were similar in the two groups and were considered unlikely to be related to the medication.

A meta-analysis of 23 randomized clinical trials assessing the efficacy and tolerance of smooth muscle relaxants in irritable bowel syndrome has shown that these drugs are superior to placebo (2). Six drugs were analysed: cimetropium bromide (five trials), hyoscine butyl bromide (three trials), mebeverine (five trials), otilium bromide (four trials), pinaverium bromide (two trials), and trimebutine (four trials). There was no overall significant difference in the frequency of adverse effects compared with placebo.

Organs and Systems

Gastrointestinal

A case of colonic perforation was described in 1990, but the patient concerned was suffering from the distal intestinal syndrome of cystic fibrosis and may have been at particular risk (SEDA-16, 428).

Mebhydrolin

See also Antihistamines

General Information

Mebhydrolin is an antihistamine, an ethylenediamine derivative, with antimuscarinic and sedative properties.

Organs and Systems

Hematologic

Cases of agranulocytosis have been attributed to mebhydrolin (1).

Skin

Exacerbation of psoriasis has been attributed to mebhydrolin (2).

References

Meclozine

General Information

Meclozine is an antihistamine, a piperazine derivative, with antimuscarinic and moderate sedative properties.

Organs and Systems

Psychological, psychiatric

Loss of memory, confusion, and disorientation has been ascribed to meclozine in an 85-year-old woman (SEDA-13, 132).

Second-Generation Effects

Teratogenicity

Delivery outcome in 16 536 women who had used meclozine in early pregnancy was compared with 540 660 women (1). Maternal diagnoses of pre-eclampsia or diabetes were less frequent when the woman had used meclozine. The twinning rate was increased and preterm births, low birth weights, short body lengths, and small head circumferences were less frequent after meclozine as were congenital malformations.

Medroxyprogesterone

General Information

Other information on medroxyprogesterone will be found in other monographs that deal with progestogens:

- Hormonal contraceptives—intracervical and intravaginal
- Hormonal contraceptives—oral
- Hormonal contraceptives—progestogen implants Hormonal contraceptives—progestogen injections
- Hormone replacement therapy—estrogens + progestogens
- Progestogens.

Medroxyprogesterone acetate is given in a relatively high dose for hormonal contraception and acts primarily by inhibiting ovulation. However, as with the other progestogen-only contraceptives, other mechanisms probably play a very significant role. It is extremely effective, with less than one pregnancy per 100 woman-years.

Depot medroxyprogesterone acetate is by far the most widely used formulation of this compound; the World Health Organization's assessment of it in 1983 (1) remains valid, as confirmed by later studies and reviews (2–4). By 1994 it was estimated that the drug had been used by 30 million women in more than 90 countries, and at the turn of the century it continues to be used on a large scale.

In addition to its use as a contraceptive, medroxyprogesterone acetate has also been used to treat benign prostatic hyperplasia, in which intermediate doses (for example 150 mg) are used (5), and to stimulate the appetite in patients receiving palliative care for cancer, although little published work can be found to support the latter indication.

General adverse effects

Reports on adverse reactions to lower doses of medroxyprogesterone acetate are not entirely consistent, probably because of differences in pharmaceutical formulation which markedly affect the drug's systemic availability. However, high doses of medroxyprogesterone acetate are extensively used for the treatment of hormone-dependent carcinomas (notably of the breast) and marked adverse effects occur consistently under these conditions (SEDA-12, 343). Such doses are likely to bring out the

© 2006 Elsevier B.V. All rights reserved.

compound's glucocorticoid potency. At a dose of some 800 mg/day, effects are likely to include excessive weight gain (in 4090% of cases), Cushingoid facies (10–20%), worsening of diabetes mellitus (up to 8%), edema (10–20%), and other effects suggestive of Cushing's syndrome. The changes are especially marked in women treated for more than 5 weeks; effects are less severe at lower doses. Smaller numbers of patients can develop rash, thromboembolism, dysuria, nervousness, headache, or nausea and vomiting.

In a condition such as benign prostatic hyperplasia, common complications are reduced libido, a reduced volume of ejaculate, and impotence; within 3 days of starting treatment, serum testosterone can reach castration concentrations.

The contraceptive efficacy of depot medroxyprogesterone acetate does not appear to be affected by interactions with other drugs; some interactions are known (6), but the doses used for contraceptive purposes are sufficient to remain effective even if metabolism is increased, for example by aminoglutethimide or phenytoin.

Organs and Systems

Cardiovascular

To date medroxyprogesterone does not seem to have been associated with thrombosis, but an authoritative review has pointed out that this remains a possible risk (7).

Medroxyprogesterone has been reported to have variable effects on blood pressure. In some studies it had no effect on blood pressure at all (8) or reduced diastolic pressure slightly (9). In 24 women (21 normotensive and three hypertensive) aged 16–35 years who received injections of medroxyprogesterone acetate 150 mg for contraception mean blood pressure fell from 124/79 to 120/75 mmHg; the change was attributable to effects in the women with hypertension (10).

Nervous system

For women with epilepsy, depot medroxyprogesterone acetate is a particularly useful contraceptive method, because it reduces seizure frequency (11). The dosage is so high that reduced efficacy due to enzyme-inducing anti-epileptic medication is not an issue. As with other hormonal contraceptives, some women tend to have headaches and mood changes.

Psychological, psychiatric

Mental or personality changes, a typical glucocorticoid effect, have been reported to be more severe and more frequent with combined aminoglutethimide plus medroxyprogesterone acetate treatment than with monotherapy in patients with bone metastases from breast cancer. The increased frequency of depressive syndromes on the two-drug therapy could not be attributed to the physical adverse effects of the combination, since the mental disorders appeared only during the first weeks of treatment, whereas the Cushingoid features did not become apparent until some 6–8 weeks of treatment had been given (12).

Endocrine

Medroxyprogesterone, while suppressing spermatogenesis, also depresses release of growth hormone induced by insulin or arginine (13).

Medroxyprogesterone reportedly increases basal growth hormone concentrations (14).

Metabolism

Treatment with low-dose medroxyprogesterone acetate (50 and 150 mg/day) for endometriosis reduces HDL cholesterol (15) confined to the HDL2 subfraction, which was lowered by as much as 58% after 24 weeks of treatment; the effect was clearly dose-related in the therapeutic dosage range.

A multicenter study of lipid metabolism conducted by the WHO showed considerable differences in serum lipids and apolipoproteins among the centers, with overall small falls in HDL cholesterol and increases in LDL concentrations (16).

In undernourished lactating women in one developing country, metabolic effects were more pronounced than among healthy users (17); serum cholesterol concentrations were somewhat higher with medroxyprogesterone during their first 6 months of lactation, but there were no alterations in glucose tolerance, serum triglycerides, or total protein concentrations during 1 year of treatment.

There is a disputed effect on carbohydrate metabolism, but it is at most mild and there is certainly no precipitation of diabetes in healthy women. Carbohydrate metabolism was unaffected by medroxyprogesterone in one study in which there was modest impairment of glucose tolerance among users of levonorgestrel-containing, low-dose combined oral contraceptives and progestogen-only tablets (18).

Depot medroxyprogesterone acetate contraception is widely used by women of the Navajo tribe of American Indians, and they constitute a high-risk population for diabetes mellitus. However, medroxyprogesterone can cause weight gain and independently reduce sensitivity to insulin, which would be particularly undesirable in such women. Contraceptive use has been studied in 284 Navajo women with diabetes and 570 non-diabetic controls. Users of depot medroxyprogesterone were more likely to develop diabetes than those who had used combination estrogen + progestogen oral contraception only (OR = 3.8; 95% CI = 1.8, 7.9). The excess risk persisted after adjustment for body mass index and it became more pronounced with longer use (19).

Metabolic effects seen when the drug is used in high doses for other purposes (notably the treatment of breast and endometrial cancer) are unlikely to be seen in contraceptive use. This applies to the glucocorticoid potency that medroxyprogesterone undoubtedly possesses to some degree; at the higher doses adrenal suppression can be observed (20) but not at contraceptive doses (21).

Fluid balance

Medroxyprogesterone acetate has a degree of mineralocorticoid potency (22). However, in 10 patients with advanced hormone-sensitive and non-hormone sensitive tumors high-dose medroxyprogesterone acetate (over

© 2006 Elsevier B.V. All rights reserved.

500 mg/day) had no effects on body weight, lean body mass, blood pressure, plasma sodium concentration, urinary sodium excretion, or the exchangeable sodium pool (8).

Hematologic

Medroxyprogesterone acetate, administered either orally or by injection, has little or no effect on blood coagulation (23).

The suitability of medroxyprogesterone for women with sickle cell disease has been evaluated in a controlled crossover trial, which showed that both hematological and clinical parameters were improved (24).

Liver

No consistent effects of medroxyprogesterone acetate on liver function have been found, and primary biliary cirrhosis and chronic active hepatitis have appeared to improve during treatment (25).

Musculoskeletal

Subgroups of users of depot medroxyprogesterone acetate may have reduced spinal bone density, but this seems to be reversible after withdrawal, even after several years of drug exposure (26). Bone mineral density in one cross-sectional study was lower among users of depot medroxyprogesterone acetate, but withdrawal was followed by complete recovery of normal bone density (26). A current study in the USA is expected to provide further data on this matter in women who have used medroxyprogesterone acetate for as long as 10 years.

Reproductive system

Poor cycle control is a problem with medroxyprogesterone acetate. Most women using the product have at first either irregular or excessive bleeding and spotting or amenorrhea linked to endometrial atrophy (27); however, only one woman in a thousand bleeds sufficiently to warrant aggressive therapy, such as curettage. As the duration of use increases, amenorrhea becomes more common. Depot medroxyprogesterone acetate is associated with greater variability in menstrual patterns than other hormonal contraceptives (28,29). Bleeding/spotting episodes are infrequent but are prolonged when they occur, and the prevalence of amenorrhea increases over time to more than half of users after the first year. Under 10% of users have bleeding patterns defined as fully satisfactory and acceptable, compared with 85–90% of women not using contraception and the majority of women taking appropriate doses of oral contraceptives. However, with appropriate patient selection and counselling, many users view amenorrhea positively and are content to continue with the medroxyprogesterone. Indeed, because they are often amenorrheic, they may experience improvements in such menstrual cycle conditions as menorrhagia and dysmenorrhea and in iron deficiency anemia. Other potential benefits include reduction in the risk of pelvic inflammatory disease, improvement in sickle cell disease parameters, and lessened seizure frequency in women with epilepsy.

Other effects are generally less prevalent with progestogen-only contraceptives than with combined oral contraceptives because of the absence of an estrogen and a lower dose of the progestogen. Headache, breast tenderness, and less commonly nausea and dizziness have been reported by users of progestogen-only contraceptives, but it is not clear whether progestogen-only contraceptives actually play a causal role. Androgenic adverse effects, such as acne, hirsutism, and weight gain, occur, but rarely.

The reduced penetrability of cervical mucus, which contributes to the contraceptive effect, may well provide some small degree of protection against pelvic inflammatory disease. However, this effect is likely to be less than that exerted by combined oral contraceptives, since the expanded cervical ectropion found among combined oral contraceptive users is not present in users of progestogen-only contraceptives.

Immunologic

Anaphylactic reactions to medroxyprogesterone are very rare.

- A 40-year-old woman developed anaphylactic shock after receiving depot medroxyprogesterone acetate 150 mg intramuscularly (30). She was not taking any other medications, and there was no history of allergy to food or cosmetics. She responded fully to immediate resuscitation. She had another episode when she received another dose 12 weeks later.

Long-Term Effects

Tumorigenicity

The effects of depot medroxyprogesterone acetate on reproductive cancers appear to be similar to those of combined oral contraceptives. Most notably, despite initial concerns about breast cancer in beagle dogs that were given large doses of medroxyprogesterone, a pooled analysis of epidemiological studies concluded that women using medroxyprogesterone are not at increased risk of breast cancer (31). Furthermore, the risk did not increase with increasing duration of use. However, women who had begun use within the past 5 years had significantly increased risk, perhaps because of accelerated growth of pre-existing tumors or increased surveillance.

Another review, dating from 1994, concluded that depot medroxyprogesterone acetate has a protective effect against endometrial cancer that is at least as strong as for combined oral contraceptives, but that, based on the limited available evidence, there is no association with ovarian cancer (32). Regarding cervical neoplasia, studies of depot medroxyprogesterone acetate do not show a strong adverse effect, but as with combined oral contraceptives it is uncertain whether there is no association or a slightly increased risk (33).

Second-Generation Effects

Fertility

Return of fertility may be delayed for several months after withdrawal of medroxyprogesterone acetate. The length of the delay is not related to the duration of use. There is no evidence of permanent impairment of fertility (2,34).

© 2006 Elsevier B.V. All rights reserved.

Teratogenicity

If a breakthrough pregnancy occurs during the use of depot medroxyprogesterone acetate, the developing embryo and fetus will continue to be exposed to it for months, and an adverse effect cannot be entirely excluded, but little concrete information has emerged. Clitoral hypertrophy has been described in three infants exposed to medroxyprogesterone in utero. In view of the hormonal spectrum of medroxyprogesterone, this is a conceivable adverse effect, but there is no confirmation, nor is it clear whether the drug harms the fetus in any other way (25).

Lactation

Many studies have shown that lactation is not adversely affected by depot medroxyprogesterone acetate and that breast-milk production may even be increased (35). Because of the low binding affinity of medroxyprogesterone to sex hormone binding globulin, the concentration of steroids in the milk is close to that in the maternal plasma, unlike the 19-nortestosterone derivatives.

Children whose mothers used depot medroxyprogesterone acetate while breastfeeding have been followed up in Thailand for 17 years and in Chile for 4.5 years, with no documented effect on growth or development (36). In undernourished lactating women the metabolic effects seem to be more pronounced than among healthy users (17).

Susceptibility Factors

Depot medroxyprogesterone acetate should not be used in women with breast cancer, genital cancer, undiagnosed uterine bleeding, or suspected pregnancy (37), but these are merely logical precautions.

The only study of depot medroxyprogesterone acetate and HIV infection, conducted among Thai prostitutes, showed an increased risk after adjustment for other variables (38).

Drug Administration

Drug administration route

An injection of medroxyprogesterone acetate 150 mg provides contraception for some 3 months. Peak concentrations in the blood are reached on around the 10th day after injection, but the drug is still detectable in the blood at the 90th day, although with wide interindividual variation.

Mefenamic acid

See also Non-steroidal anti-inflammatory drugs

General Information

The NSAID mefenamic acid is an anthranilic acid derivative. It has been argued for more than a decade that, since there is a wide range of effective and less toxic drugs, there is no reason for continuing to prescribe mefenamic acid and related drugs (SEDA-5, 93). All the same, some of the figures have been disputed, and, strictly speaking, a comparative controlled study to estimate the incidence of the adverse effects of mefenamic acid is still needed. The main reasons for concern are particular effects that are unexpected of an NSAID, such as hemolytic anemia, and which may therefore take the user by surprise.

Organs and Systems

Nervous system

Epileptic seizures in overdosed patients may indicate a degree of nervous system toxicity. Convulsions in poisoned patients are reported to be more likely with mefenamic acid than with other compounds (1). Other nervous system reactions (such as headache) are less frequent than with the arylcarboxylic acid derivatives. Coma has also been described as a consequence of mefenamic acid overdosage (2).

Sensory systems

Hyperacusia, vertigo, and tinnitus have been described in one patient (SEDA-12, 90).

Hematologic

Several hematological disturbances have been reported, although their overall incidence is probably moderate. They include Coombs' positive hemolytic autoimmune anemia, leukopenia, thrombocytopenia, and agranulocytosis (SED-8, 223) (3–5) (SEDA-4, 68). Neutropenic reactions have also been described (6). Severe neutropenia developed simultaneously with non-oliguric renal insufficiency in two elderly hypothyroid women (7).

Gastrointestinal

Gastrotoxicity due to mefenamic acid is marked. Other than the common adverse effects (nausea, anorexia, vomiting, pain, diarrhea), acute peptic ulcer, intestinal hemorrhage, hematemesis, abdominal distension, and profuse steatorrhea (SEDA-2, 97) have been reported. Mefenamic acid, unlike other NSAIDs, can provoke enteritis and colitis in patients with no known predisposing factors (8). It accelerates bowel transit in healthy volunteers (SEDA-16, 112).

Esophageal injury is a rare adverse effect of NSAIDs. The published evidence comprises only a few specific studies and a small number of single case reports regarding various NSAIDs (SEDA-15, 92). A report of

© 2006 Elsevier B.V. All rights reserved.

esophageal ulceration associated with mefenamic acid capsules has been published (9).

- Five days before he presented with esophageal ulceration, a 35-year-old man took two capsules of mefenamic acid (total dose 500 mg) in bed with a small amount of water. The following morning he noted severe retrosternal pain, which persisted until he was seen 4 days later. Endoscopy showed a 3 cm esophageal ulcer near the aortic arch. Within a few days there was complete resolution of ulceration.

All NSAIDs should be taken while standing or sitting, rather than lying, and with about 200 ml of water.

Pancreas

Pancreatitis has been attributed to mefenamic acid (10).

Urinary tract

Mefenamic acid and other anthranilic acid derivatives are nephrotoxic. Many renal effects have been demonstrated in animals. Acute renal insufficiency, renal papillary necrosis, and non-oliguric renal insufficiency have been reported in man (11,12). Renal biopsies in renal insufficiency have shown interstitial nephritis, mesangial proliferation, and focal pedicle fusion, previously undescribed (13).

Skin

Fixed drug eruption has been described in two patients within hours of taking mefenamic acid (SEDA-12, 90). In another case, a multifocal fixed drug eruption mimicked erythema multiforme (14).

Pseudoporphyria is an infrequent adverse effect of some NSAIDs, including naproxen (SEDA-12, 87), nabumetone (SEDA-16, 111), and oxaprozin (SEDA-21, 106).

- A 22-year-old woman developed pseudoporphyria during long-term treatment with mefenamic acid for menstrual problems. After withdrawal of mefenamic acid, the skin lesions gradually disappeared, and at follow-up after 18 months she did not have any skin lesions and had minimal residual scarring (15).
- An unusual skin reaction characterized by widespread pruritic papules and nodules occurred in a 62-year-old-woman who had taken long-term mefenamic acid for arthritis. The histological findings were consistent with dermatitis herpetiformis, whereas direct immunofluorescence was suggestive of atypical bullous pemphigoid or linear IgA disease. The skin eruption responded to dapsone, but an increase in the dosage of mefenamic acid caused diarrhea and steatorrhea with IgA antigliadin antibodies. A lymphocyte stimulation test with mefenamic acid was positive. Mefenamic acid was withdrawn and all her symptoms disappeared within 2 weeks (16).

Sexual function

Although mefenamic acid can be used to relieve dysmenorrhea, it can delay menstruation for several days (17).

Immunologic

Asthma and anaphylactic shock are the most dangerous acute hypersensitivity reactions. There is cross-sensitivity with other NSAIDs (18). Rash, urticaria, and pruritus accompany more serious reactions.

Susceptibility Factors

Age

The dosage of mefenamic acid that is used in preterm infants to induce closure of patent ductus arteriosus must not exceed 2 mg/kg/day in three divided doses, to avoid the danger of renal insufficiency (SEDA-19, 97). The promotion of mefenamic acid in Pakistan for fever in children, as a drug of "unsurpassed efficacy compared to [paracetamol] in fever control" and "better tolerance", has been criticized by the Medical Lobby for Appropriate Marketing. In fact, there have been no controlled comparisons of mefenamic acid with a reference drug or placebo, and its safety and efficacy have not been established in children (SEDA-19, 97).

Drug Administration

Drug overdose

Mefenamic acid overdosage is characterized by nervous system symptoms, such as generalized seizures, agitation, and confusion, sometimes progressing to coma, gastrointestinal problems (bloody diarrhea, abdominal pain, and vomiting), and renal impairment (SEDA-13, 83) (SEDA-14, 95) (19).

Drug–Drug Interactions

Lithium

Mefenamic acid may have interacted with lithium in a patient with reduced renal function, causing acute symptoms of lithium toxicity (SEDA-13, 83).

Mefloquine

General Information

Mefloquine, a fluorinated derivative of 4-quinoline methanol, is a product of the US Army's antimalarial research program. It is active against chloroquine-resistant *Plasmodium falciparum*, and has an excellent schizonticidal effect in the blood in experimentally induced *Plasmodium vivax* infections in volunteers. It is not gametocidal. *P. vivax* infections can persist after successful treatment of the falciparum infection with other drugs; the fact that mefloquine is effective against both organisms is thus of practical importance (SEDA-13, 808).

Mefloquine is readily absorbed after oral administration; absorption is influenced by the formulation and is more rapid from an aqueous solution. Maximum serum concentrations occur after 1–4 hours. Absorption is reduced by diarrhea. The half-life varies considerably and has been variously reported to be 7–23 days, 15–30 days, and 8–18 days (SEDA-13, 808) (1), (SEDA-16, 308) (2). Plasma protein binding is high. Sick patients have a prolonged t_{max}.

Mefloquine has a high cure rate after a single dose of 750–1000 mg. The use of combinations of mefloquine with other antimalarial drugs has been advocated in order to reduce the development of resistance. Mefloquine is effective as a prophylactic. Using a weekly dosage schedule, a dose of 250 mg is appropriate in adults. Because early reports also suggested that the drug was without serious adverse effects, mefloquine became widely advocated by various advisory bodies for prophylactic use, starting a week before travel to an endemic area where chloroquine resistance is common, and continuing for 4 weeks after departure from the area (SEDA-16, 306). Regrettably, but as might have been expected, it has also been used for prophylaxis in areas where its use is unnecessary (SEDA-13, 808) (3–5).

Mefloquine remains useful in the treatment of uncomplicated malaria in areas of chloroquine resistance, but recommendations for mefloquine as prophylaxis in travellers are under constant review. In visitors to the Kruger National Park (South Africa), adverse effects were reported in 325 (25%) of 1300 subjects taking mefloquine; gastrointestinal and neuropsychiatric effects were dominant (6). Four subjects required hospital attention for particularly severe neuropsychiatric reactions and 53 changed from mefloquine prophylaxis because of adverse effects. However in the same study chloroquine + proguanil prophylaxis led to reported adverse effects in 720 (29%) of 2488 subjects: one had a convulsion and 69 altered their prophylaxis because of adverse events or the dosing schedule. In this population mefloquine was as well tolerated as chloroquine + proguanil prophylaxis in general terms. This is in contrast to previous studies, in which the use of mefloquine led to higher rates of intolerance and severe adverse effects.

Observational studies

Malaria prevention measures taken by 5626 returning North American and European travellers departing from Kenyan airports have been examined in a cross-sectional questionnaire study. Mefloquine (74%) and chloroquine and proguanil (15%) were the most common drugs used (7). There were adverse events in 20% of the travellers who took mefloquine and 16% of those who took chloroquine and proguanil. Neuropsychological adverse events were reported by 7.8% of those taking mefloquine and 1.9% of those taking chloroquine. Despite adverse events, adherence was better in the mefloquine group (95 versus 81%; OR = 0.25), which may have been due to a lower dosing frequency.

Comparative studies

Atovaquone + proguanil (250/100 mg/day; $n = 493$) and mefloquine (250 mg/week; $n = 483$) have been compared in non-immune subjects attending travel clinics in North America, Europe, and South Africa in a randomized, double-blind study (8). Adverse events were reported by an equivalent proportion of subjects who had taken either drug (71 versus 67%; difference 4.1%, 95% CI = 1.7, 9.9). Those who took atovaquone + proguanil had significantly fewer treatment-related neuropsychiatric adverse events (14 versus 29%), fewer adverse events of moderate

© 2006 Elsevier B.V. All rights reserved.

or severe intensity (10 versus 19%), and fewer adverse events that caused prophylaxis to be withdrawn (1.2 versus 5%), compared with those who took mefloquine. Adherence was better in the atovaquone + proguanil group, which may have been due to the shorter duration of post-travel dosing (1 week versus 4 weeks for mefloquine). There were no confirmed cases of malaria.

Mefloquine (125 or 250 mg/week; $n = 56$) has been compared with proguanil (100 or 200 mg/day; $n = 57$) for short-term (6 months) malaria chemoprophylaxis in Nigerians with sickle cell anemia in a non-blinded, randomized study (9). Efficacy was similar (89% for mefloquine and 82% for proguanil). Adverse events were reported by 32% of those who took proguanil and 20% of those who took mefloquine. Surprisingly, only 3.6% of the mefloquine group reported neuropsychiatric adverse events.

Single-dose pyrimethamine + sulfadoxine (25 mg/kg; $n = 54$) has been compared with mefloquine (15 mg/kg; $n = 48$) in the treatment of uncomplicated *P. falciparum* malaria in an unblinded, randomized study in 102 Malawi children (10). Immediate vomiting was more common in those who took mefloquine (eight cases) than in those who took pyrimethamine + sulfadoxine (one case), with comparable parasite failure rates at 14 days (20 and 22% respectively).

General adverse effects

Although mefloquine is generally well tolerated, particularly when used prophylactically, the list of adverse effects has grown with accumulated experience. With therapeutic doses (for example 750–1500 mg in adults; 20 mg/kg in children) adverse effects are usually mild, but with occasional severe neuropsychiatric derangement. The overall incidence of adverse effects is about the same as with chloroquine, about 40–50%. Events most commonly reported include nausea, diarrhea, abdominal pain, dizziness, strange dreams, and insomnia. Adverse effects are dose-related, with an increase in dizziness and gastrointestinal complaints and fatigue at higher doses. Extensive acute, subacute, and chronic studies of mefloquine in animals have shown that it is not phototoxic, like some of the quinolone-methanols studied, nor was it mutagenic, teratogenic, or carcinogenic in these studies (SEDA-13, 808).

The adverse effects of mefloquine have been extensively reviewed both for prophylaxis (when rare neuropsychiatric adverse effects make its use controversial) and in treatment doses, when it has been linked to an increased incidence of the postmalaria neurological syndrome. A retrospective review of 5120 Italian soldiers showed an overall chemoprophylaxis curtailment rate of less than 1%, which was not significantly different from the combination of chloroquine and proguanil (11). A semi-systematic review also suggested no significant difference in tolerability compared with other antimalarial drugs (12).

The frequency and spectrum of adverse events associated with mefloquine (750 and 500 mg 6 hours apart) has been assessed in 22 healthy volunteers who were monitored for 21 days after drug administration (13). More women than men reported severe adverse reactions. The most commonly reported adverse effects were vertigo (96%), nausea (82%), and headache (73%). The vertigo was severe (grade 3) in 73% and required bed rest and specific medication for 1–4 days. In most cases (17/22) the symptoms resolved within 3 weeks after drug administration. Biochemical and hematological measures stayed within the reference ranges, but there were significant rises in serum sodium, chloride, calcium, bilirubin, gammaglutamyl transpeptidase, and lactate dehydrogenase.

Organs and Systems

Cardiovascular

Sinus bradycardia was seen in 18% of patients taking mefloquine (SEDA-12, 693) (14), occurring some 4–7 days after administration; the bradycardia was asymptomatic and lasted about 3–4 days. Transient sinus arrhythmia was also reported, without a need for treatment (SEDA-12, 808). Asymptomatic dysrhythmias were also recorded in a dosage comparison trial (SEDA-16, 308).

Nervous system

Neurological and psychiatric reactions occur to such an extent, even during prophylactic use, that a general recommendation for the use of mefloquine as prophylaxis has been called into question (SEDA-20, 258), although disabling symptoms occur in under 1% of travellers (SEDA-21, 296). Headaches, dizziness, vertigo, and light-headedness are common (SEDA-12, 693) (14,15), (SEDA-16, 307), the incidence varying between 20 and 90%. Dizziness is to some extent dose-related (16,17). Tinnitus and vertigo are less frequent.

A so-called postmalaria neurological syndrome (convulsions, tremor, confusion) has been described in about 4–5% of patients treated for severe malaria tropica with mefloquine (SEDA-21, 296).

All reports have suggested that the neuropsychiatric reactions to mefloquine are transient. They may be precipitated by alcohol (18).

Penetration into the brain of the (+) enantiomer of mefloquine is much higher than that of the (–) enantiomer (19) whilst plasma concentrations are greater for the (–) enantiomer, potentially providing a way of minimizing neurological adverse effects, which are often significantly overstated (20), by using the less toxic enantiomer. However, chiral separation technology is not sufficiently well developed to be economically realistic for clinical practice in the foreseeable future.

Sensory systems

Three cases of previously healthy patients who developed persisting high-frequency sensorineural hearing loss and tinnitus whilst taking mefloquine have been reported (21).

Psychological, psychiatric

At first thought to occur only after therapeutic doses of mefloquine, it is now clear that neuropsychiatric reactions occur after prophylactic use as well. The incidence is estimated at about one in 13 000 with prophylactic use, but as high as one in 215 with therapeutic use (SEDA-17, 329). Combination with other drugs that affect the

© 2006 Elsevier B.V. All rights reserved.

nervous system can result in unpredictable reactions. The symptoms vary in type and severity: non-cooperation, disorientation, mental confusion, hallucinations, agitation, and impaired consciousness. An acute psychiatric syndrome with attempted suicide was reported in one case. A single dose can be all that is needed to evoke a mental reaction. Convulsions have been reported, with or without psychiatric symptoms; it seems that mefloquine can aggravate and perhaps even provoke latent epilepsy (SEDA-13, 809) (22), (SEDA-16, 307) (SEDA-17, 329).

- A severe psychiatric and neurological syndrome, with agitation, progressive delirium, and generalized rigors, was seen in a 47-year-old man after he had taken mefloquine 1500 mg over 24 hours (23).
- A 7-year-old Indian boy was diagnosed as having "cerebral malaria" and received quinine followed by mefloquine (dose not given) (24). He developed hallucinations and removed his clothes and danced. His symptoms resolved within 24 hours of stopping mefloquine. This case highlights the fact that mefloquine should not be given after quinine in cases of severe malaria.
- A 42-year-old man with no previous psychiatric history suddenly developed visual symptoms after the third dose (total dose 750 mg) of prophylactic mefloquine (25). The symptoms consisted of an impression of focusing on two different planes and of perceiving his surroundings as very far from him. They were associated with slurred speech and altered comprehension. They occurred daily, lasting up to an hour, for 6 months. He had previously taken a course of mefloquine for 7 weeks without any adverse events.
- A 52-year-old woman with no psychiatric history developed anxiety, paranoia, visual hallucinations, confusion, and depressive symptoms after 3 doses of prophylactic mefloquine (250 mg/week) (26). She had previously taken mefloquine prophylaxis intermittently for 4 years with no adverse events.

These case reports illustrate important neuropsychiatric adverse effects of mefloquine in individuals who had previously taken mefloquine safely and had no psychiatric history.

A postal survey of 5446 returning Danish travellers examined the adverse effects of unstated doses of mefloquine, chloroquine, and chloroquine plus proguanil for malaria prophylaxis (27). There were 4158 responses (76%); 1223 travellers took chloroquine, 1827 took chloroquine plus proguanil, and 809 took mefloquine. Overall, although chloroquine and chloroquine plus proguanil were associated with a large number of mild (mainly gastrointestinal) adverse effects, 30–50% had diarrhea and about 20% had nausea or abdominal pain. There was a significantly larger number of reported "unacceptable symptoms" (not defined) with mefloquine: 2.7%, 1.0%, and 0.6% for mefloquine, chloroquine, and chloroquine plus proguanil respectively. Most of the more serious adverse events were in those who took mefloquine. Compared with chloroquine alone the relative risk (95% CI) of "depression," experiencing "strange thoughts," or having altered spatial perception were 5.1 (2.7, 9.5), 6.4 (2.5, 16.1), and 3.0 (1.4, 6.2) respectively. There was also a higher incidence of depression in women than in men. The relative risk of hospital admission or early termination of travel possibly related to prophylaxis was higher with mefloquine than with either chloroquine or chloroquine plus proguanil; the relative risks (95% CI) were 162 (69, 498), 612 (169, 5054), and 261 (127, 649) respectively.

A postal survey of the incidence of psychiatric disturbances in 2500 returning Israeli travellers (28) showed that travellers with this class of adverse effects were more likely to have taken mefloquine than other antimalarial drugs. Of 117 travellers with psychiatric adverse effects, 115 had taken mefloquine compared with 948/1340 for the entire cohort. This was a retrospective postal study with a response rate of 54% (1340 out of 2500), and of those who responded 71% had taken mefloquine, 5% had taken chloroquine, and 24% had taken no prophylaxis. In this study 11% (117) of the respondents reported psychiatric disturbances, mainly sleep disturbance, fatigue, vivid dreams, or "lack of mood." Only 16 of the respondents had symptoms lasting 2 months or more. Those who had had a psychiatric disturbance were also more likely to have been female and to have taken recreational drug use.

Although the above studies were limited by retrospective design, their results are in broad agreement with the results of other studies over the past few years that indicate that women have a higher incidence of psychiatric adverse effects from mefloquine than men (29–32).

In a prospective, double-blind, randomized, placebo-controlled study in 119 healthy volunteers (mean age 35 years), who took either atovaquone 250 mg/day + chloroguanide 100 mg/day or mefloquine 250 mg/week, depression, anger, and fatigue occurred during the use of mefloquine but not atovaquone + chloroguanide (33).

Airline pilots should not take routine prophylaxis with mefloquine because of the small risk of neuropsychiatric reactions.

Endocrine

- A 30-year-old woman took mefloquine, 250 mg/week, and developed abdominal pain, palpitation, and tremor; thyroid function tests were abnormal; 1 month after withdrawal the tests had returned to normal (SEDA-18, 289).

Hematologic

- Agranulocytosis occurred in a 31-year-old man with *P. vivax* parasitemia given an initial dose of mefloquine followed by 500 mg 8 hours later (SEDA-16, 307).

There have been no other reports of hematological toxicity.

Gastrointestinal

Gastrointestinal complaints, such as nausea, vomiting, abdominal discomfort, and (usually mild) diarrhea, have been mentioned in most reports, the incidence being 10–25% (SED-12, 693) (14,15), (SEDA-16, 307). The frequency increases with higher doses, for example 25 instead of 15 mg/kg (17).

© 2006 Elsevier B.V. All rights reserved.

Liver

Acute fatty liver has recently been reported after malaria prophylaxis with mefloquine (34).

- A 46-year-old woman took five, weekly, doses of mefloquine 250 mg before discontinuing treatment because of neuropsychiatric and gastrointestinal symptoms. Over the next month she had watery diarrhea, 11 kg weight loss, dependent edema, and abdominal fullness. On examination the liver was substantially enlarged; ultrasound imaging showed massive hepatomegaly with diffuse high-grade steatosis. Serological investigations for infective and autoimmune causes were negative. Her symptoms abated with fluid, electrolyte, and albumin replacement. A fine-needle liver biopsy showed features of diffuse macrovesicular hepatic steatosis. Clinical and radiological changes subsided without sequelae.

Acute fatty liver in this case may have been an idiosyncratic adverse effect of mefloquine.

Raised transaminases (up to 20 times normal activities) have been seen in a man taking mefloquine prophylaxis; they resolved after withdrawal of mefloquine (35).

Skin

Maculopapular rash, urticaria, and itching have been reported; itching may be more common with mefloquine than with chloroquine. However, there are isolated case reports concerning more serious skin conditions: exfoliative dermatitis (36); cutaneous vasculitis (SEDA-17, 3) and a bilateral facial rash, comprising raised red lesions and flat bullae (SEDA-17, 329).

Mefloquine has been associated with erythema multiforme and its variants Stevens–Johnson syndrome (SEDA-16, 307), and toxic epidermal necrolysis (37).

It has tentatively been suggested that mefloquine can exacerbate psoriasis (as can other antimalarial drugs, such as quinidine, chloroquine, and proguanil) (38).

Skin reactions to mefloquine have been reviewed, in relation to 74 case reports published between 1983 and 1997 (39). Pruritus and maculopapular rash were the most common skin reactions: in some studies, their approximate frequency was 4–10% for pruritus and up to 30% for non-specific maculopapular rashes. Adverse effects less commonly associated with mefloquine included urticaria, facial lesions, and cutaneous vasculitis. There was one case of Stevens–Johnson syndrome and one fatal case of toxic epidermal necrolysis.

Long-Term Effects

Drug tolerance

Instances of mefloquine resistance were reported in Tanzania in 1983, in Thailand in 1989, and in Africa (Malawi) in 1991. Resistance to combinations of mefloquine with sulfadoxine and pyrimethamine was reported in 1985 (SEDA-13, 808) (40–44). The possibility of cross-resistance between mefloquine and halofantrine was raised in 1990 (SEDA-13, 808) (45). Currently there are extensive areas, including Thailand, Cambodia, Laos, Papua New Guinea, and Myanmar, where *P. falciparum* is resistant to mefloquine (46). High-dose mefloquine has been tried in areas with mefloquine-resistant *P. falciparum*; and a dose of 25 mg/kg is effective, even in a multidrug-resistant area.

Early laboratory studies suggested cross-resistance between mefloquine and halofantrine, but in a later rodent model cross-resistance was not absolute (SEDA-12, 700).

Second-Generation Effects

Pregnancy

A review of the use of mefloquine in pregnancy (47) did not suggest that mefloquine has a worse effect in pregnancy than other antimalarial drugs, such as chloroquine and pyrimethamine + sulfadoxine.

A 7-day quinine regimen (10 mg/kg salt, 8-hourly for 7 days) has been compared with oral mefloquine 25 mg/kg plus artesunate 4 mg/kg/day for 3 days in 108 women on the Thai-Burmese border (48). The mefloquine plus artesunate regimen was significantly more effective than quinine (day 63, cure rate 98 versus 67%). There were more episodes of dizziness (RR = 1.93; 95% CI = 1.14, 3.25) and tinnitus (RR = 3.93; 95% CI = 1.98, 7.80) with quinine, but no serious adverse events were attributable to either drug. There were also two mid-trimester abortions with mefloquine plus artesunate and none with quinine. There were no birth defects in either group. Although the numbers were very small, the authors concluded that despite a better parasitological cure rate, the increased risk of abortion associated with mefloquine in pregnancy precluded its routine use. Larger studies are needed to confirm this observation.

Teratogenicity

Mefloquine prophylaxis was studied in a group of 339 pregnant women on the Thai-Burmese border in a double-blind placebo-controlled trial. Infants in the mefloquine group had a lower mean birth weight; there was also a higher rate of stillbirths and congenital anomalies, though these differences were not statistically significant (49,50).

However, a further study of 208 pregnant women on the Thai-Burmese border showed a significantly increased incidence of still-births compared with 1565 women treated with other antimalarial drugs (51). Other adverse effects were no more common than with other antimalarial drugs. The study was performed during a period of emerging mefloquine-resistant malaria, and the findings may also reflect the effect of suboptimal malaria treatment.

In a postmarketing survey by Roche, spontaneous reports from 1267 women who had taken mefloquine during pregnancy showed that there was neither a specific pattern of malformations nor an overall increase in congenital malformations over the 4% prevalence observed among the general population (52). These data have been confirmed by a survey among 72 US Army soldiers who had taken mefloquine during pregnancy (53).

Susceptibility Factors

Sex

A study of the pharmacokinetics of oral mefloquine in 12 healthy adults (6 men, 6 women) over 10 weeks has given insights into sex differences in mefloquine pharmacokinetics (54). Five weekly doses of mefloquine 250 mg were given to healthy volunteers. After this, half the subjects took 5 weekly doses of mefloquine 125 mg and half continued to have 250 mg per week. By the second week, all the subjects had plasma mefloquine concentrations over 1.5 μmol/l (the effective prophylactic threshold), but it was only after the fourth dose that the trough concentrations reached this threshold. The women had significantly higher values of C_{oax} and $C_{min.ss}$ than the men. Although the dose of mefloquine was reduced to 125 mg, the plasma mefloquine concentration was maintained above 1.5 μmol/l in all subjects. In this small study, the most commonly reported adverse events were headache, insomnia, and vertigo, with most adverse events occurring between weeks 5 and 8, when plasma mefloquine concentrations were highest. Women had significantly more adverse events (number of days with adverse events/total number of days exposed 149/420) than men (43/420).

These results may explain why earlier studies in male military personnel failed to detect a higher proportion of neuropsychiatric problems with mefloquine compared with other prophylactic regimens.

Neuropsychiatric events have been extensively reviewed, but little is known about the sex-related incidence. Of 179 travellers (mean age 39 years) who took mefloquine for a 3-week prophylactic period before travelling, the women reported adverse events significantly more often than the men (55). There was an increase in fatigue exclusively in the women, especially in first-time users of mefloquine.

Drug Administration

Drug overdose

Mefloquine has a relatively wide therapeutic margin, but can cause predictable and sometimes long-lasting toxicity in overdose.

- Accidental ingestion of 5.25 g of mefloquine over 6 days by a 36-year-old woman caused vertigo, difficulty in visual accommodation, myalgia, hypotension, and tachycardia; most of the anomalies disappeared in 2 weeks (SEDA-16, 307).

Two case reports have described how the antifungal drug terbinafine (Lamasil) was confused with Lariam, leading to accidental mefloquine overdosage and neuropsychiatric adverse effects, including ataxia, high-frequency hearing loss, depression, and paresthesia (56).

Drug–Drug Interactions

Alcohol

One case history has suggested that the use of alcohol with mefloquine can precipitate a neuropsychiatric reaction (18).

Other antimalarial drugs

Mefloquine has been given in combination with other antimalarial drugs, with the aim of delaying drug resistance. Empirical combinations have been made with pyrimethamine and sulfa drugs. However, no drug has been proven to be synergistic with mefloquine, which, with its very long half-life, is difficult to match.

The chemotherapeutic response of *Plasmodium berghei* to various combinations of mefloquine with other drugs (sulfadoxine + pyrimethamine, primaquine, floxacrine) have shown that the desired effects are purely additive (SEDA-13, 809), so the adverse effects too are probably only those of the individual compounds. Adverse reactions occurred in 46% of 400 patients treated with Fanimef (mefloquine + pyrimethamine + sulfadoxine) (SEDA-12, 693). Of note were dizziness (29%), nausea (9.5%), vomiting (7.3%), weakness/lassitude (5.8%), abdominal discomfort or pain (5.5%), diarrhea (3.8%), pruritus (3.0%), insomnia (2.0%), and headache (2.0%).

The combination of mefloquine with artesunate improves tolerance to mefloquine and the therapeutic response is faster (SEDA-21, 296).

Rabies vaccine

Reports of a possible interaction between concurrent mefloquine administration and intradermal rabies immunization have not been substantiated. Four cases in which rabies vaccine and mefloquine were accidentally given concurrently all led to good antirabies antibody responses (57).

Valproate

Mefloquine has been reported to oppose the effect of valproate (58).

- A 20-year-old woman with bilateral myoclonus and generalized tonic–clonic seizures which had been controlled with valproic acid was given 2 prophylactic doses of mefloquine and developed generalized tonic–clonic seizures.

The authors suggested a causal relation to the administration of mefloquine.

Mefruside

See also Diuretics

General Information

Mefruside is a diuretic that is structurally related to furosemide, but with pharmacological actions more similar to those of the thiazide diuretics (SED-8, 488) (1). Its effects on serum lipids (SEDA-11, 196) and serum magnesium (SEDA-10, 188) are also similar to those of the thiazides.

Meglitinides

General Information

The meglitinides bind with high affinity to a site, distinct from the sulfonylurea receptor site, on the ATP-sensitive potassium channels in pancreatic beta cells and stimulate insulin secretion. After binding, the ATP-dependent potassium channels are closed, reducing potassium efflux and depolarizing the cell membrane. The meglitinides do not have to be internalized in the membrane, in contrast to the sulfonylureas. This may explain their rapid onset of the action and the end of that action when glucose concentrations are falling. MgADP potentiates the effect in beta cells but not in cardiac cells (1), which may explain the reduced cardiovascular adverse effects of repaglinide in vivo. Meglitinide-stimulated insulin secretion depends on the glucose concentration; insulin secretion is not stimulated in vitro or in fasted animals. Nateglinide (and perhaps repaglinide) reduces the secretion of glycated insulin, which has poor activity, from islet cells; this may contribute to its hypoglycemic action (2).

Repaglinide (rINN) is a carbamoylmethyl benzoic acid derivative, which contains the non-sulfonylurea moiety of glibenclamide, and nateglinide (rINN) is a phenylalanine derivative. Nateglinide acts more quickly than repaglinide, and both act more quickly than sulfonylureas, which stimulate insulin secretion independent of blood glucose concentrations (3). It has been stated (4) that earlier studies (SEDA-22, 478) (SEDA-23, 462) (5) showed that the efficacy in lowering HbA_{1c} is almost equivalent for sulfonylureas and repaglinide and is slightly lower for nateglinide. When a lunch-time meal was omitted (SEDA-23, 462) patients taking glibenclamide had the lowest blood glucose concentrations, often within the hypoglycemic range, in contrast to patients taking repaglinide. Both drugs can cause hypoglycemia.

© 2006 Elsevier B.V. All rights reserved.

Repaglinide has been reviewed (6–8). It stimulates glucose-dependent insulin secretion, amplifying insulin bursts without changing burst frequency, but it does not restore disrupted pulsatile secretion in type 2 diabetes (9). It is rapidly absorbed. It is metabolized by CYP3A4 in the liver and is 90% excreted in the feces. It has a half-life of 32 minutes. Its pharmacokinetics do not differ in young or older healthy persons (10). It can be given as monotherapy (11), and the effective dose is 0.5–8 mg/day, starting with 0.5 mg/day. It has to be given before each meal and can be adapted to irregular food intake or missed meals (12). When given preprandially it improves glucose control without increasing the risk of adverse effects (13). There were no differences in action in healthy younger or older volunteers (14). Repaglinide is short-acting and seems to be associated with significantly fewer episodes of serious hypoglycemia (15). In a short review of a number of clinical studies the following contraindications were reported (16):

- known hypersensitivity to repaglinide or one of the constituents of Novonorm®;
- type 1 diabetes;
- renal or hepatic impairment.

Observational studies

In eight patients with type 2 diabetes, nateglinide given 5 minutes before a meal reduced the postprandial blood glucose excursion by 64% (17). There were no attacks of hypoglycemia even with a dosage of 180 mg/day; other adverse effects were not mentioned.

Comparative studies

In 424 patients in a European multicenter, randomized, double-blind study for 1 year, two-thirds of the patients used repaglinide (0.5–4 mg tds) and the others glibenclamide (1.75–10.5 mg/day) (18). HbA_{1c} first fell but later increased. The same trends were seen in fasting blood glucose. There were no differences in hypoglycemia. A comparable American study of 576 patients (19) showed essentially the same result.

In a 14-week, double-blind, multicenter, randomized, parallel-group trial of repaglinide and glibenclamide in 118 patients with type 2 diabetes with borderline or poor control but still responsive to oral hypoglycemic drugs, HbA_{1c} fell at the same rate in both groups (20). The 2-hour postprandial blood glucose concentration was lower with repaglinide, but fasting and mean glucose concentrations did not differ. Repaglinide was associated with 20 hypoglycemic episodes in nine patients and glibenclamide with 15 episodes in nine patients. There were no serious adverse effects.

The effects of repaglinide and glibenclamide have been compared in 235 patients during Ramadan, when people eat two meals a day (21). Before Ramadan, they were adjusted to optimal treatment with thrice-daily repaglinide or once- or twice-daily glibenclamide. During Ramadan they took twice-daily repaglinide or glibenclamide. After Ramadan they continued to take the pre-Ramadan regimen for 4 weeks. Mid-day hypoglycemia (blood glucose below 4.5 mmol/l) occurred in 2.8% of those who took repaglinide and 7.9% of those who took glibenclamide. There were 19 events reported by 15 patients in the repaglinide group and 35 by 19 patients in the glibenclamide group. During Ramadan the numbers were nine events in seven patients and 12 events in nine patients respectively. Mean serum fructosamine concentrations fell by 17 and 7 μmol/l during Ramadan in those taking repaglinide and glibenclamide respectively.

Insulin lispro and repaglinide were given to seven patients with diabetes related to cystic fibrosis (22). They had normal fasting blood glucose and insulin concentrations, but postprandial glucose concentrations were substantially raised. Insulin lispro had a larger and more sustained effect in lowering postprandial glucose than repaglinide. However, the doses of lispro (0.1 U/kg) and repaglinide (1 mg) may not have been comparable.

Placebo-controlled studies

In a randomized, double-blind, placebo-controlled, multicenter study, 289 patients took nateglinide in doses of 30 mg ($n = 51$), 60 mg ($n = 58$), 120 mg ($n = 63$), and 180 mg ($n = 57$), or placebo ($n = 60$) before main meals (23). Meal-time insulin increased rapidly and meal-time glucose excursions were reduced. HbA_{1c} concentrations were significantly reduced after 12 weeks in those taking 60 mg and more. Fasting plasma glucose was only significantly reduced in those taking 120 mg. The drug was withdrawn in one patient taking 180 mg because of increased liver enzymes; at the next visit the enzymes were normal. There were mild symptoms of hypoglycemia, such as increased sweating, tremor, dizziness, weakness, and increased appetite. Blood glucose concentrations were between 2.7 and 3.3 mmol/l in three patients taking 120 mg/day.

Single doses of nateglinide 120 mg, repaglinide 0.5 and 2 mg, and placebo 10 minutes preprandially or 2 mg repaglinide 1 minute preprandially have been compared in 15 healthy volunteers (24). Nateglinide stimulated early insulin secretion more than repaglinide, and insulin concentrations returned more promptly to the preprandial values. The highest but slowest rise was seen with placebo. There were no episodes of hypoglycemia.

In a randomized, double-blind, placebo-controlled comparison of glibenclamide and nateglinide for 8 weeks in 152 patients, nateglinide produced higher postprandial insulin concentrations (25). Hypoglycemia and low blood glucose concentrations were more common with glibenclamide.

In a multicenter, double-blind, randomized, fixed-dose trial of placebo and repaglinide 1 mg and 4 mg for 24 weeks in 361 patients there were no episodes of severe hypoglycemia (26). Most patients withdrew from the placebo group because of hyperglycemia, hypoglycemia, erythematous rash, headache, diarrhea, fatigue, or abnormal vision. Adverse effects had about the same frequencies in the two groups.

Combinations of oral hypoglycemic drugs

The different mechanisms of action of the various classes of hypoglycemic drugs makes combined therapy feasible: the sulfonylureas and meglitinides stimulate insulin production by different mechanisms, the biguanides reduce glucose production by the liver and excretion from the

© 2006 Elsevier B.V. All rights reserved.

liver, acarbose reduces the absorption of glucose from the gut, and the thiazolidinediones reduce insulin resistance in fat. It is not necessary to wait until the maximal dose of one drug has been reached before starting another. However, sulfonylureas and meglitinides should no longer be used when endogenous insulin production is minimal. Combinations of insulin with sulfonylureas or meglitinides should only be used while the patient is changing to insulin, except when long-acting insulin is given at night in order to give the islets a rest and to stimulate daytime insulin secretion.

Large studies of the effects of lifestyle changes, the effects of drugs in preventing or postponing the complications of diabetes, or the usefulness of various combinations are regularly published. The different mechanisms of action of the various classes give different metabolic effects and different adverse effects profiles (27). Comparative costs of the various therapies in the USA have been presented (28).

This subject has been reviewed in relation to combined oral therapy. In a systematic review of 63 studies with a duration of at least 3 months and involving at least 10 patients at the end of the study, and in which HbA_{1c} was reported, five different classes of oral drugs were almost equally effective in lowering blood glucose concentrations (29). HbA_{1c} was reduced by about 1–2% in all cases. Combination therapy gave additive effects. However, long-term vascular risk reduction was demonstrated only with sulfonylureas and metformin.

The adverse effects of combined drug therapy are attributable to the adverse effects of the single drugs. Increased adverse effects or new adverse effects in patients taking combinations have not been reported.

Meglitinides + biguanides

Patients with type 2 diabetes, with unsatisfactory control after taking metformin for 6 months, were randomized to metformin alone, repaglinide alone, or metformin + repaglinide (each 27 patients) (30). Combined therapy reduced HbA_{1c} after 3 months by 1.4% and fasting glucose by 2.2 mmol/l. Repaglinide alone or in combination with metformin increased insulin concentrations. The most common adverse effects were hypoglycemia, diarrhea, and headache. Gastrointestinal adverse effects were common in those taking metformin alone and body weight increased in both groups taking repaglinide.

In 12 patients with type 2 diabetes, a combination of nateglinide 120 mg or placebo with metformin 500 mg before each meal on two separate days was well tolerated (31). One patient taking nateglinide had a headache. One patient was withdrawn because of a myocardial infarction and had multivessel coronary artery disease on catheterization.

In a prospective, randomized, double-blind, placebo-controlled study for 24 weeks, 701 patients took nateglinide 120 mg before the three main meals, or metformin 500 mg tds, or the combination of the two, or placebo (32). The most frequent adverse effect was hypoglycemia, and it was most common in the combination group. There were no differences between those who took nateglinide only or metformin only and there were no episodes of serious hypoglycemia. Diarrhea was more frequent in those taking metformin or the combination, but infection, nausea, headache, and abdominal pain were comparable in the two groups.

Of 82 patients insufficiently controlled by metformin, 27 continued to take metformin with placebo, 28 took titrated repaglinide with placebo, and 27 took metformin with titrated repaglinide for 4–5 months (33). There were no serious adverse effects. Nine patients taking metformin + repaglinide reported 30 hypoglycemic events and three patients taking repaglinide reported nine events.

Meglitinides + sulfonylureas

Glipizide, nateglinide, and their combination have been compared in a double-blind, randomized, placebo-controlled study in 20 patients with type 2 diabetes not requiring insulin (34). Before a standardized breakfast, they took glipizide 10 mg, nateglinide 120 mg, both, or placebo; 4 hours after the meal, blood glucose concentrations were significantly higher after nateglinide, but peak and integrated glucose concentrations did not differ. Integrated insulin concentrations were higher with glipizide. There were three episodes of hypoglycemia in the glipizide alone group and three in the combined group; three required treatment with glucose.

Meglitinides + thiazolidinediones

In 585 patients in a double-blind, randomized, placebo-controlled, multicenter study lasting 16 weeks nateglinide 40 mg tds alone, troglitazone 200 mg/day alone, and the combination were compared (35). The combination was most effective in lowering HbA_{1c}. The most frequent adverse effects were mild hypoglycemia, most often in the combination group. Three patients (two in the combination group and one in the troglitazone alone group) withdrew because of hypoglycemia. Most of the withdrawals were related to increased liver enzymes and weight gain, known adverse effects of troglitazone. Twelve patients withdrew because of predefined changes from baseline (transaminases more than 200% and alkaline phosphatase and bilirubin more than 100% over baseline); seven were taking troglitazone alone, four combined therapy, and one placebo.

In an open trial, 256 patients with type 2 diabetes with inadequate hypoglycemic control (HbA_{1c} over 7.0% during previous therapy) took repaglinide (0.5–4 mg at meals), troglitazone (200–600 mg/day), or a combination of the two for 22 weeks (36). Combination therapy was most effective. Repaglinide only was more effective than troglitazone only. Mean body weight increased in both groups. Serious adverse events were chest pain, cerebrovascular disorders, malignancies, dysrhythmias, electrocardiographic changes suggesting myocardial infarction, and increased aspartate transaminase activity (in one patient taking troglitazone). The serious adverse effects were similar in the different groups. Hypoglycemia occurred in 4% of the patients taking combined therapy, in 16% of those taking troglitazone only, and in 27% of those taking repaglinide only; none needed assistance. There were changes in liver function tests in three patients in the combined group and in one patient each in the two other groups; the drugs were withdrawn in the

© 2006 Elsevier B.V. All rights reserved.

affected patients and liver function normalized. There were no differences in adverse effects in the different groups. Hypoglycemia occurred in 11 patients taking repaglinide, in seven taking combination therapy, and in one taking troglitazone. Anemia occurred in four patients taking combined therapy and in two taking troglitazone only.

Insulin + meglitinides

In 80 patients taking metformin 850 or 1000 mg tds plus NPH insulin at bedtime, metformin was withdrawn and repaglinide 4 mg tds added in half of the patients for 16 weeks (37). In the repaglinide group the dose of insulin increased slightly and weight gain was 1.8 kg more. Mild hypoglycemia occurred more often in the metformin group; nightly episodes of hypoglycemia occurred only with repaglinide. One patient taking repaglinide had a myocardial infarction, and one had three separate hospitalizations for chest pain (myocardial infarction was excluded). No specific data were presented about gastrointestinal adverse effects or infections.

General adverse effects

The most frequent adverse effect of meglitinides is hypoglycemia. The overall incidence of hypoglycemia with repaglinide is similar to that reported with sulfonylureas, but the incidence of serious hypoglycemia is lower. Other adverse effects are respiratory tract infections and headache. Cardiovascular events and cardiovascular mortality are not different from those in users of sulfonylureas. In Europe, repaglinide is contraindicated in patients with severe liver dysfunction and it is not recommended in people over 75 years old; in America the advice is to use repaglinide cautiously in patients with impaired liver function and there is no restriction on its use in elderly patients. In renal impairment, the half-life of repaglinide is prolonged. Reasons for withdrawal are hyperglycemia, hypoglycemia, and myocardial infarction (38).

Organs and Systems

Metabolism

Repaglinide has a short duration of action and improves postprandial hyperglycemia, a potential risk factor for cardiovascular changes (39). In a double-blind, multiple-dose, parallel-group study repaglinide stimulated mealtime insulin secretion (40). Bouts of hypoglycemia were equally frequent with placebo and repaglinide. When repaglinide was added to NPH monotherapy in patients with HbA_{1c} over 7.1% for 3 months, 38% of the patients had an HbA_{1c} below 7.1% (41). The incidence of hypoglycemia did not change.

When glipizide was compared with repaglinide in 75 patients there were no major hypoglycemic events; minor events were the same in both groups, but after the start of therapy the events occurred much later with repaglinide than glipizide (42).

The effect of a missed meal during repaglinide and glibenclamide therapy has been compared in 83 randomized patients (43). During two meals there were six separate hypoglycemic events in those taking glibenclamide. Blood glucose fell from 4.3 mmol/l to 3.4 mmol/l in those taking glibenclamide when lunch was omitted. There were no changes in blood glucose in those taking repaglinide.

Factitious hypoglycemia has been attributed to repaglinide in an 18-year-old man who had bouts of hypoglycemia for 2 months (44). After glucose administration he recovered promptly and was sent home, but the next night his glucose was 1 mmol/l with high concentrations of insulin (395 pmol/l), C-peptide (2966 pmol/l), and proinsulin (81 pmol/l). The plasma concentrations of repaglinide in three specimens were 4.8–21 ng/ml. Metformin was below the detection limit. He finally admitted to taking repaglinide 4 mg regularly.

Immunologic

- A 62-year-old woman with type 2 diabetes, hypertension, and chronic hepatitis C virus infection developed palpable purpura over her legs and buttocks 3 weeks after starting to take repaglinide 500 mg qds (45). The purpura ulcerated and became infected. Repaglinide was withdrawn and the purpura resolved. A biopsy showed leukocytoclastic vasculitis.

Repaglinide, which is metabolized in the liver, is cleared more slowly in people with liver disease, and hepatitis C may have played a part in this case. Although hepatitis C can cause a leukocytoclastic vasculitis, the clinical correlation and the rapid disappearance of the purpura after the withdrawal of repaglinide makes it likely that this was an adverse effect of the drug. Caution with repaglinide in liver disease is important.

Susceptibility Factors

Renal disease

In renal impairment the half-life of repaglinide is prolonged. Patients with severe renal impairment (creatinine clearance 20–40 ml/minute) had excess accumulation of the drug after taking multiple doses for 5 days (46).

In 235 patients with normal renal function or moderate to severe renal impairment switched from their original therapy to repaglinide (titrated to 0.5–4 mg tds within 4 weeks and continued for 3 months), the number of episodes of hypoglycemia increased with increasing severity of renal impairment during the run-in period but not during treatment (47). The final dose tended to be lower in patients with severe renal impairment. Although the concentrations of repaglinide in the patients with renal impairment were higher, they did not exceed the effective concentrations in people without renal impairment.

Patients with mild to moderate impairment can be treated with repaglinide. However, patients with severe renal impairment have other problems, and it is wise not to use repaglinide in patients with severe renal disease, or at least to adjust the dosage (46).

Hepatic disease

The clearance of repaglinide is reduced and the half-life prolonged (2.5-fold) in patients with chronic liver disease (48).

© 2006 Elsevier B.V. All rights reserved.

Drug–Drug Interactions

Clarithromycin

Clarithromycin, an inhibitor of CYP3A4, increases the plasma concentrations and the effect of repaglinide; this can enhance the blood glucose lowering effect and increase the risk of hypoglycemia (49).

Gemfibrozil

In 12 healthy subjects gemfibrozil raised the AUC of repaglinide 8-fold and itraconazole raised it 1.4-fold; however, the combination increased it nearly 20-fold (50).

Ketoconazole

In healthy subjects, ketoconazole increased mean AUC of repaglinide by 15% and mean C_{max} by 7% (51).

Nifedipine

Concomitant treatment with the CYP3A4 substrate nifedipine altered the mean AUC and mean C_{max} of repaglinide by 11 and 3% respectively (51).

Oral contraceptives

Concomitant treatment with ethinylestradiol + levonorgestrel altered the mean AUC and mean C_{max} of repaglinide by 1 and 17% respectively (51).

Rifampicin

Rifampicin 600 mg reduced the AUC of repaglinide by 57% and shortened its half-life from 1.5 to 1.1 hours in nine healthy volunteers after 5 days (52). The effect may even be greater when rifampicin is used for a longer period. In another study in healthy volunteers, rifampicin reduced the mean AUC of repaglinide by 31% and the mean C_{max} by 26%.

Simvastatin

Concomitant treatment with the CYP3A4 substrate simvastatin altered the mean AUC and mean C_{max} of repaglinide by 2 and 27% respectively (51).

Melarsoprol

General Information

Melarsoprol is a trivalent arsenical with activity against East African and West African trypanosomiasis. It is the drug of choice in the case of *Trypanosoma rhodesiense* infection with nervous system involvement (stage II disease) and in stage I patients refractory or intolerant to suramin and pentamidine. Melarsoprol administered intravenously can cause a reactive encephalopathy, with a clinical picture consisting of high fever, headache, tremor, convulsions, and on occasion coma and death. The incidence of arsenic encephalopathy varies from 3 to 18% in various series (SEDA-12, 708) (1).

In a case-control study of physical growth, sexual maturity, and academic performance in 100 young subjects (aged 6–20 years) with and without a past history of sleeping sickness, melarsoprol-treated patients weighed less, were shorter, and had sexual maturity ratings significantly different from the corresponding controls (2).

The efficacy and safety of two regimens of melarsoprol have been compared in patients with nervous system involvement from *Trypanosoma brucei gambiense*: a conventional regimen lasting 26 days, starting at 1.2 mg/kg and rising to 3.6 mg/kg ($n = 259$), and a regimen of 2.2 mg/kg for 10 days ($n = 250$) (3). Parasitological cure

© 2006 Elsevier B.V. All rights reserved.

24 hours after treatment was 100% in both groups. Disappointingly, the rates of encephalopathy were no better (in fact marginally worse) with the new schedule, despite using 30% less drug overall, and there were six drug-related deaths in each arm. However, the new schedule is quicker and cheaper, and treatment deviations were significantly fewer in the new schedule arm. In a further detailed prospective study of the drug in eight patients with advanced leukaemia, three developed seizures attributable to the drug at doses broadly comparable to those used in trypanosomiasis.

In 42 patients with late-stage *Trypanosoma brucei gambiense* trypanosomiasis, who relapsed after initial treatment with melarsoprol, a sequential combination of intravenous eflornithine (100 mg/kg every 6 hours for 4 days) followed by three daily injections of melarsoprol (3.6 mg/kg, up to 180 mg) was used (4). They were followed for 24 months. In one case the administration of eflornithine had to be interrupted for 48 hours because of convulsions, but treatment was then resumed without recurrence. Other adverse effects during treatment were abdominal pain or vomiting ($n = 4$ each), diarrhea ($n = 1$), and loss of hearing ($n = 1$). Two patients died during treatment:

- A 37-year-old man died of an acute cholera-like syndrome, with severe diarrhea, vomiting, and dehydration, after the last dose of eflornithine but before receiving his first dose of melarsoprol;
- A 34-year-old man died of an unknown cause after having received all 16 doses of eflornithine as well as the first injection of melarsoprol.

In a randomized trial in 500 patients infected with *Trypanosoma brucei gambiense* treated with 10 daily consecutive doses of melarsoprol 2.2 mg/kg, the adverse effects were: encephalopathic syndrome 5.6%, death from encephalopathy 2.4%, polyneuropathy less than 1%, severe bullous dermatitis 1.2%, severe maculopapular rash 3.2%, severe pruritus 3.2% (5). Milder reactions were fever, headache, and diarrhea.

Organs and Systems

Nervous system

Melarsoprol given intravenously in patients with trypanosomiasis can cause a peripheral neuropathy within 2–5 weeks (SEDA-14, 243). It also causes a reactive arsenical encephalopathy in 3–5% of patients with trypanosomiasis (SEDA-13, 834) (6).

- Myalgia, distal paresthesia, and rapidly progressive weakness in all limbs developed in a young woman treated for 38 days with melarsoprol; there was massive distal Wallerian degeneration in the peripheral nerve, and abnormalities in the dorsal ganglia and spinal cord. Very high concentrations of arsenic were found in the spinal cord. All the findings were typical of toxic arsenic accumulation; in this case, renal dysfunction was probably at the root of the arsenic poisoning (SEDA-16, 316).

In patients with *Trypanosoma gambiense* sleeping sickness, the incidence of drug-induced encephalopathy was increased in patients with trypanosomes present in the nervous system, in patients with high CSF lymphocyte counts, and among those in whom no trypanosomes were found in either the blood or a lymph node aspirate. The authors of this report considered that aggressive therapeutic schemes may result in greater toxicity, especially in patients with impaired blood–brain barrier (SEDA-16, 316). Without data on dosage, renal function, and cerebral involvement before therapy it is impossible to assess this conclusion.

In a large-scale review it was estimated that encephalopathic syndromes occur in 5–10% of patients, and that 10–50% of these die as a result (7).

Encephalopathic syndromes complicating treatment of stage II human African trypanosomiasis with melarsoprol in 588 patients have been reviewed (8). The overall rate of encephalopathy was 5.8% and presented in three ways: coma, convulsions, and psychotic reactions. The overall death rate was 38%. Comatose patients had a death rate of 52% and were commonly co-infected with malaria (14/16). Symptoms during treatment of fever (RR = 11.5), headache (RR = 2.5), bullous eruptions (RR = 4.5), and systolic hypotension (RR = 2.6) were associated with an increased risk of encephalopathic syndromes, especially coma.

In 56 patients with African trypanosomiasis, one treated with melarsoprol (total dose 26 mg/kg) developed a reactive arsenical encephalopathy (9).

Melatonin

General Information

Melatonin (*N*-acetyl-5-methoxytryptamine) is a neurohormone secreted by the pineal gland from the amino acid precursor L-tryptophan. Its endogenous secretion is photosensitive and has a circadian rhythm—plasma melatonin concentrations are highest at night in both diurnal and nocturnal animals, and fall with age (1). The nocturnal melatonin peak coincides with a drop in body temperature and increased sleepiness in healthy humans. Oral melatonin has a short half-life (30–50 minutes) and extensive first-pass metabolism. Its clearance is reduced in severe liver disease (2).

Uses

Melatonin has been promoted as a treatment for conditions ranging from jet lag to cancer (1,3–5) and is sometimes used for sleep induction (1). Because melatonin is present in small amounts in some foods, it is licensed as a nutritional supplement in the USA.

General adverse effects

Acute exogenous administration of melatonin causes sedation, fatigue, self-reported vigor, confusion, and a reduction in body temperature in healthy subjects. The effects of chronic treatment have not been studied, and adverse effects have not been systematically reported.

Timing is critical for melatonin to be effective: if it is given at the wrong time for sleep disorders or jet lag, it can cause increased daytime sleepiness (5,6) and worsened mental performance (7). Drowsiness and a small fall in body temperature are commonly reported effects (8), particularly after daytime administration, when endogenous concentrations of melatonin are low.

Organs and Systems

Cardiovascular

There was an increase in blood pressure throughout 24 hours in a double-blind, placebo-controlled, crossover study in 47 hypertensive patients who were also taking nifedipine (9). This finding differs from other studies in which melatonin had a mild hypotensive effect (10) and may indicate an interaction between melatonin and nifedipine. Tachycardia, chest pain, and cardiac dysrhythmias have also been reported, although the relation to melatonin was not clearly established (5).

Nervous system

Four of six children with pre-existing severe neurological disorders had increased seizure activity within 2 weeks of starting oral melatonin 5 mg at bedtime (11). Seizure frequency returned to baseline after treatment was stopped, and increased again after rechallenge with melatonin 1 mg. A convulsion during melatonin treatment, which recurred when medication was continued, has been reported to the WHO database but not published (5). Headache, which recovered after melatonin was withdrawn, has also been reported in a few cases (5).

Dyskinesia and akathisia have been reported after withdrawal of long-term melatonin (12).

- A 22-year-old woman of Ashkenazi origin, with spastic diplegia resulting from cerebral palsy and severe mental retardation, had insomnia for 6 years. She had taken melatonin 5 mg each night at 8 p.m. for the past year, with a good response. However, 1 week after melatonin was stopped, because of repeated vomiting, she gradually developed involuntary lip-smacking movements and tongue protrusion, with extreme restlessness, moaning, and shouting. These symptoms continued for 2 weeks, accompanied by marked worsening of insomnia. She was restless, could not sit still, and was shouting, moaning, and grunting. Melatonin was reintroduced in gradually increasing doses, and 2 days after a dose of 5 mg was reached, the involuntary movements disappeared and her agitated state and insomnia improved. A month later, another episode of abdominal pain and vomiting made her discontinue melatonin again. Within 2 days she developed identical involuntary lip and tongue movements and akathisia. Melatonin 5 mg was re-administered and all her symptoms disappeared by the next day. No antiemetic drugs were given during these episodes.

This case raises an important question regarding the dopamine-blocking effect of melatonin. Like dopamine receptor antagonists, melatonin should be used with care, because of the risk of tardive dyskinesia, which has serious morbidity and a low remission rate. Melatonin should be used with special caution in patients with organic brain damage.

Sensory systems

- Loss of visual acuity, reduced color vision, and altered light adaptation developed in a 42-year-old woman 2 weeks after she started to take a high protein diet and melatonin 1 mg/day (13). She had also been taking sertraline for the past 4 years. Her vision improved within 2 months of stopping the melatonin and the high protein diet.

This patient's retinal melatonin concentration may have been boosted by increased serotonin (a melatonin precursor) from the effect of sertraline, the high protein intake, and the exogenous melatonin.

Retinal damage has been briefly reported as an adverse effect of melatonin (8).

Psychological, psychiatric

A severely depressed woman developed a mixed affective state after taking melatonin for 7 days in a clinical trial (14). Confusion, hallucinations, and paranoia temporally related to melatonin have also been described (5).

Endocrine

There was suppression of endogenous melatonin secretion in two of five patients with bipolar disorder after 12 weeks of treatment with high-dose melatonin (10 mg/day) (15).

© 2006 Elsevier B.V. All rights reserved.

Gynecomastia has been attributed to melatonin (8,16).

- A 56-year-old man complained of painful asymmetrical breast enlargement, gradually developing over 3 months (16). He had had amyotrophic lateral sclerosis for 3 years and had taken riluzole 50 mg bd for 2 years and melatonin for 1.5 years (1 mg/day during the first year then gradually increasing to 2 mg/day). He had bilateral painful gynecomastia and homogeneously enlarged breasts. There was no galactorrhea. There were no signs or symptoms of other endocrine dysfunction. Withdrawal of melatonin resulted in complete regression of the gynecomastia within a few weeks.

This is a warning against the uncontrolled use of apparently innocuous substances. The absence of adverse effects in healthy people taking melatonin for various reasons does not mean complete safety, particularly in people who are unwell.

Metabolism

Impaired insulin-dependent glucose utilization occurred in a double-blind study of postmenopausal women given melatonin 1 mg in the morning (17). The authors also cited isolated reports of increased blood glucose in healthy individuals and in two men with Parkinson's disease taking melatonin.

Liver

- Autoimmune hepatitis was diagnosed in a previously healthy, 39-year-old woman 4 weeks after she started to take melatonin 3 mg at bedtime (18).

It is unclear whether this was a direct hepatotoxic effect of melatonin (or a contaminant), or if hepatitis was caused indirectly by an immunomodulatory mechanism.

Skin

Vesicular plaques and erosions developed on the penis in two men after they took melatonin for jet lag: one man had two such episodes 4 months apart (19). The lesions resolved within 10 days without any sequelae, and recurred within 8 hours of rechallenge.

Reproductive system

Melatonin affects reproduction in seasonally breeding animals. In humans, findings of increased endogenous melatonin in hypogonadism and low concentrations in precocious puberty imply an interaction between melatonin and gonadotropins; however, data on the effects of exogenous melatonin are limited (1). In a randomized study in 16 women, melatonin enhanced LH and FSH responses to submaximal GnRH stimuli in the follicular but not the luteal phase of the menstrual cycle (20).

A very high dose of melatonin (300 mg) partially inhibited ovulation in healthy young women: norethisterone enhanced the effect (21).

Immunologic

There has been a single report of a subject in a controlled trial of melatonin who had difficulty in swallowing and breathing within 20 minutes of taking melatonin 0.5 mg. The symptoms resolved without treatment after 45 minutes and recurred in a milder form after rechallenge (22).

Long-Term Effects

Drug withdrawal

There was suppression of endogenous melatonin secretion in two of five patients with bipolar disorder after 12 weeks of treatment with high-dose melatonin (10 mg/day) (15). One woman developed an unentrained sleep–wake cycle after melatonin was withdrawn (not previously a feature of her illness), which persisted for several months.

Involuntary movements of the lip and tongue, restlessness, and insomnia developed twice when chronic melatonin therapy was abruptly withdrawn in a young woman with cerebral palsy: these symptoms resolved when melatonin was restarted, but did not recur with gradual withdrawal over 2 months (12). This again suggests that endogenous melatonin secretion is suppressed after chronic use.

Drug Administration

Drug contamination

The reliability and consistency of commercial melatonin has been questioned (3). One group analysed three commercial melatonin formulations and identified analogues of the contaminant of L-tryptophan compounds implicated in an epidemic of eosinophilia–myalgia syndrome in the 1980s (23). There have been no reports of this condition associated with melatonin consumption, but food supplements are not required to comply with the same manufacturing and monitoring quality control standards as drugs.

Drug overdose

Melatonin overdose has been reported in three patients, all of whom were also taking psychotropic drugs. Drug interactions with antidepressants may have played a part in the resulting symptoms, which were not reported in cancer trials using higher doses of melatonin (1).

- A 73-year-old woman developed an acute psychosis after taking melatonin 30 mg as well as her usual fluoxetine (24).
- A 14-year-old girl became drowsy and dizzy and complained of blurred vision after taking melatonin 24– 36 mg as well as her usual trazodone and paroxetine (25).
- A 66-year old man became lethargic, confused, and disoriented after taking melatonin 24 mg with his usual amitriptyline and chlordiazepoxide (26).

All three patients recovered fully within 24 hours without specific treatment.

© 2006 Elsevier B.V. All rights reserved.

Drug–Drug Interactions

SSRIs

Fluvoxamine increases the systemic availability of oral melatonin, probably by reducing its first-pass clearance (27). In a crossover study in seven healthy subjects, serum melatonin concentrations were increased by fluvoxamine but not citalopram (28). In another study fluoxetine, paroxetine, citalopram, imipramine, and desipramine did not affect the biotransformation of melatonin at therapeutic concentrations in vitro (29).

Warfarin

There have been several reports of altered prothrombin time in patients taking warfarin and melatonin. In some cases bleeding or purpura was the presenting symptom, despite a reduced prothrombin time (5).

Meliaceae

See also Herbal medicines

General Information

The genera in the family of Meliaceae (Table 1) include mangrove and different types of mahogany.

Azadirachta indica

Azadirachta indica (bead tree, pride of China, margosa, neem or nim tree, holy tree, indiar, lilac tree) contains a variety of steroids, sesquiterpenoids, ester terpenoids, tetranortriterpenoids, and triterpenoids.

Adverse effects

Margosa oil, a long-chain fatty acid that is extracted from the seeds of the neem tree, has been implicated as a

Melitracen

See also Tricyclic antidepressants

General Information

Melitracen is structurally and pharmacologically related to imipramine, with two methyl groups attached to the central ring. It has similar efficacy to amitriptyline, with a somewhat more rapid effect and similar adverse effects (1).

Reference

Meloxicam

See also Non-steroidal anti-inflammatory drugs

General Information

Meloxicam, a COX-2 inhibitor, has been marketed in some countries and promoted as having an improved safety profile over current NSAIDs. It has a long half-life, is highly protein-bound, is metabolized to inactive compounds, and is excreted in the urine and feces. Neither hepatic insufficiency nor moderate renal dysfunction affects its pharmacokinetics, but in one study meloxicam plasma concentrations were 26% higher in patients over 65 than in younger patients.

Changes have been made to the Summary of Product Characteristics by the manufacturers of meloxicam (1), in agreement with the type of adverse drug reaction reports received by the Committee on Safety of Medicine in the UK. Warnings about gastrointestinal reactions (perforation, ulceration, and/or bleeding) and skin reactions (including erythema multiforme and Stevens–Johnson syndrome) have been strengthened (2).

Organs and Systems

Nervous system

About 7% of patients have dizziness and headache (3).

Gastrointestinal

Gastrointestinal adverse effects were the most frequently reported (in about 15–20% of patients), but their incidence was lower with meloxicam than with piroxicam, naproxen, and diclofenac in long-term double-blind studies. They were more frequent with a dosage of 15 mg/day than with 7.5 mg/day, were judged to be severe in 1.7%, and led to withdrawal in about 4% of patients. The most frequent symptoms were abdominal pain, dyspepsia, eructation, nausea, and vomiting. Upper gastrointestinal perforation, ulceration, and bleeding occurred rarely with meloxicam; the incidence was dose related and lower than with the comparators (4,5). A double-blind endoscopic microbleeding comparison of meloxicam and piroxicam in healthy volunteers showed better gastrointestinal tolerability with meloxicam. Fecal blood loss and endoscopy scores were higher in piroxicam-treated patients, and six piroxicam volunteers versus one treated with meloxicam withdrew because of severe gastrointestinal toxicity; colitis was reported in one case (6). In a few patients meloxicam suppositories can cause abdominal pain and rectal bleeding.

A large prospective comparison of meloxicam 7.5 mg/day with piroxicam 20 mg/day for a median of 28 days suggested that meloxicam has a lower propensity to cause gastroduodenal adverse events. However, serious gastrointestinal events (that is, ulceration, perforation, or bleeding), albeit rare, had similar frequencies in meloxicam and piroxicam recipients, and furthermore the difference in the incidence of adverse gastrointestinal events, although statistically significant, was clinically less relevant (7). Reports received by the Swedish Adverse Drug Reaction Advisory Committee (SADRAC) have suggested that meloxicam has a similar adverse drug reactions profile to other NSAIDs (8) and reports of gastrointestinal hemorrhage have started to appear (9).

Colitis has been described as an adverse effect of meloxicam (SEDA-20, 94).

- Ischemic colitis occurred in a 49-year-old woman 10 days after she started to take meloxicam 15 mg/day for osteoarthritis; meloxicam was withdrawn and her symptoms completely resolved within 1 week (10).

© 2006 Elsevier B.V. All rights reserved.

Although meloxicam is considered to be a preferential COX-2 inhibitor, its safety profile is not much different from other traditional NSAIDs, especially in high doses (11).

Liver

Acute cytolytic hepatitis has been described in a 46-year-old woman who took meloxicam for 4 days (12).

Urinary tract

Deterioration in renal function, reversible on withdrawal, was rare (0.4%) (3).

Skin

Rash, pruritus, and other skin problems occurred in about 6.5% of patients (3).

The manufacturers of meloxicam have recently included a warning about the possible occurrence of life-threatening skin reactions in the Summary of Product Characteristics (SEDA-23, 120).

- Erythema multiforme has been reported in a 19-year-old man 8 days after he started to take meloxicam for tendonitis; withdrawal and therapy with corticosteroids resulted in complete recovery (13).

Immunologic

Meloxicam may be relatively safe when given to patients with NSAID-induced urticaria/angioedema (14,15). Of 148 NSAID-sensitive subjects with an unequivocal history of urticaria with or without angioedema, who were challenged with increasing oral doses of meloxicam (1–7 mg/day) in a single-blind placebo-controlled trial, only two had a positive test (urticaria in one and urticaria/angioedema in the other); both had chronic idiopathic urticaria (16).

Drug Administration

Drug administration route

Local tolerability with intramuscular administration is reportedly good (17). Serum creatine kinase activity can increase slightly. Gastrointestinal disorders, central nervous system adverse events, and skin rashes have been reported with intramuscular administration.

Drug–Drug Interactions

Methotrexate

In 13 patients with rheumatoid arthritis, oral meloxicam for 1 week had no effect on the pharmacokinetics of a single dose of intravenous methotrexate 15 mg (18).

Melphalan

See also Cytostatic and immunosuppressant drugs

General Information

Melphalan (L-phenylalanine mustard) is an alkylating agent that has been used to treat a wide variety of solid malignancies, including cancers of the breast and ovary, and multiple myeloma. Intravenous melphalan has been used to treat rhabdomyosarcoma, lymphomas, multiple myeloma, and neuroblastoma (1).

The adverse effects of high-dose intravenous melphalan have been reviewed (2). Two patients who received less than 100 mg/m^2 recovered from marrow aplasia within 3 weeks without major complications. A third patient died 6 days after injection of 290 mg/m^2, probably because of a cardiac dysrhythmia before complete marrow failure had become established. After intravenous administration of more than 125 mg/m^2, gastrointestinal adverse effects, such as hemorrhagic diarrhea, or bowel perforation, can occur. These, together with reduced ADH secretion and electrolyte disturbances are the predominant clinical problems and the reasons for early death before the occurrence of infectious or bleeding complications from prolonged marrow aplasia.

Organs and Systems

Respiratory

Melphalan can cause an acute interstitial pneumonia with hypoxemia (3). This is probably due to a hypersensitivity mechanism and should be distinguished from fibrosing pneumonitis, which melphalan can also cause (4).

Fatal pulmonary fibrosis and atypical epithelial proliferation has been reported in patients with multiple myeloma treated with melphalan (4).

Urinary tract

Acute renal insufficiency has been attributed to melphalan in a patient with third stage ovarian cancer (5).

Reproductive system

Primary ovarian failure has been recognized in adults after intermittent low-dose melphalan, and has also been reported in three adolescents after high-dose melphalan (6).

Drug–Drug Interactions

Busulfan

The possibility that melphalan and busulfan may cause additive lung damage has been discussed in the light of a 59-year-old patient with chronic myeloid leukemia who developed severe interstitial lung fibrosis after short-term sequential treatment with the two drugs (7).

Memantine

General Information

Memantine is an amantadine derivative that has been studied in patients with Parkinson's disease. Its adverse effects include agitation, restlessness, insomnia, pronounced delirious states, and muscular hypotonia. All were reversible after dosage reduction or withdrawal.

Organs and Systems

Psychological, psychiatric

A toxic psychosis was reported in two patients taking memantine (1).

Meningococcal vaccine

See also Vaccines

General Information

Meningococcal vaccines have been comprehensively reviewed, distinguishing conventional polysaccharide vaccines, non-polysaccharide group B meningococcal vaccines, and conjugated meningococcal vaccines (1).

Reports of clinical trials in children, adults, and asplenic individuals have been provided (2) and surveyed (SEDA-11, 288) (SEDA-16, 379) (SEDA-17, 370) (SED-12, 813).

Polysaccharide vaccines

Polysaccharide meningococcal vaccines in various combinations against meningococcal disease caused by meningococci of groups A, C, W135, and Y have been commercially available for many years. Studies mostly using a bivalent serogroup A + C vaccine carried out in about 15 countries, including some millions of people, have shown efficacy of 61–99%. Meningococcal group A vaccine is more immunogenic than group C vaccine in infants and small children. However, infants below 6 months of age produce a weak response, and meningococcal group C vaccine should not be used before the age of 2 years. Meningococcal group B polysaccharide vaccine is poorly immunogenic in humans and is therefore not available commercially.

Adverse reactions are infrequent and mild, consisting of local soreness or localized erythema at the injection site, and systemic reactions (transient fever, headache, fatigue), lasting 1–2 days (3,4). With the quadrivalent vaccine used in Canada, fever was reported in less than 1%, local reactions in 6.3%, and rash in 1.6% among those aged 11 years or older. Local reactions were also the most reported adverse effect in other reports.

Non-polysaccharide group B meningococcal vaccines

Considering the poor immunogenicity of polysaccharide group B vaccines, different vaccines have been developed—a Norwegian outer membrane complex group B vaccine and a Cuban vaccine in which the group C polysaccharide is added to a mixture of high molecular weight B outer membrane proteins and proteoliposomes. Both vaccines have been used in clinical trials, mainly in Latin America, but more conclusive studies with these two products are awaited. Adverse reactions with the Cuban vaccine have been studied. Among 16 700 vaccinees, mostly older than 4 years, local reactions were observed in 62%, and systemic reactions in 4.3%.

From studies in 370 infants and children and 171 adults aged 18–30 years, who received three doses of outer membrane protein meningococcal vaccine developed in either Cuba or Norway or a control vaccine (Hib vaccine), the vaccines are promising candidates for the control of epidemics caused by homologous epidemic strains (5). However, the vaccines would not confer protection during a heterologous epidemic. All vaccinees had more pain, induration, and erythema at the injection site than did Hib vaccine recipients; there were no serious adverse events, and 95% of individuals who reported symptoms said that the symptoms did not interfere with their normal activities.

A genetically engineered vaccine containing six meningococcal class I (PorA) outer membrane proteins, representing 80% of group B meningococcal strains prevalent in the UK, has been assessed in 103 infants who received the vaccine at ages 2, 3, and 4 months with routine infant immunization, and a fourth dose at 12–18 months (6). The vaccine was well tolerated, and after the fourth dose there were larger bactericidal responses to all six strains.

Conjugated meningococcal vaccines

Success with the protein-conjugate formulations of *Hemophilus influenzae* vaccines has facilitated research and development on conjugated meningococcal vaccines with preference for monovalent group C or bivalent group A/group C vaccines. Conjugated meningococcal vaccines of serogroup C made by various manufacturers were first licensed in 1999 in the UK and then (at the end of 2000) in many other countries, including some other member states of the European Union (Belgium, Germany, Greece, Luxembourg, Ireland, Portugal, Spain).

Field trials in the UK and the Gambia have shown immunogenicity not only in adults but also in toddlers and even infants. Except for local tenderness in 30–75% of vaccinees, no conjugate vaccine evaluated to date has been associated with significant adverse effects (1).

Vaccine containing oligosaccharides derived from group C meningococcal capsular polysaccharide coupled to CRM197, a non-toxic mutant diphtheria toxin (manufactured by Wyeth Lederle Vaccines and Pediatrics, Pearl River, NY) was given to 114 infants at 2, 3, and 4 months of age; 57 received a vaccine containing 2 μg of oligosaccharide and 5 μg of CRM197, and 57 received a vaccine containing 10 μg of oligosaccharide and 25 μg of CRM197 (7). The infants received DTP and Hib vaccine at the same time. In each group, 25 infants received a polysaccharide vaccine booster at median age of 83 weeks. Antibody concentrations required for protection are estimated to be 1–2 μg/ml. All the infants achieved a concentration of 2 μg/ml by age 4 months after two doses of conjugated meningococcal vaccine, and concentrations of bactericidal antibodies were much higher than after meningococcal polysaccharide vaccines. Antibody concentrations fell significantly by age 14 months. After boosting with polysaccharide vaccine all the children achieved antibody concentrations over 2 μg/ml. Local and systemic reactions were rare after meningococcal conjugate vaccines and were significantly less common at the site of DTP/Hib immunization for all three doses. The high-dose cohort had more systemic reactions than the low-dose cohort (Table 1). One infant required hospitalization for a viral illness soon after the second injection.

The results of a randomized, double-blind trial of safety, immunogenicity, and induction of immunological memory in 182 healthy infants has been published (8). The infants received either conjugated meningococcal vaccine (conjugated to CRM197, a non-toxic mutant of diphtheria toxin) of lot 1 (60 infants) or lot 2 (60 infants) or hepatitis B vaccine as a control vaccine. Diphtheria and tetanus toxoids and whole cell pertussis (DTP) vaccine reconstituted with Hib-tetanus conjugate was co-administered in the other leg. Polio vaccine was given orally. According to the UK immunization schedule, these vaccines were given at 2, 3, and 4 months of age. At 12 months the children received either meningococcal A and C polysaccharide vaccine or conjugated meningococcal serogroup C vaccine. The conjugated meningococcal vaccines were

Table 1 Adverse effects of a conjugated meningococcal group C vaccine

Reaction	Conjugated meningococcal group C vaccine		DTP/Hib vaccine
	Low dose (2 μg/ml)	High dose (10 μg/ml)	
Erythema ≥2.5 cm	4/171 (2.3%)	5/173 (3.9%)	38/344 (12%)
Swelling ≥2.5 cm	2/171 (1.2%)	6/173 (3.5%)	64/344 (19%)
Fever ≥38°C for up to 3 days	7/171 (4.1%)	8/173 (4.6%)	No data
Systemic reactions in first 24 hours	26/171 (12%)	53/173 (31%)	No data
Crying for >1 hour in first 24 hours	3/156 (1.9%)	2/153 (1.3%)	No data

generally well tolerated and resulted in less tenderness and induration than the routine vaccines (DTP-Hib and hepatitis B) administered in the opposite leg. There was also no significant difference in systemic reactions between any of the vaccine groups. Parents of the children who received meningococcal polysaccharide vaccine as a booster dose reported significantly more local tenderness, general irritability, and change in eating habits than those whose children received conjugate meningococcal vaccine. There was also an increased use of antipyretic drugs in children who received the polysaccharide vaccine. There were no differences in rash, sleepiness, unusual crying, vomiting, or diarrhea. The immunological results suggested that the conjugated vaccines were highly immunogenic and able to induce both a primary response in infants and immunological memory.

A somewhat different conjugated meningococcal vaccine (purified group C meningococcal polysaccharide coupled to purified tetanus toxoid, manufactured by North American Vaccine, Columbia, Maryland, USA) has been evaluated in 30 healthy adults (9). One dose containing 10 micrograms of polysaccharide and 15.5 micrograms of tetanus toxoid was given intramuscularly. All the volunteers developed a four-fold or greater increase in serum bactericidal antibody to group C meningococcus. Most of the local and systemic reactions were mild (Table 2). The only significant local erythema and swelling (over 3 cm) was related to an injection site hematoma, which resolved rapidly.

The results of a phase 1 study in 30 children aged 12–23 months, who received two doses of tetravalent A-C-W135-Y conjugated meningococcal vaccines (conjugated to diphtheria toxoid), have been reported (10). Three different doses were used: 1, 4, and 10 micrograms/ml polysaccharide of each serogroup. The 4 micrograms/ml dose appeared to be immunologically optimal. No children had a temperature of over 39.9°C. Local reactions were reported in 40–60% of children after each injection, with no apparent relation to dose. None of these local reactions was severe. The investigators considered the results as being sufficiently promising for further evaluation of this vaccine in a larger trial in toddlers and infants.

Table 2 Adverse effects of a purified group C meningococcal polysaccharide coupled to purified tetanus toxoid

Reaction	Number ($n = 30$)
Tenderness	15
Erythema	15
Pain	15
Induration	8
Fever ≥38°C	1
Headache	2
Myalgia	1
Arthralgia	0

Combined meningococcal and typhoid fever vaccine

A combined meningococcal and typhoid vaccine (Mérieux) was evaluated in 158 volunteers in a single-blind study (11). Comparing the effects with those in vaccinees receiving monocomponent vaccines or the combination vaccine, there was no significant difference in the reported frequency or duration of local and systemic reactions. However, vaccinees who received the monocomponent typhoid fever vaccine alone were less likely to complain of swelling or pain at the injection site.

Organs and Systems

Nervous system

During an immunization campaign with a polysaccharide vaccine in 130 000 children in Auckland, New Zealand, there were 92 reports of apparent peripheral nerve involvement, including 80 reports of unexplained weakness and 57 reports of paresthesia or dysesthesia (12).

Acute disseminated encephalomyelitis has been reported 4 weeks after immunization with a polysaccharide meningococcal A + C vaccine in a 23-year-old woman; she recovered with glucocorticoid treatment (13).

During an efficacy trial using the Norwegian meningococcal group B vaccine carried out in Norwegian secondary schools from 1988 to 1991, seven of the reported events in vaccinees were classified as serious, among them one case was of acute transverse myelitis which was considered to be most probably a vaccine reaction. The remaining cases could have been triggered by the vaccine without being directly caused by the vaccine (14).

Data on adverse events reported to a passive provincial surveillance system have been evaluated after the mass immunization with a polysaccharide meningococcal vaccine of 1 198 751 people aged 6 months to 20 years in Quebec. A total of 118 reports of severe adverse events were selected. The most frequent were allergic reactions (9.2 per 100 000 doses), followed by few neurological reactions (0.5 per 100 000 doses) and very few anaphylactic reactions (0.1 per 100 000 doses). There were no reports of long-lasting sequelae or of encephalopathy, encephalitis, or meningitis (15).

© 2006 Elsevier B.V. All rights reserved.

Urinary tract

The possible risk of relapse of nephrotic syndrome after administration of meningococcal serogroup C conjugate vaccine to children has been discussed (16). In 106 children with nephrotic syndrome, there were 63 relapses during the 12-month period before immunization and 96 relapses during the equivalent 12-month period after meningococcal immunization. The increase was statistically significant and the risk was especially higher in the first 6 months after immunization. Regarding the possible pathogenesis of the increased rate of relapses the authors discussed the hypothesis that disturbance of cytokines by the conjugated vaccine might mediate the onset of proteinuria. This is the first report of possible serious adverse effects of conjugated meningococcal immunization; further studies are needed before a real risk can be confirmed.

Musculoskeletal

A polyarthropathy has been reported after the administration of a conjugated meningococcal serogroup C vaccine (17).

- A 17-year-old boy developed a widespread rash on his back and the left side of his chest and painful swelling of his left elbow, right knee, and left ankle 4 days after receiving meningococcal serogroup C vaccine. The detection of meningococcal DNA in fluid from his knee made it probable that the disease was due to natural meningococcal infection, as the meningococcal vaccine does not contain nucleic acid. As the serogroup C vaccine protects only against group C infections, natural meningococcal infection of other serogroups, particularly the commonest serogroup B, can still occur.

Menispermaceae

See also Herbal medicines

General Information

The genera in the family of Menispermaceae (Table 1) include chondrodendron and moonseed.

Stephania species

Various species of *Corydalis* (fumewort, Fumariaceae) and *Stephania* (Jin bu huan) contain tetrahydropalmatine (1), which is the active constituent in Chinese "Jin Bu Huan Anodyne" tablets, sold on the Western market. The package insert suggested that *Polygala chinensis* is the source plant, but in reality this alkaloid comes from a species of *Stephania*. Both l-tetrahydropalmatine and its racemic dl-form are used in Chinese medicine as analgesic and hypnotic agents.

Stephania has been adulterated with *Aristolochia* (2,3), and confusion is possible because of the similarity in their

Fibraurea (fibraurea)
Hyperbaena (hyperbaena)
Jateorhiza (jateorhiza)
Menispermum (moonseed)
Stephania

Chinese names: han fang ji (*Stephania*) and guang fang ji (*Aristolochia*).

Adverse effects

The reported adverse effects of Jin bu huan include vertigo, fatigue, nausea and drowsiness, which could make users unfit for driving. Life-threatening bradycardia and respiratory depression occur in small children after unintentional overdosage (4) and acute hepatitis in adults (5).

Nine adults acutely poisoned with tetrahydropalmatine recovered quickly after mild neurological disturbances; tetrahydropalmatine was metabolized rapidly and excreted as polar metabolites in the urine (6).

Menthol

General Information

Menthol is a cyclic alcohol obtained from the volatile oils of various species of *Mentha*. It occurs naturally as levomenthol (rINN), and racementhol (rINN) can be synthesized.

Menthol is largely used as a flavoring or olfactory agent in a variety of products, including cigarettes, liqueurs, cough drops, mouthwashes, toothpastes, and shampoos. Menthol has been used in different medications to relieve symptoms of asthma and rhinitis and is a constituent of cold remedies and ointments designed to be rubbed on to the chest or applied around and even into the nostrils. Applied to the skin, it acts as a rubefacient and counter-irritant, but substantial concentrations of volatile oil can be inhaled from the skin.

Organs and Systems

Respiratory

In young children, menthol can induce reflex apnea or laryngospasm and application of the compound to the nostrils can result in instant collapse. There have been reports of a relation between menthol in toothpaste and worsening of asthma in some patients, most of them sensitive to aspirin (1,2). Cases of menthol-induced asthma are almost always associated with sensitivity to aspirin (3), but an exception has been reported (4).

- A 40-year-old woman with no personal or family history of asthma had dyspnea, wheezing, and nasal symptoms for 2 years whenever she used toothpaste and/or ingested mint confections. She had no history of aspirin sensitivity, and a challenge test with a menthol solution diluted in alcohol ruled out any possibility that the asthma had been caused by preservatives, dyes, or other additives.

Hematologic

Blood dyscrasias have been attributed to menthol (5).

Skin

There have been reports of perioral dermatitis, urticaria, and stomatitis due to menthol (1,6).

Immunologic

Hypersensitivity reactions to menthol are well recognized and comprise urticaria and flushing. Twelve cases of contact sensitivity to the flavoring agents menthol and peppermint oil were reported in patients presenting with intra-oral symptoms in association with burning mouth syndrome, recurrent oral ulceration, or a lichenoid reaction (6). Nine patients were followed up and six of these described resolution or improvement of their symptoms as a result of avoiding menthol and peppermint.

Drug Administration

Drug overdose

Overdose of menthol, particularly over long periods, can occur with overuse of mentholated cigarettes. Inhalation can result in ataxia, confusion, euphoria, nystagmus, and diplopia (7).

Mepacrine

General Information

Following the administration of mepacrine in normal doses, adverse effects are usually limited to gastrointestinal upsets, with nausea and sometimes vomiting. Yellow discoloration of the skin and conjunctivae is common, but is usually considered more of a cosmetic problem. The aplastic anemia seen with the use of mepacrine may be caused by a hypersensitivity reaction.

Organs and Systems

Cardiovascular

Mepacrine inhibits phospholipase A2 and subsequently leukotrienes, which are calcium ionophores. Mepacrine also has an inhibitory effect on phospholipase C and subsequent inositol phosphate formation, which mobilizes cytosolic calcium from intracellular stores. It has therefore been suggested that this might influence myocardial contractile function (SEDA-13, 241). However, mepacrine is not cardiotoxic, although problems could arise in the presence of a "sick" myocardium.

Nervous system

Headache and dizziness are not uncommon with ordinary doses of mepacrine and after transcervical administration for sterilization (1).

Signs of central nervous system excitation, including convulsions, have been seen with the use of large parenteral doses of mepacrine in the treatment of malignancies (SEDA-11, 592).

Sensory systems

Yellow discoloration of the conjunctivae and sclerae can occur in patients taking mepacrine. The corneal deposits and mild diffuse cornea edema, which can cause blurring of vision, are reversible.

There have been occasional reports of retinopathy resembling that seen with chloroquine (SEDA-11, 593) (2). However, as a rule mepacrine is non-toxic to the retina (SEDA-14, 241).

Psychological, psychiatric

Acute psychosis has been seen with the use of large parenteral doses of mepacrine in the treatment of malignancies (SEDA-11, 592).

- An acute transient psychosis (screaming, kicking, and hallucinations) was seen in an 11-year-old boy after 5 days' treatment with quinacrine 100 mg tds for *Giardia lamblia* infestation. Recovery occurred after withdrawal (SEDA-16, 309).

Hematologic

Mepacrine used in the prophylaxis of malaria can cause aplastic anemia. The incidence among soldiers during World War II was 2.84 per 100 000 compared with 0.66 per 100 000 in controls. A skin rash or lichenoid eruption often preceded the blood dyscrasia (SEDA-11, 593).

- Aplastic anemia has been reported in a 28-year-old woman given mepacrine for several months for the treatment of lupus erythematosus (SEDA-16, 309).

Liver

Rare cases of hepatitis and even hepatic necrosis have been reported in patients taking mepacrine (SEDA-11, 593).

Skin

Mepacrine causes a marked yellow discoloration of the skin and often also the conjunctivae. This is often combined with a blue–black discoloration of the palate and a curious discoloration of the nails, which can be brownish-black, yellowish-green, or sometimes white fluorescent in appearance. This phenomenon is related to the cumulative dose, though it is occasionally also seen with short-term use. The discoloration disappears after withdrawal. Mepacrine-induced discoloration shows up under Wood's lamp as a brilliant yellow–green fluorescence of the nails and palms of the hands and also of the urine.

Skin changes attributed to mepacrine include lichen planus nodules, wart-like growths, erosions, and ulcerations (3).

In allied soldiers during World War II, the most common adverse effect of mepacrine was a drug eruption, tropical lichenoid dermatitis, which sometimes led to permanent sequelae at an early stage (4). Late sequelae occurred 7–17 years after the war, and malignancies developed in two cases. Mepacrine can cause skin cancers as late as 34 years after administration.

A skin rash or lichenoid eruption often precedes mepacrine-induced aplastic anemia (5).

Sexual function

The local placing in the cornual portion of the fallopian tube of a 250 mg quinacrine pellet caused necrosis of the epithelial lining and an acute inflammatory reaction, with subsequent progressive fibrosis and occlusion of the lumen of the tube; in that particular study it was a desired effect (SEDA-16, 309).

© 2006 Elsevier B.V. All rights reserved.

Reproductive system

In three non-comparative phase I trials of transcervical administration of quinacrine pellets 250 mg in 21 women who were scheduled to undergo hysterectomy, five women reported pelvic/abdominal cramps (1).

Long-Term Effects

Tumorigenicity

The possibility of a relation of mepacrine to the incidence of squamous cell carcinoma was suspected in Australian ex-servicemen, but causality is not clear (SEDA-13, 818) (SEDA-14, 241). Extensive sun exposure could have been a factor, and that would explain the difference in findings around the world.

Smoking

Antimalarial drugs (chloroquine, hydroxychloroquine, or quinacrine) were given to 36 patients with cutaneous lupus, of whom 17 were smokers and 19 non-smokers (6). The median number of cigarettes smoked was one pack/day, with a median duration of 12.5 years. There was a reduction in the efficacy of antimalarial therapy in the smokers. Patients with cutaneous lupus should therefore be encouraged to stop smoking and consideration may be given to increasing the doses of antimalarial drugs in smokers with refractory cutaneous lupus before starting a cytotoxic agent.

Mepenzolate bromide

General Information

The 25-mg dose of the anticholinergic drug mepenzolate bromide, often given several times a day for gastrointestinal disorders, is sufficient to cause anticholinergic adverse effects, but the compound may itself be a cause of gastric pain, and one must hence realize the risk of creating a vicious circle (1).

Mepivacaine

See also Local anesthetics

General Information

Mepivacaine is an aminoamide local anesthetic. Systemic toxicity is its major complication and can prove fatal. Vasoconstrictors are not warranted, as they do not alter the rate of systemic reactions.

Organs and Systems

Cardiovascular

Severe bradypnea and bradycardia requiring external ventricular pacing occurred in a previously asymptomatic 30-year-old woman with a known cardiac conduction defect 85 minutes after a paracervical block with mepivacaine 400 mg (1). First-degree atrioventricular block has been reported (2).

Nervous system

Hyperbaric mepivacaine has also been implicated in causing transient radicular irritation after spinal anesthesia, of the same order of magnitude as lidocaine (3,4). Three cases of transient radicular irritation have been reported after spinal anesthesia with isobaric 2% mepivacaine (5).

Immunologic

An allergic reaction has been described in a patient given mepivacaine (6).

Susceptibility Factors

Renal disease

Mepivacaine toxicity has been studied in 10 patients with end-stage chronic renal insufficiency undergoing vascular access surgery (7). These patients represent a high-risk group for general anesthesia, as they often have concomitant coronary artery disease, hypertension, and diabetes. Brachial plexus block is often used: as well as avoiding systemic effects, it enhances regional blood flow.

Meptazinol

General Information

Meptazinol is a centrally-acting opioid analgesic with an affinity for $OP_3(\mu)$ receptors (1). Common adverse effects are typically opioid in character; vomiting seems to be a problem and abdominal pain can occur in some patients. Euphoria and hallucinations are uncommon.

Organs and Systems

Respiratory

Clinically and statistically significant respiratory depression can occur within 1 minute of the start of a meptazinol infusion 1 mg/kg. Respiratory depression was less than after pethidine 1 mg/kg, but more than after 0.5 mg/kg (2). Other studies have confirmed these effects. In 49 patients who received either PCA with meptazinol (20 mg bolus, maximum 120 mg/hour) or morphine (2 mg bolus, maximum 12 mg/hour) after major orthopedic surgery, there was a tendency for more patients receiving meptazinol to have obstructive apnea and central apnea.

Drug Administration

Drug administration route

Prophylactic administration of intramuscular prochlorperazine 12.5 mg did not prevent meptazinol-induced emesis; in fact, the incidence of vomiting with this combination was twice the expected frequency; cyclizine was an effective antiemetic (3). Prolonged vomiting has followed the use of intravenous meptazinol 50 mg (4).

Mequitazine

See also Antihistamines

General Information

Mequitazine is a first-generation antihistamine (SED-13, 15) (SEDA-22, 179).

In a comparative study with placebo, there was no significant difference in the incidence of drowsiness, while dry mouth was reported in nine of 23 patients taking mequitazine compared with six of 25 taking placebo.

Organs and Systems

Nervous system

Mequitazine 10 mg, but not 5 mg, has central effects (1). Syncopal attacks occurred in a patient taking mequitazine plus spiramycin for 48 hours.

Sensory systems

Disturbance of accommodation was seen in three patients treated with mequitazine (2).

Liver

Liver damage has been attributed to mequitazine (3).

Mercaptamine

General Information

Mercaptamine (cysteamine), an aminothiol, is used to reduce tissue cystine content in patients with nephropathic cystinosis, an autosomal recessive lysosomal storage disorder in which intracellular cystine accumulates due to impaired transport out of lysosomes (1). The clinical manifestations include renal tubular Fanconi syndrome in the first year of life, with hypophosphatemic rickets, hypokalemia, polyuria, dehydration and acidosis, growth retardation, hypothyroidism, photophobia, renal glomerular deterioration by 10 years of age, and late complications such as myopathy, pancreatic insufficiency, and retinal blindness. The cystinosis gene, CTNS, codes for cystinosin, a 367 amino acid protein with seven transmembrane domains. More than 50 CTNS mutations have been identified, but about 50% of Northern European patients have a 57257-bp deletion which removes the first nine exons of CTNS. The mainstay of cystinosis therapy is oral mercaptamine, 60–90 mg/kg/day qds every 6 hours, and generally achieves about 90% depletion of cellular cystine, as measured in circulating leucocytes. This delays renal glomerular deterioration, enhancing growth, preventing hypothyroidism, and lowering muscle cystine content. In one study, for every month of treatment before 3 years of age, 14 months' worth of later renal function were preserved.

Mercaptamine is available for oral administration as hydrochloride and bitartrate salts and as sodium phosphomercaptamine. Topical mercaptamine prepared from the oral formulation has been used to treat severe photophobia from corneal crystal deposition in cystinosis (2).

- An 8-year-old boy with nephropathic cystinosis had debilitating and worsening photophobia from corneal crystal deposition (3). After 8 months of topical application of mercaptamine, he has marked improvement, both subjectively and objectively.

Mercaptamine has also been used to treat paracetamol overdose (4).

Adverse effects include lethargy, hyperthermia, and rash (5), and nausea and vomiting (6). The risk of vomiting correlates inversely with body weight (7).

Organs and Systems

Sensory systems

In 93 children with nephropathic cystinosis oral mercaptamine 51 mg/kg for up to 73 months produced 82% cystine depletion from leukocytes and improved creatinine clearance and growth (8). However, 14% of the patients could not tolerate the taste and smell of mercaptamine, which is excreted in the breath.

Hematologic

In a phase I trial myelosuppression was the main adverse effect of mercaptamine in five of 24 patients (9). One had grade 4 thrombocytopenia and two had grade 3 thrombocytopenia; anemia and leukopenia were milder (grade 1 to 2).

Gastrointestinal

In four children with nephropathic cystinosis receiving mercaptamine 14.35 mg/kg qds serum gastrin concentrations up to 90 minutes later rose as did gastric acid output (10). Two of the four subjects had visual and histological evidence of gastric inflammation. The clinical effect of this acid production is unknown.

Skin

Mercaptamine hydrochloride contained in "neutral" permanent-wave preparations has been used in American beauty salons since 1993 and can cause contact dermatitis (11).

- A hairdresser, allergic to mercaptamine hydrochloride, had positive patch-test reactions to mercaptamine hydrochloride, glyceryl thioglycolate, diglyceryl thioglycolate, and *p*-phenylenediamine.

There were negative results with mercaptamine hydrochloride (1.0% in petrolatum) in 64 controls. People whose hair had been waved with mercaptamine hydrochloride were not allergic.

Mercury and mercurial salts

General Information

Mercury is a silver-colored metallic element in fluid form (symbol Hg; atomic no. 80). Its symbol derives from the Greek name for the element hydrargyros. It is found as the sulfide salt in cinnabar, the source of the pigment vermilion.

With a few exceptions, the use of metallic mercury in medicine is considered to be outdated; the few exceptions include its use in certain preservatives and in dental amalgam. The radioactive nuclides ^{197}Hg and ^{203}Hg have been used diagnostically, but the amount of mercury involved is very small. Even the mercury thermometer is rapidly being replaced by safer alternative devices. The use of mercury in dermatological therapy should be abandoned because of the risk of mercury intoxication (1).

Aryl mercurials that have been used medicinally include phenylmercuric acetate, phenylmercuric nitrate, nitromersol, thiomersal, merbromin (mercurochrome), and mercurobutol. These compounds are variously used as preservatives in drugs, including vaccines, for skin disinfestation, the treatment of infections of the skin and mucosa, and in contraceptive jellies and hemorrhoidal remedies; they have also been used in some cosmetics. The aryl mercurials are better absorbed across the mucous membranes than most inorganic mercury salts.

Regrettably, some therapeutic exposure to mercury continues, more particularly generally outside the Western world. Non-prescription laxatives containing mercurial compounds are still sold in some countries. The presence of mercury may not always be divulged on the label. Mercury poisoning can also occur through consumption of fish that have swum in waters that have been contaminated with methyl mercury from industrial waste (Minamata disease) (2). When it was first described, in May 1956, the marine products in Minamata Bay contained high concentrations of mercury (6–36 ppm). Mercury was also found in the hair of patients, their families, and the inhabitants of the Shiranui Sea coastline (maximum 705 ppm). Typical symptoms include sensory disturbances (glove and stocking type), ataxia, dysarthria, constriction of the visual fields, auditory disturbances, and tremor. Mercury poisoning has also been seen in the children of mothers who have eaten contaminated marine life (congenital Minamata disease).

Acute and chronic mercury poisoning

The characteristic clinical picture of acute mercury poisoning includes sudden profound circulatory collapse with tachycardia, hypotension and peripheral vasoconstriction, vomiting, and bloody diarrhea due to hemorrhagic colitis. Renal insufficiency usually develops within 24 hours and is associated with albuminuria, epithelial cell casts, and red cells in the urine, glycosuria, and aminoaciduria. Oliguria can proceed to complete anuric failure. There is also neutrophilic leukocytosis due to tissue necrosis (SED-11, 483) (3).

Symptoms of chronic mercury poisoning have been reviewed (4–6). The symptoms are listed in Table 1. The urinary tract is very sensitive to poisoning by all forms of mercury, a sensitive indicator of early injury being a rise in the urinary excretion of *N*-acetyl-beta-D-glucosaminidase (NAG) (7).

In 70 patients with psoriasis treated with an ointment containing ammoniated mercury, symptoms and signs of mercury poisoning were detected in 33 (8): albuminuria, headache, gingivitis, erythroderma, nausea, dizziness, precordial pain, contact dermatitis, conjunctivitis, epistaxis, keratitis, tremor, neuritis, hematological changes, metallic taste in mouth, and purpura.

Acrodynia ("pink disease") is thought to be a particular form of mercury hypersensitivity, which can be caused by organic or inorganic mercury; it formerly occurred in young children exposed to teething formulations containing mercury compounds. Typical signs include pink scaling palms and soles, flushed cheeks, pruritus, photophobia, profuse irritability, and insomnia. A modern case of acrodynia involved a patient with congenital agammaglobulinemia who had received merthiolate-containing gammaglobulin injections for 15 years (SEDA-6, 225).

Mercury poisoning has been reported in a child who took a Chinese herbal medicine (9).

- A 5-year-old Chinese boy developed oral ulceration, mainly affecting the left lateral aspect of his tongue, and 5 weeks later motor and vocal tics. Herpetic ulceration was diagnosed and confirmed by the isolation of

Table 1 The symptoms of chronic mercury poisoning

System	Symptom
Cardiovascular	Hypertension, hypotension
Nervous system	Emotional disturbances, irritability, hypochondria, psychosis, impaired memory, insomnia, tremor, dysarthria, involuntary movements, vertigo, polyneuropathy, paresthesia, headache
Sensory systems	Corneal opacities and ulcers, conjunctivitis, hypacusis
Endocrine	Hyperthyroidism
Hematologic	Hypochromic anemia, erythrocytosis, lymphocytosis, neutropenia, aplastic anemia
Mouth	Loose teeth, discoloration of the gums and oral mucosa, mouth ulcers, fetor
Gastrointestinal	Anorexia, nausea, vomiting, epigastric pain, diarrhea, constipation
Urinary tract	Nephrotic syndrome
Skin	Tylotic eczema, dry skin, skin ulcers, erythroderma
Musculoskeletal	Acrodynia, arthritis in the legs
Reproductive system	Dysmenorrhea

Herpes simplex virus type 1 from a tongue swab. The lesion improved with oral aciclovir (200 mg five times a day for 5 days), but relapsed a few days later. A local pharmacist prescribed a Chinese medicinal herb mouth spray called "Watermelon Frost", said to be useful in controlling pain and healing difficult mucosal wounds. Over the following weeks his oral symptoms improved but he became irritable and cleared his throat frequently. He developed a transient skin rash on his trunk and motor tics (eye blinking, head turning, and shoulder shrugging). His blood lead concentrations was 0.31 μmol/l (normal below 1.5) and his blood manganese concentration was 246 nmol/l (normal 70–280); his urine arsenic concentration was 10 nmol/mmol creatinine (normal <68). His blood mercury concentration was 83 nmol/l (normal for adults <50). The mercury content of the spray was 878 ppm (2% methyl mercury and 98% inorganic mercury). There was a significant difference in mercury content between different brands and between batches of the same brand of the Chinese medicinal herb. The spray was withdrawn and his tics completely resolved within 4 weeks.

Metallic mercury

Metallic mercury (SEDA-21, 239) is poisonous, and prolonged or acute inhalation can be fatal; organic damage results in a severe chemical pneumonitis. Gingivitis, sometimes proceeding to loss of the teeth, is a well-recognized consequence of prolonged low-level exposure to the metal. Inhalation of vapor from broken thermometers by persons allergic to mercury or even skin exposure can give rise to allergic contact dermatitis (10). If the liquid metal enters the system, even a small amount can cause complications (SEDA-22, 248), although much of the metal is likely to remain at the site of entry and some will be trapped by the lymphatic system.

In one remarkable case, a nurse accidentally pierced her hand with a broken mercury thermometer, and developed amyotrophic lateral sclerosis 3 years later; the causal link was uncertain but there was some reason to believe that the metal had activated a latent predisposition to the disorder (11).

- A man who attempted suicide by injecting 40 ml mercury was found to have mercury deposits at the injection site and in the lungs (12).
- A man who injected mercury intravenously developed malaise and weight loss, and a bilateral cervical adenopathy was found (13).

Dental amalgam

Dental amalgam (SEDA-10, 210) (SEDA-15, 233) (14,15) is still used for about 75–80% of single-tooth restorations. The modern amalgam consists of a metallic alloy (silver, tin, and copper, sometimes with small amounts of zinc, indium, and/or palladium) mixed with mercury in a percentage of 40–54% mercury by weight. The resultant plastic mass sets and hardens over a period of 8–24 hours.

Contrary to previous belief, measurable amounts of mercury escape from dental amalgam fillings in the form of vapor, ions, and abraded particles, and individuals who are accustomed to chew their food thoroughly are exposed to particularly high levels of mercury. This finding has led to a widespread belief in some countries, supported by certain scientific workers (16), that mercury released from amalgam may be the cause of some hitherto unexplained diseases, and a demand has arisen for the removal of amalgam fillings. A number of case histories have been published of individuals in whom chronic (primarily neurological) disorders appear to have responded to removal of amalgam.

Although it is acknowledged that occasional individuals are allergic to metallic mercury, the view that it presents any other risk has generally been contested by the dental profession, citing evidence that the mercury released from amalgam will not accumulate in the body as long as there is adequate renal function. A meta-analysis has shown numerous logical and methodological errors in the anti-amalgam literature (17). The author concluded that the evidence supporting the safety of amalgam is compelling. The debate continues (18,19).

There have been reports of allergic reactions to dental amalgam.

- A 32-year-old dentist had multiple exudative erythematous pruritic plaques on his limbs and trunk for 3 years (20). Although the eruptions were seen almost throughout the year, his symptoms tended to be worse in the summer. Topical corticosteroids, white petrolatum, and oral antihistamines had given slight relief, and an oral corticosteroid gave him transient relief from the itchy eruptions. Patch tests showed that he reacted to 1% ammoniated mercuric chloride in petrolatum and to 0.05% mercuric chloride in water. It was suggested that his dental amalgam should be removed and that he avoid contact with amalgam during his work. Two weeks later his skin symptoms had dramatically improved, leaving pigmentation. Thereafter he was free of symptoms for several months. However, when he handled amalgam again, similar but less severe eruptions appeared on his legs the next day. Subsequent strict avoidance of amalgam improved his eruptions.
- A 70-year-old man had multiple coin-sized exudative eczematous plaques on his legs and trunk for several months (20). Various kinds of corticosteroid ointments and white petrolatum as an emollient gave him little relief. Patch tests showed that he reacted to 1% ammoniated mercuric chloride in petrolatum and 0.05% mercuric chloride in water. He had all his dental amalgam removed, and 1 month later his eruption had subsided, leaving pigmentation.
- A 50-year-old man complained of soreness of the left buccal mucosa and the right side of his tongue, made worse by consuming spicy foods and acidic drinks (21). He had a heavily restored dentition, with asymmetrically distributed white striated and red atrophic lesions on the left buccal mucosa and the right and left borders of the tongue. The lesions were in direct contact with the buccal and palatal surfaces of an old corroding and amalgam restoration and the lingual surface of an amalgam restoration. A provisional diagnosis of a lichenoid reaction to amalgam was made and patch tests showed a strong positive response to mercury and a slightly weaker response to amalgam after 72 hours. One amalgam filling was covered with a bonded porcelain crown

© 2006 Elsevier B.V. All rights reserved.

and the other was replaced with glass ionomer cement. Within 2 months he was asymptomatic, and after 12 months the lichenoid lesions had completely resolved.

- A-57-year-old woman (21) had a recurrent urticarial rash on the skin of her face, scalp, and neck precipitated by restorative dental treatment. The reactions were fully established within 12 hours and would resolve over 2–3 days and be completely gone within 1 week. Patch tests showed a strong reaction to mercury. She was advised that alternative dental materials should be used and that existing amalgam should be removed.

Organic salts

Organomercurials have been a common cause of allergic contact dermatitis or rash (22) and even exfoliative dermatitis has been described (23). Some reagents for intracutaneous testing (tuberculin, etc.) may contain thiomersal, which can cause sensitization and thus elicit false-positive delayed-type skin reactions. Mercury compounds inhibit most lymphocyte functions (SEDA-21, 240). An early indicator of an immunological response to mercury exposure, for example in occupational medicine, appears to be a change in the lymphocyte count with a differential increase in T helper cells and a rise in the T helper/T suppressor ratio (24).

Merbromin

Merbromin (mercurochrome, the disodium salt of 2,7-dibromo-4-hydroxymercurifluorescein) is the oldest organic mercurial antiseptic in use, but it is active only as a bacteriostatic agent. In contrast to earlier assumptions, it is absorbed through burned or otherwise absorptive surfaces, and can cause severe and lethal intoxication. High mercury concentrations in blood, urine, and organs have been demonstrated (SED-11, 483). Young children run a particular risk of renal damage from absorption of organic mercury compounds used as antiseptics; in one case, frequent application of merbromin to an omphalocele apparently resulted in anuria, respiratory arrest, and death (SED-8, 520). Neither merbromin nor thiomersal can be considered useful in the management of large omphaloceles.

- A patient developed mercury intoxication, including aplastic anemia, after local application of merbromin to an operation wound (SED-11, 483) (25).
- A 37-year-old patient with burns involving 50% of the body surface was treated by Grob's three-phase method (2% merbromin, 5% tannic acid, and 10% silver nitrate solutions) (26). By day 6 he had pink-coloured urine and progressively developed restlessness, confusion, and coma, with hypothermia on day 8. He died on day 10 with respiratory arrest. The mercury concentration of the urine was 2170 ng/ml on day 6 and 1250 ng/ml on day 9.

The authors pointed out that merbromin should no longer be used in the treatment of burns. However, good results were reported in a retrospective study on the treatment of second-degree burns in 129 children using the same method (solutions with 7% silver nitrate and 2% merbromin). The authors pointed out that the indication is given only in second-degree burns, with burned surfaces of maximally 10–20% of the body surface, preferably in burn injuries of the trunk and non-mobile areas of the extremities. The most important factor seems to be careful attention to the serum sodium concentration and sufficient substitution with infusion therapy (SED-11, 483).

An anaphylactic reaction occurred after local application of merbromin in one patient, and several mercury-sensitive patients had severe local reactions in patch tests (SED-11, 483) (27).

Thiomersal

Thiomersal (*O*-ethylmercurithiobenzoic acid), an organic mercurial, was first added to childhood vaccines as a preservative in the 1930s. It contains 50% ethyl mercury by weight. It was the potential for infants to be exposed to cumulative doses of mercury from thiomersal in vaccines that prompted the European Medicines Evaluation Agency and the UK's Committee on Safety of Medicines (CSM) to recommend that it would be prudent to promote the use of vaccines without thiomersal as a precautionary measure (SEDA-26, 259). Thiomersal is also widely used in cutaneous test solutions and in contact lens cleaners and creams. The danger of toxic effects and the efficacy of thiomersal are similar to those of merbromin. Toxic amounts can be absorbed during omphalocele treatment.

The aryl mercurials, such as thiomersal are particularly likely to elicit hypersensitivity reactions (10,28), including attacks of asthma in patients who have received hepatitis B vaccine (29). Ethyl mercury toxicity and sensitization from thiomersal-containing vaccines have been indecisively discussed (30,31). The toxicity of ethyl mercury has also been discussed (32).

Fatal mercury (and borate) intoxication has been reported after irrigation of the ear with 0.1% thiomersal and 0.14% sodium borate for purulent otitis media, which was refractory to antibiotic therapy over 4 weeks (SED-11, 483) (33).

The histories of 25 patients with chemical burns caused by preoperative skin preparation have been reviewed. Thiomersal was the most common agent implicated. The burns did not occur in the main area of preparation, but more peripherally where the solution was in close contact with the skin in the drapes or was more closely applied to the skin by pressure, either because of the patient's own weight or to tourniquet dressings. No burning occurred under a sterile wound drape (although solutions stagnate at this site and do not evaporate), perhaps because there was no pressure. There are particular risks in patients placed in the lithotomy position to undergo gynecological operations (the burns being on the buttocks), and in those undergoing orthopedic operations (the burns then being on the extremities and under a tourniquet) (SED-11, 483) (34).

Thiomersal is one of the most frequent sensitizers in the world (3,35). It is used as a preservative in vaccines, test solutions, and topically administered applications, for example creams and solutions used on eczematous skin, ear-drops, eye-drops, and cleanser solutions for ocular contact lenses. The concentration of thiomersal varies between 0.0005 and 0.01% in these formulations.

Sensitization can be provoked by immunization with thiomersal-containing vaccines. Even in sensitized

© 2006 Elsevier B.V. All rights reserved.

patients, thiomersal-induced adverse effects due to immunization has not been shown to be a severe risk, and a positive patch test to thiomersal does not represent a contraindication to immunization with thiomersal-containing vaccines. Many of the reactions seen in patch tests with 0.1% thiomersal are probably caused by the irritant nature of thiomersal. It has been pointed out that only half of a series of subjects tested with a solution of 0.1% thiomersal had a positive reaction in patch tests with concentrations of 0.05 and 0.01% (36).

Thiomersal included in patch-test series has given varying frequencies of positive reactions. Cross-reactions occur to a few organic mercurials, but not to inorganic or metallic mercury. The allergic determinant seems to be the ethyl mercury radical in thiomersal.

Frequencies of positive reactions have been reported in the following countries:

- USA: 13.4% in 1967 (37) and 8% in 1972 (38)
- Japan: 5.6 (39) and 16.3% (40)
- Finland: 2.0% (41)
- Denmark: 1.3% (42)
- GDR: 6.9% (43)
- Czechoslovakia: 5.3% in infant inpatients (44)
- France and Belgium: 2.3% in a multicenter study in 200 adult patients submitted to routine patch-testing (45)
- Italy: 5.3% (46)
- Poland: 5.7% (13.8% of all medicinal personnel, tested in this study) (47).

There was a very high peak frequency of positive patch tests in the 20–30 years age group in Sweden (48): 16% of male recruits and 10% of other healthy subjects in nursing schools and among medical students. A common reason for sensitization to thiomersal in the younger generation in Sweden arises from intracutaneous testing with tuberculin containing thiomersal as a preservative. It was shown experimentally that tuberculin could act as adjuvant during sensitization to thiomersal. The iatrogenic occurrence of thiomersal allergy in the Swedish population does not result in eczematous reactions, but merely in false-positive skin tests.

Thiomersal takes second place, after nickel, as a contact allergen in Austria. As in Sweden this high incidence is probably due also to frequent immunization with vaccines containing thiomersal (49).

- A generalized allergic reaction occurred in a 50-year-old nurse with a documented allergy to thiomersal, who received 10 ml of human euglobulin with thiomersal as a preservative.
- A 38-year-old man treated a mild sore throat himself with a thiomersal spray, and about 30 hours after the second application developed a severe laryngeal obstruction, for which emergency tracheotomy was necessary. A subsequent patch test produced a severe disseminated allergic reaction to thiomersal (SED-11, 484) (50).

Serious allergic reactions were reported in 18 patients after the use of a Japanese encephalitis vaccine containing thiomersal (51). Reactions in 15 patients were thought to be related to the product; 13 had urticaria affecting the whole body, one had erythema multiforme, and one had a rash. Fourteen reactions arose after the second immunization. Seven of the 13 urticarial reactions began within 24 hours of vaccination, and the other six within 72 hours. In five patients encephalitis vaccine was the only vaccine given. The thiomersal concentration had been increased from 0.0005% in previous vaccine batches, to 0.0067% in the batch used. However, the concentration of thiomersal was that used in most vaccines.

In topical formulations thiomersal can lead to an allergic contact dermatitis. There was a high incidence of thiomersal allergy in patients with pompholyx, that is vesicular eruptions on the palms and soles (48).

Thiomersal is more soluble and stable than the older mercurials. It does not influence tear-film wetting of cornea or contact lenses, or the stability of the tear film itself. Thiomersal has been known to cause both a blepharoconjunctivitis and a punctate keratitis in contact lens wearers. Thiomersal keratoconjunctivitis accounted for 32 of 312 consecutive referrals to an outpatient department for problems related to contact lenses (52). The typical appearances included non-specific conjunctival changes, limbal follicles, superficial punctate keratopathy, and superior corneal epithelial opacities. Atypical cases presented with superior limbitis, coarse punctate keratopathy, severe keratopathy with visual loss, pseudodendritic corneal lesions, or acute conjunctival hyperemia without keratopathy. In atypical cases, the diagnosis can be difficult but can be aided by the use of topical challenge with thiomersal. The condition can be incorrectly attributed to allergy. However, a large number of cases of allergic conjunctivitis have been attributed to thiomersal as a constituent of a solution for preserving soft contact lenses (SED-11, 484) (53).

- A 26-year-old man with a 2-year history of repeated episodes of dermatitis, swelling of the eyelids, and burning eyes was thought to have delayed contact allergy (54). The original diagnosis was of occupational allergy, but patch tests confirmed that the conjunctivitis was due to thiomersal-containing eye-drops, which had been used to treat the condition.

In an effort to reduce exposure to mercury the FDA have recommended that vaccine manufacturers phase out its use. In response to this, some blood products are also being manufactured free of thiomersal (55). In July 1999 the American Academy of Pediatrics and the US Public Health Service issued a joint statement calling for the removal of thiomersal, a mercury-containing preservative, from vaccines. This action was prompted partly by a risk assessment by the FDA, which consisted of hazard identification, dose–response assessment, exposure assessment, and risk characterization (56). The review showed no evidence of harm caused by the doses of thiomersal in vaccines, except for local hypersensitivity reactions. However, it was noted that some infants may be exposed to cumulative doses of mercury during the first 6 months of life that exceed the Environmental Protection Agency recommendations. In the UK the Committee on Safety of Medicines and the Department of Health reviewed the available data relating to thiomersal in vaccines and possible neurodevelopmental disorders, including autism, an issue that has gained media attention (57). There was no evidence of neurodevelopmental harm, a known effect of acute

© 2006 Elsevier B.V. All rights reserved.

intoxication with mercury, caused by the amounts of thiomersal that are found in vaccines.

The amounts of thiomersal in the UK schedule of childhood vaccination are lower than in the USA. No specific action has been recommended in the vaccination program. European and American regulatory authorities have recommended that vaccine manufacturers should phase out their use of thiomersal whenever possible as a precaution (SEDA-25, 278).

Inorganic salts

Chronic mercurialism with nervous system involvement, renal insufficiency, and progressive colitis has been described after the long-term use of remedies containing inorganic mercury. Such remedies may also explain the persistence of other unexplained disorders, such as pink disease. Inorganic and organic mercury compounds may cause allergic dermatitis (SEDA-22, 247) (28). Frank poisoning from these sources, although uncommon today, is still possible, and occasional case reports appear (SEDA-13, 195); in one instance, injudicious chronic use of an ammoniated mercury ointment led to a peripheral polyneuropathy, which was only partly reversible (SEDA-22, 247). As with other metals, reactions to mercury can occur after occupational or environmental exposure; in one case, a child already known to be hypersensitive to mercurochrome developed a severe rash after wearing plastic boots which were found to contain mercurous chloride (58).

Despite several warnings over many years, the use of mercuric chloride solutions during operations in an attempt to kill cancer cells implanted in healthy tissues persists in some countries. Intraperitoneal administration, when seeding of a visceral cancer is feared, carries the risk of mercury absorption and nephrotoxicity. Death from intoxication after peritoneal lavage with a mercuric chloride solution has been reported (3).

Health authorities in Canada have warned consumers not to use Diana Cream (Diana de Beauté), a product that is used for skin lightening, mainly by Afro-Caribbean communities. The Directorate General of Pharmaceutical Affairs & Drug Control has prohibited the registration, import, and sale of the product, which is manufactured in Lebanon and is being illegally imported. It contains ammoniated mercury, bismuth subnitrate, and salicylic acid. The mercury content poses a high risk of mercury poisoning in adults and a serious health hazard to unborn and nursing infants of women who use the product (59).

Peripheral polyneuropathy as a result of chronic ammoniated mercury poisoning has been studied and followed over 2 years (60).

- A 36-year-old man developed peripheral polyneuropathy after chronic perianal use of an ammoniated mercury ointment. He had very high blood and urine mercury concentrations. Sural nerve biopsy showed mixed axonal degeneration/demyelination. His symptoms improved progressively over 2 years after withdrawal of the ointment, but neurophysiological recovery was incomplete.
- A 4-month-old boy was hospitalized with a weeping eczema covering more than the half of the body surface and complicated by skin hemorrhage and infection by *Klebsiella pneumoniae* and *Proteus mirabilis*. Apart from general therapy, a compound zinc oxide ointment containing, among other ingredients, yellow mercuric oxide 2 g per 40 g of base was applied daily. After 12 days, he rapidly developed cardiovascular collapse, acute pulmonary edema, and coma Stage II, with right hemiparesis, generalized hypertonia, and muscular tremor. The mercury concentrations in blood, urine, and CSF were respectively 120 ng/ml (normal <10 ng/ml), creatinine 260 micrograms/g (normal <5 micrograms/g), and 4.8 ng/ml (normal <0.1 ng/ml). Despite therapy with dimercaprol and vigorous supportive measures, the child's condition deteriorated, he developed *Klebsiella aerogenes* septicemia, and died 6 weeks later (61).

Organs and Systems

Sensory systems

Topical treatment with phenylmercuryl acetate can cause band-shaped corneal opacities (62). Long-term use of eye-drops containing phenylmercuric nitrate as a preservative can cause pigmentation of the anterior lens capsule. In 31 patients who used eye-drops containing phenylmercuric nitrate as a preservative for 3–15 years, a brownish pigmentation of the anterior capsule of the pupillary area developed. Light and electron microscopic studies on two lenses showed deposits of dense particulate material resembling melanin pigment on and in the anterior capsule of the lens in the area of the pupil (63). Electron microprobe analysis and neutron activation analysis established the presence of mercury. However, the pigmentation does not seem to be associated with visual impairment.

The use of mercurials in the eye can lead to a bluish-gray deposit of mercuric oxide on the eyelids, conjunctivae, and Descemet's layer. Phenylmercuric nitrate used in a 0.004% concentration can cause mercuria lentis. Mercurial compounds have been found in the aqueous humor, having penetrated the eye from hydrophilic-gel contact lenses preserved with thiomersal. Although it remains to be established whether deposition of mercury in the eye is clinically important, the concentrations found are similar to those reported in cases of systemic poisoning by organic mercurials (64).

Psychological, psychiatric

There is continuing debate that there is an association between autism and thiomersal-containing vaccines. Some authors believe that review of the literature supports the hypothesis that mercury in vaccines may be a factor in the pathogenesis of autism (65). The World Health Organization's Global Advisory Committee on Vaccine Safety (GACvS) has also kept this issue under review and concluded in November 2002 that there is no evidence of toxicity in infants, children, or adults who have been exposed to thiomersal in vaccines. The CSM is also keeping the issue under close review and studies of the possible toxicology of thiomersal continue to appear (66).

The usual dose of ethyl mercury in pediatric vaccines is small (about 12.5–25 micrograms of mercury). However, the metabolism of ethyl mercury in infants who receive

© 2006 Elsevier B.V. All rights reserved.

vaccines containing thiomersal is unknown. The mean doses of mercury in 40 full-term infants exposed to thiomersal-containing vaccines were 46 (range 38–63) micrograms in 2-month-old children and 111 (range 88–175) micrograms in 6-month-old children. Blood mercury concentrations in the thiomersal-exposed 2-month-old children ranged from less than 3.8 to 21 nmol/l; in 6-month-old children all the concentrations were below 7.5 nmol/l. Only one of 15 blood samples from 21 controls contained measurable concentrations of mercury. Urine concentrations of mercury were low after vaccination, but stool concentrations were high in thiomersal-exposed 2-month-old children (mean 82 ng/g dry weight). The mean half life of ethyl mercury was 7 days.

This study was not designed as a formal assessment of the pharmacokinetics of mercury. However, it showed that the administration of vaccines containing thiomersal did not seem to raise blood concentrations of mercury above safe values in infants. Ethyl mercury seems to be eliminated from the blood rapidly via the stools. The authors concluded that the thiomersal in routine vaccines poses very little risk in full-term infants.

Urinary tract

Membranous glomerulonephritis has been attributed to mercury in a patient with diabetes mellitus.

- A 21-year-old man with a 16-year history of diabetes mellitus, who had been using an ointment containing 10% mercuric ammonium chloride for eczema for about 3 weeks, became tired, with fasciculation in the limbs and poor control of his diabetes (67). Nephrotic syndrome and hypertension were diagnosed 1 month later, and at 2 months he was very weak with tremor of the hands, was almost unable to walk, and had lost 20 kg. His behavior suggested an acute psychosis. The urine mercury concentration was 250 micrograms/l. He was treated with sodium 2,3-dimercaptopropane-1-sulfonate (Dimaval) capsules for 12 days (total dose 6.3 g). The highest urine mercury excretion during antidote treatment was 2336 micrograms/day. He had proteinuria of up to 11 g/day and renal biopsy showed diffuse membranous glomerulonephritis without diabetic nephropathy. Similarly, his neuropathy did not have typical features of diabetic neuropathy. He improved over the next year.

Immunologic

Merthiolate was tested as a matter of routine in an extended standard series of skin tests in patients with different subtypes of eczema and varicose complex (68). Of 880 patients 53% responded positively to one or more allergens, 3.9% to merthiolate. The latest results of skin tests in adults have confirmed the persistence of contact allergy to merthiolate and justify further follow-up and systematic screening.

Attention has been given to mercury as a cause of autoimmune responses, especially in the kidney (69). Exposure to mercury can cause immune responses to various auto-antigens and autoimmune disease of the kidney and other tissues. Although epidemiological studies have shown that occupational exposure to mercury does not usually result in autoimmunity, mercury can cause the formation of antinuclear antibodies, scleroderma-like disease, lichen planus, or membranous nephropathy in some individuals. In experimental animals mercury causes autoimmune disease similar to that observed in humans, with emphasis on the importance of immunogenetic and pharmacogenetic factors.

Homeopathic medicines can cause mercury allergy (baboon syndrome).

- A 5-year-old girl developed an itchy erythematous macular rash, symmetrically distributed in the anogenital area and thighs (70). The lesions developed into a widespread maculopapular vesicular rash in 48 hours, sparing the face, palms, and soles. The eruption cleared after systemic corticosteroids and antihistamines, with scaling and post-inflammatory hypopigmentation. She had had neonatal periumbilical dermatitis associated with the application of merbromin to the cord, and 24 hours before the onset of the rash had taken a single homeopathic tablet (Mercurius Heel), which contained soluble mercury. Allergy tests to a standard series of foods and respiratory allergens were negative and total IgE was normal. Patch-testing to allergens showed positive reactions to thiomersal and metallic mercury.

Previous sensitization and the subsequent development of an allergic contact dermatitis from vaccines that contain thiomersal has received more attention than before (71). Cross-reactivity, exposure factors, and tolerance to vaccines containing thiomersal have been studied in 125 patients sensitized to mercury derivatives in a cross-sectional study (71). Childhood vaccinations, merbromin used as an antiseptic, broken thermometers, and the use of drops were the main sources of previous exposure. There was sensitization to thiomersal in 57 patients and 24 had a positive intradermal reaction. Ammoniated mercury elicited positive reactions in 78% of all patients and merbromin in 66%. In most cases (100/125) there was cross-reactivity among different mercury derivatives. Intramuscular thiomersal caused a mild local reaction in only five patients (4% of the total, 9% of thiomersal positive reactions). Most of the patients had positive tests to both organic and inorganic mercury derivatives. Vaccination with thiomersal is relatively safe, even for individuals with delayed type hypersensitivity, since more than 90% of allergic patients tolerated intramuscular challenge tests with thiomersal. However, in such patients it would be advisable to restrict the use of mercurial antiseptics and mercury thermometers.

Drug Administration

Drug administration route

Mercury toxicity has resulted from the use of an ointment containing mercuric ammonium chloride (67).

Mescaline

General Information

Mescaline is one of eight hallucinogenic alkaloids derived from the peyote cactus, slices of which (“peyote buttons”) have been used in religious rites by North and South American Indian tribes. Mescaline itself is only one of the alkaloids present in peyote, but it produces the same effects as the crude preparation. Chemically, it is related to amfetamine. In doses of some 300–500 mg it depresses nervous system activity and produces visual and occasionally auditory hallucinations, illusions, depersonalization, and depressive symptoms. The total picture can closely resemble that caused by lysergic acid diethylamide. Its physical effects include nausea, tremor, and sweating.

Organs and Systems

Psychological, psychiatric

The effects of mescaline have been investigated in a psychiatric research study (1). Psychosis induced during the experiment was measured with the Brief Psychiatric Rating Scale and the Paranoid Depression Scale. During use of mescaline neuropsychological measures showed reduced functioning of the right hemisphere. Single photon emission computed tomography (SPECT) studies showed a hyperfrontal pattern, with an emphasis on the right hemisphere. The authors discussed the possible educational value of experimentally induced psychosis in understanding the psychotic state.

Mesna

General Information

Mesna is used to prevent or ameliorate hemorrhagic cystitis produced by the anticancer drugs cyclophosphamide and ifosfamide. It is excreted by the kidney and binds and detoxifies acrolein in the urine; mesna also prevents the breakdown of acrolein precursors. It is also used as a mucolytic.

Endotracheal instillation of mesna was compared with instillation of saline in mechanically ventilated patients. Following instillation of mesna, there was a significant increase in maximal airway resistance and impairment of oxygenation with a slight increase in $PaCO_2$ (SEDA-20, 183). A single episode of

© 2006 Elsevier B.V. All rights reserved.

bronchorrhea occurred 10 minutes after the instillation of mesna.

In a randomized, crossover study, 25 volunteers received single doses of intravenous mesna and four different formulations of oral mesna (1). One subject withdrew from the study because of ocular inflammation followed by loss of appetite, nausea, and vomiting. Another developed a rash during the period in which three of his four oral doses were given. Two further subjects developed loose stools after one of the oral doses. Another reported dizziness after an oral dose. One reported pain at the site of the intravenous infusion. The adverse effects were all considered to be mild or moderate and resolved spontaneously without treatment.

Organs and Systems

Respiratory

Bronchorrhea due to inhaled mesna may be the result of mucolysis, but could also be caused by stimulation of bronchial secretions. Application by aerosol or nebulizer is occasionally followed by bronchospasm, but mesna is usually well tolerated by people with asthma (SEDA-20, 183).

Drug–Drug Interactions

Platinum cytotoxic agents

Platinum agents are now combined with ifosfamide in the treatment of cancer. The possibility that mesna may interfere with the anticancer effects of platinum has been investigated using cultured malignant glioma cells (2). Mesna protected tumor cell lines from the cytotoxic effect of the platinum agents. This in vitro study emphasizes the importance of specifying in detail the infusion schedules of mesna and platinum agents.

Mesulergine

General Information

Mesulergine is an 8-alpha-aminoergoline derivative that acts as a dopamine receptor agonist. In a blind, crossover study in six patients with hyperprolactinemia, mesulergine 0.5 mg caused fewer adverse effects than bromocriptine 2.5 mg, while the prolactin release-inhibitory effect of the two was of the same order (1).

The most frequent adverse effect of mesulergine is dyskinesia, mostly in patients who have had similar reactions with levodopa. Orthostatic light-headedness and visual hallucinations are also common. Other adverse effects include anorexia, nausea, drowsiness, ankle swelling, insomnia, confusion, irritability, visual disturbance, chest pain, rash, and augmented body odor.

In one study of 17 patients with mild Parkinson's disease who were given either mesulergine or pergolide, mesulergine impaired the quality of life; frequent adverse effects were vomiting, lassitude, abdominal discomfort, depression, right bundle-branch block, fuzzy-headedness, and increasing insulin requirements in a patient with diabetes (SEDA-13, 113).

Mesuximide

See also Antiepileptic drugs

General Information

Mesuximide (*N*,2-dimethyl-2-phenylsuccinimide) is a succinimide anticonvulsant with actions similar to those of ethosuximide. Its activity is mostly due to its main metabolite, *N*-desmethylmesuximide, which has a half-life of about 48 hours (1).

Mesuximide has been used in 112 children with intractable epilepsy taking other anticonvulsants (2). There was a 50% or greater reduction in seizure frequency in 40 patients after 9 weeks. After a mean of 3.7 years, 39 patients were still taking mesuximide and 22 of them had derived long-term benefit. In patients with good seizure control, fasting plasma concentrations of desmethylmesuximide were 25–45 μg/mg. Of the 112 patients 41 developed adverse effects while taking mesuximide treatment, but none was serious or irreversible.

Of 26 patients with complex partial seizures refractory to phenytoin, carbamazepine, phenobarbital, or primidone, mesuximide produced a 50% or greater reduction in seizure frequency in eight after 8 weeks, and five of those continued to benefit after 3–34 months (1). Drowsiness, gastrointestinal disturbances, hiccups, irritability, and headache were the common adverse effects.

Drug Administration

Drug overdose

Mesuximide can cause profound nervous system depression (3). In one patient this responded to charcoal hemoperfusion (1).

© 2006 Elsevier B.V. All rights reserved.

Drug–Drug Interactions

Lamotrigine

In a retrospective study, in which 376 samples from 222 patients were analysed, mesuximide induced the metabolism of lamotrigine and reduced lamotrigine concentrations by about 70% (4).

Valproate

In 17 patients (12 men, 5 women; aged 8–19 years) the mean valproic acid concentration was 82 μg/ml while not taking mesuximide and 56 μg/ml while taking mesuximide (5). In eight patients who stopped taking mesuximide the mean serum concentration increased from 50 μg/ml to 72 μg/ml.

Metalloporphyrins

General Information

Synthetic tin protoporphyrin is a specific inhibitor of heme oxygenase and reduces plasma bilirubin concentrations in both adults and neonates, thereby preventing jaundice (1–3). A variety of heme analogues, such as tin, zinc, chromium, and manganese metalloporphyrins, act by competitive inhibition of cleavage of heme to biliverdin and carbon monoxide. Stannic porphyrins seem to be the most effective. The adverse effects are few, with only occasional erythema attributable to the phototoxicity of the metalloporphyrins.

Metamizole

General Information

Metamizole and phenyldimethylaminophenazone are the main derivatives of aminophenazone (amidopyrine) and are expected to provoke the same adverse reactions as aminophenazone itself.

Metamizole is still widely prescribed and openly sold as a headache remedy in some developing countries, but has been withdrawn from the market in many parts of the world. Curiously, in some Western countries it still enjoys a reputation as an injectable product that relieves renal colic. In other places it is entirely unknown and apparently not missed. Although it was German in origin, in 1987 the German authorities decided to subject all metamizole products to prescription-only regulations, a clear message to the regulatory authorities in other countries where it is sold without prescription (SEDA-12, 82). According to the Japanese authorities, suppositories and injectable formulations should be used only as a last resort, and warnings should be included in the package insert (SEDA-12, 83).

Metamizole was the single most commonly used agent causing adverse reactions (mainly hypersensitivity reactions, anaphylactic shock, and two deaths) in India, based on reports to an adverse drug reactions monitoring center by general practitioners (SEDA-16, 108).

Organs and Systems

Cardiovascular

In one case, intravenous injection of metamizole caused arterial hypotension (1).

Fluid balance

Fluid and salt retention have been observed in small children given metamizole (2).

Hematologic

The absolute risk of blood dyscrasias associated with the use of metamizole, particularly agranulocytosis (3), is unacceptably high.

In the International Agranulocytosis and Aplastic Anemia study (4), an epidemiological study organized by the manufacturers (Hoechst) of metamizole, the overall annual community agranulocytosis incidence was 4.4 per million (6.2 including hospital cases), with a fatality rate of 10% and an annual mortality rate of 0.4 per million. Analgesics significantly associated with agranulocytosis were metamizole, indometacin, oxyphenbutazone, and phenylbutazone. The International Agranulocytosis Study has been both criticized (5) and strongly defended (6).

© 2006 Elsevier B.V. All rights reserved.

An analysis of all reports of blood disorders attributed to NSAIDs that were submitted to the Finnish National Board of Health during 1973–85 showed that metamizole was suspected of causing 14 cases of agranulocytosis (three fatal), other pyrazolones four cases, indometacin two cases, and ibuprofen one case (7).

In a study of all spontaneous reports of serious blood dyscrasias associated with metamizole and an analysis of prescription data the incidence was estimated to be at least one in 1439 prescriptions (95% CI = 850, 4684), of which 92% occurred during the first 2 months of treatment (8). These results stimulated comments and criticisms (9,10), but despite criticisms about the small number of cases identified in the study, this result confirms earlier ones (10).

Hemolysis has also been reported with metamizole (11). It is possibly due to cell membrane absorption of drug-antibody immune complexes.

Urinary tract

Nephrotoxicity from metamizole is rare (SEDA-17, 108).

Skin

An active amide group on metamizole has been shown to cause pemphigus vulgaris (12,13).

Drug Administration

Drug overdose

In a retrospective review of 243 patients who had taken an overdose of metamizole, median age 17 years (range 4 months to 83 years), median amount 5 g (250 mg to 45 g), and median time to consultation 2 hours (5 minutes to 48 hours), there were toxic effects in 39 (16%); 57% of these were gastrointestinal and all were mild (14). The time to consultation was longer in the symptomatic patients (4 versus 1.5 hours) and in children (8 versus 3.5 hours in adults). There were no cases of agranulocytosis. Suggested treatment includes gastrointestinal decontamination and supportive measures.

Metaraminol

General Information

Metaraminol (2–10 mg intramuscularly) is used to treat serious hypotension. It has no noticeable central nervous effects and the beta-adrenoceptors of the heart usually do not react. The maximum effect of a dose is not at once apparent, and one should wait for some 10 minutes before deciding to give a further dose. In two patients an intravenous infusion of metaraminol to treat paroxysmal supraventricular tachycardia resulted in acute hypertension and pulmonary edema (1). Subcutaneous administration is risky and can result in dangerous sloughing.

Drug–Drug Interactions

Guanethidine

Guanethidine and related drugs make adrenoceptors highly sensitive to metaraminol (2).

Methadone

General Information

Methadone is an OP_3 (μ) receptor agonist with pharmacological properties similar to those of morphine. It is an attractive alternative OP_3 opioid receptor analgesic, because of its lack of neuroactive metabolites, a clearance that is independent of renal function, good oral systemic availability, a longer half-life with fewer doses needed per day, and extremely low cost. It is mainly metabolized by CYP3A4.

Drug studies

Pain relief

Experience with methadone in cancer pain is limited. Its long half-life tends to produce delayed toxicity, especially in older patients, but in chronic renal insufficiency and stable liver disease methadone is safe, unlike morphine.

Methadone is being used increasingly for treating chronic pain and cancer pain (neuropathic and somatic) that is non-responsive or has lost responsiveness because of tolerance to high-dose μ opioid receptor agonists (for example morphine, fentanyl, oxycodone) (1). There are several protocols for converting from morphine to methadone and for initiating and stabilizing maintenance dosages.

In a prospective uncontrolled study, 45 patients with advanced cancer were given 0.1% methadone 2–3 times a day as required (2). Ten had nausea and vomiting, none had drowsiness, and 17 had constipation. In another study, nine of 29 patients in a tertiary level cancer pain clinic could not take opioid analgesics owing to uncomfortable adverse effects: nausea, vomiting, and drowsiness in four and other adverse effects in five (3). The average daily dose of methadone at the end of the titration phase (range 1–79 days) was 208 (range 15–1520) mg. Twenty patients had methadone toxicity during titration. In 12 patients mild drowsiness was a problem, six patients had nausea, and one patient each had confusion and severe headaches. In a third cross-sectional prospective study, 24 patients with advanced cancer pain were rapidly switched form oral morphine to oral methadone using a fixed ratio of 1:5 (4). There was a significant reduction in pain intensity and adverse effects intensity within 24 hours of substitution, although five patients required alternative treatments.

In a prospective, open, uncontrolled study 50 patients with a history of cancer taking daily oral morphine (90–800 mg) but with uncontrolled pain with or without severe opioid adverse effects were switched to oral 8-hourly methadone in a dose ratio of 1:4 for patients receiving less than 90 mg of morphine daily, 1:8 for patients receiving 90–300 mg daily, and 1:12 for patients receiving more than 300 mg daily (5). Methadone was effective in 80% of the patients when comparing analgesic response with opioid-related adverse effects. Ten patients were switched because of uncontrolled pain, eight because of moderate or severe adverse effects in the presence of acceptable pain control, and 32 because of uncontrolled pain with morphine-related adverse effects. In the last 32 there were significant improvements in pain intensity, nausea and vomiting, constipation, and drowsiness, with a 20% increase in methadone dose over and above the recommended starting dose.

In a prospective uncontrolled study of intrathecal methadone in 24 patients with a history of intractable chronic non-malignant pain, methadone was a better analgesic than morphine, with improved quality of life and no adverse effects in 13 patients (6). The final rates of methadone infusion were 20% higher than the preceding morphine rates.

Opioid dependence

An analysis of the balance of benefit to harm during methadone maintenance treatment for diamorphine dependence has shown lower mortality and morbidity with improvement in quality of life (7). The risks of methadone treatment include an increased risk of opiate overdosage during induction into treatment, and adverse effects of methadone in some patients. However, with careful management the benefits of prescribing methadone outweigh the risks.

The validity of self-reported opiate and cocaine use has been studied in 175 veterans enrolled in a methadone treatment program (8). Urine analysis showed higher rates of substance use than the patients themselves reported. The authors encouraged the development of more objective measures for assessing patient progress and the performance of the methadone program.

Organs and Systems

Cardiovascular

A variety of complications following parenteral self-administration of oral methadone were noted, including regional thrombosis, often associated with shock and multiorgan failure (9).

The use of methadone/dihydrocodeine has been linked to an acute myocardial infarction (10).

- A 22-year-old man with a 6-year history of intravenous heroin use was maintained on methadone 60 mg/day and dihydrocodeine 0.5 g/day. He had an extensive anterior myocardial infarction as a result of occlusion of the left anterior descending coronary artery, which was reopened by percutaneous transluminal coronary angioplasty.

This case presents circumstantial evidence only, and the association was probably not a true one.

There has been a report of five cases of episodes of syncope and an electrocardiogram showing ventricular tachydysrhythmias with prolonged QT intervals and episodes of torsade de pointes; all the patients were taking high doses of methadone (270–660 mg/day) with no previous history of cardiac disease (11). Torsade de pointes also occurred when high doses (3 mg/kg) of the long-acting methadone derivative, levomethadyl acetate HCl (LAAM), were given to a 41-year-old woman with a history of heroin dependence (12). She was also taking fluoxetine and intravenous cocaine, which can prolong the QT interval, and fluoxetine and marijuana, which

© 2006 Elsevier B.V. All rights reserved.

inhibit the activity of CYP3A4, which is responsible for the metabolism of LAAM and its active metabolite.

In a retrospective case study in methadone maintenance treatment programs in the USA and a pain management center in Canada, 17 methadone-treated patients developed torsade de pointes during 5 years (13). The dose of methadone was 65–1000 mg/day. Six patients had had an increase in methadone dose in the months just before the onset of torsade de pointes. One patient had taken nelfinavir, a potent inhibitor of CYP3A4, begun just before the development of torsade de pointes. The above two risk factors (increased drug dosage and drug interactions) are important when eliciting the cause of torsade de pointes in patients taking methadone.

Respiratory

In 10 stable methadone-maintained patients (50–120 mg/day) and nine healthy subjects assessed using polysomnography, the methadone-maintained patients had more abnormalities of sleep architecture, with a higher prevalence of central sleep apnea (14). Methadone depresses respiration, probably by acting on μ opioid receptors in the ventral surface of the medulla and possibly on other receptor sites in the lung and spinal cord. All the patients taking methadone also used benzodiazepines and cannabis, which may have influenced the above findings.

Nervous system

Reversible choreic movements of the upper limbs, torso, and speech mechanism developed in a 25-year-old man taking methadone as a heroin substitute (15).

Spastic paraparesis has been attributed to methadone (16).

- A 43-year-old patient taking methadone for pain secondary to a squamous cell carcinoma of the larynx, which progressed despite surgery and radiation therapy, developed reversible spastic paraparesis with prominent extensor spasms in the legs while receiving an infusion of high-dose intravenous methadone 100 mg/hour. On the second day, after 5 hours on 100 mg/hour, he noted weakness in both legs, uncontrollable trembling, bilateral tinnitus, and generalized anxiety. Dexamethasone 6 mg intravenously every 6 hours was started and the methadone was reduced to 60 mg/hour. Dexamethasone was withdrawn when an MRI scan confirmed the absence of metastases in the thoracic and cervical spinal cord. Because of persistent spastic paraparesis, methadone was switched to levorphanol 40 mg/hour intravenously, and there was complete resolution of symptoms 24 hours later.

Methadone can cause movement disorders characterized by tremor, choreiform movements, and a gait abnormality (17).

- A 41-year-old woman with a 15-year history of chronic neuropathic pain was given methadone 5 mg tds and then qds. One month after the final increase she had bilateral tremor spreading from her arm up to her neck, followed by choreiform movements of the torso, a broad-based gait, and staccato-like speech. She was switched from methadone to modified-release oxycodone 60 mg/day, with complete resolution after 3 weeks.

Psychological, psychiatric

In a randomized, double-blind, crossover study of 20 patients on a stable methadone regimen, a single dose of methadone caused episodic memory deficits (18). This was significant in patients with a history of diamorphine use averaging more than 10 years duration. Such deficits can be avoided by giving methadone in divided doses.

Psychomotor and cognitive performance has been studied in 18 opioid-dependent methadone maintenance patients and 21 non-substance abusers (19). Abstinence from heroin and cocaine for the previous 24 hours was verified by urine testing. The methadone maintenance patients had a wide range of impaired functions, including psychomotor speed, working memory, decision making, and metamemory. There was also possible impairment of inhibitory mechanisms. In the areas of time estimation, conceptual flexibility, and long-term memory, the groups performed similarly.

Endocrine

Prolonged therapy with methadone causes increases in serum thyroid hormone-binding globulin, triiodothyronine, and thyroxine, as well as albumin, globulin, and prolactin, and these must be monitored (SEDA-15, 71) (SEDA-17, 81).

Fluid balance

Methadone-induced edema soon after start of treatment is recognized, and distal leg edema after 7 years of treatment has been described (SEDA-17, 81).

Gastrointestinal

In a randomized, double-blind, placebo-controlled trial of the efficacy of intravenous methylnaltrexone (0.015–0.095 mg/kg) in treating chronic methadone-induced constipation in 22 patients attending a methadone maintenance program (oral methadone linctus 30–100 mg/day), methylnaltrexone induced immediate bowel movements in all subjects (20). There were no opioid withdrawal symptoms or significant adverse effects.

Skin

Subcutaneous administration can cause skin erythema and induration at the injection site (SEDA-16, 81).

Parenteral self-administration of oral methadone can cause cellulitis, abscess formation, and necrosis of the skin and deeper tissues (9).

Death

There has been a cross-sectional survey of 238 patients in New South Wales who died during a methadone maintenance program in a 5-year period (21). There were 50 deaths (21%) in the first week of methadone maintenance

© 2006 Elsevier B.V. All rights reserved.

treatment, 88% of which were drug-related. These findings reinforce the importance of a thorough drug and alcohol assessment of people seeking methadone maintenance treatment, cautious prescribing of methadone, frequent clinical review of patients, and tolerance to methadone during stabilization.

In a retrospective study of cases from the Jefferson County Coroner/Medical Examiners Office, Alabama, USA between January 1982 and December 2000 there were 101 deaths in patients in whom methadone was detected in the blood (22). Methadone was the sole intoxicant in 15 cases, with a mean concentration of 0.27 μg/ml. A benzodiazepine was the most frequently detected co-intoxicant in 60 of the 101 cases and the only co-intoxicant in another 30 cases. In 26 cases methadone had been taken with a range of non-benzodiazepine substances, including antidepressants, antipsychotic drugs, antiepileptic drugs, and cocaine. The high incidence of benzodiazepine + methadone related deaths can be explained by synergistic respiratory depression. Higher concentrations of methadone can occur with chronic abuse of methadone plus benzodiazepines, because over time benzodiazepines inhibit the hepatic enzymes that metabolize methadone. This might explain why the mean methadone concentration in the 30 deaths attributed to methadone plus a benzodiazepine was only 0.6 μg/ml.

Long-Term Effects

Drug tolerance

Several methadone studies have focused on opioid-dependent or opioid-abusing subjects. For example, six opioid-dependent individuals maintained on methadone subsequently developed cancer and continued to use methadone, but in a higher dose as an analgesic (16,23). The first five were partly refractory to the analgesic effects of opioids other than methadone, but all six achieved adequate analgesia without sedation or respiratory depression from aggressive upward intravenous methadone titration using an infusion of 100 mg/hour. Methadone was given in divided doses every 6–12 hours rather than once daily, as is customary in maintenance therapy for opioid dependence. The reasons for increasing the methadone dosage and frequency of administration are cross-tolerance to other opioids and the presence in methadone-maintained individuals of hyperalgesia to pain (a low pain tolerance to pain detection ratio) (24). These issues are also relevant to determining whether other drugs are more effective than morphine in managing acute pain in these patients.

Drug withdrawal

Four patients with methadone withdrawal psychosis have been described (SEDA-20, 79).

Second-Generation Effects

Pregnancy

Methadone is extensively used in opioid withdrawal and maintenance programs (see Drug tolerance in this monograph), and has been safely used for this purpose in pregnancy, with only mild effects on the offspring (25). However, fetal exposure to methadone in utero can cause a neonatal abstinence syndrome after delivery.

The outcomes in 100 chronic opiate-dependent pregnant women who received levomethadone substitution treatment have been reported (26). The average gestational age at delivery was 38 weeks and the mean birth weight was 2869 g. The rate of premature labor was 19% and the risk of premature delivery 11%. There were withdrawal symptoms in 74% of the neonates at a mean of 39 hours and all responded well to levomethadone.

Fetotoxicity

A newborn girl born of an HIV-positive mother who took antiretroviral drugs and methadone during pregnancy developed a methadone abstinence syndrome at day 7 (27). She was HIV-negative and was treated symptomatically for 15 days with chlorpromazine. The platelet count was 1049×10^9/l on day 17 and fell progressively to 290×10^9/l at 8 weeks. The authors suggested that the thrombocytosis had been secondary to intrauterine methadone exposure.

Susceptibility Factors

From a literature search and subsequent analysis of data on the relation between methadone prescribing and mortality, it was concluded that (28):

(a) 69% of deaths attributed to methadone occurred in subjects who had not previously received methadone;
(b) 51% of deaths attributed to methadone occurred during the dose-stabilizing period of methadone maintenance treatment;
(c) the dose of illicit methadone exceeded that prescribed for methadone maintenance therapy;
(d) deaths were attributed to discharge from prison and immediate intravenous injection of methadone in people who had lost their tolerance to high doses of methadone when incarcerated.

Subsequent advice related to the above identifiable susceptibility factors included:

(a) restriction of take-home prescriptions with daily supervised consumption of methadone in pharmacy premises;
(b) meticulous evaluation of substance abuse history;
(c) slowing down of increases and tolerance testing during the stabilization period of methadone maintenance; enhanced psychosocial assistance during the first months out of prison;
(d) use of naloxone as an adjunct to methadone syrup.

Drug Administration

Drug dosage regimens

The role of opioid rotation in cancer pain management has been described, highlighting the limitations of equianalgesic tablets and the need for monitoring and individualization of dose. This is particularly important

© 2006 Elsevier B.V. All rights reserved.

when methadone is used as the opioid for conversion. The authors referred to a greater than expected potency of methadone, with excessive sedation and opioid-related adverse effects, if the switch is done on a one-to-one basis. They suggested that the calculated equianalgesic dose of methadone should be reduced by 75–90% and the dose then titrated upwards if necessary (29,30).

Drug administration route

Methadone has been used for intrathecal administration. Although this route can provide prolonged analgesia, the adverse effects have been reported to be unacceptable (SEDA-16, 81).

Of 90 patients undergoing abdominal or lower limb surgery randomly assigned double-blind to two groups, 60 received racemic methadone in initial doses of 3–6 mg followed by 6–12 mg by continuous infusion over 24 hours, and 30 received repeated boluses of 3–6 mg every 8 hours (31). In both groups the highest visual analogue score occurred 2 hours after surgery. From then on the pain diminished gradually and significantly at each recording. Opioid-related adverse effects were not different between the two groups, except for miosis, which was significantly more common in the bolus group. The results suggested that both epidural methadone protocols used in this study provide effective and safe postoperative analgesia. However, the infusion method should be preferred, as the doses of methadone can be reduced after the first day of treatment.

Drug–Drug Interactions

Antiretroviral drugs

Methadone is often used for opioid replacement therapy in intravenous drug abusers. The incidence of HIV infection is significantly higher in this population than in the general public, and interactions with drugs used for the treatment of AIDS are therefore important.

Methadone is predominantly metabolized by CYP3A4. Antiretroviral therapy with a non-nucleoside reverse transcriptase inhibitor (for example efavirenz, abacavir, and nevirapine) and/or a protease inhibitor (for example amprenavir) will induce the metabolism of methadone. This therapeutic combination is becoming increasingly common in HIV-positive substance misusers. Two studies have explicitly shown a significant reduction of methadone concentration by 28–87%. In the first study, 11 patients taking methadone maintenance therapy were given efavirenz and had a mean increase in methadone dosage requirement of 22% (32). In the second study, five methadone-maintained opioid-dependent individuals were given a combination of abacavir and amprenavir; the methadone concentration fell to 35% of the original concentration within 14 days (33).

In a prospective study of 54 patients taking antiretroviral drugs who also took methadone and a further 154 patients who did not take methadone there were similar clinical, virological, and immunological outcomes after 12 months (34). These results support the usefulness of methadone in the management of intravenous drug users with HIV infection.

Ritonavir, indinavir, saquinavir

In an in vitro study of the effects of the HIV-1 protease inhibitors, ritonavir, indinavir, and saquinavir, which are metabolized by the liver CYP3A4, all three protease inhibitors inhibited methadone demethylation and buprenorphine dealkylation in rank order of potency ritonavir > indinavir > saquinavir (35). Clinical studies are required to establish the further relevance of these observations.

Zidovudine

The metabolism of the antiviral nucleoside zidovudine to the inactive glucuronide form in vitro was inhibited by methadone (36). The concentration of methadone required for 50% inhibition was over 8 μg/ml, a supratherapeutic concentration, thus raising questions about the clinical significance of the effect. However, in eight recently detoxified heroin addicts, acute methadone treatment increased the AUC of oral zidovudine by 41% and of intravenous zidovudine by 19%, following the start of oral methadone (50 mg/day) (37). These effects resulted primarily from inhibition of zidovudine glucuronidation, but also from reduced renal clearance of zidovudine, and methadone concentrations remained in the target range throughout. It is recommended that increased toxicity surveillance, and possibly reduction in zidovudine dose, are indicated when the two drugs are co-administered.

Cimetidine

Cimetidine increases the effects of methadone, probably by inhibition of methadone metabolism (38).

Enzyme inducers

Enzyme-inducing drugs, such as carbamazepine, phenobarbital, phenytoin, and rifampicin, enhance the metabolism of methadone, leading to lower serum methadone concentrations (39).

Fluconazole

In a randomized, double-blind, placebo-controlled trial, oral fluconazole increased the serum methadone AUC by 35% (40). Although renal clearance was not significantly affected, mean serum methadone peak and trough concentrations rose significantly, while renal clearance was not significantly altered.

Phenytoin

Phenytoin enhances the metabolism of methadone (40).

Rifampicin

Enzyme-inducing drugs, such as rifampicin, enhance the metabolism of methadone, leading to lower serum methadone concentrations (40). This interaction is thought to have caused acute methadone withdrawal symptoms in two patients with AIDS (SEDA-16, 81).

Selective serotonin re-uptake inhibitors

Fluvoxamine

Fluvoxamine increases the effects of methadone, probably by inhibition of methadone metabolism (41).

© 2006 Elsevier B.V. All rights reserved.

Paroxetine

Paroxetine 20 mg/day, a selective CYP2D6 inhibitor, was given for 12 days to 10 patients on methadone maintenance (42). Eight were genotyped as CYP2D6 homozygous extensive metabolizers and two as poor metabolizers. Paroxetine increased the steady-state concentrations of *R*-methadone and *S*-methadone, especially in the extensive metabolizers.

Use of methadone in opioid withdrawal

A widely used technique for opioid detoxification, pioneered by Isbell and Vogel (43), involves the substitution of methadone for the illicit opioid, followed by a gradual reduction in the amount of methadone taken.

Methadone maintenance treatment was established in 1964 in New York City by Vincent Dole and Marie Nyswander. In the initial studies, subjects who were heavily addicted to heroin were evaluated and stabilized on daily methadone doses as inpatients before transfer to an outpatient clinic for continued treatment. With further experience, it was feasible to drop the inpatient phase (44).

Methadone is used to substitute for a variety of opioid drugs. It is well absorbed after oral ingestion, with peak blood concentrations after about 4 hours. Steady-state concentrations are reached after about 5 days. By virtue of its long duration of action (the half-life with regular dosing is about 22 hours), methadone suppresses opioid withdrawal symptoms for 24–36 hours. In the early stages of treatment patients may report problems such as drowsiness, insomnia, nausea, euphoria, difficulty in micturition, and excessive sweating. With the exception of chronic constipation and excessive sweating, these effects do not generally persist.

Methadone maintenance treatment is considered to be a medically safe treatment with relatively few and minimal adverse effects. However, the danger of serious adverse effects and death with the increasing use of methadone as maintenance therapy in drug addicts has been highlighted. It must be emphasized that a daily maintenance dose of 50–100 mg is toxic in a non-tolerant adult and as little as 10 mg can be fatal in a child. There is an increasing number of reports of the deaths of children of mothers on maintenance therapy from inadvertent ingestion.

British studies have shown that, using methadone, about 80% of inpatients, but only 17% of outpatients, were successfully withdrawn (45,46). However, the technique is not without problems, one being that the methadone reduces but does not eliminate withdrawal symptoms. The withdrawal response has been described as being akin to a mild case of influenza, objectively mild but subjectively severe (47). The fear of withdrawal symptoms expressed by those dependent on drugs should not be underestimated: these factors are associated with the subsequent severity of withdrawal symptoms, and they are more closely related to symptom severity than drug dosage (48). Methadone substitution can result in a protracted withdrawal response, with patients still experiencing significantly more symptoms than controls 2 weeks after withdrawal (49).

In a study of methadone withdrawal, patients who were withdrawn over 10 days had a withdrawal syndrome that began to increase in severity from day 3, with peak severity of symptoms on day 13; in those who were withdrawn over 21 days, symptoms began to increase about day 10 with a peak on day 20 and abated thereafter, although some patients did not recover fully until 40 days after starting withdrawal (50). Thus, the duration of the withdrawal syndrome is much the same for both treatments in terms of symptom severity. It is possible that an exponential rather than linear reduction in dosage may improve the withdrawal response. These results may be of clinical significance, in that patients may feel it important that they recover from withdrawal as quickly as possible, in order to participate fully in other aspects of drug withdrawal programs. However, although there was no difference between the 10-day and 21-day programs regarding completion rates for detoxification (70 and 79% respectively), the dropout rates after detoxification were significantly different. During the 10 days after the last dose of methadone, the dropout rate in the 21-day group was 18% compared with 30% in the 10-day group. These results may also have financial implications in respect of the number of subjects who can be admitted to treatment programs.

In some treatment programs, total abstinence is not considered to be a practical objective and treatment may involve the use of drugs such as methadone as maintenance therapy with the expectation of reducing illicit drug consumption (51). Well-organized methadone maintenance treatment can reduce the intake of illicit opioids in many injecting drug users (52,53).

Outcome studies of methadone maintenance treatment have reported favorable results. High rates of patient retention, reduced criminality, and improved social rehabilitation are reported. Despite its proved effectiveness, it remains a controversial approach among substance abuse treatment providers, public officials, policy makers, the medical profession, and the public at large. Nevertheless, almost every nation with a significant narcotic addiction problem has established a methadone maintenance treatment program.

For patients entering treatment from an institution where they have been drug-free, initial daily methadone doses should be no more than 20 mg. Otherwise initial daily doses of 30–40 mg should be sufficient to obtain the necessary balance between withdrawal and narcotic symptoms. Thereafter, stabilization is achieved by gradually increasing the dose. When methadone is given in adequate oral doses (usually 60 mg/day or more), a single dose in a stabilized patient lasts 24–36 hours, without creating euphoria and sedation. Tolerance to methadone seems to remain steady, and patients can be maintained on the same dose, in some cases for more than 20 years. The methadone dose must be determined individually, owing to individual variability in pharmacokinetics and pharmacodynamics. Maintenance of appropriate methadone blood concentrations is recommended.

© 2006 Elsevier B.V. All rights reserved.

Tolerance to the narcotic properties of methadone develops within 4–6 weeks, but tolerance to the autonomic effects (for example constipation and sweating) develops more slowly.

The major adverse effects during treatment occur during the initial stabilization phase. In addition to constipation and sweating, the most frequently reported adverse effects are transient skin rash, weight gain, and fluid retention. Since the main metabolic pathway of methadone is CYP3A4, numerous drug interactions can be expected. Drugs that interact with methadone are listed in the table in the monograph on opioids.

Methanthelinium

General Information

Oral doses of 25–100 mg methanthelinium have typical anticholinergic adverse effects. Methanthelinium is considered to be more toxic than propantheline, mainly because its ganglion-blocking activity is relatively more marked than its antimuscarinic effect. Perhaps for this reason, impotence (1) has appeared to be a greater problem with this drug; central nervous adverse reactions, even including psychosis, have been reported in the past.

Reference

Methapyrilene

See also Antihistamines

General Information

Methapyrilene is a first-generation antihistamine with a relatively strong sedative effect. It is therefore a constituent of many sedative and sleep-inducing over-the-counter formulations.

Long-Term Effects

Drug abuse

Owing to easy access and abuse, intoxication with a fatal outcome has been reported with methapyrilene (1).

Methohexital

See also General anesthetics

General Information

Methohexital is an ultrashort-acting barbiturate that is widely used in dental anesthesia because of its rapid onset and short duration of action.

Of 4379 dental patients who received methohexital, 6.7% experienced restlessness, 5.5% respiratory disorders (respiratory obstruction, hiccuping, laryngeal spasm, apnea, or sneezing), 1.1% venous complications, 1.0%

© 2006 Elsevier B.V. All rights reserved.

delayed recovery, 0.5% excitation, 0.27% nausea and vomiting, and 0.2% other mild reactions (1). Pain at the site of injection occurs in up to 64% of patients; the addition of lidocaine 10 mg significantly reduced the incidence to 22% (2).

A selective inhibitor of neuronal nitric oxide synthase, 7-nitroindazole, prolonged the duration of methohexital-induced narcosis in rats (3). This finding is consistent with previous work showing potentiation of anesthetic agents by non-specific nitric oxide synthase inhibitors.

Organs and Systems

Cardiovascular

Vasodilatation and depressed myocardial contractility are possible hemodynamic consequences of high-dose methohexital anesthesia (4).

Respiratory

Rectal administration of methohexital, sometimes used for children with needle-phobia, can cause apnea, particularly if there are pre-existing nervous system abnormalities (SED-12, 242) (5).

Nervous system

Seizures are a possible but rare complication of methohexital (6); it is inadvisable to use it in a patient with a history of epilepsy.

Methotrexate

General Information

Methotrexate is a folic acid antagonist that acts by inhibiting dihydrofolate reductase. Owing to its immunosuppressive and anti-inflammatory properties, low-dosage methotrexate (7.5–15 mg/week) has been extensively investigated for other therapeutic purposes characterized by inflammation or cellular proliferation. Since the mid-1980s, methotrexate has become one of the most widely used disease-modifying anti-rheumatic drugs (DMARDs) in rheumatoid arthritis. It also has a significant degree of efficacy in psoriasis, asthma, and inflammatory bowel disease, and may also be effective in systemic lupus erythematosus, giant cell arteritis, and Wegener's granulomatosis. The exact mechanisms by which methotrexate affects these diseases are still uncertain, and its clinical effects probably result from multiple biochemical events at a variety of cellular sites (1).

General adverse effects

Most of the experience regarding the adverse effects of low-dose methotrexate has accumulated in patients with rheumatoid arthritis. Adverse effects are very common during the first year of treatment and reach an incidence of 60–70%. However, they are rarely severe enough to require permanent drug withdrawal, even after very long-term treatment. Based on a cohort study of 152 patients with rheumatoid arthritis, the probability of methotrexate continuation was 30% at 10 years, and adverse effects were the most frequent reason (50%) for drug withdrawal (2). Even though the overall withdrawal rate for methotrexate-induced adverse effects is 7–16%, long-term methotrexate treatment required drug withdrawal because of adverse effects less often than several other second-line DMARDs (SEDA-22, 416). In a retrospective analysis of 437 rheumatoid arthritis patients treated for 3–106 months (mean = 35 months), the most common adverse effects were gastrointestinal disorders (20%), raised liver function tests (13%), respiratory disorders (6.4%), hematological abnormalities (4.4%), weakness (3.4%), central nervous system disorders (2.8%), infections (2.3%), mucocutaneous disorders (2.3%), and arthralgia (1.8%) (3). A Ritchie's index of 10 or less, a low polymorphonuclear leukocyte count, and the absence of rheumatoid factor predicted the occurrence of adverse effects.

In one study, 10 patients (of an original 29) were still taking methotrexate after a mean of 13 years and a mean cumulative dose of 9.7 g (4). The overall drug withdrawal rate was 48%, and the rate of adverse effects, particularly on the gut and central nervous system, fell with time (85% at baseline, 90% at 90 months, 62% at 160 months). It was felt that routine folate supplementation might have contributed to the observed reduction in toxicity, except for mouth ulcers or soreness. Very similar findings were found in another long-term (132 months) prospective study (5).

Raised methotrexate serum concentrations (over 100 nmol/l at 36–42 hours after ingestion) are expected to increase the likelihood of several adverse effects, that is, gastrointestinal and hematological effects, but similar adverse effects can be found even with low methotrexate serum concentrations. Reduced red cell folate concentrations during methotrexate treatment also related to adverse effects and rises in liver enzymes, and red cell folate concentrations above 800 nmol/l protected against common adverse effects and treatment withdrawal (6). Several investigators now advocate the concomitant use of folic acid (5–7 mg/week and up to 27.5 mg/week) to reduce some of methotrexate-associated adverse effects without reducing its efficacy (7).

© 2006 Elsevier B.V. All rights reserved.

Prevention of adverse effects

It is possible to reduce the incidence of several adverse effects of methotrexate by using folic or folinic acid. The usual practice is to give weekly folic acid in patients who are taking weekly methotrexate (on a different day) and daily folinic acid in those who are taking daily methotrexate. Folic acid supplementation is now commonly given to reduce the adverse effects of methotrexate, in particular its mucosal and gastrointestinal toxic effects (SED-14, 1297) (SEDA-23, 406), but less is known about how long this should be continued in patients taking long-term treatment.

In a meta-analysis of 307 patients with rheumatoid arthritis from seven randomized clinical trials, of whom 147 took folate supplementation, hematological adverse effects were not significantly reduced in the folate group (8). However, there was a 79% reduction in mucosal and gastrointestinal adverse effects in patients taking folic acid and a non-significant trend toward a reduction (42%) in patients taking folinic acid. Disease activity was not modified by low doses of folate. Finally, the authors noted that folinic acid is more expensive.

In 75 patients with rheumatoid arthritis taking methotrexate (up to 20 mg/week) and folic acid (5 mg/day), folic acid was withdrawn and the patients were randomized to restart folic acid ($n = 38$) or to take placebo ($n = 37$) double-blind, and were regularly assessed for 1 year (9). There were more withdrawals with placebo (46%) than with folic acid (21%) and more nausea. There were no obvious differences in efficacy. This suggests that folic acid supplementation is still helpful in the long term.

Organs and Systems

Cardiovascular

Cardiovascular adverse effects of methotrexate are extremely rare.

- There has been one detailed report of ventricular dysrhythmias and myocardial infarction, with recurrence of frequent ventricular extra beats on each readministration of methotrexate in a 36-year-old man (10).

It has been suggested that methotrexate increases mortality in patients with rheumatoid arthritis with cardiovascular co-morbidity (11). This assumption was based on a retrospective analysis of 632 patients with rheumatoid arthritis, of whom 73 died. The simultaneous presence of methotrexate and evidence of cardiovascular disease was an independent predictor of mortality. There was no such association with other DMARDs. The authors suggested that this effect may result from a methotrexate-induced increase in serum homocysteine, encouraging atherosclerosis.

Respiratory

Isolated and sustained cough is an unusual adverse effect of methotrexate. Among 13 patients who had a cough, only three met the criteria for methotrexate-induced pneumonitis (12). An irritant effect of methotrexate on the airways was therefore suggested.

Pneumonitis

Acute or subacute interstitial pneumonitis is an important but unpredictable and potentially life-threatening adverse effect of low-dose methotrexate (13–16).

Presentation

In patients with definite or probable methotrexate-induced lung injury, the predominant clinical features include shortness of breath, cough, and fever (13). Pathological examination usually shows an interstitial inflammatory cell infiltrate (sometimes granulomatous or with alveolar damage), and variable degrees of interstitial fibrosis. Unfortunately, confirmatory evidence is sometimes hard to obtain, particularly in patients with rheumatoid arthritis in whom rheumatoid interstitial lung disease can also occur. Infectious pneumonias, particularly viral or *Pneumocystis jiroveci* pneumonia, which resemble methotrexate pneumonitis and can occur as a result of immunosuppression, should also be carefully excluded.

- Pulmonary endoalveolar hemorrhage was a possible complication of pneumonitis in a 57-year-old woman who voluntarily increased her dosage of methotrexate from 7.5 mg once a week to 7.5 mg/day for 15 days (17).

The potential severity of methotrexate pneumonitis was finally exemplified in a careful retrospective multicenter study of 29 patients with definite or probable criteria for methotrexate-induced lung injury (13). Overall, five patients (17%) died, two of them after methotrexate rechallenge.

Frequency

The prevalence of methotrexate pneumonitis has been variably estimated from 0.3 to 18%, with a mean estimated prevalence of 3.3% (14,16). In a review of the respiratory complications of methotrexate, the authors concluded that pneumonitis occurs in 7% of patients, in 25% of whom it is fatal as a result of respiratory failure (18). This can occur with any dose of methotrexate, given via any route; it has occurred after the intrathecal administration of 12 mg given for central nervous system prophylaxis (19). In a review of 194 patients with rheumatoid arthritis and 38 with psoriatic arthritis, the prevalences of pneumonitis were 2.1 and 0.03% respectively (14), which is similar to the 3.2% incidence in a prospective study of 124 patients with rheumatoid arthritis (20). Another analysis performed over 5 years showed that the estimated prevalence of definite or probable pneumonitis was only 0.86% in 1162 patients (10 patients, of whom three died), but this conclusion was based on a limited retrospective identification of cases (21).

Mechanism

Even though methotrexate pneumonitis was first described about 30 years ago, very little is known about the mechanism, and whether it is due to direct cumulative toxicity, hypersensitivity, or an idiosyncratic reaction. In one case, interleukin-8 was speculated to play an important role in the pathogenesis (22).

Susceptibility factors

Susceptibility factors for methotrexate pneumonitis are still poorly understood. In one study, no risk factors were

© 2006 Elsevier B.V. All rights reserved.

identified and periodic pulmonary function tests were not predictive (20). In contrast, advanced age, diabetes, pre-existing rheumatoid pleuropulmonary involvement or previous lung disease, previous use of DMARDs, and hypoalbuminemia were suggested as the most reliable predictors of methotrexate-induced pneumonitis in a large historical case-control study (15,23). The weekly dose, the cumulative dose, and the duration of treatment were not related to its occurrence. A history of drug-induced pulmonary disorders was also thought to favor methotrexate pneumonitis, but this was based on a single case report in a patient who previously had aminorex-induced primary pulmonary hypertension (SEDA-22, 416).

Management

The management of methotrexate pneumonitis primarily requires methotrexate withdrawal and supportive care. Although glucocorticoids are commonly used, there is as yet no evidence that they positively influence the outcome. Any readministration of methotrexate is dangerous, and four of six patients treated again with methotrexate developed recurrent lung toxicity, of whom two died (13).

Based on a report of 9 cases and a careful reanalysis of 123 previously published cases, the clinical spectrum and histopathology of methotrexate-induced pneumonitis have been reviewed (24). The authors stressed that methotrexate pneumonitis should be promptly recognized to avoid a severe outcome, although no specific features could be identified compared with other drug-induced adverse lung effects and no definite pathological findings compared with rheumatoid lung. Diagnostic criteria therefore mostly included a history of exposure, the exclusion of other pulmonary diseases, especially infections, and the presence of pulmonary infiltrates on the chest X-ray. Once methotrexate pneumonitis developed, 13% of the patients died from respiratory failure, clearly underlining the fact that methotrexate pneumonitis is potentially life-threatening. Methotrexate reintroduction should also be strongly discouraged in such cases, because about 25% of patients experience recurrence.

Nervous system

Reports of necrotizing leukoencephalopathy in association with methotrexate have been verified by biopsy or autopsy (25,26). Serial electroencephalography can predict this, since slow-wave activity develops during the administration of high-dose methotrexate. Autopsy has shown widespread necrosis and spongiosis in the cerebral and cerebellar white matter in such cases (25).

Chronic brain edema, multifocal white matter necrosis, and deep brain atrophy have been reported in patients who received high-dose methotrexate therapy, with an incidence of 4% (27). All patients received methotrexate 8–9 g/m^2 intravenously over 4 hours. The encephalopathy began abruptly, an average of 6 days after the second or third weekly treatment, presenting with behavioral abnormalities. These ranged from laughter to lethargy or unresponsiveness. In some patients, there were focal sensorimotor or reflex signs and generalized seizures. The disorder lasted from 15 minutes to 72 hours, and it disappeared as abruptly as it began, without specific treatment.

A rare case of a reversible neurological disturbance associated with focal subcortical white matter pathology has been described after administration of methotrexate 3 g/m^2. In patients who received 8–12.5 g/m^2, the incidence of neurological abnormalities was 4%. All of these patients were also receiving methotrexate intrathecally as well, but the relevance of this is not known (28).

In one case, low-dose methotrexate was implicated in leukoencephalopathy (29).

Treatment with intrathecal methotrexate of children under 5 years of age with acute lymphoblastic leukemia (irrespective of other drugs) has structural and functional effects on the developing neocerebellar–frontal subsystem (30).

Acute dysarthria has been attributed to methotrexate (31).

- A 71-year-old man was given oral methotrexate (15 mg/week) for a cutaneous T cell lymphoma. Within 3 weeks he developed progressive dysarthria and incoordination, and neurological examination showed mild buccofacial dyskinesia. Complete examination was otherwise normal, and he fully recovered 6–8 weeks after methotrexate withdrawal.

This case is reminiscent of other previously reported neurological abnormalities with low-dose methotrexate.

Psychological, psychiatric

There was a significantly higher risk of late cognitive impairment (concentration and memory) in patients ($n = 39$) taking adjuvant cyclophosphamide, fluorouracil, and methotrexate than in controls matched for age, disease, surgery, and radiation dose (32).

In studies of the neurotoxic effects of low-dose methotrexate treatment, dizziness, headache, visual disturbances or hallucinations, lack of concentration, cognitive dysfunction, and depression-like symptoms were detected in 1–35% of patients (33,34). Advanced age and mild renal insufficiency were possible susceptibility factors (34).

Nutrition

Of patients receiving high-dose methotrexate (5–8 g/m^2), 95% developed a significant increase in serum phenylalanine concentrations, probably due to inhibition of dihydropteridine reductase (35). The clinical significance of this is not obvious, although it is possible that it may contribute to the transient neurological disturbance observed in some patients taking high-dose methotrexate.

Hematologic

Significant hematological abnormalities occur in 10–24% of patients who take methotrexate. Mild to moderate leukopenia is the most frequent, followed by thrombocytopenia. Isolated thrombocytopenia and anemia are uncommon (SEDA-22, 416) (36). In a retrospective study in 315 patients, 13 had thrombocytopenia, two of whom also had pancytopenia (37). Thrombocytopenia correlated with the weekly dosage of methotrexate administered on the same day as NSAIDs, and methotrexate was safely reintroduced in patients who developed thrombocytopenia as a result of concomitant administration of

© 2006 Elsevier B.V. All rights reserved.

both drugs, provided that NSAIDs were withheld at least on the day of methotrexate administration.

Pancytopenia is a rare but potentially fatal complication, and numerous reports have been published. The characteristics and incidence of pancytopenia have been carefully re-evaluated from case reports and clinical trials published from 1980 to 1995 (38). Of 70 reported cases, 12 patients died (17%). Impaired renal function was the most important contributing factor (54%), particularly in fatal cases (10/12). Other important susceptibility factors included advanced age (over 65 years), hypoalbuminemia, concurrent infection, and/or concomitant multiple medications (particularly co-trimoxazole). The mean cumulative dosage was 675 (10–4800) mg, and the minimal cumulative methotrexate dose leading to fatal pancytopenia was 10 mg. This confirms that pancytopenia can occur at any time during treatment, even in the absence of known susceptibility factors. Bone marrow biopsy showed megaloblastosis and hypocellularity. Eosinophilia and increased mean corpuscular volume were rarely observed. In an overall review of five long-term prospective studies (511 patients), the calculated incidence of methotrexate-induced pancytopenia was 1.4%. Although severe myelosuppression sometimes required folinic acid, there are as yet no data to determine whether prophylactic folate supplementation can reduce the incidence of pancytopenia.

In a double-blind, placebo-controlled study of the safety and efficacy of methotrexate therapy combined with glucocorticoids in patients with giant cell arteritis over 24 months, adverse events were defined as a new diagnosis of any condition during treatment (39). The combination of methotrexate plus prednisolone reduced the number of relapses and improved the course of the disease. Methotrexate was withdrawn in three patients who had adverse events that were clearly drug-related. One had leukopenia, anemia, and mucositis, one developed pancytopenia, and one oral ulcers. These patients were not taking folic acid or folinic acid supplements.

Gastrointestinal

Gastrointestinal adverse effects (stomatitis, anorexia, abdominal pain, dyspepsia, nausea, vomiting, diarrhea, and weight loss) are very common, particularly after oral administration of methotrexate (up to 50%), and often require dosage adjustment (3). Folic acid supplementation reduces the incidence of several gastrointestinal adverse effects.

Stomatitis can sometimes be particularly harmful and has been reported as the cause of transient or permanent treatment withdrawal in 4.5 and 1.1% of 1539 patients respectively (40). However, one study did not show significant differences in the number of oral lesions or the duration or frequency of stomatitis between patients with rheumatoid arthritis taking methotrexate and those not taking methotrexate (19/51 versus 9/46), although the prevalence of ulceration was higher in the methotrexate group (41).

Liver

Cytolytic hepatitis has been reported in a 58-year-old man being treated with intramuscular methotrexate 10 mg/week (total dose over the previous 4 years 2.3 g); it resolved within 2 weeks of stopping therapy (42).

Hepatic fibrosis and cirrhosis

The main concern over long-term treatment with methotrexate is hepatic fibrosis and cirrhosis. Methotrexate hepatotoxicity was initially reported in children given high daily dose methotrexate for leukemia. After its introduction for the treatment of psoriasis, several papers published in the late 1960s pointed out the possible risk of severe hepatic fibrosis and cirrhosis in patients taking moderate daily doses. Since then many studies have focused on the extent of long-term methotrexate hepatotoxicity in patients taking low-dose methotrexate for psoriasis and rheumatoid arthritis. However, the evidence on the frequency and severity of severe liver disease in these patients is still highly controversial, since there may be liver histological changes before methotrexate treatment, particularly in patients with psoriasis. Furthermore, there are numerous confounding factors (Table 1) which can contribute to histological liver changes, leading several authors to suggest as early as 1990 that methotrexate-induced hepatic fibrosis and cirrhosis is uncommon and only occurs in patients with other susceptibility factors (43).

Frequency

The incidence of liver cirrhosis after a mean dose of 2 g is 7–10%. Once 1.5 g has been administered (44), or 2 years after starting long-term treatment, biopsy should be discussed (45).

Liver failure or cirrhosis were identified among 24 patients in a retrospective survey of more than 16 600 patients with rheumatoid arthritis who had taken

Table 1 Susceptibility factors for hepatotoxicity of methotrexate

Strong association	Previous or concurrent heavy alcohol use
	Pre-existing liver disease
	Daily methotrexate administration
	Renal insufficiency
Probable association	Duration of methotrexate treatment (over 2 years)
	Cumulative methotrexate dose (over 1500 mg)
	Prior treatment with arsenicals
	Obesity with diabetes mellitus
Possible or potential association	Maximum weekly dose over 25 mg
	Obesity alone
	Diabetes mellitus alone
	Heterozygous alpha$_1$ -antitrypsin deficiency
	Felty's syndrome
	Prior treatment with vitamin A
	Concurrent NSAID use
	Concurrent treatment with ciclosporin
	Concurrent PUVA treatment
No association	Sex
	HLA phenotype
	Extent of psoriatic skin involvement
	Duration of rheumatoid arthritis
	Glucocorticoid therapy
Negative association	Concurrent folate supplementation
	Concurrent hydroxychloroquine use

methotrexate for at least 5 years, giving an estimated 5-year frequency of one in 1000 (46).

No morphological features of methotrexate hepatotoxicity were demonstrated after 2 years of methotrexate treatment in 48 patients with primary biliary cirrhosis (47).

Collectively, the available data suggest that methotrexate rarely causes significant serious liver damage in patients who have been otherwise carefully selected, who present no risk factors for methotrexate-induced hepatotoxicity, and who have received lower weekly dosages with strict monitoring of liver function (for example transaminases) in order to reduce methotrexate doses when liver enzymes are persistently raised (48).

Diagnosis and monitoring

Routine liver function tests do not reliably indicate liver damage, and they may not become abnormal until there is already considerable liver damage. It is therefore common practice to monitor patients by conducting annual liver biopsies. Measurement of the serum amino-terminal propeptide of type III procollagen (PIII PI) has been used as an alternative to liver biopsy; high concentrations correlate with fibrosis on liver biopsy (49). No patient with a normal serum concentration had an abnormal biopsy. An increase in the plasma phenylalanine/tyrosine ratio in children and adolescents can provide clinical evidence of liver damage before the appearance of symptoms in patients who have taken high doses of methotrexate (50).

Methods of monitoring patients for possible methotrexate hepatotoxicity and guidelines have been reviewed (48,51,52). It should be mentioned that the frequent rise in serum transaminases (involving 30–80% of patients) after the start of treatment is transient and does not predict liver damage; only persistently abnormal transaminases are potential indicators of methotrexate hepatotoxicity.

Mechanism

Folate depletion may be a factor in the pathogenesis of methotrexate-induced liver disease. In 30 patients on long-term methotrexate therapy, aimed at determining whether erythrocyte concentrations of folate and methotrexate might provide an indication for liver biopsy, there was no difference between red cell folate concentrations in patients with cirrhosis or progressive liver fibrosis and patients without fibrosis or with non-progressive hepatic fibrosis. Erythrocyte methotrexate concentrations were higher in patients with progressive hepatic disease, but cumulative dose and length of treatment were stronger predictors. In individual cases, erythrocyte folate and methotrexate concentrations were not a reliable guide (53).

Pathology

In patients with rheumatoid arthritis, baseline histological liver abnormalities were less common, with mild fibrosis only in 0–15% of patients. In retrospective studies with no pre-methotrexate liver biopsies, mild fibrosis was found in 3–35% of patients taking methotrexate, moderate or severe fibrosis in 0–10%, and cirrhosis in 0–2%. However, no case of cirrhosis was identified in studies which compared pre- and postmethotrexate biopsies or sequential biopsies while on long-term methotrexate, that is, a mean cumulative dose of 1200–5000 mg (52). Again, both worsening and improvement of histological lesions occurred. The application of guidelines to prevent methotrexate hepatotoxicity may account for these reassuring results. Liver biopsy changes were moderate or absent in patients with juvenile rheumatoid arthritis who took a cumulative dose of over 3000 mg (SEDA-21, 388) (52).

In 22 of 29 patients (76%) who were treated with low-pulse doses of methotrexate for rheumatoid arthritis, liver biopsy specimens showed variability in liver cell nuclear size, glycogenated nuclei, and fatty change. Occasionally there was mild portal infiltration with lymphocytes. There were no significant differences in age, duration of treatment, or cumulative dose amongst the cases. Serial increases in serum transaminases and/or alkaline phosphatase activity and development of hypoalbuminemia during treatment were indicators of development of liver disease (54).

In another study, the pathological lesions found in liver biopsies from patients treated with methotrexate were non-specific, consisting usually of macrovesicular steatosis, nuclear pleomorphism, chronic inflammatory infiltrates in the portal tracts, focal liver cell necrosis, fibrosis, and cirrhosis (52).

The pathological features of methotrexate-induced liver damage have been comprehensively reviewed (52). In patients with psoriasis, baseline liver biopsies were often abnormal, with mild fibrosis, moderate or severe fibrosis, and cirrhosis in 0–30, 0–7, and 0–1.5% respectively. These figures increased after methotrexate use, with fibrosis and cirrhosis in 14–34 and 0–21% respectively.

Ultrastructural studies have sometimes identified Ito cell prominence and collagen deposition in the perisinusoidal space of Disse during the first months of treatment and before the appearance of any signs of fibrosis, but these findings have been disputed in rheumatoid arthritis patients. Using immunohistochemical quantification, increased matrix proteins, collagen and transforming growth factor alpha were also found as possible early markers of methotrexate hepatotoxicity (55).

Susceptibility factors

The susceptibility factors for methotrexate-induced hepatotoxicity are listed in Table 1.

In a meta-analysis of 636 patients from 15 studies, who took chronic low-dose methotrexate for rheumatoid arthritis or psoriasis, the risk of liver toxicity increased with cumulative dose and heavy alcohol intake (56).

In one study, the risk of developing cirrhosis progressively increased with the total cumulative dose of methotrexate, from 13% at 2200 mg to 26% at 4000 mg (57). However, studies that compared sequential liver biopsies in patients on treatment and included specific recommendations for patient selection and the monitoring of methotrexate hepatotoxicity, gave contrasting results, with a lower incidence of cirrhosis even after high cumulative methotrexate doses (up to 5100 mg) (52). In addition, although histological lesions can worsen during treatment, improvement or absence of progression of prior fibrosis/cirrhosis has been found in very long-term follow-up of patients still taking methotrexate after 10 years (58).

© 2006 Elsevier B.V. All rights reserved.

The incidence and susceptibility factors of rises in serum transaminases have been detailed from a retrospective analysis of 66 patients with rheumatoid arthritis (59). There was an asymptomatic increase in serum transaminases in 42 and 49% of patients respectively, an incidence 4–5 times greater than that found in 21 patients taking other DMARDs. Although most of the rises in transaminases were transient and spontaneously reversible, 14 patients had sustained rises. There was a close relation between the incidence of high transaminases and the weight-adjusted dose of methotrexate. In a multivariate regression analysis, only obesity, methotrexate dose (over 0.15 mg/kg/week), and the concomitant presence of gastrointestinal adverse effects were significantly and independently associated with the likelihood of a rise in alanine transaminase. In the 14 patients who had persistently high transaminases, weekly folic acid 5 mg produced a sustained fall in serum alanine transaminase within 3 months, but three patients had to be withdrawn because of exacerbation of rheumatoid arthritis.

Urinary tract

Low-dose methotrexate is usually not regarded as nephrotoxic, and one report of nephrotic syndrome with minimal change disease on renal biopsy should be regarded with caution, since there was recovery after glucocorticoid treatment and withdrawal of concomitant NSAIDs (SEDA-22, 416).

However, renal toxicity occurs with high-dose methotrexate and more likely to occur with concomitant administration of other nephrotoxic agents, such as aminoglycosides, cephalosporins, NSAIDs, and diuretics (60).

The pathogenesis of methotrexate-induced nephrotoxicity is not understood, but it is thought to result from crystallization of methotrexate in the renal tubules. Adequate hydration and urinary alkalinization are necessary to minimize this effect (61). Urinary beta$_2$ microglobulin may be a useful marker of methotrexate nephrotoxicity (62).

When serum methotrexate concentrations are high, leucovorin (folinic acid) rescue may protect against renal damage. Methotrexate concentrations are only transiently lowered by hemoperfusion, and they are unaffected by peritoneal dialysis once there is acute renal insufficiency. Sustained reductions in drug concentrations and recovery of renal function have been reported after charcoal hemoperfusion followed by hemodialysis (63,64).

Co-administration of methotrexate and procarbazine in the treatment of medulloblastomas increases the risk of methotrexate nephrotoxicity. Delayed administration of methotrexate until 72 hours after procarbazine therapy has been given may reduce this risk (65).

Skin

Since the first descriptions of the rapid development of a large number of nodules, also termed "accelerated nodulosis," in methotrexate-treated patients, a number of such reports have accumulated in patients with rheumatoid arthritis or, more rarely, psoriatic arthritis (66–68). Nodulosis is characterized by the development of small, painful, multiple nodules, sometimes disseminated; pulmonary, meningeal, or pericardial nodulosis has also been reported in a few patients (SEDA-21, 387) (67,69,70). Four cases of nodulosis and four of cutaneous vasculitis were noted during a long-term follow-up of 437 rheumatoid arthritis patients (3), but the estimated incidence of accelerated nodulosis was found to be higher in other studies: that is, 8–12% (5,66,70).

The nodules can appear at any time during treatment, with or without concomitant cutaneous vasculitis, and are usually found in patients with erosive disease and a high titer of rheumatoid factor. This has raised the question as to whether they are a reason to modify treatment, and whether they are rheumatic or represent a true adverse effect of methotrexate; certainly, methotrexate-associated nodulosis is very similar to idiopathic rheumatoid arthritis nodulosis and sometimes disappears despite continuation of methotrexate. However, prompt regression on methotrexate withdrawal and recurrence on rechallenge in several patients strongly argue for a causal drug-related effect.

There was a characteristic clinical and histopathological spectrum of skin lesions, distinct from rheumatoid papules, in four patients who took low-dose methotrexate for acute flares of collagen vascular disease (71). These so-called methotrexate-induced rheumatoid papules developed shortly after methotrexate administration consisted of erythematous indurated papules mostly affecting the proximal limbs, and disappeared after methotrexate was withdrawn or tapered. Histology showed inflammatory infiltrates of interstitially arranged histiocytes and a few neutrophils, but no features of leukocytoclastic vasculitis.

Isolated cutaneous leukocytoclastic vasculitis occurs infrequently in patients taking methotrexate, and an immediate-type hypersensitivity reaction has been thought to be involved, in view of prompt recurrence after drug readministration or a positive mast cell degranulation test as recorded in several patients (SEDA-21, 388) (SEDA-22, 417) (72).

Other isolated reports included the occurrence of skin ulceration (SEDA-22, 388) and one fatal case of toxic epidermal necrolysis (SEDA-21, 388).

Persistent hyperpigmentation is an unusual manifestation of weekly administration of methotrexate (73).

- Severely ulcerated psoriatic plaques and acute extensive exfoliative dermatitis occurred in a 37-year-old man who had taken methotrexate for 5 years for psoriasis (74).

In the context of a case of severe reactivation of recent sunburn after a single injection of methotrexate for ectopic pregnancy in a 40-year-old woman, the authors reviewed the literature on methotrexate photosensitivity (75). Photodermatitis reactivation is the only well-documented type of photosensitivity associated with methotrexate. It can occur if methotrexate is given at 2–5 days after excessive exposure to ultraviolet or X-radiation.

A previously unreported skin reaction mimicking Stevens–Johnson syndrome has been reported (76).

- A 61-year-old woman inadvertently took a high dose of methotrexate (10 mg/day) for psoriasis, and developed mucosal ulcers after 3 months. One month later, methotrexate (20 mg/week) was restarted, but she developed

© 2006 Elsevier B.V. All rights reserved.

painful oral ulceration and burning skin lesions 3 days later. She had an erythema multiform-like rash and several buccal ulcers. There was a moderate pancytopenia. Histological examination of the skin showed features consistent with an acute graft-versus-host reaction. All medications except aspirin were withdrawn, and she recovered fully after treatment with calcium folinate and prednisolone.

The authors speculated that concomitant aspirin may have contributed to this severe reaction.

Hair

Mild alopecia is common in patients taking methotrexate (77,78).

Nails

Yellow nail pigmentation without paronychia has been noted in a patient with psoriasis taking methotrexate (79).

Musculoskeletal

Arthralgia and myalgia sometimes occur within 24 hours of methotrexate injections in patients with rheumatoid arthritis. These transient effects, which can be accompanied by fatigue, malaise, and various neuropsychological disorders, have escaped recognition, but they occurred in 10% of patients over 18 months and sometimes resulted in treatment withdrawal (80).

Leg pain and spontaneous fractures attributed to prolonged high-dose methotrexate therapy in pediatric oncology have been recognized since the 1970s, but there have been some cases in patients taking low-dose methotrexate (81,82). All the same, it is still controversial as to whether methotrexate can actually cause changes in bone metabolism (83). There was a significant reduction in bone mineral density in 11 postmenopausal women taking methotrexate for primary biliary cirrhosis compared with 11 matched controls not taking methotrexate (84). Among 133 patients with rheumatoid arthritis, methotrexate without glucocorticoids was not associated with changes in the bone mineral density after 3 years of treatment, but methotrexate plus prednisone (over 5 mg/day) produced greater bone loss than prednisone alone (85). In contrast, another study failed to show accelerated bone loss in methotrexate users compared with non-users, but the study was limited to 10 patients in each group (86).

The possible effects of methotrexate on bone metabolism and bone loss have been discussed in the context of two adults (87) and in relation to a study in children with juvenile rheumatoid arthritis (88) who had delayed bone healing after surgery. The two adults, aged 52 and 62 years, had been taking methotrexate (7.5 and 15 mg/week) for 14 and 15 months when they underwent metatarsal and tibial osteotomy. Because X-ray examination 5 and 6 months after surgery showed non-union, methotrexate was withdrawn; the bone healed promptly in both patients within 2 months. The authors thought that the outcome in these patients without risk factors for bone fragility suggested that temporary methotrexate withdrawal should be considered in cases of delayed bone healing after surgery.

In contrast, in a longitudinal study of 32 patients with juvenile rheumatoid arthritis, there was no evidence of deleterious effects of long-term, low-dose methotrexate on bone mass density (88). The cumulative dose of glucocorticoids, weight, and height were the main determinants of bone mass changes.

Furthermore, there is evidence that it is disease activity rather than methotrexate that accounts for changes in bone mass (89). This 2-year longitudinal study involved 22 patients taking methotrexate and 18 patients taking other DMARDs; it was strictly controlled for the use of glucocorticoids. There were significant and equal reductions in trabecular bone mineral density in both groups. Bone loss was most marked in patients with active disease.

Sexual function

Impotence has very rarely been attributed to methotrexate (90).

Reproductive system

Although the occurrence of gynecomastia requiring surgical excision in two patients might have been coincidental (91), in another patient it disappeared after methotrexate withdrawal and recurred on rechallenge (92).

Immunologic

Immediate hypersensitivity reactions are rare after low-dose methotrexate.

- A 53-year-old woman had three episodes of angioedema while taking methotrexate, with no recurrence after withdrawal (93).

Vasculitis has been infrequently reported in patients taking low-dose methotrexate (SEDA-21, 388) (SEDA-22, 417) (94). Although most cases have been observed in patients with rheumatoid arthritis, suggesting that the underlying disease plays a part, vasculitis has also been described in a patient with ankylosing spondylitis (95). Methotrexate was also reported to have exacerbated pre-existing urticarial vasculitis in a 32-year-old woman; the lesions recurred after rechallenge (96).

Infection risk

Methotrexate-related immunosuppression can be expected to increase the likelihood of infections. The infection rate reported in patients taking low-dose methotrexate has varied from one study to another. In a literature review focusing on patients with rheumatoid arthritis taking methotrexate, the mean infection rate was 1.8% in retrospective studies, 4.6% in open studies, and 11.6% in double-blind studies (97). Infections usually occurred within 1.5 years of starting treatment and mostly comprised common respiratory or cutaneous bacterial infections, *Herpes zoster*, and, more rarely, opportunistic infections. In one comparative study, the overall risk of infections was considered to be low and similar in patients taking methotrexate and azathioprine (97), but others have found a higher prevalence of infections and an increase in antibiotic use in patients with rheumatoid arthritis taking methotrexate as compared to other DMARDs, except cyclophosphamide (98,99).

© 2006 Elsevier B.V. All rights reserved.

An accumulating series of case reports has focused on the possible more frequent occurrence of opportunistic infections despite normal leukocyte counts in patients treated for rheumatoid arthritis or, less often, psoriasis (97,100,101). Various bacterial, fungal, and viral opportunistic infections have been described, with *Pneumocystis jiroveci* pneumonia as the most frequently reported (SEDA-21, 389) (SEDA-22, 417). Although the most severe, sometimes fatal, infectious diseases were usually observed in patients also taking glucocorticoids (SEDA-22, 417) (102,103), severe infections can also occur in occasional patients not taking concomitant glucocorticoids (SEDA-21, 389) (101,104–107).

Acute reactivation of a presumed quiescent chronic hepatitis B infection in one reported case after methotrexate withdrawal suggests that T cell-mediated immunological rebound might lead to rapid destruction of infected hepatocytes (108).

Long-Term Effects

Tumorigenicity

The evidence that methotrexate is carcinogenic is inconclusive and mostly based on case reports or analyses of cohort studies without control groups (100,109). For example, malignant neoplasms (urothelial carcinoma of the bladder, a malignant teratoma, and a dermal squamous cell carcinoma) have been described in three patients taking prolonged courses of methotrexate 7.5–15 mg/week (110).

From a retrospective study in more than 16 000 rheumatoid arthritis patients, the risk of hematological malignancy in methotrexate-treated patients was thought to be very small and not different from that observed in patients who used other DMARDs (111). In 426 patients with rheumatoid arthritis who took methotrexate for a mean of 37 months (follow-up period 4.6 years), the incidence rate of new cancers (4 cases/1000 person-years) was similar to that found in the general population (2.8 cases/1000 person-years) (112). Another preliminary study did not show an excess in the risk of lymphoproliferative disorders in patients with rheumatoid arthritis receiving long-term methotrexate maintenance (113). Earlier studies in patients with psoriasis did not show a higher incidence of cancers in patients on methotrexate compared with the general population (100,114).

In contrast, there have been several isolated reports of methotrexate-induced lymphomas (SEDA-21, 388) (SEDA-22, 417) (115,116). The pathological features in these cases have ranged from benign lymphoid hyperplasia to non-Hodgkin's lymphoma, and more rarely Hodgkin's disease (115), and patients usually had the typical features of lymphoproliferative disorders as found in immunosuppressed patients, that is, transplant patients or patients with congenital or acquired immune deficiency syndromes. Exceptionally, cases of pseudolymphoma have also been reported (SEDA-21, 389).

- Two patients developed lymphomas within 3 years of methotrexate treatment, and the authors suggested that an increase in serum IgE concentrations might anticipate the development of lymphoma in patients with rheumatoid arthritis treated with methotrexate (117).
- A cutaneous B cell lymphoma occurred in a 58-year-old man who had been treated with intramuscular methotrexate 10 mg/week for 4 years (total dose 2.3 g); the lymphoma resolved spontaneously 2 weeks after withdrawal of therapy (118).

A convincing argument implicating methotrexate as the cause of lymphomas is the possible spontaneous remission of lymphoproliferation after methotrexate withdrawal, as reported in several cases (SEDA-22, 389) (115,116). However, the putative pathophysiological mechanisms of methotrexate-induced lymphomas are unclear, and the drug's precise role, as well as that of the underlying disease as a confounding factor, needs to be investigated. The risk of a lymphoma in rheumatoid arthritis probably has more to do with the disease and its activity than with methotrexate treatment (113,119).

Low-dosage methotrexate is also a possible factor in the development of Epstein–Barr virus-associated lymphoproliferative disease, but the role of the Epstein–Barr virus in these cases is unclear. Epstein–Barr virus infection does not appear to be mandatory for the development of lymphoproliferation in patients taking methotrexate, but it was nevertheless found in about one-half of patients who developed lymphomas (SEDA-22, 389) (115,120).

Lymphoproliferative disorders have been observed during treatment of sarcoidosis and connective tissue diseases with low-dose methotrexate.

- A 51-year-old man with systemic sarcoidosis took methotrexate for 36 months and developed a large anal fissure with a diffuse polymorphic infiltrate containing large Epstein–Barr virus-positive lymphoid cells, similar to the classical B cell lymphoproliferative disorders that occur in immunosuppressed transplant recipients of solid organs (121).

This case supports the hypothesis that immunosuppressant therapy may contribute to an increased risk of Epstein–Barr virus-associated lymphoproliferative disorders.

Some of the mechanisms and risk factors of methotrexate-associated non-Hodgkin's lymphoma in patients with rheumatoid arthritis have been reviewed, including an analysis of the characteristic features of 25 detailed published cases (122). Although the epidemiological evidence is limited, several reports of spontaneous remission of lymphomas after methotrexate withdrawal strongly support a cause-and-effect relation.

A second malignancy in a patient taking methotrexate for chronic lymphatic leukemia has been described (123).

- A 55-year-old man with chronic lymphocytic leukemia and rheumatoid arthritis took methotrexate for 4 years and developed a B cell non-Hodgkin's lymphoma in the shoulder and axillary lymph nodes; he had Epstein–Barr viral antigens in the serum. After radiation and chemotherapy had failed, complete remission was achieved with a combination of rituximab and EPOCH (etoposide + prednisone + vincristine + cyclophosphamide + doxorubicin).

© 2006 Elsevier B.V. All rights reserved.

The authors thought that T cell deficiency induced by methotrexate, chronic lymphatic leukemia, and rheumatoid arthritis may have contributed to the development of the B cell lymphoma.

Other malignancies, such as malignant melanoma, multiple myeloma, leukemia or solid cancers, have been seldom reported (SEDA-21, 389) (SEDA-22, 389) (90,124), and the association with methotrexate therapy is uncertain.

Second-Generation Effects

Teratogenicity

Owing to its known teratogenic effects, methotrexate is usually considered to be contraindicated in pregnancy, and several authors have recommended withdrawing methotrexate at least 3 months before a planned pregnancy. Most of our knowledge on the consequences of in utero exposure to methotrexate is derived from oncology patients. In this setting, the fetal methotrexate syndrome mimics the aminopterin syndrome, with central nervous system abnormalities, skeletal defects, and more rarely cardiac abnormalities. The critical period of exposure is 6–8 weeks after conception and the minimal weekly dose is 10 mg (125), but one report suggested that the critical period may extend to week 11 in patients exposed to high-dose methotrexate (SEDA-22, 417).

- A 3-year-old infant born to a woman who had taken methotrexate 37.5 mg/week throughout the first 8 weeks after conception had significant developmental delay with mental retardation, which might therefore be a feature of the fetal methotrexate syndrome (126).

The developmental effects of in utero exposure to methotrexate have been reviewed, including a brief mention of three original cases (127), and a series of pregnancy outcomes in four patients exposed to low-dose methotrexate during early pregnancy has been reported more extensively (128). Of 24 patients available for evaluation, who took 2.5–35 mg/week and were accidentally exposed from the beginning of pregnancy up to 19 weeks gestation, pregnancy ended in spontaneous abortion in four and elective abortion in three (including one case of major malformation). Of the 17 neonates, three had major malformations. The malformations mostly consisted of central nervous system or craniofacial abnormalities and skeletal defects. Three patients had been exposed up to 8 weeks of gestation and one from 8 to 10 weeks, and the methotrexate doses were 12.5–35 mg/week. This is consistent with the threshold dose of 10 mg/week and the timing of exposure previously suggested for fetal methotrexate syndrome.

Susceptibility Factors

Renal disease

Impaired renal function is a susceptibility factor for methotrexate-induced pancytopenia.

- A 57-year-old man who had been on hemodialysis for the past 5 years developed severe pancytopenia 12 days after a single dose of methotrexate 5 mg (129).
- Severe complications, mostly bone marrow suppression and related complications, occurred in three patients on regular hemodialysis for end-stage renal disease (130).

Drug–Drug Interactions

Aspirin

Aspirin and methotrexate compete for renal tubular secretion, and aspirin alters the systemic and renal clearances of intravenous methotrexate (131). However, the clinical relevance of this interaction is not clear. In one study, aspirin (mean dose 4.5 g) in 12 patients did not cause more toxicity than other NSAIDs taken by 22 other patients (132).

Co-trimoxazole

Drugs that inhibit folate metabolism increase the likelihood of serious adverse reactions to methotrexate, particularly hematological toxicity. The additional risk of myelosuppression and subsequent severe pancytopenia has been particularly exemplified by the combination of methotrexate and co-trimoxazole (trimethoprim plus sulfamethoxazole) (133). This should also be taken into account in patients taking trimethoprim alone (SEDA-22, 418).

Etretinate

A case of severe hepatitis has been attributed to the combination of methotrexate with etretinate (134), a finding that was not explained by a pharmacokinetic interaction between the two drugs (135).

Fluorouracil

There is sequence-dependent synergy between fluorouracil and methotrexate. Pre-treatment with methotrexate enhances the formation of fluorouridine monophosphate and hence fluorouridine triphosphate; this enhances RNA-directed toxicity. In studies in which methotrexate has been given 1 hour before fluorouracil, response rates did not differ significantly. However, when it was given 4 hours or more before, there were significantly better response rates (136).

Glucocorticoids

Dexamethasone increased the hepatotoxicity of methotrexate in 57 children with brain tumors (137). The hepatotoxicity was not related to differences in serum concentrations and was independent of bone marrow toxicity or mucositis.

There have been conflicting studies on the interaction between low-dose methotrexate and long-term glucocorticoids. In one study, there was a significantly increased AUC and a reduction in methotrexate clearance compared with patients not taking glucocorticoids (138), and in another there was no change (139). Collectively, the data suggest that the interaction, if any, is of little clinical significance.

NSAIDs

Theoretically, NSAIDs can increase methotrexate serum concentrations by competition for renal tubular secretion (140). Since the publication of case histories reporting severe toxic effects in patients taking methotrexate and NSAIDs, there has been much concern among patients taking low-dose methotrexate (SEDA-20, 89) (SEDA-21, 100). However, most of the reports related to patients taking doses of methotrexate higher than those recommended in rheumatoid arthritis. From often mutually contradictory data, it appears that co-administration of most NSAIDs and stable low-dose methotrexate is relatively safe and that the supposed risks have little clinical significance in patients with normal renal function who are regularly monitored for hepatic, hematological, and renal toxicity (141).

In one study there was a significant reduction in renal methotrexate clearance and creatinine clearance in patients who took NSAIDs plus a high maintenance dose of methotrexate (16.6 mg/week), but no change in either variable in patients taking a stable maintenance dose of 7.5 mg/week (142). This suggests that patients taking higher doses should be more closely monitored for early signs of renal impairment that could predispose them to methotrexate toxicity.

Penicillin

Concomitant penicillin administration has been reported to exacerbate the hematological toxicity of low-dose methotrexate (143). This could have been due to inhibition of the tubular secretion of methotrexate.

Probenecid

Probenecid competes with methotrexate for renal tubular secretion, and can cause severe hematological toxicity.

- Severe pancytopenia occurred in an elderly patient taking low-dose methotrexate and probenecid (144).

Triamterene

Drugs that inhibit folate metabolism increase the likelihood of serious adverse reactions to methotrexate, particularly hematological toxicity. Bone marrow suppression and reduced plasma folate concentrations resulted from the concomitant administration of triamterene with methotrexate (145).

Methoxamine

General Information

Methoxamine is a relatively selective alpha$_1$-adrenoceptor agonist that has been used to a limited extent in the management of urinary stress incontinence. It has also been used locally as a nasal decongestant and in the emergency treatment of hypotension. No matter what the route of administration, methoxamine can cause adrenergic effects, including cold limbs, pilomotor stimulation, and a desire to micturate. Tachyphylaxis has been seen in experimental animals.

The effects of methoxamine have been examined in a double-blind, placebo-controlled trial in only six women (1). There was little effect on maximum urethral pressure, the surrogate end-point used in the trial. The drug was given by intravenous infusion at a maximum dose of 1.0 mg/70 kg/minute. There was a significant rise in systolic blood pressure of about 13 mmHg and a fall in pulse rate of some 18 beats/minute. All subjects taking methoxamine had headache, cold extremities, and piloerection. The authors understandably concluded that this is not a very promising treatment for stress incontinence.

Methoxyflurane

See also General anesthetics

General Information

Methoxyflurane is a volatile halogenated anesthetic.

Organs and Systems

Liver

Hepatitis has been reported (1), with possible cross-allergy between halothane and methoxyflurane.

Urinary tract

The nephrotoxicity of methoxyflurane is well established (2).

Methoxyphenamine hydrochloride

General Information

Methoxyphenamine is a sympathomimetic drug that has been used as a bronchodilator (1) and to treat nasal congestion. It has been claimed to be relatively free of cardiostimulant and psychomotor effects, but there is little published evidence suggesting marked beta-adrenoceptor selectivity, and the normal oral dose of 50–100 mg can in a minority of cases produce tightness of the chest and palpitation. Drowsiness, mouth dryness, nausea, and faintness have been anecdotally reported.

Methyldopa

General Information

The presynaptic alpha-adrenoceptor agonists, particularly methyldopa and clonidine, are agonists at presynaptic alpha$_2$-adrenoceptors. Guanabenz, guanfacine, and tiamenidine appear to be qualitatively similar to clonidine; clear evidence of quantitative differences remains to be confirmed.

The mechanism of action of these drugs depends on reducing sympathetic nervous outflow from the nervous system by interference with regulatory neurotransmitter systems in the brainstem. Because none of the drugs was selective or specific for circulatory control systems, the hypotensive effects were invariably accompanied by other nervous system effects. However, the identification of imidazoline receptors has suggested that it may be possible to develop drugs, such as moxonidine and relminidine, with greater selectivity for circulatory control mechanisms and a reduced likelihood of unwanted nervous system depressant effects (1).

Organs and Systems

Cardiovascular

Although postural hypotension is often quoted as a complication of treatment with methyldopa, there is no convincing evidence that this unwanted effect is more likely with methyldopa than with other commonly used antihypertensive drugs.

Complete heart block, which resolved after the withdrawal of methyldopa but recurred on rechallenge, has been reported in two elderly patients and attributed to the central sympatholytic effect of methyldopa (2).

Nervous system

Treatment with centrally acting agents is characterized by a relatively high incidence (up to 60% in some studies) of nervous system depressant effects (dizziness, drowsiness, tiredness, dry mouth, headache, depression), particularly during the initial period of treatment or after dosage increments. Some tolerance develops during long-term treatment, but the insidious presence of these depressant effects may not be fully apparent until the patient is given alternative treatment.

Methyldopa should probably be avoided in patients with parkinsonism, because in theory the production of alpha-methyldopamine can worsen the disease, and there have indeed been reports of exacerbation (3).

Endocrine

Acutely methyldopa promotes the release of growth hormone and prolactin, but the long-term significance of this is unclear. However, there have been reports of hyperprolactinemia, leading to amenorrhea and galactorrhea (4).

Hematologic

Coombs' positivity (in about 20% of cases) and Coombs' positive hemolytic anemia (in about 2%) are well-recognized complications of methyldopa.

- Anemia, reticulocytosis, and a positive Coombs' test were seen in a 64-year-old woman taking methyldopa 1000 mg bd; these problems resolved after withdrawal (5).

Gastrointestinal

Dry mouth occurred twice as often with methyldopa (41%) as with atenolol (21%) in a crossover comparison in 69 hypertensive patients (6).

There is an association between methyldopa and diarrhea.

- An 84-year-old black woman over a period of 7 years was free of diarrhea during periods when methyldopa was stopped but suffered diarrhea as soon as methyldopa was re-introduced (7).
- Similar recurrences on repeated exposure occurred in a 71-year-old man who took methyldopa 250 mg bd (8).

Liver

Hepatotoxicity due to methyldopa is most often an acute hepatitis, which resolves when the drug is withdrawn. It can start at any time after the start of therapy, but it usually occurs within the first few weeks and ranges in severity from a minor disturbance of liver function tests to acute hepatic necrosis.

- Fatal toxic hepatitis occurred in a 22-year-old woman treated with methyldopa in late pregnancy (9).

Sometimes, a more chronic picture develops after treatment for 2 or 3 years, with features of chronic active hepatitis (10).

© 2006 Elsevier B.V. All rights reserved.

Immunologic

Lupus-like syndrome has been attributed to methyldopa, causing hemolytic anemia, arthritis, photosensitivity, and high titers of antinuclear antibody (1:256) and of IgG antibodies to class I histones in a 55-year-old man who took methyldopa 250 mg bd for 13 months; the syndrome resolved spontaneously when methyldopa was withdrawn (11).

Long-Term Effects

Drug withdrawal

A withdrawal syndrome with rebound hypertension has been reported with methyldopa (12). Although it is similar to that associated with clonidine, it is less well defined, less severe, and less frequent.

- Withdrawal of methyldopa has been associated with the development of an acute manic syndrome in a 62-year-old man who had had methyldopa withdrawn 4 weeks before; there had been no previous history of psychiatric disorder (13).

Drug–Drug Interactions

Mianserin

Mianserin has alpha-adrenoceptor activity and so might interact with methyldopa (14). In 11 patients with essential hypertension, the addition of mianserin 60 mg/day (in divided doses) for 2 weeks did not reduce the hypotensive effect of methyldopa. In patients treated with methyldopa, there were additive hypotensive effects after the first dose of mianserin, but these were not significant after 1 or 2 weeks of combined treatment. The results of this study appear to have justified the authors' conclusion that adding mianserin to treatment with methyldopa will not result in loss of blood pressure control.

Methylenedioxymetamfetamine

See also Amphetamines

General Information

Methylenedioxymetamfetamine (MDMA, ecstasy) is a recreational drug with actions like those of amphetamine. It is the usual and expected constituent of the tablets that are known as ecstasy, although adulteration with other substances is not uncommon (see the section on Drug contamination in this monograph). MDMA and other drugs, such as its *N*-demethylated derivative (MDA), 3,4-methylenedioxyamfetamine (MDA), 3,4-methylenedioxyethylamfetamine (MDEA), *N*-methylbenzodioxazolylbutamine (MBDB), and 4-bromo-2,5-dimethoxyphenylethylamine (2-CB or Nexus), are often grouped together as "ecstasy". Some have used the term "enactogen", meaning "touching within", to describe ecstasy.

In low doses MDMA produces a pleasant altered state of mind, with enhanced emotional closeness, but it is also used in high doses and settings in which toxicity is often reported (1). In the UK, considerable adverse effects have been reported from its use at rave dances. In the 1970s and 1980s its mind-altering effect caused some clinicians to advocate its use as an adjunct to psychotherapy (2).

Concern has been raised about the increasing use of ecstasy in Europe (3), particularly the UK and the Netherlands. The patterns and trends of substance use among college students have been evaluated over a 30-year period (4). Alcohol use remained stable, but illicit drug use peaked in 1978 and fell sharply over the next 20 years. Ecstasy was the exception: its use rose from 4.1% in 1989 to 10% in 1999. Ecstasy was the second most frequently tried illicit drug after marijuana.

Associated with increased physical activity and altered thermoregulation, ecstasy has been reported to cause unconsciousness, seizures, hyperthermia, tachycardia, hypotension, disseminated intravascular coagulation, and acute renal insufficiency, as well as death.

© 2006 Elsevier B.V. All rights reserved.

Ecstasy has a mild stimulant effect and is modestly hallucinogenic. The results of one study suggested that tolerance to its effects develops, but that adverse effects can increase with continued use (5). Recent reports have highlighted some disturbing effects, particularly when it is used while dancing vigorously at rave parties (6). In this setting, with increased physical activity, ecstasy can cause unconsciousness, seizures, hyperthermia, tachycardia, hypotension, disseminated intravascular coagulation, rhabdomyolysis, and acute renal insufficiency (7). Severe complications are also linked to uncontrolled fluid intake, hemodilution, and salt-losing syndromes. Deaths after the use of ecstasy in such settings have been described (8). It has been suggested that severe toxicity from ecstasy can result from altered thermoregulation in the face of excessive activity in warm environments (9).

Deaths related to ecstasy and MDEA in seven young white men, two of whom had hyperthermia, have been reviewed (10). In all cases, autopsy showed striking liver damage with necrosis; five patients had heart damage (contraction band necrosis and cell necrosis with inflammation), and others had brain damage, including focal bleeding, gross edema, and hypoxic changes. In one patient, who died of acute water intoxication, the pituitary gland was necrotic and there was accompanying cerebral edema. The authors proposed that the spectrum of pathological findings suggested more than one mechanism of damage, injury being caused by hyperthermia in some cases and a toxic effect (directly accountable for damage to liver and other organs) in others.

Ecstasy that is sold on the streets is a heterogeneous substancer, with enormous variations in its main active ingredients. It most often contains derivatives of MDMA and 3,4-methylenedioxy-*N*-ethylamfetamine (MDEA). Other amphetamine derivatives that it can contain include 3,4-MDA, *N*-methyl-1-(1,3-benzodioxol-5-yl)-2-butanamine (MBDB), and 2,5-dimethoxy-4-bromamfetamine (DOB). The amount of active ingredient in street ecstasy ranges from none to very high. In addition, other amphetamines or hallucinogens can be mixed in. A survey of 3021 young adults (14–24 years old) in Germany showed that regular use of ecstasy by itself is uncommon (2.6%). Among lifetime users, 97% have also used cannabinoids, 59% cocaine, 48% other substances, 46% hallucinogens, and 26% opiates. However, the interviews revealed that the use of ecstasy and hallucinogens is increasing, especially in young people. The authors observed that a large number of first-time users are at risk of regular use (11).

As recreational use of ecstasy has dramatically increased in recent years, deaths related to its use have been reported. In a retrospective review of all violent deaths from 1992 to 1997 in South Australia, six deaths were associated with ecstasy abuse; all occurred after September 1995. Three victims had documented hyperthermia and there was evidence of hyperthermia in another. The authors suggested that individual susceptibility to MDMA may be caused by impaired metabolism by CYP2D6 or through genetically poor metabolism (seen in 5–9% of Caucasians). One woman, who died with a cerebral hemorrhage, had fluoxetine (a CYP2D6 inhibitor) present in her blood. Furthermore, toxicology identified paramethoxyamfetamine (PMA) in all the cases, amfetamine/metamfetamine in four cases, and MDMA in only two cases. PMA, which is sold as an MDMA substitute or is present as a contaminant, is associated with a high rate of lethal complications (12).

- A 35-year-old male criminal died under suspicious circumstances (13). The police had seen him alive about 1.5 hours before the alleged time of death during a patrol visit to his home. Evaluation of the corpse showed an obvious head injury and the body was in an advanced stage of rigor mortis, despite the fact that the alleged time of death had been less than 4 hours earlier. The body temperature was significantly raised (42°C). A witness testified that the deceased had taken ecstasy at various times during the night, after which he had been groaning, before taking off his clothes and thrashing on the floor while hitting his head and bumping into things. When resuscitation had been attempted, his jaw had been locked. Toxicology detected amfetamine, metamfetamine, and PMA in the blood.

The authors suggested that in a subgroup of amfetamine abusers, a triad of amfetamine use, prolonged exertion, and hyperthermia can be potentially lethal. Any temperature above 42°C requires active cooling (to below 38.5°C) and carries a poor prognosis. In this case rigor mortis may have started almost at the time of death. An ecstasy tablet that was allegedly from the same batch contained 50 mg of PMA.

The pharmacological and pharmacokinetic effects of ecstasy have been studied in healthy volunteers (14). In the pilot phase, two subjects each took ecstasy 50, 100, and 150 mg. In the second phase, eight subjects took ecstasy 75 and 125 mg. All were CYP2D6 extensive metabolizers. The ecstasy plasma concentrations were not proportional to dose, probably indicating non-linear kinetics in the dosage range usually taken recreationally. While the results were not conclusive (owing to problems in the study design) and require further exploration, the finding that relatively small increases in the dose of ecstasy ingested can translate to disproportionate rises in ecstasy plasma concentrations, if confirmed, would be important.

Organs and Systems

Cardiovascular

Cardiotoxicity following ecstasy use has been reported (15).

- A 16-year-old boy took three tablets of ecstasy and amfetamine 0.3 g and several hours later had convulsions and a temperature of 40.9°C. His heart rate was 210/minute and his blood pressure 100/75 mmHg. His creatine kinase activity was raised and he had myoglobinuria, renal impairment, hyperkalemia, and hypocalcemia. An electrocardiogram showed ventricular and supraventricular tachycardias but no myocardial ischemia. A diagnosis of serotonin syndrome due to ecstasy ingestion with associated hyperpyrexia and rhabdomyolysis was made. Following active treatment, his condition stabilized, with restoration of sinus rhythm and normal urine output. However, 12 hours later he developed jaundice, raised liver enzymes, and coagulopathy, suggesting acute liver failure due to ecstasy. With supportive treatment, his liver function improved. However, another 12 hours later, he developed

© 2006 Elsevier B.V. All rights reserved.

shortness of breath associated with right-sided chest signs and X-ray changes compatible with aspiration pneumonia, and required emergency intubation 4 days later. He developed pulmonary edema, his pulmonary artery was occluded, and an echocardiogram showed globally impaired left ventricular function with an ejection fraction of 30–35%; there was electrocardiographic T wave inversion. Primary myocardial damage causing cardiac dysfunction was investigated using serial creatine kinase and troponin measurements. He recovered completely with treatment and an echocardiogram showed an ejection fraction of 60%.

The authors reported that this was the first case report of clinical, radiological, biochemical, and echocardiographic evidence of myocardial damage and cardiac dysfunction following ecstasy and amfetamine use.

Transient myocardial ischemia associated with ecstasy has been reported (16).

- A 25-year-old man, a regular alcohol drinker with a history of asthma, had been out drinking 8 pints of lager and 4 gins. His last drink was spiked with a tablet that was presumably ecstasy. He scooped the tablet out, and even though some of the tablet may have dissolved, he finished the drink. He awoke 3 hours later with restlessness, nausea, and abdominal cramps. In the emergency room, his temperature was 37.2°C, and he was sweating. His heart rate was 120/minute and his blood pressure 130/70 mmHg. He had some abdominal discomfort. A diagnosis of ecstasy ingestion was made, although urine MDMA concentrations were not measured. His electrocardiogram on admission showed sinus tachycardia, with T wave inversion in leads I, aVL, and V4–6 and the voltage criteria for left ventricular hypertrophy. The next day the electrocardiogram had returned to normal. An echocardiogram was within normal limits. He was well on discharge.

The authors suggested that this was the first report of transient myocardial ischemia after ecstasy. They reasoned that the myocardial ischemia did not proceed to necrosis or a dysrhythmia because the amount of drug exposure was low.

Cardiovascular autonomic functioning during MDMA use has been investigated in 12 MDMA users and a matched group of non-users (17). Resting heart rate variability (an index of parasympathetic tone) and heart rate response to the Valsalva maneuver (Valsalva ratio, an index of overall autonomic responsiveness) were both reduced in the drug users. Thus, seemingly healthy users of MDMA had autonomic dysregulation, comparable to that seen in diabetes mellitus. In several users there was a total absence of post-Valsalva release bradycardia, a sign of parasympathetic dysfunction. Since no cardiac data were available for these patients before their use of ecstasy, and since all were multidrug users, the findings must be interpreted with caution.

Extensive aortic dissection with cardiac tamponade and mesenteric ischemia has been attributed to ecstasy (18).

- A 29-year-old man who took ecstasy and alcohol at a rave had no immediate adverse effects, slept well later on, and was in good health until he suddenly collapsed to the floor about 2 hours after waking. When seen 36 hours after the last dose of ecstasy he was short of breath and had abdominal pain, diarrhea, and vomiting. He had a loose bloody bowel movement but refused further investigations. He was discharged with a diagnosis of gastroenteritis, only to be readmitted 8 hours later after sudden deterioration and hypertension. Despite extensive efforts, his condition deteriorated and he died 5 hours later. At autopsy, there was a type I aortic dissection, starting at the root and spreading to the bifurcation, which had resulted in cardiac tamponade. The dissection had involved the mesenteric arteries, resulting in bowel ischemia.

Since this condition is rare in young adults, diagnosis can be difficult. The authors believed that this was the first case report of aortic dissection secondary to ecstasy.

Ecstasy has been associated with sudden death and cardiovascular complications. Eight healthy self-reported ecstasy users participated in a four-session, ascending-dose, double-blind, placebo-controlled comparison of the echocardiographic effects of ecstasy and those of dobutamine (19). Ecstasy 1.5 mg/kg increased the mean heart rate by 28 beats/minute, systolic blood pressure by 25 mmHg, diastolic blood pressure by 7 mmHg, and cardiac output by 2 l/minute. The effects of ecstasy were similar to those produced by dobutamine (40 μg/kg/minute), except that ecstasy had no measurable inotropic effects. Thus, ecstasy increases systolic and diastolic blood pressures in the absence of a significant change in cardiac contractility and end-systolic wall thickness. The resulting increase in the tension of the ventricular wall leads to disproportionately higher myocardial oxygen consumption than would be expected from the observed changes in the heart rate and blood pressure. The authors commented that the behavioral and environmental factors accompanying the use of ecstasy—sustained exercise from dancing, often in crowded nightclubs with high ambient temperature and humidity—could further potentiate toxicity. They recommended a combination of beta-blockers and vasodilators for the emergency treatment of ecstasy-associated vascular instability.

Respiratory

Pneumomediastinum after MDMA has been reported.

- Spontaneous pneumomediastinum occurred in a 17-year-old man who presented with chest pain and vomiting after taking two tablets of ecstasy (20).
- A 16-year-old boy took six ecstasy tablets over 2 hours (21). A period of vomiting ensued and he developed chest pain and swelling in the neck. A chest X-ray showed pneumomediastinum. He was managed conservatively and his emphysema settled uneventfully within 2 days.

The authors of the second case reported that five such cases have been reported in the past 4 years in the British literature; the respiratory complications were thought to be due to severe physical exercise or secondary to vomiting. It is therefore possible that this complication may not be due to a direct effect of MDMA, but rather a consequence of repeated Valsalva maneuvers associated with the dance habits of ecstasy users or vomiting induced by the drug.

© 2006 Elsevier B.V. All rights reserved.

Two cases of pneumomediastinum occurred in people who took ecstasy at the same rave party (22).

- A 23-year-old woman developed chest, back, and neck pain, and surgical emphysema over the chest and neck 7 hours after taking ecstasy. She had surgical emphysema in the mediastinum and neck and was given intravenous fluids and antibiotics.
- A 22-year-old man developed anterior chest and neck pain and surgical emphysema over the neck and chest 8 hours after taking four ecstasy tablets. He had surgical emphysema in the mediastinum and neck and contrast swallow showed a leak at the posterolateral aspect of the mid-esophagus. He was given intravenous fluids and antibiotics.

These symptoms were possibly related to the use of ecstasy, but it is also possible that a corrosive additive in the ecstasy was responsible. Ecstasy can cause gastrointestinal dysmotility, which could have resulted in esophageal rupture.

Adverse effects can develop after amphetamines are abused in combination (23).

- A 28-year-old healthy woman had left-sided pleuritic chest pain for 18 hours, having taken one tablet of ecstasy and one tablet of speed (metamfetamine hydrochloride) 4 hours earlier. There was surgical emphysema in her neck. On auscultation there was a crunching cardiac systolic sound. Chest X-ray showed pneumopericardium and pneumomediastinum. She was given analgesics and monitored. The chest pain subsided after 4 days.

Her respiratory problems could have been due to alveolar rupture, caused by an increase in intra-alveolar pressure, due to the exertion while she had been dancing strenuously. Alternatively, it could have been secondary to her use of positive ventilatory pressure after taking the drugs; this is done by a partner, either by direct mouth-to-mouth contact or through a cardboard cylinder, to enhance the user's experience of the stimulant's effects.

Nervous system

Two previously reported cases of cerebral edema associated with the syndrome of inappropriate secretion of antidiuretic hormone (SIADH) after ingestion of ecstasy elicited strong responses (24). The writers questioned the certainty of the clinical diagnosis on the basis of the biochemical details, specifically the plasma and urine osmolalities (25). They pointed out that cerebral edema can occur secondary to severe water consumption without SIADH and suggested that the use of intravenous fluids or water consumption after exposure to MDMA requires close monitoring. The original authors replied that they strongly agreed with the potential risks of unlimited fluid intake in MDMA users.

Dry mouth, with possible increased risk of enamel erosion and dental caries, has also been described (26).

Since the toxic effects of MDMA resemble certain features of both the serotonin syndrome and the neuroleptic malignant syndrome, some have suggested that MDMA may have combined actions on both the dopamine and serotonin systems (27). However, dantrolene (which may be helpful in cases of neuroleptic malignant syndrome) does not appear to be useful in dealing with MDMA toxicity (28).

A report linking ecstasy use and parkinsonism generated considerable discussion (29).

- A 29-year-old man developed difficulty in walking and lost the ability to write or drive 4 weeks after developing clumsiness of his extremities. He was unable to work or live independently. His electroencephalogram, lumbar puncture, and MRI and positron emission tomography (PET) scans were normal. Eleven weeks after the onset of symptoms he had disturbed gait and fine motor coordination; his condition deteriorated and 8 weeks later he had bradykinesia of the face and limbs, absence of blinking, hypokinesia in relation to speech, postural instability, and a markedly parkinsonian gait. However, his cognitive function was intact.

This patient had taken ecstasy 10 times during the year before, the last time about 3 months before the onset of symptoms. Apart from marijuana, he denied using other substances. He was treated with maximal tolerable doses of levodopa and pramipexole, without improvement. The authors reported that they had no explanation for this patient's symptoms, other than the use of ecstasy. They felt that the parkinsonian symptoms most closely resembled MPTP-induced parkinsonism. They further postulated that this could be a delayed neurotoxic effect of ecstasy in the substantia nigra and striatum and could have occurred as a result of neuronal damage by free radicals.

This report brought many responses. The first criticized the authors' conclusion that the neurotoxic effects in their patient were similar to those seen with MPTP (30). They argued that the PET scan was normal, and that the patient's condition did not respond to the use of antiparkinsonian drugs, unlike MPTP-induced damage, which does respond. They further argued that the extensive animal and human experience involving MDMA has not shown damage to the dopaminergic system. Furthermore, MDMA and MPTP are chemically unrelated and share neither precursors nor metabolites. Although the purity of street drugs is suspected and a contaminant could have been responsible, they seriously doubted that MPTP was one of the contaminants ingested.

Another group expressed the concern that although other types of amfetamine can cause dopaminergic neurotoxicity in animals and are sometimes sold as MDMA, they have not been associated with parkinsonism, despite more than 60 years of worldwide therapeutic and illicit use (31). Furthermore, they observed that the pattern in this case, in which symptoms began 8 weeks after drug exposure, did not fit the expected pattern of drug toxicity. They proposed that the problem had either been caused by contaminants or by a highly idiosyncratic reaction. However, if the toxicity had been from a contaminant, a cluster of cases would have been expected, as was seen with MPTP. On the other hand, if this had been an idiosyncratic case, the symptoms would have emerged soon after drug use. They were also puzzled by the absence of hair analysis to confirm MDMA use.

The authors of the original report responded by citing evidence that MDMA can be toxic to dopaminergic

© 2006 Elsevier B.V. All rights reserved.

neurons and can cause lasting changes in neuronal responses to dopamine (32). They further stated that although parkinsonism has not been reported after MDMA, the possibility that such an association exists cannot be excluded. They raised the possibility that clinical evidence of parkinsonism can be missed, particularly when the disorder is mild and, as in their patient, when tremor is absent. They pointed out that with valproate the first full report of parkinsonism did not appear until 18 years after its introduction into the USA, even though those who commonly prescribe it (neurologists and psychiatrists) should have noticed it earlier. The authors clarified that they had mentioned MPTP as an example of a substance that may have a delayed neurotoxic effect on monoaminergic neurons, without intending to suggest that MDMA acts chemically in the same manner as MPTP. They agreed that a contaminant could have played a role, and raised a concern that contaminants also put MDMA users at risks of adverse effects. They countered the argument that all idiosyncratic responses have to be immediate, by quoting examples from the literature to suggest that the course of a reaction depends on the underlying mechanism.

The patient discussed in the case report also responded, alleging that his permission had not been obtained before publication (33). Contradicting the original published report, he stated that he had never used marijuana; the authors defended their data by stating that when the patient's friend, who had accompanied him to the clinic, mentioned cannabis use the patient did not deny it. He also reported using creatine, ephedrine, caffeine, and aspirin, none of which, the authors noted, has previously been associated with parkinsonian symptoms.

Other neurological adverse effects have been reported in a first-time ecstasy user (34).

- A 19-year-old man, an occasional user of benzodiazepines and heroin, developed dizziness and loss of consciousness the morning after taking ecstasy for the first time. He was intubated and ventilated. He had a monocular hematoma, pulmonary edema, and cutaneous emphysema, without focal neurological deficits. There was rhabdomyolysis with renal insufficiency but no rise in temperature. Body fluid toxicological analysis showed only benzodiazepines and amphetamines. After he was weaned from the respirator, although awake, he did not react to noxious stimuli and showed no spontaneous movements. A CT scan of the brain had been normal on admission, but 2 and 3 weeks later it showed multiple hypodense lesions in the white matter. One month after admission, he was in a vegetative state, with marked spasticity, intermittent non-specific reactions to noise, and sustained generalized myoclonus. An electroencephalogram showed generalized slowing with intermittent theta wave activity. An MRI scan showed bilateral severe white matter damage.

Brain damage in this patient was restricted to the white matter. Although hypoxia was present at the time of admission, the authors did not believe that it was the only causative factor. By a process of elimination, they concluded that ecstasy might have caused the toxic encephalopathy, although it was not detected by toxicological analysis. They suggested that myelin damage might be an indirect sequel of MDMA-related metabolic oxidative stress and multiorgan failure due to individual susceptibility. They also entertained the idea of a lipophilic toxic contaminant rather than MDMA as the causative toxic agent.

An unusual case of bilateral sixth nerve palsy associated with ecstasy has been reported (35).

- A 17-year-old man developed horizontal diplopia in all directions of gaze while using ecstasy tablets every 5–7 days for 2 months. A diagnosis of bilateral sixth nerve palsy was confirmed. Ocular motility returned to normal within 5 days without treatment. There was no evidence of inflammation or degenerative disease of the central nervous system.

The authors speculated that the most likely cause of the lesion was either an interaction of ecstasy with serotonergic neurons or cerebral edema (albeit not detected by MRI) secondary to ecstasy.

Psychological, psychiatric

Concerns have been raised about the long-term nervous system effects of MDMA use from animal data, which suggest that the dose of MDMA used for recreational purposes by humans can cause toxic effects in nonhuman primates, especially involving the serotonin system. In a case-control study, 10 long-term MDMA users were compared with 10 controls who had not used MDMA but were drug abusers and were matched for age, sex, education, and premorbid intellect (36). All participated in a single photon emission computed tomography (SPECT) study with a serotonin transporter (SERT) ligand. Dopamine transporter binding was determined from scans acquired 23 hours after injection of the tracer. Hair analysis, which covers about the last 4 weeks of drug use, generally confirmed the drug use history, although two ecstasy users tested negative for both amfetamine and metamfetamine. On neuropsychological testing, both groups showed comparable performances in tests of verbal and spatial memory, psychomotor speed, attention, and executive function. Larger lifetime doses of ecstasy were associated with reduced verbal memory performance on the California Verbal Learning Test and more errors in the Spatial Working Memory Test. Ecstasy users showed a cortical reduction of SERT binding prominently in primary sensorimotor cortex, with normal dopamine transporter binding in the lenticular nuclei. There was also an association between the length of the MDMA-free period (mean 18 days) before the scan and ligand binding in the cingulate. Spatial working memory performance and SERT binding in the left calcarine cortex were negatively correlated with the estimated lifetime dose of MDMA in the ecstasy users. While these results could be coincidental, or reduced SERT binding could be the imaging correlate of a psychobiological predisposition to heavy use of ecstasy, the authors suggested that this study provided evidence for specific albeit temporary serotonergic neurotoxicity of MDMA in humans. If confirmed, these effects on the serotonergic system could underlie psychiatric morbidity in ecstasy users.

© 2006 Elsevier B.V. All rights reserved.

The neurotransmitter systems involved in the psychological and information processing effects of ecstasy have been studied in 16 ecstasy-naïve subjects (37). Ecstasy produced a state of enhanced mood, well-being, increased emotional sensitiveness, little anxiety, moderate thought disturbances, but no hallucinations or panic reactions. It caused thought disturbances, such as difficulty in concentrating, thought blocking, and difficulty in reaching decisions. Women had greater subjective responses to ecstasy than men. For instance, they scored higher on ratings of anxiety, adverse effects, and thought disturbances, suggesting differences in the metabolism of ecstasy. Prepulse inhibition of the startle response was used to measure physiological changes. Prepulse inhibition and startle habituation have been used as operational measures of sensorimotor gating and habituation functions, respectively, in investigations of attention. Moreover, some studies have associated prepulse inhibition with endogenous serotonin release. Ecstasy 1.7 mg/kg increased prepulse inhibition, suggesting that the overflow of endogenous serotonin caused by ecstasy may interfere with the startle response and cause a breakdown of cognitive integrity. This effect further suggests serotonin dysregulation in response to ecstasy.

Reports of adverse neuropsychiatric effects of MDMA have included descriptions of flashbacks, anxiety, insomnia (38), panic attacks (25,39), and psychosis (40). Subacute adverse effects that have been reported following MDMA use include drowsiness, depression, anxiety, and irritability (41). Prolonged or chronic effects have also been reported, including panic disorder (42,43), psychosis (40,44,45), flashbacks (40), major depressive disorder (25,46), and memory disturbance (25). The observation that only certain individuals develop neuropsychiatric disturbances after using ecstasy suggests that certain predisposing psychiatric factors (or high-dose regimens) may make some individuals more vulnerable to these untoward effects.

With increasing use of ecstasy, there is considerable interest in its effects on psychopathology and cognition. The residual effects of ecstasy on psychopathology and cognition have been examined in 18 current regular users, 15 ex-users with an average abstinence of 2 years, 16 ecstasy-naïve polydrug users, and 15 non-drug users (47). Both current and previous users had significantly worse psychopathology than the controls and polydrug users. Ecstasy users had higher scores on the Symptoms Check List SCL-90-R Global Severity Index and the Positive Symptom Distress Index. They also scored significantly higher on eight specific factors on the SCL-90-R: somatization, obsessive-compulsive disorder, anxiety, phobic anxiety, interpersonal sensitivity, depression, paranoid ideation, and altered appetite/restless sleep. Current users had higher scores across more categories, but the values were not significantly different from ex-users. Current and ex-users had lower working memory and verbal learning abilities than the controls and polydrug users, but there were no significant differences between the two groups. Using regression analyses, the investigators found that the best indicator of increased psychopathology was a high consumption of cannabis, while cognitive deficits were best predicted by the amount of previous ecstasy use. Thus, the investigators suggested that ecstasy-induced cognitive impairment may not be reversible over time and with abstinence, suggesting that ecstasy is a potent neurotoxin.

The neuropsychological effects of ecstasy have been studied in 20 polydrug users (48). Various functions and processes throughout the brain, such as verbal fluency, spatial working memory, and attention, were assessed. Ecstasy users showed a significant deficit in complex visual pattern recognition and spatial working memory compared with the polydrug abusers who were not taking ecstasy. Since these tests are sensitive to temporal lobe functioning, the authors suggested that there is a selective temporal lobe deficit in ecstasy users, with relative sparing of executive functioning. Based on previous studies, they postulated that serotonin dysfunction in the temporal lobe may be associated with impaired visuospatial working memory. However, they did not study a drug-free control group and the ecstasy group used higher amounts of drugs in general. In addition, the sample size was small.

Some reports have suggested that the relation between the dose of ecstasy and its complications may not be straightforward (49). Some people have problems with very small amounts.

- A 21-year-old woman developed a protracted psychotic depersonalization disorder with suicidal tendency after taking two tablets of ecstasy for the first time (50).
- A 23-year-old man with no prior psychiatric history developed panic disorder after taking a single dose of ecstasy (42).
- A psychosis occurred in an 18-year-old man who had used ecstasy on an occasional recreational basis (51).

The acute and short-term effects of a recreational dose of MDMA (1.7 mg/kg) given to 13 MDMA-naïve healthy volunteers in a double-blind, placebo-controlled study have been reported (52). MDMA produced a state of enhanced mood, well-being, and enhanced emotional responsiveness, with mild depersonalization, derealization, thought disorder, and anxiety. The subjects also had changes in their sense of space and time, heightened sensory awareness, and increased psychomotor drive. MDMA increased blood pressure moderately, except in one case of a transient hypertensive reaction. The most frequent somatic adverse effects were jaw clenching, poor appetite, restlessness, and insomnia. Lack of energy, difficulty in concentrating, fatigue, and feelings of restlessness during the next day were also described. The authors suggested that MDMA produces a psychological profile different from classic hallucinogens or psychostimulants. The potential risk of hypertensive effects of recreational dosages of ecstasy should also be considered in the safety profile.

Using PET with a radioligand that selectively labels the serotonin (5-HT) transporter, 14 MDMA users who were currently abstaining (for 3 weeks) from use and 15 MDMA-naïve controls were studied (53). MDMA users showed a reduction in global and regional brain 5-HT transporter binding, a measure of the number of 5-HT neurons, compared with controls. Deficiency in SERT correlated positively with the extent of previous drug use. The authors suggested that ecstasy users are susceptible to MDMA-induced serotonin neural injury.

Panic disorder

A case of ecstasy-related panic disorder has been reported (54).

- A 21-year-old man used increasing dosages of ecstasy (seven tablets or 400–500 mg/day) over a period of 5 months. After taking six tablets on one day, he developed palpitation, chest pain, sweating, vertigo, and a fear of dying. He responded well to alprazolam and was discharged. Several days later, the panic attacks recurred spontaneously. Five weeks later, he had a complete medical work-up that was unrevealing. Since his panic attacks persisted in the absence of any drugs, he was given the SSRI paroxetine 20 mg/day plus alprazolam; his panic attacks gradually abated and stopped 3 months later. The paroxetine was gradually tapered over the next 3 months and he continued to be symptom-free at 6 months.

The authors suggested that this case may have exemplified dose-dependent serotonergic neurotoxicity from ecstasy abuse.

Psychoses

Psychoses, both acute and chronic, have been reported following the use of ecstasy.

- A 26-year-old man without previous psychopathology (except social phobia) unknowingly consumed ecstasy with alcohol and developed an acute psychosis 12 hours later (44,55).

The authors reported that 12 cases of acute psychosis have previously been reported after the use of ecstasy once or twice. Based on a previously suggested hypothesis, they proposed that the psychosis was probably due to the indirect effects of MDMA on the dopaminergic system, secondary to serotonergic deregulation. Most patients who went on to develop a chronic psychosis were either chronic ecstasy users or multiple substance users. However, in the case mentioned here, after 6 months the patient still had symptoms of psychosis. The authors further suggested that genetically slow metabolizers of ecstasy are probably more vulnerable to this adverse effect, even with a single exposure.

Past reports have suggested that ecstasy use is associated with increased scores on self-report measures of depression. The long-term effects of ecstasy consumption on depression have been examined in 29 individuals who had consumed large quantities of the drug in the past, but were now leading relatively drug-free lives (56). They had taken an average of 1.5 ecstasy tablets in the last month, 8.4 in the last 6 months, and 23.3 in the last 12 months. None had taken it in the last 14 days. The former chronic ecstasy users had not taken ecstasy for an average of 26 weeks. The female former users had taken ecstasy more recently than the men (15 versus 31 weeks respectively). The levels of depression, as measured by Beck's depression inventory (BDI), were significantly increased compared with a matched non-drug using control group. The depression scores were independent of alcohol and cannabis use. Peak usage (maximum ecstasy usage in 12 hours) and current levels of perceived stress together significantly predicted depression scores. Thus, former chronic ecstasy users may be at a high risk of developing more severe depression.

Cognitive effects

Several studies have focused on the cognitive effects of ecstasy, and a review of the adverse effects of MDMA in animals has raised concerns about potential toxicity in humans (57). MDMA can selectively damage brain serotonin (5-HT) neurons in animal brains, even at doses within the range of those typically used recreationally. In many studies, lasting reductions in various brain 5-HT markers have been reported in MDMA-treated animals. Axons of 5-HT neurons were damaged in MDMA-treated animals, including monkeys, and neurotoxic effects of MDMA have been observed in every animal species studied so far. In non-human primates, the toxic dose of MDMA closely approaches the dose used by humans.

In 30 regular ecstasy users (drug use 10 or more times per month) and 31 ecstasy-free controls, prospective memory—the process of remembering to do things at some future time—was assessed using a self-report questionnaire (58). Ecstasy users reported global impairment in prospective memory, even after controlling for the use of other drugs. The authors observed that their finding of impairment of cognitive functions, especially memory, in regular ecstasy users is similar to findings in other recent studies. They postulated that serotonergic toxicity secondary to chronic ecstasy exposure can cause cognitive impairment, as serotonergic pathways are involved in memory function.

More support for a relation between memory impairment, serotonin neurotoxicity, and chronic ecstasy use has come from a study of cognitive performance and serotonin function in two groups of 21 men with moderate or heavy ecstasy use and a control group of 20 men who had not used ecstasy (59). Ecstasy users had a broad spectrum of statistically significant but clinically subtle impairment of memory and prolonged reaction times. Heavy users had larger effects than moderate users. Serotonergic function was assessed in a double-blind crossover challenge with dexfenfluramine 30 mg or placebo. Release of cortisol, but not prolactin, after dexfenfluramine was significantly reduced in both groups of ecstasy users compared with controls. According to the authors, these neuroendocrine findings are similar to those observed in animals and humans. Recent exposure to ecstasy, psychosocial profiles, and the use of other drugs did not explain the differences.

The density of serotonin transporters (SERTs) in humans can be measured by neuroimaging techniques, such as SPECT and PET. Two groups of ecstasy users (22 recent but abstinent and 16 ex-users) were compared with ecstasy-naïve controls (60). In subjects who had stopped using ecstasy more than 1 year before the study, cortical densities of SERTs did not differ from those of controls. However, recent ecstasy users had global reductions in SERTs. In addition, individuals who had stopped using ecstasy had a deficit in verbal memory similar to that in current ecstasy users. Higher lifetime doses of ecstasy were associated with greater impairment of immediate verbal memory. The authors suggested that the absence of reductions in SERT densities in ex-ecstasy

© 2006 Elsevier B.V. All rights reserved.

users suggested reversibility of ecstasy-induced changes in brain SERTs. Thus, ecstasy use can lead to neurotoxic changes in human cortical 5-HT brain neurons, but these changes may be reversible. However, functional consequences of ecstasy on cortical brain 5-HT neurons may not be reversible, as seen by impaired memory function in this group, similar to that in current ecstasy users.

The amino acid *N*-acetylaspartate is a robust, non-specific marker of neuronal loss or brain dysfunction. It is detectable by proton magnetic resonance spectroscopy (MRS). The ratio of creatine to phosphocreatine, another marker that remains stable in many brain diseases, can also be assessed using MRS. In a recent study, the ratio of *N*-acetylaspartate to creatine/phosphocreatine was used to determine whether there are memory deficits in ecstasy users and whether there are changes in specific brain regions (61). Eight men with a history of ecstasy use and seven ecstasy-naïve male controls took part. The findings included a significant difference in delayed recall between ecstasy users and ecstasy-naïve controls. There was a strong association between impaired memory function in ecstasy users and neuronal pathology, specific to the prefrontal cortex. Poorer performance on verbal memory testing was associated with greater neuronal loss or dysfunction in ecstasy users. These findings implicate ecstasy as a cause of serotonergic neuronal damage and memory impairment.

Another group has assessed cognitive function in 80 subjects who were non-users, novice users, regular users, or currently abstinent users of ecstasy (62). Compared with the non-users, all three groups of ecstasy users had significantly poorer verbal fluency and immediate and delayed prose recall. Days since last use and total lifetime consumption of ecstasy made separate contributions to the variance in recall scores. Novice and currently abstinent users likewise had significantly poorer immediate recall than non-users. The novice users had milder impairment than the regular users, while those who were currently abstinent performed at a similar level to regular users. These deficits were not attributable either to differences in general reasoning ability or to impairment of working memory. The authors expressed concern that increased use of ecstasy in large numbers of young people and its enduring effects on memory are under-appreciated consequences.

However, cognitive impairment and ecstasy use is a complex association to study, with difficult confounding variables. For example, ecstasy users may consume cannabis to relieve the negative experience that occurs when ecstasy-related euphoria diminishes. In a recent study the concurrent use of cannabis was controlled by the recruitment of 31 drug-naïve controls, 11 ecstasy/cannabis users, and 18 cannabis users (63). Users were instructed to abstain from drug use for 48 hours before testing. The ecstasy/cannabis user group had deficits in learning, memory, verbal word fluency, speed of processing, and manual dexterity compared with the healthy controls. The authors suggested that the deficits in the drug group were not related to ecstasy. They observed that the study group did not perform poorly compared with those who used cannabis only. Moreover, the finding that the ecstasy/cannabis group was no different from the cannabis group suggested that ecstasy does not cause significant cognitive deficits. The poorer performance of the ecstasy/cannabis users was very little affected by the frequency of use or total ecstasy consumption. However, co-varying for indices of cannabis consumption removed most of the significant differences between the groups. On the other hand, ecstasy did affect the measures of working memory, such as forward and backward digit span. The authors raised the question of whether previous evaluations of the effects of ecstasy on cognition had been confounded by the concomitant use of cannabis.

Susceptibility factors

Sex differences in subjective experiences of ecstasy use have been reported. Three previously published controlled studies of the acute effects of ecstasy in healthy subjects with no or single previous ecstasy experience have been summarized (64). There were 74 subjects (54 men and 20 women), aged 20–49 (mean 27) years, of whom 69 were ecstasy-naïve and five had used it on one or two occasions before. All had been screened using a semi-structured interview, and anyone with a personal or family history of mood disorders, schizophrenia, or other psychiatric disorders was excluded. The analysis included psychological and physiological effects of ecstasy in controlled settings. Generally, subjective effects of ecstasy were more intense in women than men. Women had especially higher scores for ecstasy-induced perceptual changes, anxiety, and adverse effects. In contrast, men were slightly activated by ecstasy compared with women and had significantly higher increases in systolic blood pressure. The authors suggested that women may be more sensitive to the effects of ecstasy. Many previous studies have suggested sex differences in markers for serotonergic activity in ecstasy users, with suggestions that serotonergic function is relatively impaired in women compared with men. The authors, based on their findings coupled with data from previous reports, raised the question of whether women might be more susceptible to ecstasy-induced depletion of serotonin.

Electrolyte balance

A death from hyponatremia after ecstasy use has been reported from New Zealand, where it is a commonly used recreational drug (65).

- A 27-year-old woman was admitted to the intensive care unit with coma and respiratory arrest. She had been seen taking two ecstasy tablets while dancing at a nightclub about 5 hours before admission. She had drunk copious amounts of water to cool herself. When she reached the hospital, her Glasgow score was 3 and she was in respiratory arrest with fixed dilated pupils. Her serum sodium concentration was 124 mmol/l with a low serum osmolarity (267 mmol/l) and normal renal function. Her toxicology screen was positive for ethanol, and MDMA was found in her serum. The electrocardiogram showed a sinus tachycardia without ischemia, and a chest X-ray showed gross pulmonary edema. A CT scan of the brain showed generalized cerebral edema, diffuse cerebral swelling, and significantly increased intracranial pressure; the basal cisterns and extracerebral spaces were completely effaced. Brain death was confirmed by cerebral angiography,

© 2006 Elsevier B.V. All rights reserved.

which showed no intracranial flow in the carotid or vertebral arteries. The post-mortem report confirmed marked cerebral edema with signs of cerebellar tonsillar herniation.

The authors reviewed the possible explanations, which included excess water ingestion, SIADH, and the serotonin syndrome. While many ecstasy users drink water to counter its hyperthermic effects, others do it because of "health advice" given at such parties to prevent toxic effects. However, death can occur due to water intoxication, albeit infrequently.

In a retrospective analysis of all cases of hyponatremia associated with ecstasy (SEDA-25, 37) at the London Centre of the National Poisons Information Service from December 1993 to March 1996, 17 patients were identified with a serum sodium concentration under 130 (range 107–128 mmol/l) (66). In 10, ecstasy was identified analytically, and six of them had SIADH. The clinical presentation was very consistent, with initial vomiting and delirium, and 11 had seizures. There was complete recovery in 14, but two died of cerebral edema 5 hours after ingestion.

- A 20-year-old woman attended a "rave", where she took ecstasy and drank large amounts of water (often suggested to prevent dehydration and other life-threatening consequences) (67). She felt drowsy and had a headache. After lying still for 3 hours, she had a tonic-clonic seizure and was brought to hospital, where her plasma sodium concentration was 112 mmol/l and she had cerebral edema. She was treated with hypertonic saline and recovered fully.

These reports show that hyponatremia due to ecstasy occurs primarily due to inappropriate secretion of antidiuretic hormone and relative excess liquid intake, usually in the setting of a warm environment and possible hyperthermic effects of ecstasy. Excess water ingestion should be discouraged in ecstasy users.

Two deaths in patients with hyponatremia after ecstasy intoxication have been reported (68).

- A 15-year-old woman developed impaired consciousness and psychomotor agitation and 10 minutes later reactive bilateral mydriasis and decerebration. A CT scan showed diffuse brain edema and subarachnoid hemorrhage. She had hyponatremia (119 mmol/l) and was considered brain dead 32 hours later.
- A 19-year-old woman became disoriented and had hyponatremia (131 mmol/l) and a serum ethanol concentration of 2.4 mmol/l. Her serum sodium had fallen to 120 mmol/l 10 hours later, and 5 hours later she suddenly deteriorated and had a respiratory arrest, coma, and sinus tachycardia of 180/minute with bigeminy. A CT scan showed diffuse edema in the posterior fossa. She was considered brain dead 23 hours after taking the ecstasy.

Mineral balance

SIADH has been associated with MDMA (69,70).

- A healthy 19-year-old woman complained of nausea and vomited 8 hours after taking unknown quantities of MDMA and beer; 3 hours later, she suddenly clenched her jaw, had tonic contractions of all four limbs, and collapsed. She was obtunded, with occasional moaning and non-purposeful movements of the limbs. Head CT scan showed mild cerebral edema. Her serum electrolytes, including a sodium of 115 mmol/l and a corresponding urine osmolality of 522 mosm/kg, suggested SIADH. Despite treatment, the serum sodium concentration 10 hours later was 116 mmol/l, but 18 hours after treatment, it rose to 125 mmol/l. She became progressively more responsive, with normalization of her sodium concentration, and after 48 hours was awake and alert, with a serum sodium concentration of 136 mmol/l.

The authors reviewed nine other reported patients with MDMA-related SIADH, all of whom were women. They concluded that MDMA-associated SIADH is multifactorial and that MDMA may stimulate vasopressin secretion in susceptible individuals. They further suggested that hyponatremia can also occur secondary to voluntary increases in fluid or water intake aimed at preventing the adverse effects of MDMA. With appropriate treatment, full recovery is possible in almost all cases of this life-threatening condition.

- An 18-year-old woman developed impaired consciousness, psychomotor shaking, hallucinations, tics, and delirium. Her serum sodium concentration was low at 120 mmol/l with a plasma osmolality of 242 mosm/kg and a urine osmolality of 562 mosm/kg, suggesting SIADH. Most other blood tests were within the reference ranges, except for a raised creatine kinase. Urine toxic screen was positive for amphetamines. Treatment with hypertonic saline brought about resolution of symptoms. The patient recalled taking three ecstasy tablets over 6 hours.

Hematologic

Transient anemia has been associated with ecstasy (71).

- A 36-year-old HIV-positive man taking zidovudine, lamivudine, and indinavir was noticed to have a mild asymptomatic anemia (hemoglobin 10.2 g/l, white cell count 10.4×10^9/l with a normal differential count, and platelets 237×10^9/l). The blood film suggested hemolysis. He had taken ecstasy 2 weeks earlier for the first time. The anemia was reportedly "secondary to oxidative stress, probably due to drug toxicity." Three weeks later his hemoglobin returned to normal.

In the absence of other explanations, the authors concluded that this syndrome had probably been caused by ecstasy toxicity.

Mouth and teeth

An unusual adverse effect of MDMA, tooth wear, has been reported (72).

- A healthy 17-year-old boy, who complained of dental sensitivity that occurred only when he consumed fizzy drinks, presented with marked tooth wear. All the teeth were involved, especially the premolars and permanent molars. He ate a poorly balanced diet, with 500 ml carbonated drinks twice daily. He subsequently admitted to frequent MDMA abuse.

© 2006 Elsevier B.V. All rights reserved.

Current health promotions advise that ecstasy users should frequently consume "sports" type or fruit drinks to counteract dehydration and avoid ion imbalances. These particular drinks may be erosive to the teeth. Bruxism and trismus associated with ecstasy use can also contribute to tooth wear.

Liver

Cases of ecstasy-associated hepatotoxicity have been reported.

- A 27-year-old man developed jaundice without fever (73). He used ecstasy regularly and had recently increased his consumption. All other possible causes of acute hepatitis were ruled out. After withdrawal of ecstasy, the condition resolved completely.
- A 17-year-old girl developed progressive jaundice and weight loss (74). Four months before, she had had malaise, anorexia, a sore throat, and tender cervical lymph nodes. Two months later she reported eating "hallucinogenic mushrooms." Five weeks before admission she observed blood clots in her stool. Three weeks later, she ate more mushrooms. She then developed progressive jaundice, with vomiting, dark urine, light-colored stools, and raised aminotransferases. She drank alcohol in binges and reported marijuana use since the age of 15. She had used ecstasy on several occasions during the previous 2 months. She had a minimally tender enlarged liver. Her viral hepatitis screen was negative. Genetic, metabolic, and autoimmune disorders were also ruled out. A urine screen for drugs was positive only for cannabinoids. Abdominal ultrasound showed periportal edema and contraction of the gall bladder, but no gallstones or dilated bile ducts. A CT scan showed moderate amounts of free fluid in the abdomen and pelvis and periportal hepatic edema. Percutaneous liver biopsy showed acute cholestatic hepatitis with cholangitis, eosinophils, and histiocytes, strongly suggesting a hypersensitivity reaction. There was no evidence of chronic liver disease. Within 24 hours after the liver biopsy, her liver enzymes and coagulopathy had begun to improve.
- A 21-year-old soldier had nausea, vomiting, abdominal pain, and fever, having taken 7–8 ecstasy tablets a week (75). He was treated with intravenous fluids and paracetamol (650 mg/day) for 3 days. His symptoms did not improve and he developed jaundice. He had increased transaminase activities and total bilirubin concentrations and all tests for viral hepatitis were negative. He was considered for liver transplantation, but over the next 2 weeks improved spontaneously.

The authors of the last report postulated a hyperthermic effect of ecstasy on the liver or a direct toxic effect of ecstasy on hepatocytes as possible mechanisms.

Cases of successful liver transplantation after ecstasy-induced hepatotoxicity have been reported (68,76,77).

- A 19-year-old man with no significant past history of medical problems took 1½ tablets of ecstasy and some alcohol. Within 2–4 days, he developed tiredness, nausea, malaise, and vomiting and on the fifth day weakness and anorexia; 12 days later, he was admitted to hospital with marked jaundice and weight loss. He deteriorated and developed hepatomegaly and an abnormal prothrombin time; his total bilirubin was 571 (reference range 5–17) μmol/l, aspartate transaminase 213 (14–50) U/l, and alanine transaminase 336 (11–60) U/l. By day 20, his condition had deteriorated, with increased jaundice, somnolence, mild disorientation, and altered glucose metabolism. His total bilirubin was 654 μmol/l, aspartate transaminase 1290 U/l, and alanine transaminase 1932 U/l. A liver biopsy showed swollen hepatocytes, patches of necrosis, and patchy cholestasis. Two days later, he developed a grade III encephalopathy and further disturbances of coagulation. Abdominal ultrasonography showed hepatic atrophy, and a liver biopsy showed massive necrosis. Serological tests for viral infections were negative. The probable diagnosis was toxic hepatitis secondary to MDMA. On day 31, he had a right auxiliary liver transplantation, but there was no clinical and laboratory improvement during the next 48 hours. Histopathology of the transplanted liver showed massive liver necrosis consistent with a "diagnosis of primary non-function". A second liver transplant on day 33 was successful.
- A 17-year-old girl with no history of drug abuse took two tablets of ecstasy at a disco 10 days apart, and reported malaise, constipation, and icterus 6 days after taking the second. She had severe acute hepatic failure. Viral hepatitis was ruled out. Following rapid clinical and neurological deterioration (encephalopathy grade I–II), she had an urgent liver transplant and made a good recovery. In the affected liver, there was submassive centrilobular hemorrhagic necrosis (75–80%) with massive periportal and lobular lymphocytic infiltration (CD 8+) and moderate fatty changes.
- A 25-year-old woman developed abdominal pain, jaundice, and vomiting 5 days after consuming ecstasy. She had hepatocellular failure with a prothrombin ratio of 6.5, cytolysis, cholestasis, renal insufficiency, and encephalopathy. She had a liver transplant 2 days later and recovered fully.
- A 17-year-old man developed toxic subacute hepatitis with grade II encephalopathy and coagulation disorders a few days after consuming ecstasy. Liver transplantation was performed and he recovered fully.
- A 16-year-old woman consumed ecstasy and developed jaundice, hepatic failure, a prothrombin ratio of 9, and grade I encephalopathy. She had a liver transplant and was asymptomatic at 11 months.

Many cases of hepatotoxicity and some deaths have occurred in drug-naïve subjects after the ingestion of relatively small amounts of ecstasy. The authors reported that more than 70 deaths have been reported worldwide between 1990 and 1998 after the onset of severe hepatic damage from ecstasy. Although many patients died after liver transplantation, a significant number recovered. The authors suggested that in emergency care the use of ecstasy should be suspected in young people who present with unexplained jaundice, hepatomegaly, or altered liver function, in the absence of other known substance exposure. Early referral for liver transplantation may be significantly beneficial. The prognosis may be better with grade I–II encephalopathy than grade III–IV, which is

© 2006 Elsevier B.V. All rights reserved.

usually associated with rapid deterioration and a poor prognosis.

Skin

Two cases of facial papules have been reported (78).

- A 20-year-old woman developed diarrhea and a pruritic yellowish skin 7 days after she had taken half a tablet of ecstasy. Her liver was enlarged and tender. Her urine was positive for MDMA. A diagnosis of acute hepatotoxicity after MDMA was made. She rapidly developed reddish papules over the face with a perioral and acne-like distribution.
- A 21-year-old-man developed similar skin lesions after using ecstasy, without hepatotoxicity.

Both patients responded to a low fat diet and 1% metronidazole ointment. The authors suggested that serotonin indirectly affects the nerve endings of the eccrine glands via other peptides, and that the interaction of MDMA with serotonin may have caused the rapid development of pimples in these abusers.

Immunologic

Four healthy male MDMA users volunteered for a randomized, double-blind, double-dummy, crossover pilot study in which they took single oral doses of MDMA 75 mg ($n = 2$) or 100 mg ($n = 2$), alcohol (0.8 mg/kg), MDMA plus alcohol, or placebo to study the effects on their immune system. The doses of MDMA were compatible with those used for recreational use (79). The baseline immunological parameters were within the reference ranges. Acute MDMA use produced time-dependent immune dysfunction, which paralleled MDMA plasma concentrations and MDMA-induced cortisol stimulation kinetics. The changes in the immune system after MDMA peaked at 1–2 hours. Although the total leukocyte count remained unchanged, there was a fall in the ratio of CD4 to CD8 T cells and in the percentage of mature T lymphocytes (CD3 cells), probably because of a fall in both the percentage and the absolute number of T helper cells. The fall in CD4 cell count and in the functional responsiveness of lymphocytes to mitogenic stimulation with phytohemagglutinin A was MDMA dose-dependent. Alcohol produced a decrease in T helper cells, B lymphocytes, and mitogen-induced lymphocyte proliferation. Combined MDMA and alcohol use produced the greatest suppressive effect on CD4 cell count and mitogen-stimulated lymphoproliferation. Immune function was partially restored at 24 hours. According to the authors, these results provided the first evidence that recreational use of MDMA alone or in combination with alcohol alters immunological status. The reaction of the immune system to MDMA appears to be an alteration of physiological homeostasis, similar to that seen in volunteers exposed to acute physiologic stress, suggesting that MDMA could be a "chemical stressor". Moreover, combined MDMA and alcohol use produced additive effects. This is an important finding, since in the general population alcohol and MDMA are commonly taken together.

Because other drugs of abuse can cause immune dysfunction in regular users, the effects of acute administration of ecstasy on the immune system have been studied in both controlled and natural settings (80). In the controlled study, 18 male ecstasy users were given two doses of ecstasy 100 mg at intervals of 4 or 24 hours. There were significant reductions in CD4 T helper cells (30%) and the lymphoproliferative response to phytohemagglutinin mitogenic stimulation (68%) 1.5 hours after the first dose, and a 103% increase in the number of natural killer cells. At 4 hours, CD4 T helper cells and lymphocyte proliferative responses were reduced by 40% and 87%, but natural killer cell numbers increased to 141%. At 24 hours, the second dose augmented the alterations in the numbers of CD4 T helper cells and natural killer cells about threefold. The authors suggested that this large effect after repeated administration of ecstasy increases the interval during which the immune response is compromised, leading to a higher risk of illness and infection in ecstasy abusers.

In the uncontrolled study, 30 recreational users of ecstasy (mean age 24 years) were observed for 2 years and had lymphocyte counts at yearly intervals. The ecstasy users tended to have lower white blood cell counts over time. Lymphocyte counts were significantly lower than in healthy controls by year 1 and significantly lower than that the following year. CD4 and CD19 cell numbers fell significantly from basal to year 1 and from year 1 to year 2. Natural killer cell numbers were always lower than in healthy controls but did not fall with time. The authors extended these results to suggest a possible role of serotonin dysregulation caused by ecstasy in compromising immune function. These findings suggest that ecstasy abusers may be at a significantly higher risk of infectious diseases.

Death

MDMA and MDEA, or "eve," have rapidly become popular drugs of abuse in recent years in Europe and to some extent in other developed countries as well. Over the years, reports of deaths following their use at "rave" parties have generated considerable public concern.

In a study of all ecstasy-positive deaths (22 of 19 366 deaths) in New York City from January 1997 to June 2000, 18 were men, average age 27 years (81). The deaths fell into three categories: acute drug intoxication ($n = 13$), mechanical injury ($n = 7$), and a combination of natural causes and acute drug intoxication ($n = 2$). Only two of the deaths due to acute drug intoxication were caused by ecstasy alone, and one death was caused by a combination of ecstasy and coronary artery disease. Seven deaths were caused by a combination of cocaine/opiates and ecstasy. Acute ecstasy poisoning includes symptoms such as hypertension, hyperthermia, and delirium, and can progress to intracranial hemorrhage, status epilepticus, and death. Based on reports from harm-reduction organizations and previous studies, the authors discussed the lack of standardization of ecstasy tablets and the danger of harmful additives that could react with other drugs to cause life-threatening symptoms.

Death rate

In a report from the UK it was noted that the annual death rate from ecstasy use is uncertain (82). A meta-analysis of surveys of illegal drug use by 15–24-year-old

© 2006 Elsevier B.V. All rights reserved.

individuals in the UK in 1996 showed that 7% had used ecstasy in the previous year and 3% in the previous month, a rate 44% higher than in 1993–1995. But the actual numbers of ecstasy-related deaths are more difficult to ascertain. In Scotland, ecstasy-related deaths are defined as "ecstasy found in the body"; in England, on the other hand, it is defined as "ecstasy written on the death certificate." Using these disparate definitions, 11 deaths were reported in Scotland and 18 in England in the 15–24-year-old category. Based on all available data, the author of the report suggested a 26-fold range (0.2–5.3) of possible ecstasy-related deaths per 10 000 within this age group. To make death estimates more reliable, the author recommended that the definition of "ecstasy-related-death" should be unified, and that surveys should ask directly about regular, sporadic, and first-time drug use, so as to determine which group is at most risk. The author expressed concern that these data (poor as they are) may be used by the courts and policy makers as if they were more valid, citing the example of Switzerland, which has recently liberalized the guidelines on sentencing people who supply ecstasy tablets, in contrast to suppliers of heroin, based on their interpretation of the data that the death rate in ecstasy users is at the lower end of the range.

This report generated two responses. One group felt that estimating such death rates is even more complex than noted (83). They asked whether, if someone purchased ecstasy but instead got a contaminated or a very different compound, causing death, the death would be classified as ecstasy-related or as something else? Furthermore, they wondered if the definition of ecstasy-related death is based on the detection of MDMA (or its metabolites) in the blood or on detection of other compounds (consumed under the presumption of its being ecstasy). Citing their own experience, they suggested that criteria for inclusion should include: "Would the deceased still be alive if (s)he had not abused the substance?" Thus, even deaths from causes such as traffic accidents, when the death was secondary to intoxication with the compound, should be included.

The second group, while agreeing with the original report, raised the concern that surveys that are more frequent would be economically prohibitive (84). They noted that in 1997 The National Program on Substance Abuse Deaths (NPSAD) was established to monitor drug-related deaths in the UK. It uses a "cause of death ratio," which looks at the number of drug-related deaths in specific categories (for example 15–24-year-olds) and the drugs implicated in these deaths. According to the authors, this method allows rapid surveillance of the pattern of deaths over time.

Pathology

Three deaths have been reported after the ingestion of MDMA/MDEA, in which immunohistological studies further elucidated the causes of the deaths (85). One death was caused by MDMA intoxication, one was from MDEA, and the third was from combined intoxication. One case had been reported previously (SEDA-22, 31).

- A 19-year-old man consumed ecstasy for the entire duration of a discotheque party (lasting until morning) and had respiratory difficulty, uncoordinated movements, generalized hypertonia, and hyperpyrexia (40.6°C). The diagnosis was disseminated intravascular coagulation and was treated with heparin but suffered severe blood loss from the oral cavity and injection wounds. He subsequently had a cardiac arrest.
- A 20-year-old man took many ecstasy tablets at a discotheque, returned home complaining of feeling feverish (axillary temperature 40°C), went to bed, and was found dead 10 hours later, his pillow soaked with blood.
- A 19-year-old man was found unconscious near a discotheque. His course progressively worsened, with the appearance of diffuse subcutaneous petechiae. While being treated for hypotension, he developed sustained convulsions and uremia and later died.

In all cases, amphetamines were detected in the urine. The pathological findings showed diffuse subserous petechiae and polyvisceral stasis. The brains showed massive edema and signs of neuronal hypoxia. In two cases, the heart showed coagulative myocytolysis, while one had areas of subendocardial hemorrhage. The lungs showed subpleural and intra-alveolar hemorrhages with severe edema, and in two cases microthrombotic formations inside lung capillaries. In two cases, the liver showed evidence of microvesicular steatosis and in one case centrilobular necrosis. Liver cells in the central zones showed coagulation necrosis with precipitation of fibrin in the whole area affected by necrosis. In the kidney, fibrin thrombi in the renal glomeruli were observed in two of the cases, while acute tubular necrosis was observed in one.

The findings in these three cases were similar to those seen in deaths from hyperthermia and disseminated intravascular coagulation. The myocardial necrosis (coagulative myocytolysis) without infarct necrosis suggested adrenergic overdrive. In two cases the muscle showed the typical pathological changes observed in deaths due to malignant hyperpyrexia. Myoglobin was detected in the proximal tubules in all three cases. The authors interpreted the clinical, histopathological, and toxicological data as indicative of an idiosyncratic response to ecstasy.

Long-Term Effects

Drug dependence

There are few preclinical or clinical data to suggest that repeated use of MDMA is associated with increased tolerance or dependence. However, anecdotal reports suggest that in some individuals, increasing amounts of MDMA are used in order to achieve the same reinforcing psychoactive effects (44,86).

Second-Generation Effects

Pregnancy

Workers in Canada have tried to characterize women who reported gestational exposure to ecstasy (87). The Motherisk Program is a large Teratogen Information Service based in Toronto and receives over 150 calls daily about exposure to various agents during pregnancy. The authors reviewed the data from 1998 to 2000. The

© 2006 Elsevier B.V. All rights reserved.

study group consisted of all pregnant women who had been exposed to ecstasy. The control group was randomly selected pregnant women who visited the Motherisk Clinic during the same week as the subject who called about ecstasy. The 132 ecstasy-exposed women were significantly younger, earlier in gestational age, and weighed less than the non-exposed controls. The ecstasy users had had significantly fewer pregnancies and live births and had a higher rate of therapeutic abortions but not spontaneous abortions. Significantly more ecstasy users reported unplanned pregnancies and were more likely to be single and white. The ecstasy users were more likely than controls to have had alcohol exposure in pregnancy, and significantly more drank heavily. The ecstasy-exposed women were more likely to binge-drink and smoke cigarettes during pregnancy, and more were significantly heavy smokers. Ecstasy users also had a greater tendency to use marijuana, cocaine, amphetamines, ketamine, gamma-hydroxybutyrate, and psilocybin.

Of the 132 women who reported ecstasy use, 129 had used it during pregnancy, of whom 101 reported previous use of ecstasy before their pregnancy, but had discontinued it. The mean gestational age of last ecstasy exposure was 5.0 weeks (range 1–24 weeks). All but three used tablets: two snorted and one used a liquid formulation. The mean dose taken on one occasion was 1.24 tablets. Of the 122 patients whose data were included in the analysis, most (57%) had only one exposure to ecstasy during pregnancy; 10 women had more than five exposures. One 15-year-old girl did not realize she was pregnant until 24 weeks gestation and had used two tablets of ecstasy four times a day. Only seven of the ecstasy group reported exposure to ecstasy alone. Ecstasy-associated adverse events were reported by 33 of 77 respondents. The physical adverse effect most commonly reported was vomiting (23%). The authors raised significant concerns about the potential teratogenic effects in these women, due to clustering of risk factors.

Drug Administration

Drug formulations

In New Zealand, "herbal ecstasy" is a term used for many different herbal formulations, none of which contains ecstasy. Some of the names for these herbs (which can be sold in stores) include "The Bomb", "Reds", and "Sublime". Analysis of "The Bomb" showed substantial amounts of ephedrine; the Ministry of Health in New Zealand removed it from the market. Some symptoms associated with herbal ecstasy include headache, dizziness, palpitation, tachycardia, and raised blood pressure. Thus, in countries where the term "herbal ecstasy" is commonly used, it is important that those who see patients who have taken herbal ecstasy should not confuse it with ecstasy, as toxicity and medical management may be quite different (88).

Drug contamination

It is not uncommon for people to be deceived into consuming other substances, believing them to be MDMA. At dance parties and "raves" for young adults, compounds passed as ecstasy may be more lethal than MDMA, either because they contain more potent amphetamines than MDMA or because of adulteration with other substances. In three fatal cases reported in the USA, the victims (two men aged 19 and 24 and a woman aged 18) believed that they were using MDMA but had in fact taken PMA, a more potent central stimulant with structural and pharmacological similarities to MDMA (89). They became agitated and developed bruxism, severe hyperthermia, convulsions, and hemorrhages. The presence of PMA was confirmed by enzyme immunoassay, and MDMA was not detected. PMA is not a contaminant of MDMA.

Drug–Drug Interactions

Alcohol

The pharmacokinetic and pharmacodynamic interactions of single doses of ecstasy 100 mg and alcohol 0.8 g/kg have been investigated in nine healthy men (mean age 23 years) in a double-blind, double-dummy, randomized, placebo-controlled crossover design (90). Each underwent four 10-hour experimental sessions, including blood sampling, with 1 week between each. For the task used to test the recognition and recording of visual information, the conditions involving ethanol yielded significantly more errors and fewer responses than ecstasy alone or placebo alone. The combination of ecstasy with ethanol reversed the subjective effect of sedation caused by alcohol alone. In addition, the combination extended the sense of euphoria caused by ecstasy to 5.25 hours. The addition of ethanol caused plasma ecstasy concentrations to rise by 13%. These results show that the combination of ecstasy with alcohol potentiates the euphoria of ecstasy and reduces perceived sedation. However, psychomotor impairment of visual processing caused by alcohol is not reversed. This is a concern for road safety, as people who take both drugs would feel sober, but their driving would still be compromised, although the extent of driving impairment under these conditions is not known. The increase in plasma concentrations of ecstasy caused by alcohol could exacerbate the adverse effects of ecstasy.

Ritonavir

An important consideration in the use of all HIV-1 protease inhibitors, but of ritonavir in particular, is their potential for drug interactions through their effects on cytochrome P450 isozymes. The various interactions of ritonavir with other antiretroviral drugs have been reviewed (91). Ritonavir, which inhibits CYP2D6, the principal pathway by which MDMA is metabolized, can also produce clinically relevant interactions with recreational drugs (92).

- A 32-year-old HIV-positive man, who added ritonavir 600 mg bd to his antiretroviral regimen of zidovudine and lamivudine, became unwell within hours after having taken two and a half tablets of ecstasy, estimated to contain 180 mg of MDMA. He was hypertonic, sweating profusely, tachypneic, tachycardic, and cyanosed. Shortly after he had a tonic-clonic seizure and a cardiorespiratory arrest. Attempts at resuscitation were

© 2006 Elsevier B.V. All rights reserved.

unsuccessful. Blood concentrations obtained post-mortem showed an MDMA concentration of 4.56 mg/l, in the range of that reported in a patient with a life-threatening illness and symptoms similar to this patient after an overdose of 18 tablets of MDMA.

A patient infected with HIV-1 who was taking ritonavir and saquinavir had a prolonged effect from a small dose of MDMA and a near-fatal reaction from a small dose of gamma-hydroxybutyrate (93).

Selective serotonin re-uptake inhibitors (SSRIs)

An MDMA-related psychiatric adverse effect may have been enhanced by an SSRI (94).

- A 52-year-old prisoner, who was taking the SSRI citalopram 60 mg/day, suddenly became aggressive, agitated, and grandiose after using ecstasy. He carried out peculiar compulsive movements and had extreme motor restlessness, but no fever or rigidity. He was given chlordiazepoxide and 2 days later was asymptomatic. Citalopram was reintroduced, and 2 days later he reported visual hallucinations of little bugs in the cell. Promazine was substituted for citalopram and his condition improved 2 days later.

The authors suggested that SSRIs such as citalopram can potentiate the neurochemical and behavioral effects of MDMA.

Methylnaltrexone

See also Opioid antagonists

General Information

Methylnaltrexone is an opioid receptor antagonist that acts peripherally and can be of value in preventing the unwanted effects of opioids while maintaining their central analgesic effects (SEDA-21, 92) (1).

© 2006 Elsevier B.V. All rights reserved.

Methylphenidate

See also Anorectic drugs

General Information

Methylphenidate is a piperidine derivative, structurally related to amphetamine, but a milder central nervous system stimulant. However, large doses produce symptoms of generalized central nervous system stimulation and convulsions. It is more active than amphetamine as an antidepressant, as a treatment for overdosage of depressant drugs, and in exacerbating schizophrenic symptoms. Occasionally, anorexia, nausea, dry mouth, nervousness, insomnia, dizziness, and palpitation have been recorded.

Considerable concern surrounds the use of methylphenidate, and to a lesser extent amphetamine and pemoline, in hyperactive children or those with attention deficit hyperactivity disorder (ADHD), because of possible detrimental effects on general physical and emotional growth and central nervous system development. The Psychopharmacology Pediatric Subcommittee of the FDA in the USA has reviewed the literature relevant to growth suppression by stimulants in the treatment of hyperkinesia. There is clear evidence of temporary retardation in weight increase and a suggestion of temporary slowing of height increase related to dose and absence of drug holidays during the prepubertal period (1–3). Drug holidays allow growth rebound in children who require higher doses.

At an NIH Consensus Conference, one of the conclusions was that "... careful therapeutic use of stimulants is effective in treating the core symptoms of ADHD as long as a child is taking the medication" (4). However, the panel identified "... the need to study the benefits and risk of long-term use of such medications. Although behavioral treatments produced positive short-term results it remains unclear what combinations of these strategies are most effective... Although little information exists concerning the long-term effects of psychostimulants, there is no conclusive evidence that careful therapeutic use is harmful. When adverse drug reactions do occur, they are usually related to dose. It is well known that psychostimulants have abuse potential ...". However, drugs used for ADHD, other than psychostimulants, have their own adverse reaction patterns: "tricyclic antidepressants may induce cardiac arrhythmias, bupropion at high doses can cause seizures, and pemoline is associated with liver damage." Effects associated with moderate doses include reduced appetite and insomnia. These effects occur early in treatment and may abate with continued dosing. There may be negative effects on growth rate, but final height does not appear to be

affected. Rarely, children and adults who take high doses have hallucinogenic responses. The need for long-term follow-up looking for potential adverse effects was highlighted by the conference.

The short-term and long-term efficacy and safety of pharmacological and nonpharmacological interventions in patients with ADHD have been discussed in a systematic review of 92 reports of 78 randomized clinical trials (5). There was substantial heterogeneity in the data, and so a meta-analysis was not performed. In 22 comparisons of stimulants, the drugs did not generally differ in efficacy. The evidence was too limited for a reliable assessment of the effectiveness of stimulant drugs compared with tricyclic antidepressants. Of six comparisons of drugs and non-drug interventions, five showed that stimulants were more effective. In 20 trials of combined interventions there was no compelling evidence to support combination treatment. Of nine comparisons of tricyclic antidepressants with placebo, six showed benefit with desipramine, whereas the effect of imipramine (three trials) was inconsistent. The study with the highest methodological score showed greater benefit with methylphenidate than placebo. Adverse effects, such as sleep disorders, headache, tics, reduced appetite, abdominal pain, irritability, nausea, and fatigue, were assessed in 29 trials. No evidence was available for more severe, long-term adverse effects, such as the risk of addiction with stimulants, liver toxicity with pemoline, or cardiac dysrhythmias with antidepressants. The authors concluded that in patients with ADHD published studies of treatment regimens provide limited information of effectiveness because of small sample sizes, flawed methods, and heterogeneity across outcomes. Thus, pharmacological interventions in ADHD are consistently more effective than nonpharmacological interventions. Combined interventions are not more beneficial than single interventions.

Two reviews have addressed the diagnosis and management of ADHD and have summarized the effects of stimulants, including those of methylphenidate and Adderall® (a mixture of equal components of D-amfetamine saccharate, D,L-amfetamine aspartate, D-amfetamine sulfate, and D,L-amfetamine sulfate, which seems to be gaining popularity in the treatment of ADHD) (6,7).

The results of the National Institute of Mental Health Collaborative Multimodal Treatment Study of children with attention deficit hyperkinetic disorder have been analysed (8). This double-blind, placebo-controlled methylphenidate titration trial identified the optimum dose and replicated previously reported methylphenidate response rates and dose-related adverse events. For parent ratings, the severity of the following adverse events increased as the dose was raised: appetite suppression, dull/listless appearance, stomachache, tearfulness, and trouble sleeping. For teacher ratings, the only significant drug-related adverse event that had a dose-related trend was reduced appetite. Other adverse events reported by teachers were dull/listless appearance, crabbiness, and buccal movement or chewing. However, these teacher-reported adverse events improved with increased methylphenidate dosage. The authors also emphasized that parents report more dose-related adverse events than teachers do, making them better reporters of safety during dosage titration.

As more adults with ADHD are being treated with methylphenidate, the possibility of drug interactions with methylphenidate increases (9). However, based on a study in extensive and poor CYP2D6 metabolizers, it has been suggested that CYP2D6 is not involved in the metabolism of methylphenidate, and that drugs that are inhibitors of CYP2D6 should not affect methylphenidate plasma concentrations (10).

Organs and Systems

Cardiovascular

Significant increases in blood pressure and/or pulse rate after methylphenidate are more frequent when it is given parenterally (11) (SEDA-4, 9).

Cardiac dysrhythmias, shock, cardiac muscle pathology, and liver pathology have all been reported (12).

Ambulatory blood pressure monitoring showed changes in blood pressure and heart rate in boys aged 7–11 years taking stimulant therapy (13). This preliminary study with chronic methylphenidate or Adderall® (dexamfetamine + levamfetamine) for ADHD showed alterations in awake and asleep blood pressures, with profound nocturnal dipping. Modified-release formulations of methylphenidate and Adderall® now allow more sustained blood concentrations in children. The effects of these newer formulations on cardiovascular indices should be evaluated.

Nervous system

A first case of neuroleptic malignant syndrome probably caused by methylphenidate has been reported in a child with multicystic encephalomalacia due to severe perinatal hypoxic/ischemic encephalopathy (14). At 1.5 years of age, because her circadian rhythm was irregular or reversed, methylphenidate (3 mg/day) was given for its antihypnotic effect. The diagnostic criteria of neuroleptic malignant syndrome (15) were fulfilled in this case, including three major manifestations (fever, rigidity, and raised creatine kinase activity) and six minor ones (tachycardia, abnormal blood pressure, tachypnea, altered consciousness, sweating, and leukocytosis). Other predisposing factors, such as pre-existing severe brain damage suggestive of organic fragility and infection, may have contributed.

There is continuing concern about the potential for methylphenidate to precipitate tics or Tourette's syndrome, in subjects with and without pre-existing tics. However, in a placebo-controlled crossover study in 91 children with ADHD, the usual doses of methylphenidate did not produce significantly more tics than placebo in children with or without pre-existing tics (16). This study had limitations of sample size and statistical power. Moreover, these conclusions cannot be generalized to patients who use higher doses of methylphenidate, because a dose-dependent relation between methylphenidate and tics has been proposed (17). Until the effect of methylphenidate in larger populations has been studied with more exacting measures of tics, it would be wise to monitor for tics, especially if higher doses (0.5–1.3 mg/kg) of methylphenidate are required.

© 2006 Elsevier B.V. All rights reserved.

The risk of using methylphenidate for long periods has been highlighted by a case of a stroke in a child (18).

- An 8-year-old boy, who had taken methylphenidate (20 mg/day) for 18 months, suddenly developed paresthesia in his left arm, with spontaneous resolution after a few days. Two months later he had intense paresthesia in the left arm, spreading to the left side of the face; 48 hours later he developed weakness of the arm that extended to the whole of the left side of the body. He remained lucid. The episode resolved spontaneously within 24 hours. After a symptom-free period of 2 months, he had a third episode, similar to the previous ones, but more severe and leaving a residual deficit. Methylphenidate was withdrawn and he did not subsequently relapse. A CT scan showed a hypodense area in the left thalamus, and an MRI scan showed multiple lesions in both thalami. A cerebral angiogram showed enlargement of the basilar artery and the proximal segment of both posterior cerebral arteries.

The authors suggested that in this case the stroke was due to a vasculitis, which has previously been reported with methylphenidate (19).

Episodes of explosive behavior, apparently due to methylphenidate, masquerading as unmanageable ADHD, have been reported (20).

- A 10-year-old boy developed motor and vocal tics and severe obsessive-compulsive symptoms, predominantly about symmetry. These were not evident before he started taking methylphenidate. At 7 years of age he had begun a regimen of methylphenidate 20 mg/day in divided doses. Paradoxically, his impulsive behavior increased and he began to have explosions of aggressive and violent behavior, during which he would lash out at his family or destroy things. After a year of methylphenidate therapy, the tics subsided spontaneously but other symptoms remained. Eventually, because of severe impairment resulting from obsessive-compulsive symptoms, his parents stopped giving him methylphenidate. A few months later there were no further obsessive-compulsive preoccupations and no tics, and he did not have any explosive behavior.

It is well recognized that in vulnerable individuals, methylphenidate can induce or aggravate Tourette's syndrome, most often characterized by motor tics and occasionally vocal tics (21). Moreover, obsessive-compulsive symptoms caused by methylphenidate have also been reported (22,23). However, it is not clear whether explosive episodes associated with Tourette's syndrome are an integral part of the disorder or occur as part of a co-morbid disorder, predominantly ADHD or obsessive-compulsive disorder. In this case the explosive episodes coincided with a period of treatment with methylphenidate. In view of the extreme, sudden, discrete nature of the outbursts and the temporal relation to treatment, it was concluded that the episodes were behavioral problems caused by methylphenidate, rather than a feature of the underlying ADHD.

As with other stimulants, chorea (24) and choreoathetosis (25) can be precipitated in children and adults at methylphenidate doses ranging from therapeutic to abuse levels. These symptoms respond to drug withdrawal or neuroleptic drugs.

Psychological, psychiatric

Methylphenidate-induced obsessive-compulsive symptoms are very rare (26); a second case has been reported (22).

- An 8-year-old boy had unusual difficulties in completing a trial of methylphenidate for ADHD. Methylphenidate 10 mg/day initially improved his school performance, but by the end of the second week of treatment severe obsessive-compulsive behavior began to emerge, requiring drug withdrawal. He eventually refused to eat because he suspected that his food was being poisoned. His parents reported that he became more sensitive and easily upset, appearing increasingly tense and fearful. He continued to have intrusive distressing contamination worries. He had repetitive tic-like movements of his head and neck, frequently rubbed his face with his shirtsleeves, and avoided touching his face directly with his fingers for fear of contamination. His symptoms gradually and completely dissipated over 2–3 months without specific intervention. While very mild symptoms of ADHD persisted, he remained entirely free of symptoms at 1 year. Medication was not restarted.

This case lends further support to existing anecdotal evidence associating methylphenidate with obsessive-compulsive disorder of acute onset. However, rechallenge was not attempted, and causality should be viewed as being uncertain.

In a small percentage of hyperactive children, there were gross behavioral changes with hallucinations after brief administration of modest doses of methylphenidate; the reaction subsided after withdrawal (27).

Endocrine

Methylphenidate has been reported to cause stunting of growth by impairing growth hormone secretion (28).

- A 10-year-old boy with ADHD and chronic asthma, who was using inhaled corticosteroids, developed almost complete growth arrest during methylphenidate treatment. Growth hormone stimulation tests and measurement of growth hormone-dependent growth factors suggested that methylphenidate had altered growth hormone secretion and had impaired growth. Determination of growth velocity was a sensitive marker for the evaluation of growth.

Metabolism

The association between childhood treatment with methylphenidate and adult height and weight has been investigated in 97 boys, aged 4–12 years, who were referred to a child psychiatry out-patients clinic and took methylphenidate for an average of 36 months (29). They were re-evaluated between ages 21 and 23 years. Hierarchical analysis predicted adult height and weight from sets of both nonmedication-related and medication-related variables. Medicated individuals who had attained their final stature did not differ in average height or weight from family, community, or nonmedicated

© 2006 Elsevier B.V. All rights reserved.

controls. In some individuals, nausea and vomiting and the use of higher doses of methylphenidate were associated with growth impairment. It should be emphasized that the correlations in this study do not demonstrate cause and effect relations between medication and ultimate stature.

Gastrointestinal

Methylphenidate can occasionally cause abdominal distress, which can be alleviated either by reduction of the dose or by administering the drug immediately after meals (30,31).

Liver

Increased activities of aspartate transaminase, alanine transaminase, and alkaline phosphatase were reported in a 67-year-old woman with a stroke who had taken methylphenidate 10 mg tds. Nausea, vomiting, and dizzy spells occurred. The drug was withdrawn and liver enzymes returned to normal, but when she was rechallenged with a small dose (2.5 mg), the pathological changes recurred (32).

Long-Term Effects

Drug abuse

Abuse and psychosis

Methylphenidate shares the pharmacological properties and the abuse potential of the amphetamines. When given intravenously, it activates psychotic symptoms in schizophrenic patients if administered during the active phase of their illness, but not after remission. It failed to produce a psychotic reaction in most manic or depressed patients or in healthy subjects (27). Adults with childhood-onset ADHD had an earlier onset of psychoactive substance use disorders, independent of any psychiatric co-morbidity (33). However, bipolar disorders conferred a significantly increased risk for early onset psychoactive substance use disorders independent of ADHD. The question arises as to the contribution of stimulant treatment to psychoactive substance use disorders. There were no differences in medicated versus unmedicated adolescents with ADHD in a review of eight outcome studies comprising 580 adolescents briefly treated with stimulants for six months to five years (34).

In a double-blind study, undesirable personality changes, consisting of lethargic and apathetic behavior, occurred in six of 98 hyperactive children aged 6–12 years and treated with methylphenidate for 16 weeks. Withdrawal resulted in a prompt switch from the characteristic mental depression to normal behaviour (35).

There is large variation in individual responses to methylphenidate among hyperactive children with minimal brain dysfunction. It is therefore advisable to start with small divided doses, since some symptoms (extrapyramidal and seizure-like) could be dose-related.

Complications of abuse

Chronic parenteral injection of methylphenidate hydrochloride tablets intended for oral use has led to cutaneous reactions. Pulmonary granulomata were seen in two patients who died as a consequence of drug abuse (SED-8, 22). In one case, bullous erythema multiforme was described and considered unlikely to be due to the excipients in the tablets. However, cornstarch, talc, and binders cause significant microemboli, noticeable on retinoscopic examination, and can cause pulmonary hypertension (SEDA-4, 9).

Five patients suffered skin abscesses or cellulitis after parenteral methylphenidate abuse (SED-9, 11). Such lesions can arise from local vasospasm and chemical irritation and can be susceptible to secondary infection.

Susceptibility Factors

Untreated ADHD is a significant risk factor for substance abuse disorders in adolescents (36). In contrast, pharmacotherapy, that is stimulants, was associated with an 85% reduction in the risk of substance abuse disorders in youths with ADHD. Most authorities recommend complete assessment and diagnosis of both ADHD and any dual diagnoses before starting stimulant medication.

Drug Administration

Drug formulations

A modified-release, once-daily formulation has been evaluated in 282 children with ADHD in a double-blind, placebo-controlled trial for 28 days (37). For core ADHD symptoms, both once-daily modified-release and thrice-daily immediate-release methylphenidate were superior to placebo and not different from each other. A similar percentage of patients reported at least one adverse event with both formulations. The most commonly reported adverse events were headache and upper respiratory infections, followed by abdominal pain, cough, pharyngitis, vomiting, and otitis media. Of these, only headache and abdominal pain were considered to be related to the study medication. One patient withdrew because of depression with modified-release methylphenidate and one because of tics with placebo. Headache occurred in 14%, 5.8%, and 10% of patients taking modified-release methylphenidate, immediate-release methylphenidate, or placebo respectively, and abdominal pain in 6.7%, 5.8%, and 1.0%. Other adverse events included appetite suppression (modified-release methylphenidate) and insomnia (all three). The results of this study suggest that once-daily modified-release methylphenidate provides efficacy superior to placebo and is not significantly different from thrice-daily immediate-release methylphenidate.

Drug overdose

A death due to intranasal abuse of methylphenidate in a teenager has been reported (38).

- A teenager presented with a history and physical signs characteristic of methylphenidate abuse, including hyperpyrexia and tachycardia. The plasma methylphenidate concentration was less than 0.05 mg/l in the admission sample. However, the concentration of ritalinic acid, the principal metabolite of methylphenidate,

© 2006 Elsevier B.V. All rights reserved.

was 0.4 μg/ml. Ethanol was also found in a concentration of 22 mmol/l (100 mg/dl).

Comparable toxicity with other stimulants is well known (39,40).

Of 289 patients exposed to excessive doses of methylphenidate, 31% had symptoms, including most commonly tachycardia, agitation, and lethargy (41). No patient developed severe symptoms, although there was a less favorable outcome with intentional versus unintentional exposure. Peak exposure occurred in 6- to 9-year-old children, in whom therapeutic error was the most common reason for exposure.

Drug–Drug Interactions

Carbamazepine

Carbamazepine can reduce methylphenidate concentrations markedly (42). Since these drugs are often used together, the authors suggested that the worsening of behavior in a 13-year-old girl with ADHD might have been due to a fall in blood concentration of methylphenidate, resulting from carbamazepine.

Ciclosporin

Potential drug–drug interactions of ciclosporin with methylphenidate and amfebutamone (bupropion) have been described (43).

- A 10-year-old boy with a heart transplant had a potentially life-threatening reduction in ciclosporin blood concentrations with amfebutamone. He subsequently had an increase in ciclosporin concentrations while taking methylphenidate.

These interactions merit further systematic investigation.

Citalopram

There is growing interest in using stimulants, particularly methylphenidate, in the management of elderly depressed patients, either alone (44) or in combination with antidepressants such as citalopram (45). In a preliminary trial in 10 elderly patients a combination of methylphenidate and citalopram was well tolerated.

Clonidine

There has been a scare regarding the use of clonidine in combination with methylphenidate, based on frequently cited cases of four children who died, presumably while taking clonidine together with methylphenidate (46,47). It has been argued that "... cases of fatality in people receiving the combination have a paucity of supporting evidence, with prominent mitigating and extenuating circumstances nullifying any scientific attempts at association. Given that no association can be drawn, there are insufficient data to support any 'causal mechanisms'." Further discussion of the dangers beyond solid evidence does little to ease the task of thoughtfully using medications in the treatment of children and adolescents with psychopathology (48).

© 2006 Elsevier B.V. All rights reserved.

Ethanol

A novel metabolite of methylphenidate, ethylphenidate, has recently been detected in human blood and liver samples obtained from two suicide victims who had taken a large dose of methylphenidate and ethanol (49). The concentrations of ethylphenidate were small relative to those of methylphenidate and ritalinic acid. Nevertheless, given the frequent occurrence of methylphenidate and ethanol co-ingestion, the detection of ethylphenidate warrants further studies on the extent of its formation, as well as any associated toxicity associated with normal doses. A transesterification reaction, analogous to that known to produce cocaethylene after cocaine and ethanol co-ingestion (50), has been described with methylphenidate (51).

Levodopa

Methylphenidate increased some of the motor effects of levodopa in selected patients with Parkinson's disease (52). Changes in self-assessed analogue ratings of mood, anxiety, arousal, or concentration did not differ.

Oral anticoagulants

Methylphenidate slows the rate of clearance of ethylbiscoumacetate and can therefore enhance its anticoagulant action (53).

Phenobarbital

Methylphenidate increases serum concentrations of phenobarbital (54).

Phenytoin

Methylphenidate increases serum concentrations of phenytoin (SED-14, 176).

Tricyclic antidepressants

Hypertensive episodes occurred in three adults who combined methylphenidate with tricyclic antidepressants (SED-9, 11). Methylphenidate increases serum concentrations of imipramine (55).

Valproic acid

Two cases of dyskinesia and bruxism in children have been attributed to an interaction of methylphenidate with valproic acid. These adverse effects were severe, occurred a few hours after the ingestion of methylphenidate 5 mg, and lasted for 4 and 7 hours (56).

Methylphenobarbital

See also Antiepileptic drugs

General Information

The adverse effects of methylphenobarbital are similar to those of phenobarbital, to which methylphenobarbital is metabolized.

Organs and Systems

Immunologic

Giant cell myocarditis has been reported in a patient taking phenytoin, phenobarbital, and methylphenobarbital, and in one taking primidone (1).

Second-Generation Effects

Teratogenicity

There is an association of methylphenobarbital with oral clefts and cardiac malformations (2).

Methyl-tert-butylether and monoctanoin

General Information

Methyl-tert-butylether and monoctanoin are solvents that are used for the rapid dissolution of cholesterol gallstones in patients who are not considered suitable for surgery. They are given by direct infusion into the gallbladder (1). However, they are suitable only for cholesterol stones, take too long to act, are often not successful, and have high rates of adverse effects (2).

The results of contact dissolution of gallstones using infusions of methyl-tert-butylether by percutaneous transhepatic gallbladder puncture have been assessed in 803 patients (3). Stones were dissolved in 724 of 761 patients in whom gallbladder puncture was successful. The 30-day mortality was 0.4%. Common complications were biliary leak, fever, leukocytosis, abdominal pain, and mild increases in transaminases. Toxic effects due to ether were not reported.

Fever, abdominal pain, nausea, vomiting, and diarrhea all occur frequently with methyl-tert-butylether and monoctanoin. Activities of serum amylase or liver enzymes can be slightly raised.

In 343 patients treated with monoctanoin there were adverse effects in 67% (4). Abdominal pain was the commonest (in 40%), followed by nausea (25%), vomiting (15%), diarrhea (16%), and fever (5%). One patient with hepatic cirrhosis developed an acidosis and encephalopathy. The adverse effects were usually dose-related and responded to reduction in infusion rate. The effects were life threatening in 12 patients (5%), but there were no permanent sequelae and no deaths.

Of 42 patients, 19 of whom received methyl tert-butylether alone and 23 with bile acid-ethylenediaminetetraacetate, there were mild complications in 40: vomiting in 12, pain at the start of treatment in 32, raised liver enzymes in six, and fever and leukocytosis in five (5). In those given methyl tert-butylether alone, there were two serious complications (gallbladder wall necrosis with

© 2006 Elsevier B.V. All rights reserved.

perforation in one and catheter dislocation in the other). In those given combination therapy there were five serious complications: pericystic extravasation in two and catheter dislocation, sterile perihepatic abscess, and perihepatic biloma in one each. A CT scan with intravenous contrast after treatment was performed in 27 patients and showed gallbladder mural hyperemia and edematous swelling of the pericystic tissue layer in 26 cases.

Organs and Systems

Respiratory

Non-cardiogenic pulmonary edema has been reported with monoctanoin after appropriate intra-biliary use (6). If monoctanoin is injected intravenously in error, fatal respiratory and cardiac arrest can occur (7).

Biliary tract

Cholecystitis can be induced, at least when methyl-tert-butylether is used alongside ethylenediaminetetraacetic acid (SEDA-16, 428). Most such effects are probably attributable to over-rapid infusion.

Necrotizing choledochomalacia has also been described with monoctanoin (8). Gallstone impaction has been described.

Methylthioninium chloride

General Information

Methylthioninium chloride (methylene blue) has been used for a variety of purposes, including marking of polyps, identification of sinus and fistula tracts, localizing islet cell tumors (1), marking of skin incisions in plastic surgery (2), labelling of vascular malformations, and the treatment of methemoglobinemia. Transient burning and blue discoloration can occur (3).

Organs and Systems

Hematologic

Severe hemolytic reactions have been attributed to methylthioninium chloride (4).

Immunologic

Methylthioninium chloride marking of a colonic polyp resulted in an inflammatory mass with small arteries showing both segmental and circumferential fibrinoid necrosis with thrombosis (5).

- A 68-year-old Hispanic woman had multiple polyps associated with recurrent episodes of hematochezia over several years. All but a single polyp were removed endoscopically. The region of the remaining polyp was labelled with 2 ml of methylthioninium chloride injected in divided doses to aid operative localization. Because surgery was postponed, methylthioninium chloride was again injected. At surgery the polyp and a 5 cm perirectal indurated mass were identified, and there was a blue track from the submucosal to the outer portions of muscularis propria into the adjacent fat. Microscopically, the mucosa was intact and the submucosa was edematous. There were acute inflammatory cells in the submucosa and muscularis propria. Inflammation (acute and chronic), fibroblastic proliferation, and fat necrosis were seen in areas outside the muscularis propria and extending to the connective tissue margin. A prominent finding was fibrinoid necrosis of small arteries, in some cases segmental and in others circumferential. The internal elastic lamina was destroyed and there were thromboses and vessel wall inflammation. There was no evidence of infiltrating carcinoma in the adenomatous polyp or the adjacent colon. The inflammation and vascular changes were only in the mass defined grossly by induration; sections away from this area were unremarkable. The blue track contained blue–black pigment within macrophages.

The mechanisms of the tissue damage and vascular changes in this case were unclear.

Anaphylactic shock has been attributed to methylthioninium chloride (SEDA-22, 526).

Second-Generation Effects

Pregnancy

Significant neonatal morbidity can occur after transabdominal infusion of methylthioninium chloride to diagnose premature rupture of fetal membranes, to stain the amniotic fluid in twin pregnancies, or after postpartum administration of methylthioninium chloride. Toxic manifestations include hyperbilirubinemia, Heinz body hemolytic anemia, and possible desquamation of the skin. In most cases it appears that toxicity was the result of an overdose of methylthioninium chloride (6–9).

Fetotoxicity

Multiple ileal occlusions have been reported in babies born to mothers who had twin pregnancies and who had received methylthioninium chloride administered during amniocentesis (10–12). In a number of cases it was found that methylthioninium chloride had been injected into the amniotic sac of the affected twins.

Methylthioninium chloride phototoxicity may also be related to the high prenatal dose of the dye relative to patient's small size and young gestational age (13).

The fetal death rate appears to increase after the use of methylthioninium chloride during pregnancy. In a retrospective cohort study of all women who had an amniocentesis during twin pregnancy from 1980 to 1991 in New South Wales in Australia, women who were exposed to methylthioninium chloride dye during the procedure were compared with women who had amniocentesis without dye exposure (14). Fetal death occurred in 32% of pregnancies that had exposure to a high concentration of methylthioninium chloride, compared with 15% of pregnancies exposed to a low concentration and 4.3% of pregnancies with no exposure to dye. It was concluded that methylthioninium chloride dye use during mid-trimester amniocentesis in twin pregnancy increases the risk of fetal death.

Drug Administration

Drug administration route

Methylthioninium chloride is sometimes given intrathecally to track the source of a cerebrospinal fluid leak. This procedure involves considerable risk of spinal cord damage, with its attendant neurological consequences (15–17).

- A 59-year-old man had 6 ml of unbuffered methylthioninium chloride injected into the lumbar theca in an attempt to localize the source of cerebrospinal fluid rhinorrhea (18). After injection of the dye he became shocked, and within the next few days developed a mild paraparesis, which subsequently progressed to total paraplegia.

Drug overdose

Overdosage of methylthioninium chloride given intravenously, which has happened inadvertently during urinary tract surgery, can cause shock and pseudocyanosis. The latter is due to the blue tinge of methylthioninium chloride, and it can create confusion as to the patient's circulatory status. Patients receiving methylthioninium chloride should be examined for unstable hemoglobins or an abnormal hexose monophosphate pathway if the risk of methemoglobinemia is to be minimized; this has been described with a normal dose (19).

Methysergide

General Information

Methysergide is a semisynthetic ergot derivative that is structurally similar to ergometrine. However, its spectrum of activity differs substantially. It is a potent 5-HT receptor antagonist and has been used prophylactically in migraine and to control the symptoms of the carcinoid syndrome. However, it has been replaced by other more effective and safer drugs and should now be regarded as obsolete, given its tendency to cause retroperitoneal fibrosis (1). For any patients who still take it, a program of 3-monthly monitoring, including clinical examination, plasma electrolytes, full blood count, and erythrocyte sedimentation rate, has been recommended. The authors suggested that methysergide should be withdrawn if any abnormalities emerge, and also concurred with the widespread practice of "drug holidays" for 3–6 months, although these are not of proven value. Despite the title of their paper, they did not describe the management of established retroperitoneal fibrosis, and indeed there is no treatment of proven value.

Although a third of patients have some adverse effects, only about 10–15% have to stop treatment acutely for this reason. Mild gastrointestinal upsets, abdominal cramping and a tendency to dizziness, light-headedness, and nervousness are the most frequent complaints. Less frequent but more serious symptoms include those attributable to fibrosis. Its vasoconstrictor and oxytocic effects are generally slight.

Organs and Systems

Cardiovascular

Methysergide can cause tachycardia, postural hypotension, and angina pectoris.

Aortic and mitral valvular fibrosis can lead to congestive cardiac failure; fibrosis rarely affects the endocardium more extensively (extending into the myocardium) or the pericardium (resulting in constrictive pericarditis). Vasospastic effects can occasionally be as severe in susceptible subjects as with ergotamine; especially dangerous are combinations with ergotamine tartrate, as are combinations of ergot alkaloids with beta-blockers (SEDA-9, 128).

Nervous system

Methysergide can cause restlessness, insomnia, drowsiness, and mild psychic changes (2).

Psychological, psychiatric

An LSD-like reaction has been observed with as little as 2 mg (3). There is a risk of dependence and the drug is better avoided in patients with a history of mental disorders.

Hematologic

Hemolytic anemia, neutropenia, and eosinophilia have all been described (4).

Postpartum hemolytic–uremic syndrome has been reported (SEDA-12, 124).

Skin

Various skin disorders have been described in patients taking methysergide (2). In one case, hair loss occurred (5).

Serosae

Serious fibrotic changes occur in about 1% of patients who take methysergide continuously for 1 year or more, and provide the main reason for reducing doses and withdrawing the drug at intervals. Most commonly the fibrosis is retroperitoneal and starts in the pelvis or the lumbar region, where it can constrict the ureters, arteries, veins, and lymph vessels. Both infarction and obstruction of the bowel have occasionally been described. Fibrotic syndromes elsewhere can involve the heart, pleura, chest wall, and lungs.

Drug–Drug Interactions

Sumatriptan

The combination of methysergide with sumatriptan has been associated with vasospasm in the coronary arteries (6).

- A 43-year-old woman with controlled hypertension, but no other known coronary risk factors, had an acute myocardial infarction. She took two oral doses of methysergide 2 mg 12 hours apart, followed by sumatriptan 6 mg subcutaneously. About 10 minutes after the sumatriptan, she complained of chest pain, and on arrival in hospital, an anterior myocardial infarction was diagnosed. Subsequent angiography showed a solitary stenosis in the left anterior descending coronary artery, and it was therefore presumed that she had suffered vasospasm associated with this stenosis. She made an excellent recovery after stenting.

The danger of combining two cerebral and coronary vasoconstrictors needs no emphasis.

Metirosine

General Information

Metirosine (alpha-methyl-para-tyrosine) inhibits the formation of dopamine (1) and is sometimes used to prepare patients with pheochromocytoma for surgery (2), although not always successfully (3).

Organs and Systems

Nervous system

In one study, metirosine 5.25 g caused reduced happiness, euphoria, energy, talkativeness, vigor, and attentiveness, and increased sleepiness, fatigue, sedation, and eye blink rate (4).

Psychological, psychiatric

In 14 drug-free subjects with a history of depression metirosine 5 g caused marked, transient increases in core depressive and anxiety symptoms (5).

When tested in 21 healthy subjects, metirosine produced panic attacks on several occasions in three of them (6).

Urinary tract

Metirosine can cause crystalluria unless there is a high fluid intake (7).

Metoclopramide

General Information

Metoclopramide is a dopamine receptor antagonist used in the treatment and prevention of nausea and vomiting. It also has effects on HT_3 receptors in the gut, but at concentrations higher than are generally achieved during routine therapy.

Although metoclopramide has lost some ground to newer congeners, it has been the most widely used of the neuroleptic-type antiemetic drugs and is therefore the one for which the clearest picture of adverse effect, typically neuroleptic and endocrine effects, has emerged. Reactions are generally short-lived provided treatment is withdrawn; the duration of reactions does not always seem to be explained by simple pharmacokinetic considerations.

Organs and Systems

Cardiovascular

Complete heart block (SEDA-12, 939) (1) and supraventricular tachycardia (2), presumably due to a vagolytic effect, have been described with metoclopramide. If there are predisposing conditions, heart failure can be precipitated (SEDA-16, 418). In one study in which 56 patients were treated with metoclopramide, a single case of second-degree atrioventricular heart block was observed (SEDA-20, 316).

- Complete heart block has been reported in a 65-year-old woman with type 2 diabetes, hypertension, and ischemic heart disease, who was given intravenous metoclopramide 20 mg (3).

A hypertensive crisis has been precipitated by metoclopramide in patients with pheochromocytoma (4).

Respiratory

Two cases of acute bronchospasm have been reported after the intravenous administration of metoclopramide, one in a patient with pre-existing asthma (SEDA-16, 419).

Nervous system

Dyskinesias of various types are classic effects of metoclopramide in adults. Tardive dyskinesia and myoclonus have been described (SEDA-9, 312) (SEDA-17, 414). Dyskinesias tend to occur after some months of use. As with the classic neuroleptic drugs, neuroleptic malignant syndrome can occur (5).

Adverse reactions to metoclopramide in 52 children aged 2.5–4.5 years who were admitted to hospital over 6 years have been studied retrospectively (6). All had various dystonic symptoms that occurred several hours after

© 2006 Elsevier B.V. All rights reserved.

taking the drug. The prominent clinical effect was an oculogyric crisis in all cases, while children who took higher doses also became drowsy. All extrapyramidal symptoms were treated successfully with a single intravenous dose of procyclidine hydrochloride 0.1 mg/kg.

Severe parkinsonism has been reported in a 73-year-old woman with tuberculosis of the large intestine who had taken metoclopramide for nausea; she recovered on withdrawal of the drug and treatment with biperiden (7).

The "blue tongue" sign, in which the tongue is blue and swollen and obstructs the upper airway, is an unusual but dangerous manifestation of the same group of adverse effects (SED-12, 940) (8).

Acute dystonia has been reported in three men with AIDS who had received metoclopramide; they recovered on withdrawal and treatment with biperiden or diazepam (9). Dystonic reactions seem to be particularly problematic in the very young and the very old, but the frequency is disputed (10). In one overview acute movement disorders were thought to have occurred in about one in 80 young adults (SEDA-17, 414). When metoclopramide is given by intravenous injection, for example as an aid to gastric emptying imaging, akathisia seems to occur mainly in women or young men, and more often if the injection is more rapid.

The fact that the neurological reactions can be difficult or impossible to distinguish from spontaneous parkinsonism perhaps explains reports of apparently irreversible effects; almost certainly in such cases the disorders were not exclusively due to the drug.

A lengthy withdrawal reaction has also been described after 6 months of treatment, characterized by an alternation of an akinetic state and akathisia reminiscent of the restlessness seen in parkinsonism (11); even after a year of symptomatic treatment the effects had not fully subsided.

Psychological, psychiatric

Supersensitivity psychosis has been reported in two men, aged 74 and 65 years, who had taken metoclopramide 5 mg qds for 6 and 3 months respectively (12). Hallucinations and delusions developed 12 hours after the drug was withdrawn in one patient and 3 days after withdrawal in the other. Both recovered after treatment with risperidone.

Endocrine

Hyperprolactinemia and galactorrhea, sometimes with gynecomastia, are classic complications of metoclopramide that can equally well occur in adults, children, or neonates (13) (SEDA-22, 390).

Vasopressin release has been claimed to be enhanced by metoclopramide, while aldosterone release is impaired (SED-12, 940).

Hematologic

Effects of metoclopramide on the blood are very uncommon, but neutropenia has been reported in circumstances suggesting that a causal link is likely (SEDA-13, 329).

Methemoglobinemia has been reported following gross accidental overdosage of metoclopramide in an infant (SEDA-15, 392).

Liver

Complex liver disorders very occasionally occur with metoclopramide, with cholestasis and opening of arteriovenous shunts in the liver (SEDA-16, 419). In two cases a condition resembling Reye's syndrome has been seen (14).

Susceptibility Factors

Hepatic disease

If there is impaired liver function, metoclopramide can accumulate. In eight patients with severe alcoholic cirrhosis there was a 50% lower clearance than in eight healthy volunteers; the apparent volume of distribution and absolute systemic availability were similar in the two groups (15).

Other features of the patient

Metoclopramide is contraindicated when stimulation of gastrointestinal motility could be dangerous, for example when there is hemorrhage, obstruction, or a risk of perforation.

Patients with pre-existing dyskinesias should not be given metoclopramide, and both the very young and the very old have a greater risk of adverse reactions, as do patients with cardiac disorders or asthma.

Drug Administration

Drug formulations

In a four-way crossover study in 16 healthy men a modified-release formulation of metoclopramide (30 mg) administered fasting and after a high-fat meal, an immediate-release formulation (30 mg) and a short intravenous infusion of 30 mg have been compared (16). The absolute systemic availability of the modified-release formulation was about 17% lower than that of the immediate-release formulation. Food had no significant effect on absorption. Uniform absorption of the drug from modified-release formulations supports their use in long-term treatment.

Seven patients from Peru developed extrapyramidal symptoms when supposedly taking lincomycin: in fact each capsule contained no less than 500 mg of metoclopramide (17).

Drug–Drug Interactions

Alcohol

Intravenous metoclopramide 20 mg accelerated gastric emptying and increased the rate of absorption of alcohol in seven subjects (18). In another similar study the sedative effects of alcohol were enhanced (19).

Ciclosporin

It has been suggested that metoclopramide increases the systemic availability of ciclosporin (SED-11, 783) (20).

© 2006 Elsevier B.V. All rights reserved.

Cisplatin

Metoclopramide reduces renal plasma flow, suggesting that concurrent use could increase the nephrotoxicity of cisplatin (21), an important observation in view of the specific usefulness of metoclopramide to treat cytotoxic drug-induced emesis.

Digoxin

When digoxin is given in a slowly dissolving form, the plasma concentrations achieved are reduced by about one-third if metoclopramide is given at the same time (22); liquid or readily dissolvable solid forms of digoxin are unlikely to be affected.

Paracetamol

In five health subjects intravenous metoclopramide increased the rate of absorption of a single dose of paracetamol 1.5 g (23).

Quinidine

Metoclopramide increases the serum concentrations of quinidine by up to 20% (24).

Theophylline

Metoclopramide reduces serum concentrations of theophylline (25).

Metocurine

See also Neuromuscular blocking drugs

General Information

Metocurine is a non-depolarizing neuromuscular blocker, a synthetic derivative of D-tubocurarine. No metabolites have been detected and it depends almost entirely on renal function for its excretion; 40–50% of the drug is

© 2006 Elsevier B.V. All rights reserved.

excreted in the urine and about 2% (possibly more) in the bile in 24 hours (1). It is about twice as potent as D-tubocurarine and a quarter as potent as pancuronium, measured during narcotic/nitrous oxide anesthesia. It has similar onset and duration of action and speed of recovery to D-tubocurarine and pancuronium (2).

The dose of metocurine for intubation is 0.3 mg/kg and adequate abdominal relaxation is achieved with 0.1–0.2 mg/kg in most patients. As with all neuromuscular blocking agents, there is great individual variation in response, and if it is desired to give minimal doses, monitoring of the neuromuscular response is advisable. Volatile anesthetics and prior suxamethonium would be expected to reduce dosage requirements, but clinical reports are lacking. Patients with burns require 2–3 times higher doses of metocurine (3) and this phenomenon can persist (in lessening degree) for 1 year or more (4).

Organs and Systems

Cardiovascular

Metocurine has significantly less ganglion-blocking activity than D-tubocurarine (5) and much less of a tendency to provoke histamine release (6,7). It does not block cardiac muscarinic receptors at neuromuscular blocking doses (8). Cardiovascular stability is therefore to be expected (9). Slight tachycardia and fall in blood pressure have been reported in one-third of patients given larger doses (0.4 mg/kg) rapidly, probably as a result of histamine release, but no bronchospasm was seen (2).

Susceptibility Factors

Renal disease

Greatly prolonged duration of paralysis and a reduced rate of return of neuromuscular function can occur in renal insufficiency, because of a reduced plasma clearance and a prolonged half-life (10). Metocurine is not the relaxant of choice when renal function is poor.

Drug–Drug Interactions

Phenytoin

Resistance to metocurine is also described in patients taking long-term phenytoin (SEDA-10, 110) (11).

Metolazone

See also Diuretics

General Information

Metolazone occupies an intermediate position between the thiazide diuretics and the more potent loop diuretics (1). It is more effective than the thiazides in moderate to advanced renal insufficiency (SED-8, 488) (SED-9, 355). In patients with normal renal function its antihypertensive effect compares favorably with that of bendroflumethiazide. When severe heart failure is refractory to conventional triple therapy (high-dose loop diuretic, digoxin, and angiotensin-converting enzyme inhibitor) metolazone can restore diuresis, with weight loss and clinical improvement.

Organs and Systems

Electrolyte balance

Metolazone causes a greater degree of potassium depletion than thiazides (SED-11, 424). In order to avoid serious electrolyte disturbances when metolazone is introduced in patients taking loop diuretics, the metolazone should be given in low doses to start with in hospital, and at the same time the dosage of the loop diuretic should be reduced under careful biochemical monitoring (SEDA-16, 225).

Long-Term Effects

Drug abuse

Neutropenia is a rare complication of metolazone (2).

Metoprolol

See also Beta-adrenoceptor antagonists

General Information

Metoprolol is a cardioselective beta-adrenoceptor antagonist with some membrane-stabilizing activity. It is metabolized by polymorphic hydroxylation (1).

Organs and Systems

Liver

Metoprolol was associated with hepatitis in a patient who was a poor metabolizer (2).

Musculoskeletal

A metoprolol-induced polymyalgia-like syndrome (3) has been described.

Susceptibility Factors

Genetic factors

The metabolism of metoprolol varies six-fold higher between poor metabolizers of debrisoquine and extensive metabolizers (1).

Drug Administration

Drug formulations

A modified-release formulation of metoprolol has been associated with more skin reactions, probably due to the succinate component, instead of the tartrate component used in the old fast-acting formulation (SEDA-16, 195).

Metrifonate

General Information

Metrifonate, which is given orally, is effective in *Schistosoma hematobium* infections in three doses of 7.5–10 mg/kg 14 days apart. When metrifonate was used in daily doses, as in the treatment of *Onchocerca volvulus* infections, it produced muscarinic effects, and in one case there was proximal weakness due to a nicotinic effect. The combination of polyarthritis, fever, and a raised sedimentation rate was described in 11 of 34 patients treated. Metrifonate inhibits blood cholinesterase activity for up to 48 hours, and common reactions that probably result from this effect comprise nausea, vomiting, abdominal pain, diarrhea, dizziness, weakness, headache, and muscle cramps. Because of its prolonged inhibition of brain cholinesterase and increased steady-state concentrations of acetylcholine in the cortex and the hippocampus, it is now also increasingly used in the treatment of Alzheimer's disease.

Metrifonate has been used for the treatment of schistosomiasis for almost 40 years. Its identification as a cholinesterase inhibitor, together with recognition of the cholinergic deficit in Alzheimer's disease, has led to its use in Alzheimer's disease.

The pharmacology and pharmacokinetics of metrifonate and experience with its use in Alzheimer's disease have been reviewed (1).

Two reviews (2,3) of the use of metrifonate in Alzheimer's disease have been published. Both reported a positive effect of metrifonate, with generally mild and usually transient adverse effects, consisting of gastrointestinal symptoms (such as abdominal pain, diarrhea, flatulence, and nausea, probably reflecting cholinergic overactivation) and leg cramps, possibly caused by the overstimulation of nicotinic receptors at the neuromuscular junction. No laboratory abnormalities were reported.

In a randomized, double-blind, placebo-controlled trial in 408 patients with Alzheimer's disease, metrifonate (20 mg/kg/day for 2 weeks followed by 0.65 mg/kg/day for 24 weeks) significantly improved several mental performance scales (4). Of the 273 patients treated with metrifonate 12% discontinued treatment because of adverse effects, compared with 4% of the 134 patients treated with placebo. The adverse effects that led to withdrawal were mainly gastrointestinal in nature. Diarrhea occurred in 18% of the patients treated with metrifonate (leading to withdrawal in 3%) and in 8% of the patients treated with placebo; 2% of the patients treated with metrifonate discontinued treatment because of nausea and vomiting and 1% because of dyspepsia. Nausea occurred in 12% of the patients treated with metrifonate and in 10% of the patients treated with placebo. Vomiting occurred in 7% and 4% respectively.

In a second randomized, double-blind, placebo-controlled trial (5) 480 patients were randomized to receive placebo ($n = 120$), a low dose of metrifonate (0.5 mg/kg/day for 2 weeks followed by 0.2 mg/kg/day for 10 weeks) ($n = 121$), a moderate dose of metrifonate (0.9 mg/kg/day for 2 weeks followed by 0.3 mg/kg/day for

10 weeks) ($n = 121$), or a high dose (2.0 mg/kg/day for 2 weeks followed by 0.65 mg/kg/day for 10 weeks) ($n = 118$). These doses were selected to achieve steady-state erythrocyte acetylcholinesterase inhibition of 30%, 50%, and 70% respectively. There was a significant dose-related improvement in several mental performance scales with metrifonate. Most of the adverse events were mild and transient. Adverse events that occurred more often in the patients treated with metrifonate were abdominal pain (placebo 4%, low dose 3%, moderate dose 11%, high dose 12%), diarrhea (8%, 9%, 11%, 19%, respectively), flatulence (9%, 2%, 8%, 16%), and leg cramps (1%, 1%, 3%, 8%). Bradycardia, presumably related to the vagotonic effect of acetylcholinesterase inhibition, led to withdrawal of treatment in three patients with asymptomatic bradycardia. All three were in the loading-dose phase of the highest metrifonate dosage regimen.

In 16 patients with Alzheimer's disease, adverse effects were dose-related (6). In eight patients who took 2.5 mg/kg/day for 14 days, 4 mg/kg/day for 3 days, and then 2.0 mg/kg/day for 14 days (acetylcholinesterase inhibition 88–94%) treatment had to be withdrawn because of moderate to severe adverse effects in 6 patients on day 28 of the planned 31. In eight patients treated with 2.5 mg/kg/day for 14 days followed by 1.5 mg/kg/day for 35 days (acetylcholinesterase inhibition 89–91%), the frequency of more severe adverse effects was considerably lower despite similar acetylcholinesterase inhibition. The most frequent adverse events in the high-dose group were muscle cramps and abdominal discomfort during the loading-dose phase, followed by increasing gastrointestinal symptoms in the second loading phase, accompanied by headache and muscle aches. The adverse events profile initially improved during the maintenance phase. However, after 11 days of maintenance treatment, six patients complained of generalized moderate to severe muscle cramps, weakness, inability to resume daily activities, and difficulties with coordinations. The adverse events profile was much more favorable with the lower dose, with the same, but much less severe, range of adverse effects. Again, the most frequent adverse effects were gastrointestinal disturbances, muscle cramps, and light-headedness. One patient had increased sweating, dizziness, and palpitation on day 29 and another developed severe abdominal tenderness on day 31, which led to termination of treatment. There were no abnormalities in laboratory parameters. The authors proposed a maximum tolerated dose of 1.5 mg/kg/day of metrifonate for maintenance therapy in patients with Alzheimer's disease.

The Metrifonate Alzheimer's Trial (MALT) was designed to evaluate a wide range of symptoms and efficacy measures in four main clinical domains of Alzheimer's disease: cognition, psychiatric and behavioral features, activities of daily living, and global functioning (7). These are considered key targets for antidementia drugs. This prospective, multicenter, randomized, double-blind, parallel group study was conducted at 71 independent study centers, and 605 patients were randomized to placebo ($n = 208$), metrifonate 40 or 50 mg/day ($n = 200$), and metrifonate 60 or 80 mg/day ($n = 197$); within each treatment group the dose was determined according to body weight, and treatment lasted for 24 weeks. Metrifonate improved a wide range of symptoms across all four clinical domains of Alzheimer's disease in a dose-dependent manner, and was well tolerated at both doses. One patient withdrew from the study during the high-dose loading phase owing to cholinergic effects, resulting in muscle weakness. Metrifonate was also associated with a slight gradual lowering of hemoglobin, hematocrit, and erythrocyte count in both groups during the first 12 weeks; these were nonprogressive, stabilized over the 6-month treatment period, and hence were not considered to be clinically relevant. Metrifonate was associated with a higher incidence of bradycardia (under 50/minute); serious adverse events possibly related to bradycardia (hypotension, postural hypotension, syncope, dizziness, malaise, and accidental injury) occurred in three patients taking placebo, eight taking low-dose metrifonate (three of whom were withdrawn from the study), and two taking high-dose metrifonate.

In patients with mild to moderate Alzheimer's disease metrifonate significantly improved behavior as well as cognition, function in activities of daily living, and global functional status, as shown by a pooled analysis of four prospective, multicenter, randomized, double-blind, parallel-group, placebo-controlled trials, meeting FDA guidelines (8).

The safety and tolerability of once-daily oral metrifonate has been evaluated in patients with probable mild to moderate Alzheimer's disease in a randomized, double-blind, placebo-controlled, parallel-group study (9). Metrifonate was given to 29 patients as a loading dose (2.5 mg/kg) for 2 weeks, followed by maintenance dose (1 mg/kg) for 4 weeks; 10 patients received placebo. The proportion of patients who had at least one adverse event was comparable in the two groups: metrifonate 76%, placebo 80%. Selected adverse events, defined as those for which the incidence in the metrifonate and placebo group differed by at least 10%, were diarrhea, nausea, leg cramps, and accidental injury. The adverse events were predominantly mild and transient. Those who took metrifonate had a significantly lower heart rate. Metrifonate had no clinically important effect on laboratory tests, such as liver function tests, and did not affect exercise tolerance or pulmonary function.

Organs and Systems

Nervous system

Patients with Alzheimer's disease taking long-term treatment with metrifonate suffered seizures after abrupt withdrawal of antimuscarinic agents (10).

- A 58-year-old woman was given hyoscyamine for abdominal cramps by her local physician without the knowledge of her neurologists. She had a generalized seizure 36 hours after stopping the drug.
- A 66-year-old woman was treated for a skin allergy with doxepin cream in large doses. Withdrawal of this treatment led to two complex partial seizures.

The authors speculated that the antimuscarinic drugs impaired the cholinergic receptor down-regulation that would normally occur in the presence of the increased concentrations of acetylcholine caused by

© 2006 Elsevier B.V. All rights reserved.

acetylcholinesterase inhibition. Withdrawal of the antagonist therefore abruptly exposed the receptors to high concentrations of the neurotransmitter, leading to seizures.

Second-Generation Effects

Teratogenicity

The birth of a hydrocephalic infant with a large meningomyelocele to a mother who had been treated with metrifonate for an infection with *Schistosoma hematobium* during the second month of pregnancy has been reported, but the report is not recent and the association was probably coincidental (SED-11, 598).

Drug Administration

Drug dosage regimens

The effects of a loading dose on the adverse events of metrifonate 50 mg/day have been studied in Alzheimer's disease. The regimen without a loading dose was better tolerated during the 4-week study period (11).

Drug–Drug Interactions

Organophosphorus insecticides

Theoretically, suxamethonium will be potentiated after administration of metrifonate and, in view of its ability to suppress enzyme activity, metrifonate should be used with great caution in areas where organophosphorus insecticides are used, since they have a similar effect.

Metronidazole

General Information

Metronidazole is a benzimidazole derivative.

Uses

Metronidazole is effective in the treatment of many protozoal diseases, notably trichomoniasis, amebiasis, schistosomiasis, strongyloidiasis, and giardiasis, and has been in use for over 20 years.

For amebiasis there is still discussion about the use of a single high dose versus repeated lower doses, both as regards efficacy and adverse effects.

The use of metronidazole against infections with anerobic bacteria has increased over the years, and with this indication the use of metronidazole in combination with many other drugs used by patients with conditions likely to develop secondary anaerobic bacterial infections. With increased use there is also a widespread and increasing incidence of resistance of various strains of bacteria. The use of metronidazole as an added medication merely "to make assurance double sure" is to be discouraged. It is to be especially discouraged in immunocompromised patients, because of the risk of emergence of resistant bacterial strains. With increased use there is also an increased number of reports of some more unusual adverse effects. Overall, metronidazole can still be considered safe, if used in generally recommended doses.

Metronidazole has been formulated as a vaginal gel (0.75%) for the treatment of bacterial vaginosis. A single daily 5-day regimen has been approved by the FDA and has been shown to be as effective as oral metronidazole (1).

In the eradication of *Helicobacter pylori,* metronidazole plus bismuth is effective, but causes more adverse effects than omeprazole plus amoxicillin plus either clarithromycin or metronidazole.

© 2006 Elsevier B.V. All rights reserved.

Pharmacokinetics

Metronidazole has excellent systemic availability, and absorption after oral administration is not significantly affected by food. Peak serum concentrations occur about 1 hour after ingestion. Multiple doses every 6–8 hours result in some drug accumulation, the half-life averaging about 8 hours. There is a linear relation between dose and serum concentration. Rectal administration results in serum concentrations about half those seen after oral administration. Systemic absorption after local use in the vagina is slow, maximum serum concentrations being reached only after 8–24 hours; they are only about 20% of those attained after oral administration. Metronidazole is extensively metabolized, and only about 20% of the dose is excreted unchanged in the urine. Tissue concentrations are similar to serum concentrations, and metronidazole penetrates readily into the central nervous system. As with many metabolized drugs, the half-life is markedly prolonged in neonates; there is an inverse relation between gestational age and half-life. Prolonged elimination times are also seen in the presence of serious liver disease (SEDA-13, 831) (SEDA-16, 310) (SEDA-17, 332) (SEDA-18, 294).

Preliminary case reports have suggested that azithromycin or metronidazole can improve ciclosporin-induced gingival hyperplasia (SEDA-19, 350).

General adverse effects

Metronidazole is generally well tolerated. With high doses and high-dose prolonged treatment, nausea, vomiting, and central nervous system symptoms ranging from headache and dizziness to neuritis can occur. The commonest reactions are nausea, a metallic taste in the mouth, furry tongue, and vulvovaginal irritation in patients who take metronidazole for bacterial vaginosis (SEDA-13, 831) (SEDA-18, 295). Reports of pancreatitis, neuropathy, and optic neuritis call for caution. Hypersensitivity reactions are unusual, but rashes have been described.

Organs and Systems

Cardiovascular

Thrombophlebitis can occur after intravenous administration of metronidazole; an incidence of 6% has been cited (SEDA-7, 297) (2).

Respiratory

Pneumonitis has been attributed to metronidazole, with recurrence after rechallenge (SEDA-14, 242).

Nervous system

Central nervous system symptoms can occur with standard doses of metronidazole, but they are mainly seen with high doses and especially when such doses are given for a long time. Under the latter conditions, there was a 25% incidence of such symptoms as headaches, dizziness, tremor, ataxia, and confusion.

A polyneuropathy is a well-recognized adverse effect of metronidazole (3). A 6% incidence of neuropathy has been quoted; polyneuropathy, mainly sensory in nature, has been recorded during the treatment of Crohn's disease, but again in connection with the prolonged use of high doses (SEDA-12, 705) (4,5). This complication is not restricted to patients with Crohn's disease; it is also seen when metronidazole is given for other purposes, such as radiosensitization. Electrophysiological studies have suggested distal sensory axonal degeneration, with loss of sensory nerve potential over the distal segment and normal motor nerve conduction. In some cases the severity of clinical and electrophysiological abnormalities is closely related to the total amount of metronidazole administered (SEDA-14, 242). Metronidazole is structurally similar to thiamine, and thiamine-synthesizing gut flora may synthesize a neurotoxic analogue of thiamine from ingested metronidazole. However, this hypothesis is weakened by the fact that nitroheterocyclic drugs other than metronidazole are also neurotoxic, despite a much weaker structural analogy to thiamine (SEDA-12, 706) (6).

Peripheral neuropathy was associated in one case with intermittent use of metronidazole (2 g/day for 5 days every other month) (7).

- A 65-year-old white woman with small intestine bacterial overgrowth developed persistent numbness and tingling of her upper and lower extremities. She had been taking alternating courses of tetracycline and metronidazole for 5 days every other month for about 1 year. Other medications included amitriptyline, lisinopril, digoxin, omeprazole, and tamoxifen. Serum vitamin B_{12} and folate concentrations were within the reference ranges. She had reduced sensation in a stocking-glove distribution, reduced sensation to touch and pin-prick, intact reflexes, and no weakness. Neuropathy was attributed to metronidazole, which was withdrawn. After 4 months she reported improvement. On follow-up at 5 months, there was no evidence of peripheral neuropathy.

Metronidazole-associated sensory neuropathy usually presents with pain and reduced thermal and pin-prick sensation, but normal strength, proprioception, and tendon reflexes. Four patients with metronidazole-associated sensory symptoms had detailed electrodiagnostic studies and nerve or muscle biopsies (8). All had taken different doses of metronidazole and one (with a mitochondrial myopathy) had only used the drug topically. After withdrawal, sensory complaints persisted without progression in two patients and resolved in one. In the fourth, a lower dosage led to partial resolution. Nerve conduction studies were normal in all four cases, but quantitative sensory testing and quantitative sudomotor autonomic reflex testing showed abnormalities of small-fiber function. A sural nerve biopsy from one patient confirmed some loss of small myelinated axons. Metronidazole probably caused a small-fiber neuropathy in these four cases. The authors also reviewed nerve conduction studies in 30 reported cases of metronidazole-associated neuropathy; they were sometimes normal, suggesting that sensory symptoms related to metronidazole may be caused by a mixture of small-fiber and large-fiber sensory dysfunction.

Aseptic meningitis is a rare, possibly allergic adverse effect of metronidazole; the one published case was well documented, with positive rechallenge (9).

© 2006 Elsevier B.V. All rights reserved.

There has been a report of visual loss and headache after metronidazole (10).

- A 68-year-old man with a tooth abscess had a tooth extraction and received amoxicillin. A few weeks later he developed toothache again and was given amoxicillin and metronidazole 400 mg tds; he took no other drugs. Six hours after the first dose he developed a headache. He continued with metronidazole for a total of three doses, and 6 hours after the last dose the headache resolved. Two days later he noticed flashing lights in both eyes. He then developed a central visual field defect and progressive visual loss. His blood pressure was 220/120 mmHg, but it settled spontaneously. Visual acuity was 6/12 in both eyes and fundoscopy showed marked disc swelling with hemorrhages, without other features of hypertensive retinopathy. Full blood count, plasma viscosity, routine biochemistry, vasculitis screen, anticardiolipin antibodies, angiotensin converting enzyme assay, chest X-ray, CT of the brain and orbits, MRI, and MRA were all normal. CSF examination showed an opening pressure of 24 cm of water and 13 white cells/μl. Over the next few months his visual symptoms slowly improved but he developed secondary optic atrophy.

In this case there was no other obvious cause for visual loss and it could have been caused by metronidazole. The exact mechanism was unclear, but it may have been related to raised intracranial pressure.

Convulsions occurred in an 87-year-old man who had taken metronidazole (11).

Encephalopathy associated with metronidazole has been reported in a patient with chronic renal insufficiency (12).

- A 58-year-old woman with end-stage renal insufficiency secondary to diabetic nephropathy developed abdominal wall cellulitis 4 days after insertion of a peritoneal dialysis catheter. She was given vancomycin, cefepime, and metronidazole in reduced doses (doses not stated) and 2 days later developed dysarthria, an intention tremor, dysmetria, and dysdiadochokinesia. "Routine" biochemical tests were unchanged and a CT scan of the brain was unremarkable, but an MRI scan showed cerebral and cerebellar atrophy with multifocal ischemic glial lesions. Metronidazole was withdrawn and 2 days later her symptoms and signs had completely resolved.

It is difficult to ascribe encephalopathy unequivocally to metronidazole in this case.

Sensory systems

Eyes

Acute myopia occurred after 11 days of treatment with metronidazole for *Trichomonas* infection; it resolved within 4 days after withdrawal but recurred on rechallenge. The combined figures of two major American reporting systems for adverse reactions listed seven cases of retrobulbar or optic neuritis associated with oral metronidazole; two had a concurrent peripheral neuropathy. However, there is insufficient information to evaluate these reports (SEDA-17, 333).

Ears

Two reports of moderate to severe sensorineural deafness after metronidazole therapy, which resolved slowly after therapy ended suggest that this is an additional adverse effect (13). Both cases of deafness were preceded by tinnitus, which may be a warning to withdraw the drug.

Hematologic

Metronidazole can produce leukopenia and neutropenia, usually only associated with prolonged therapy and reversible on withdrawal (SEDA-13, 832). One case each of agranulocytosis and of aplastic anemia have been reported (SEDA-11, 595) and a single case of hemolytic–uremic syndrome in six children (SEDA-15, 298).

Gastrointestinal

Anorexia, nausea, vomiting, abdominal pain, and diarrhea have all been reported in patients taking metronidazole (14). The use of a large single dose most commonly leads to these complaints. A metallic taste also seems to be quite common (14), as is the occurrence of a black tongue (SEDA-13, 832) (15).

Although metronidazole is often used to treat pseudomembranous colitis, it can also occasionally cause it (16,17).

Liver

Raised serum liver enzyme activities were reported in one case about 15 years ago (SEDA-11, 595) (18), but there has been no more recent confirmation.

Pancreas

Pancreatitis has been reported in various individual case histories (SEDA-15, 298), but there is reason to think that some of these cases at least were due to other factors, such as alcohol use (SEDA-13, 832).

- Pancreatitis has been described in a 63-year-old woman with Crohn's disease, coinciding with the administration of metronidazole and disappearing 1–2 days after withdrawal, but even here there was little support for a causal link (19–21).
- Pancreatitis was attributed to metronidazole in a 61-year-old woman given intravenous metronidazole 500 mg 6-hourly (22). The relation between pancreatitis and metronidazole in this case was less convincing than in previously reported cases, as there was no rechallenge.

Urinary tract

Darkening of the urine can occur in patients taking metronidazole (23); this is a harmless discoloration, mostly seen during prolonged treatment.

Skin

Pruritus and rashes have been reported in patients taking metronidazole, including a fixed drug eruption (24) and a pityriasis rosea-like eruption. Urticaria after a single dose has been reported but could have been coincidental (SEDA-17, 333).

© 2006 Elsevier B.V. All rights reserved.

In a case of fixed drug eruption, a provocation test showed cross-reactivity with tinidazole but not with secnidazole (24).

Reproductive system

A genital mucosal erosion occurred in a 38-year-old woman who had taken metronidazole 400 mg tds for 10 days for bacterial vaginitis (SEDA-16, 310).

Long-Term Effects

Drug tolerance

Resistance of *H. pylori* to metronidazole was found in 30% of isolates in the Lebanon (25), 42% in Brazil (26), and 80–90% in Africa (27).

Mutagenicity

Mutagenicity of metronidazole has been demonstrated in some bacterial systems (SEDA-13, 832). Studies on breakages in single-stranded DNA in the lymphocytes of patients treated with metronidazole for *Trichomonas* vaginitis have suggested that such breakages were repaired after withdrawal. Another study reported chromosomal aberrations in the lymphocytes of ten volunteers taking metronidazole (SEDA-21, 301). A mutagenic effect would theoretically be possible in patients with a DNA repair defect (SEDA-16, 310).

There has been concern that metronidazole may be genotoxic, as there have been reports of mutagenicity in several bacterial species. The genotoxic effects of metronidazole (250 mg bd for 10 days) and nalidixic acid (400 mg bd for 10 days) have been assessed in women with *Trichomonas vaginalis* infections (28). The genotoxic potential of these drugs was evaluated using a sister chromatid exchange test in peripheral blood lymphocytes. Metronidazole had no effect but nalidixic acid caused an increase in sister chromatid exchange frequency. This result confirms that there is little evidence of genotoxicity with metronidazole.

Tumorigenicity

Prolonged high-dose exposure of mice to metronidazole leads to an increased incidence of lung tumors, and in one study there was an increase in lymphoreticular neoplasia in female animals. These results, which caused much concern when first published, are probably non-specific and not relevant to humans; these and other neoplasms have also been induced in mice merely by varying the diet. Several long-term follow-up studies in man have failed to demonstrate an excess cancer risk (SEDA-13, 831). There has been a single report of cancers in three patients with Crohn's disease who had taken metronidazole for years (SEDA-11, 595) (29), but they had also taken sulfasalazine and glucocorticoids, and this cannot be regarded as constituting reasonable evidence of a causal link.

Second-Generation Effects

Teratogenicity

Tests for embryotoxicity and teratogenicity in different animal species have been negative, and there have been no reports of adverse effects on the fetus in pregnant women given metronidazole for trichomoniasis. Despite this, it is still wise to avoid metronidazole during the first trimester of pregnancy.

In a retrospective cohort study using the national birth registry in Denmark, comparing 124 women who took the drug with 13 327 who did not, there was no evidence of any increased risk to the unborn child (30).

In a prospective case-control study in Israel of 857 pregnant women seeking telephone advice regarding gestational exposure to prescribed drugs, 228 women who had taken metronidazole were compared with 629 controls exposed to non-teratogenic agents (31). The mean daily dose of metronidazole was 973 mg for a mean duration of 7.9 days; 90% had used the medication orally, 6% by suppository, and 4% intravenously. Most (86%) had been exposed to metronidazole in the first trimester of pregnancy. There was no difference in the rate of major congenital malformations between the groups (1.6 versus 1.4%), even after accounting for terminations due to prenatally diagnosed malformations. Neonatal birth weight was reduced in the metronidazole group (3.2 versus 3.3 kg) and this was not explained by an earlier gestational age at delivery or a higher prematurity rate but may have been due to the underlying conditions for which metronidazole was prescribed. These findings agree with previous meta-analyses showing that the use of metronidazole in pregnancy is not associated with an increased risk of fetal abnormality, despite in vitro evidence of mutagenesis and inconsistent animal evidence of fetal abnormalities caused by metronidazole.

Lactation

Metronidazole is excreted in the breast milk. There were no adverse effects in nursing infants (SEDA-13, 832), but one should still be cautious in using metronidazole in nursing mothers (SEDA-18, 295).

Susceptibility Factors

Age

In a randomized trial in 100 Iranian children, mebendazole (200 mg tds for 5 days, $n = 50$) was compared with metronidazole (5 mg/kg tds for 7 days, $n = 50$) in giardiasis (32). The two drugs were equally effective (over 85% cure rates). There were no adverse effects of mebendazole, whereas nausea, anorexia, and metallic taste were respectively observed in 4.9, 6, and 24% of those taking metronidazole.

Drug–Drug Interactions

Alcohol

Metronidazole has a disulfiram-like effect in users of alcohol, sufficient to justify a warning (SEDA-13, 833).

© 2006 Elsevier B.V. All rights reserved.

An unusual Antabuse-type reaction reported on one occasion seems to have been due to an interaction of metronidazole with the alcohol present in X-Prep (SEDA-15, 398).

Antibiotics

In vitro, the combination of metronidazole with antibiotics has an additive effect against anaerobic bacteria (SEDA-13, 833).

Carbamazepine

Metronidazole can increase the toxicity of carbamazepine (33) by inhibiting its metabolism.

Cephalosporins

The use of high doses of metronidazole in combination with cefamandole and clindamycin has been associated with encephalopathy (SEDA-12, 705).

Ciclosporin

An interaction with metronidazole and ciclosporin, in which ciclosporin blood concentrations rise, has been suggested, though only in isolated case histories (SEDA-19, 351) (34).

It has been confirmed that metronidazole can produce a two-fold increase in blood concentrations of ciclosporin and tacrolimus, with a subsequent increase in serum creatinine in both cases (35).

The interaction of metronidazole with ciclosporin significantly increased blood ciclosporin and tacrolimus concentrations in two patients (35). Since both of these immunosuppressive drugs are toxic in overdosage, and since patients taking them are prone to infections, this is potentially a serious interaction.

Fluorouracil

Pretreatment with metronidazole increased the toxicity of fluorouracil given by a daily bolus dose (36). The clinical significance of this is yet to be determined.

Gentamicin

In guinea pigs, metronidazole augmented gentamicin-induced ototoxicity, determined by the measurement of compound action potentials (37).

Lithium

Metronidazole can increase the toxicity of lithium (38).

Phenytoin

In a patient taking phenytoin, there was a disproportionate increase in the serum concentration of the hydroxylated metabolite of metronidazole, suggesting that phenytoin induces metronidazole-metabolizing enzymes (SEDA-12, 706) (39).

Quinidine

Serum quinidine concentrations rose during concomitant administration of metronidazole (40). The authors speculated that the mechanism was inhibition of cytochrome P_{450}.

Tacrolimus

A possible interaction with metronidazole recently reported is that it significantly increased blood ciclosporin and tacrolimus concentrations in two patients (35). Since both of these immunosuppressive drugs are toxic in overdosage, and since patients taking them are susceptible to infections, this is potentially a serious interaction.

Vecuronium bromide

Metronidazole can potentiate the effects of non-depolarizing muscle relaxants (41).

Serum concentrations of metronidazole rose during concomitant administration of ciprofloxacin and metronidazole (42). The authors speculated that the mechanism was inhibition of cytochrome P_{450} by ciprofloxacin.

Warfarin and other coumarins

The effect of warfarin is potentiated by metronidazole (43,44). The mechanism is stereoselective inhibition by metronidazole of the metabolism of *S*-warfarin, the more potent isomer (43). There is a similar interaction with acenocoumarol (45,46).

Mexazolam

See also Benzodiazepines

General Information

Mexazolam is a benzodiazepine with effects similar to those of diazepam.

The anxiolytic effects of mexazolam have been compared with those of alprazolam in 64 outpatients with generalized anxiety disorder in a multicenter, double-blind, parallel-group, randomized trial (1). Five mexazolam and nine alprazolam recipients reported mild adverse events: drowsiness in three patients in each group; dizziness in one taking mexazolam and two taking alprazolam; blurred vision in one patient taking mexazolam; and weight gain, nausea, and insomnia in one patient taking alprazolam. Both drugs were effective anxiolytics and both were well tolerated.

Mexiletine

See also Antidysrhythmic drugs

General Information

Mexiletine is a class Ib antidysrhythmic drug, similar in action to lidocaine, but it can be given orally. Its adverse effects occur in up to 50% of patients (1) and withdrawal is often necessary (2). The most common adverse effects are on the cardiovascular and central nervous systems. The pharmacokinetics, clinical use, and adverse effects and interactions of mexiletine have been reviewed widely (3–8).

In addition to its use as an antidysrhythmic drug, mexiletine has also been used in the treatment of various types of neuropathic pain and dystonias (9,10). The adverse effects in these circumstances have been reported (11–13) and reviewed (14).

Observational studies

In an open study of the antidystonic effect of mexiletine (200 mg/day increasing to a maximum of 800 mg/day) in spasmodic torticollis in six patients, mexiletine produced significant improvement and there were no adverse effects in five of the six patients; in the other patient dizziness occurred at the highest dose and required a reduction in dosage (11).

In studies in patients with diabetic peripheral neuropathy, adverse effects included nausea, hiccups, tremor, headache, weakness and dizziness, tachycardia, and allergic reactions (14).

Mexiletine has been used to treat painful peripheral neuropathy in patients with HIV infection, without any evidence of efficacy (15,16). In one study of 22 patients, nine had adverse effects probably related to mexiletine, including nausea in five, vomiting in four, and abdominal pain, diarrhea, dizziness, insomnia, rises in liver enzymes, and skin rash in one patient each (15). Adverse effects in seven patients required dosage reduction in four cases and withdrawal in three (because of a rash in one case and gastrointestinal effects in two).

In a study in which 48 patients with painful peripheral neuropathy due to HIV infection were treated with mexiletine, 10 had nausea and vomiting that required dosage modification; dosage modification was also occasioned by dizziness in one case and urinary retention in three cases (16).

Comparative studies

In 51 patients with serious ventricular tachydysrhythmias mexiletine alone or in combination with other class Ia drugs (quinidine, procainamide, disopyramide) was ineffective in 41% and there was no difference between those who had mexiletine alone and those who had the combinations (17). The incidence of adverse effects was also the same in both groups (about 70%), despite a lower mean dose of mexiletine in the latter.

The adverse effects of mexiletine have been compared with those of quinidine in a randomized, double-blind comparison in 491 patients (18). The commonest adverse effects in the 246 patients given mexiletine were upper gastrointestinal distress (38%), light-headedness (20%), tremor (13%), and co-ordination difficulties (11%). These all occurred more frequently than with quinidine. However, quinidine more often caused diarrhea (35 versus 7%) and dysrhythmias (19 versus 12 patients). The other reported adverse effects, associated in equal frequency with the two drugs, were fatigue, changes in sleep habit, weakness, headache, angina-like pain, and rash. Visual problems (7 versus 3%) and nervousness (6 versus 2%) occurred slightly more often with mexiletine.

Placebo-controlled studies

In a double-blind, placebo-controlled, crossover study of the use of mexiletine in 20 patients with neuropathic pain with prominent allodynia the dosage was titrated to maximum of 900 mg/day or until dose-limiting adverse effects occurred. Mexiletine produced little beneficial effect and the two most common adverse effects were nausea and sedation (12). Other adverse effects that occurred in one or two patients each included insomnia, trismus, headache, agitation, nightmares, and tremor.

In a double-blind, placebo-controlled, crossover study in 12 healthy volunteers mexiletine, in a dosage that was titrated to a maximum of 1350 mg/day or until there were dose-limiting adverse effects, was used to alleviate capsaicin-induced allodynia and hyperalgesia (13). Mexiletine had no significant effect on any of the major measures of pain or neurosensory thresholds after intradermal capsaicin; however, it did reduce the flare response. All 12 subjects had dose-limiting adverse effects and the mean maximum tolerable daily dose was 850 mg. The adverse effects included nausea, light-headedness, muscle twitching and weakness, blurred vision, headache, tremor, difficulty in concentrating, dysphoria, sedation, pruritus, and rash. These adverse effects occurred at an average daily dose of 993 mg. The three most common adverse effects were nausea, dizziness, and tremor in ten, nine, and four of the subjects respectively.

The analgesic effects of mexiletine 600 mg/day and gabapentin 1200 mg/day have been investigated in 75 patients with acute and chronic pain associated with breast surgery in a double-blind, randomized, placebo-controlled study for 10 days (19). Pain at rest and after movement was reduced by both drugs on the third postoperative day and pain after movement was reduced by gabapentin at 2–5 days postoperatively. Two women given mexiletine withdrew from the study because of adverse events, one with an axillary vein thrombosis and one with nausea and vomiting.

Organs and Systems

Cardiovascular

Prodysrhythmic effects of mexiletine have been reported in up to 29% of patients, although it has been suggested that on average the incidence is lower than has been reported with other antidysrhythmic drugs (20).

Mexiletine can have major hemodynamic effects in patients with pre-existing impairment of left ventricular dysfunction (21). Circulatory depression with bradycardia and hypotension have been reported (17,22,23).

Other cardiovascular effects include widening of the QRS complex, atrioventricular dissociation, heart block, sinus arrest, and cardiac arrest (23,24).

Respiratory

Mexiletine has been associated with pulmonary fibrosis and eventual respiratory failure (25).

Nervous system

The commonest adverse effects of mexiletine are on the nervous system, and include centrally mediated gastrointestinal distress (38%), light-headedness (20%), tremor (12%), and coordination difficulties (11%). The figures in parentheses are quoted from a study in which mexiletine was compared with quinidine (26). Other reported adverse effects include changes in sleep habit, weakness, headache, visual problems, and nervousness. Slurred speech, dysarthria, diplopia, and ataxia have also been reported (18).

Mexiletine 300–400 mg/day has been used to treat some of the symptoms of multiple sclerosis in 30 patients with painful tonic seizures, attacks of neuralgia, paroxysmal itching, and Lhermitte's sign (27). Mexiletine produced similar therapeutic effects to lidocaine. In one patient, weakness worsened during the administration of mexiletine. In two patients when mexiletine was replaced by placebo there was a suggestion of some rebound in painful tonic seizures.

In three patients with neuropathic pain, mexiletine added to the analgesic regimen caused some improvement in visual analogue scores for pain (10). All three had some symptoms of nausea, and two became depressed. One patient also reported feeling "trembly and shaky" on occasion, but there was no objective evidence of tremor.

Sensory systems

In two patients with neuropathic pain and pre-existing ocular disease, mexiletine caused persistent ophthalmic changes (28).

- A 39-year-old woman took mexiletine 300 mg tds for 3 days and developed transient blindness with residual reduced visual acuity due to an acute pigmentary retinopathy. Her vision improved markedly after withdrawal of mexiletine, but when she restarted it she developed clouding of the vision, which resolved again on withdrawal. The pigmentary changes persisted.
- A man with a history of glaucoma took mexiletine 300 mg tds and developed worsening visual acuity. Mexiletine was withdrawn and he took carbamazepine 200 mg/day instead. However, he started to see red and green spots. The serum carbamazepine concentration was below that usually associated with visual disturbances. No structural abnormalities were detected.

Hematologic

Mexiletine can cause a spuriously low platelet count as a result of clumping of platelets due to antibodies (29); however, it can also cause a true thrombocytopenia (30,31).

Eosinophilia and atypical lymphocytosis associated with liver dysfunction have also been described (32).

Gastrointestinal

Nausea and vomiting are common and probably central in origin, since they occur with intravenous as well as oral therapy (17).

Mexiletine affects the esophagus, and can cause heartburn (1) and esophageal spasm and ulceration (1,33).

Liver

Changes in liver function tests, resolving on withdrawal, have been reported (34). In one case there was histological evidence of cholestasis.

Skin

Mexiletine can occasionally cause generalized rashes (SEDA-17, 224) (26,32), pseudolymphomatous change with erythroderma (35), and contact urticaria (36).

- Exfoliative dermatitis has been reported in a 68-year-old man who had taken mexiletine and diltiazem for 3 weeks (37). Patch tests with 1, 10, and 30% mexiletine and diltiazem in petrolatum were positive, but a lymphocyte stimulation test was negative.
- Drug eruptions occurred in a 56-year-old woman, a 50-year-old man, and a 66-year-old woman, who developed disseminated maculopapular eruptions with high fever after oral mexiletine (38). In all cases the liver transaminase activities were raised and there was an eosinophilia with atypical lymphocytes; in two cases there was a lymphadenopathy. In all cases patch tests were positive.
- An acute exanthematous pustular eruption has been reported in a 56-year-old man who had taken mexiletine 300 mg/day for 1 month (39). There was mild liver dysfunction. Patch tests with mexiletine 10 and 20% were subsequently positive, but a lymphocyte stimulation test was negative.

In addition to these cases, 37 cases of drug eruption due to mexiletine have been reported in Japan, with several common clinical features (37). The interval between initial drug therapy and the start of the eruption was relatively long (48–88 days); there was a high proportion of positive patch tests (86–97%) but a low incidence of positive lymphocyte stimulation tests (23–27%); there were frequent systemic symptoms, such as fever (93–94%) and liver dysfunction (43–78%); finally, some patients had multiple drug eruptions.

© 2006 Elsevier B.V. All rights reserved.

Immunologic

Mexiletine caused an increased incidence of positive antinuclear antibody (ANA) titers in some studies (8,40), but not in others (41,42). The clinical significance of this effect is not clear. For example, there have been no reports of a lupus-like syndrome attributable to mexiletine.

Mexiletine caused increases in the serum activities of aspartate transaminase, alanine transaminase, and alkaline phosphatase in a few patients (8).

Susceptibility Factors

Renal disease

Mexiletine is mainly cleared polymorphically by CYP2D6 in the liver, and poor metabolizers and the slower among the extensive metabolizers have a higher incidence of mild adverse effects (nausea and light-headedness) (43). However, renal insufficiency can also be associated with an increase in plasma mexiletine concentrations (44).

Hepatic disease

Mexiletine is mainly cleared polymorphically by CYP2D6 in the liver, and poor metabolizers and the slower among the extensive metabolizers have a higher incidence of mild adverse effects (nausea and light-headedness) (43).

Drug Administration

Drug overdose

Overdosage with mexiletine resulted in death in two cases due to cardiovascular effects (45,46).

- Status epilepticus was the chief presenting feature in a 17-year-old boy who took an unspecified amount of mexiletine (47). The seizures responded to intravenous diazepam and phenytoin, but he also had agitation and hallucinations, which took 24 hours to abate. A urine specimen was positive for both benzodiazepines and amphetamines, but this was subsequently found to be a false positive result, because of the presence of large amounts of mexiletine, confirmed by thin-layer chromatography. The serum mexiletine concentration was 44 μmol/l, the usual target range being about 4–11 μmol/l.

Drug–Drug Interactions

Antacids

Mexiletine interacts with antacids, but the interaction is unlikely to be clinically important (48).

Antidysrhythmic drugs

Interactions of mexiletine with other cardioactive drugs have been reviewed (48). The most important are beneficial interactions with beta-adrenoceptor antagonists, quinidine, and amiodarone in the suppression of ventricular tachydysrhythmias. During these interactions the adverse effects of mexiletine may also be less common, although this effect is inconsistent (17).

Fluvoxamine

Mexiletine is metabolized by CYP2D6, CYP1A2, and CYP3A4; fluvoxamine inhibits CYP1A2. It is not surprising therefore that fluvoxamine 50 mg bd for 7 days increased the C_{max} and AUC of a single oral dose of mexiletine 200 mg in six healthy Japanese men (49).

Omeprazole

Mexiletine is metabolized mainly by CYP2D6 and CYP1A2. Omeprazole is an inducer of CYP1A2 and might therefore be expected to interact with mexiletine. However, in a study in nine healthy men there was no evidence of an effect of steady-state omeprazole 40 mg/day on the single-dose kinetics of mexiletine 200 mg (50).

Phenytoin

Mexiletine interacts with phenytoin, but the interaction is unlikely to be clinically important (48).

Propafenone

Mexiletine and propafenone are metabolized by the same enzymes, CYP2D6, CYP1A2, and CYP3A4. In 15 healthy volunteers, eight of whom were extensive metabolizers of CYP2D6, administration of oral mexiletine 100 mg bd on days 1–8 and oral propafenone 1 mg bd on days 5–12 significantly reduced the clearance of R(–) mexiletine from 41 to 28 l/hour and of S(+) mexiletine from 43 to 29 l/hour in the extensive metabolizers (51). The new values were no different from the clearance values in the poor metabolizers. Propafenone also reduced the partial metabolic clearances of mexiletine to hydroxymethylmexiletine, parahydroxymexiletine, and metahydroxymexiletine by about 70% in the extensive metabolizers. Propafenone had no effect on the kinetics of mexiletine in the poor metabolizers. There were no electrocardiographic changes during this interaction. Smokers had higher clearance rates than non-smokers, but the effects of propafenone were similar in the two groups. In contrast, mexiletine had little effect on the disposition of propafenone. The authors proposed that these effects could explain at least in part the increased efficacy that sometimes occurs when mexiletine and propafenone are combined in patients in whom a single drug was not effective. They also recommended that the dosages of the drugs should be titrated slowly when they are used together, in order to reduce the risk of adverse effects.

Rifampicin

Mexiletine interacts with rifampicin, but the interaction is unlikely to be clinically important (48).

Sevoflurane

- A 79-year-old woman was given mexiletine 125 mg intravenously over 10 minutes during anesthesia after

© 2006 Elsevier B.V. All rights reserved.

having been given lidocaine 100 mg intravenously, and had a marked drop in blood pressure 1 hour later (52). The blood pressure rose when sevoflurane was withdrawn.

The authors proposed that the effect had been brought about by the combination of mexiletine and sevoflurane, although it is more likely that the effect was due to the combination of mexiletine with lidocaine.

Xanthines

Mexiletine reduces the clearance of theophylline, and this combination has been reported to cause ventricular tachycardia (53). A similar interaction with caffeine has been reported (54).

Mianserin

See also Antidepressants, second-generation

General Information

Mianserin is a tetracyclic compound, related to cyproheptadine (SEDA-5, 18). It is an effective antidepressant with antiserotonergic properties and a sedative profile, but minimal anticholinergic effect and less action on the cardiovascular system than tricyclic antidepressants (1).

Organs and Systems

Cardiovascular

Cardiotoxic effects are relatively uncommon with mianserin (2). In a placebo-controlled study in 50 patients with a variety of cardiac conditions who were taking anticoagulants, mianserin (up to 30 or 60 mg) had no effects on electrocardiography, blood pressure, or pulse rate after 3 weeks. In a second phase, mianserin (up to 60 mg/day) was compared with amitriptyline (up to 150 mg/day) and placebo in 18 healthy volunteers. Measurements included systolic time intervals, electrocardiography at rest and during exercise, echocardiography, and blood pressure. Amitriptyline had a negative inotropic effect; mianserin increased ejection fraction. The results of both these experiments led the authors to conclude that mianserin is an antidepressant with very low cardiac toxicity.

In another study of the electrocardiographic effects of mianserin and a review of previous experiments with doses up to 120 mg/day, there were no consistent cardiovascular effects, although four patients who took 40 mg/day for 13 months had significant increases in pulse rate, with prolonged PR intervals and reduced T-wave amplitude (3). Fainting and persistent bradycardia were noted in one woman after a single dose of mianserin 60 mg, and her symptoms recurred on rechallenge (SEDA-17, 21).

There have been two instances of possible cardiac effects due to mianserin in elderly patients with pre-existing cardiovascular disorders (4).

- A 71-year-old man with hypertension who took 30 mg/day developed cardiac failure.
- A 66-year-old woman with mitral regurgitation and atrial fibrillation developed hypokalemia and a variety of rhythm disturbances at dosages of 40 mg or more per day.

Nervous system

In 40 patients who had seizures while taking therapeutic dosages of mianserin it was concluded that mianserin is probably no more likely to produce convulsions in therapeutic dosages than tricyclic compounds (5). When it does so, seizures are more likely to occur in the first 2 weeks of treatment in patients with a family or personal history indicative of risk, and after a dosage increase.

Mianserin can cause restless legs (SEDA-14, 15) (SEDA-17, 21).

Hematologic

In 1979 the first case of leukopenia due to mianserin was reported (6), followed by another soon after (7). In July 1980, the Australian Drug Evaluation Committee issued a preliminary caution concerning further cases that had been reported to its National Monitoring Centres and 6 months later published detailed reports of four other cases (8), all of which had occurred within 1 year of marketing in Australia, despite 6 years of use in Europe. Inquiries unearthed reports of seven similar episodes held by drug surveillance organizations in other countries, and the Committee expressed its concern that "if a causal relationship between mianserin and these blood disorders is subsequently confirmed, the incidence of disorders due to mianserin may be significantly greater than that of disorders due either to the phenothiazines or the tricyclic antidepressants" (9). In 1985 the UK Committee on Safety of Medicines issued a statement concerning 15 reports that the Committee had received during 5 years (10). Three of the patients subsequently died, one with aplastic anemia, one with granulocytopenia, and one with both erythrocyte and leukocyte hypoplasia. The New Zealand Department of Health's Clinical Services Letter mentioned three cases of agranulocytosis that occurred in New Zealand in 1982 (11). Another report (12) described thrombocytopenia and leukopenia based on an immune mechanism without generalized marrow depression. A high rate of agranulocytosis has been reported by the IMMP in New Zealand: one case out of 1822 and one fatal case out of 11 537 (12).

Mouth and teeth

The lack of anticholinergic effects reported in clinical studies has been supported by a double blind, placebo-controlled comparison of mianserin (10–60 mg/day) and amitriptyline (25–150 mg/day) in healthy volunteers (13). Mianserin tended to increase saliva flow, while amitriptyline significantly reduced it. However, a further experiment in healthy volunteers showed that single doses of mianserin (50–70 mg) produced a significant 29% reduction of salivation compared with placebo (14). This may account for the glossitis that has previously been reported (SEDA-9, 23).

Liver

Hepatotoxicity from mianserin has been reported in eight cases (SEDA-17, 22).

Musculoskeletal

Mianserin can cause joint symptoms and arthritis (SEDA-16, 11).

Drug Administration

Drug overdose

One of the putative benefits of mianserin is its alleged safety in overdose, which may be related to a reduced risk of cardiovascular adverse effects and convulsions. Data from the UK Committee on Safety of Medicines suggest that mianserin accounts for 11% of reported convulsions and 5.8% of use, putting it intermediate between amitriptyline and maprotiline (15). On the other hand, in the London Poisons Unit survey, involving 84 patients who took mianserin alone (up to 1000 mg), there were no deaths and no patients with convulsions, although this could represent a frequency of up to 3.6% (12).

A survey of 100 cases of overdose with mianserin reported to the London Centre of the UK Poisons Information Service included 54 patients who took mianserin alone in amounts up to and in three cases in excess of 1000 mg (12). Plasma mianserin concentrations were 70–665 ng/l (the usual mean target concentration is 50 ng/l). There were no reports of convulsions, cardiac dysrhythmias, or profound coma in any patient taking mianserin alone, but there were two deaths in patients who took multiple drugs. The authors concluded that in acute overdosage mianserin is less toxic than tricyclic antidepressants.

Drug–Drug Interactions

Clonidine and methyldopa

Mianserin lacks potential for peripheral adrenergic interactions, but since it has α-adrenoceptor activity, it might interact with the centrally acting α-adrenoceptor agonists clonidine and methyldopa. In healthy volunteers, pretreatment with mianserin 60 mg/day for 3 days did not modify the hypotensive effects of a single 300 mg dose of clonidine, and in 11 patients with essential hypertension, the addition of mianserin 60 mg/day (in divided doses) for 2 weeks did not reduce the hypotensive effects of clonidine or methyldopa (16). In patients taking methyldopa, there were additive hypotensive effects after the first dose of mianserin, but these were not significant after 1 or 2 weeks of combined treatment. The results of this study appear to have justified the authors' conclusion that combining mianserin with centrally-acting hypotensive agents will not result in loss of blood pressure control.

Mibefradil

See also Calcium channel blockers

General Information

Mibefradil is a member of a class of calcium antagonists that specifically block the T-type calcium channel. It was marketed as an antihypertensive and antianginal drug with an adverse effects profile similar to that of placebo (1) and a favorable pharmacokinetic profile, allowing once-a-day dosage (2).

Owing to its attractive pharmacological profile, namely an anti-ischemic action with little or no negative inotropism, mibefradil was tested in a large-scale mortality trial in heart failure (MACH-I, Mortality Assessment in Congestive Heart Failure Trial). However, early in June 1998, only a few months after its launch, Roche Laboratories withdrew mibefradil from the market, after several dangerous interactions with at least 25 drugs had been reported (3,4) associated with rhabdomyolysis and life-threatening cardiac dysrhythmias; these problems were detected by postmarketing surveillance (4). The FDA stated that: "since [mibefradil] has not been shown to offer special benefits (such as treating patients who do not respond to other anti-hypertensive and antianginal drugs), the drug's problems are viewed as an unreasonable risk to consumers."

In the MACH-1 (Mortality Assessment in Congestive Heart Failure) trial, 2590 patients with moderate to severe congestive heart failure were randomized to mibefradil or placebo (5). Mibefradil given for a maximum of 3 years did not affect mortality or morbidity. However, a subgroup analysis by concomitant drugs showed that digoxin, class I antidysrhythmic drugs, amiodarone, and other drugs associated with torsade de pointes increased the risk of death with mibefradil. These worrisome drug–drug interactions were consistent with the results of postmarketing surveillance, which prompted withdrawal of mibefradil from the market by its manufacturers in June 1998, even before complete results of the trial became available.

The safety and efficacy of mibefradil in association with beta-blockers was assessed in 205 patients with chronic stable angina, randomized to placebo or mibefradil 25 or 50 mg/day for 2 weeks (6). Besides an improvement in angina with mibefradil, it dose-dependently reduced heart rate and increased the PR interval. One patient taking mibefradil had an escape junctional rhythm 26 hours after the last dose of 50 mg. The nodal rhythm disappeared on withdrawal of mibefradil, but based on the overall results it was concluded that mibefradil was safe and effective when given for a short time with beta-blockers.

In a Prescription-Event Monitoring study in 3085 patients, mean age 65 years, the commonest reported adverse events and reasons for stopping were malaise/lassitude, dizziness, edema, and headache (7).

Organs and Systems

Cardiovascular

Mibefradil causes slight bradycardia associated with its hypotensive effect. In a Prescription-Event Monitoring study in 3085 patients, mean age 65 years, there were seven reports of serious bradycardia/collapse thought to be possible adverse drug reactions to mibefradil (7). All were in patients over 65 years and six were thought to have resulted from a drug interaction. In all, there were 11 possible drug interactions. Nine (eight reports of bradycardia and one of syncope) involved beta-blockers. Collapse and severe bradycardia occurred in a patient who had started to take a dihydropyridine calcium channel blocker within 24 hours of stopping mibefradil. Palpitation and dyspnea occurred in a patient taking digoxin and sotalol. None of the 53 deaths during the study was attributed to mibefradil.

Abrupt switch of therapy from mibefradil to other dihydropyridine calcium antagonist was reported to cause shock, fatal in one case, in four patients also taking beta-blockers (8).

Drug–Drug Interactions

General

Mibefradil inhibits CYP3A4 (2). Other drugs that are metabolized by this pathway accumulate as a result. Drugs that were commonly affected included amiodarone, astemizole, ciclosporin, cisapride, erythromycin, imipramine, lovastatin, propafenone, quinidine, simvastatin (9), tacrolimus (10), tamoxifen, terfenadine, thioridazine, and drugs that impair sinoatrial node function (for example beta-blockers) (6).

- Severe rhabdomyolysis occurred in an 83-year-old woman who developed progressive immobilizing myopathy, low back pain, and oliguria; she was taking simvastatin and mibefradil (9). The symptoms disappeared completely after 4 weeks of withdrawal.

© 2006 Elsevier B.V. All rights reserved.

Mibefradil was probably responsible for raising plasma concentrations of simvastatin to toxic concentrations.

Beta-blockers

In a Prescription-Event Monitoring study in 3085 patients, mean age 65 years, there were 11 possible drug interactions. Nine involved beta-blockers, with eight reports of bradycardia and one of syncope. One patient developed palpitation and dyspnea while also taking digoxin and sotalol.

Calcium channel blockers

In a Prescription-Event Monitoring study in 3085 patients, mean age 65 years, one patient developed collapse and severe bradycardia after starting to take a dihydropyridine calcium channel blocker within 24 hours of stopping mibefradil (7).

Miconazole

See also Antifungal azoles

General Information

Miconazole has been evaluated as a topical, oral, and intravenous agent. Its absorption is slightly better than that of clotrimazole, but is still insufficient for use as a systemic agent, particularly in view of its relatively short half-life of around 8–9 hours (1). Miconazole has also been given intravenously and intrathecally. It is highly protein-bound and does not diffuse well into the CSF; however, it does penetrate readily into synovial and vitreous fluids (2).

The indications for miconazole have diminished with the advent of newer antifungal azoles (3) and it has largely been superseded by other azoles; infection with *Pseudallescheria boydii* remains one of the few indications (4).

General adverse effects

Topical miconazole is well tolerated. Parenteral administration carries a higher frequency of adverse effects, some probably being caused by Cremophor (polyethoxylated castor oil, the carrier). Adverse effects include fever, chills, pruritus, rash, nausea, vomiting, diarrhea, hyponatremia, cardiac toxicity, phlebitis, hyperlipidemia, and central nervous system disturbances. Hypersensitivity reactions can occur. Tumor-inducing effects have not been reported.

Organs and Systems

Cardiovascular

Local phlebitis is not uncommon after intravenous miconazole (5); the type of intravenous solution used is of importance.

Collapse after rapid intravenous injection has been described, as have some cases of tachycardia, ventricular tachycardia, and even, in a few instances, cardiorespiratory arrest, attributable to the histamine-releasing properties of Cremophor (SED-12, 679) (2).

Nervous system

Arachnoiditis has been described after intrathecal injection (6).

Psychological, psychiatric

Acute toxic psychosis is a rare consequence of miconazole (SED-12, 679) (7).

Endocrine

Hyperlipidemia has been described in many patients given miconazole; this may be caused by the solvent (SED-12, 679) (2).

Skin

Pruritus and rashes have been reported with miconazole but do not seem to be frequent (5).

Drug–Drug Interactions

Anticoagulants

Miconazole can potentiate the effects of coumarin anticoagulants (SED-12, 679) (2). Potentiation of the anticoagulatory effects of acenocoumarol was noted after vaginal administration of miconazole capsules to two postmenopausal patients (8) and after oral administration of miconazole gel in three elderly patients with oral candidiasis (9). In both instances there were no major bleeding complications. However, it appears prudent to consider the use of non-azole topical antifungal agents in patients who are taking CYP3A4 metabolized drugs with a narrow therapeutic index.

Phenytoin

Miconazole can increase serum concentrations of phenytoin (SED-12, 679) (10).

Sulfonylureas

Enhancement of the effects of hypoglycemic sulfonamides has been reported (SED-12, 679) (2).

Midazolam

See also Benzodiazepines

General Information

Midazolam is used mainly in parenteral form in anesthesia, as a sedative adjunct to medical and dental procedures, and in status epilepticus (1). Its pharmacology and therapeutics have been extensively reviewed (2). It produces greater amnesia than diazepam, useful in terms of its anesthetic use, but carries a risk of cardiorespiratory depression and death (SED-12, 99), particularly at the extremes of age and when combined with the opioid fentanyl (SEDA-22, 42), which can cause accumulation of midazolam (see Drug–Drug Interactions in this monograph). Vomiting has been reported in 10% of children having midazolam sedation before radiology (SEDA-22, 41). Behavioral disinhibition (SEDA-18, 44), acute withdrawal, and hiccups appear to be relatively common (SEDA-22, 41); hallucinations, flumazenil-reversible dystonia, and hypersensitivity have all been observed (SED-12, 99) (SEDA-17, 44).

Clinical electrophysiological procedures can be very complex and prolonged, requiring safe and effective conscious sedation. A study in 700 patients has shown that intermittent midazolam plus fentanyl in electrophysiological procedures is safe and efficacious (3). All the staff were ACLS-certified and had successfully completed conscious sedation training courses, but none was an anesthetist; one team member was dedicated to monitoring conscious sedation and providing rescue defibrillation if required.

The pharmacology and adverse effects of midazolam in infants and children have been reviewed (4).

Midazolam has been carefully evaluated for adverse effects when used in critically ill infants and children; several difficulties, including prolonged obtundation and paradoxical behavioral and withdrawal reactions, have been noted (SEDA-19, 35) (5). Midazolam by the buccal route has been evaluated in children with persistent seizures; it was both effective and well tolerated (6), offering obvious practical advantages to rectal or parenteral administration. The availability of flumazenil, a specific benzodiazepine antagonist, to correct any adverse or overdose effects from injected midazolam should not encourage laxity in its use. Recent reports have highlighted kinetic interactions between midazolam and a variety of other drugs (see Drug–Drug Interactions in this monograph), and its effects can be magnified or prolonged in patients with hepatic or renal insufficiency (SEDA-20, 32).

Midazolam was used in a wide range of doses (0.03–0.6 mg/kg) in 91 children undergoing diagnostic or minor operative procedures with intravenous midazolam sedation (7). Opioids were co-administered in 84% and oxygen desaturation occurred in 32%, most of whom had received high doses of opioids in addition to the midazolam. Other adverse events included airway obstruction ($n = 3$) and vomiting ($n = 1$). The presence of independent appropriate trained personnel not directly involved in performing the procedure, appropriate resuscitation

© 2006 Elsevier B.V. All rights reserved.

equipment, and monitoring were recommended whenever midazolam and opioids are co-administered for intravenous sedation.

A cherry-flavored midazolam syrup was evaluated for premedication in 85 children requiring general anesthesia (8). The patients received a randomly assigned dose of 0.25, 0.5, or 1 mg/kg. All clinicians and observers were blinded to the treatment group. There was satisfactory dose-related sedation in 81%, and 83% had satisfactory non-dose-related anxiolysis at separation from parents and at anesthetic induction. One or more adverse events occurred in 36%, but only 31% of these were judged as possibly related to midazolam (hiccups 6%, hypoxemia 6%, vomiting 5%, hallucinations 4%, drooling 4%, agitation 2%, coughing 2%, diplopia 2%, dizziness 2%, and hypotension 2%). The authors suggested that although adverse effects were common, they were minor.

Intranasal midazolam 0.2 mg/kg and intravenous diazepam 0.3 mg/kg have been compared in a prospective randomized study in 47 children (aged 6 months to 5 years) with febrile seizures that lasted over 10 minutes (9). Intranasal midazolam controlled seizures significantly earlier than intravenous diazepam. None of the children had respiratory distress, bradycardia, or other adverse effects. Electrocardiography, blood pressure, and pulse oximetry were normal in all children during seizure activity and after cessation of seizures.

In a Canadian multicenter, open, randomized trial in 156 patients to determine whether sedation with propofol would lead to shorter times to tracheal extubation and length of stay in ICU than sedation with midazolam, the patients who received propofol spent longer at the target sedation level than those who received midazolam (60 versus 44% respectively) (10). Propofol allowed clinically significantly earlier tracheal extubation than midazolam (6.7 versus 25 hours). However, this did not result in earlier discharge from the ICU.

In a double-blind, randomized, placebo-controlled study during coronary angiography in 90 patients, midazolam with or without fentanyl and local anesthesia provided better hemodynamic stability than placebo (11).

In a randomized study in 301 agitated or aggressive patients, intramuscular midazolam was more rapidly sedating than a mixture of haloperidol + promethazine (12). There was only one important adverse event, transient respiratory depression, in one of the 151 patients who were given midazolam.

Organs and Systems

Cardiovascular

The incidence of hypotension with the use of midazolam for pre-hospital rapid-sequence intubation of the trachea has been assessed in a retrospective chart review of two aeromedical crews (13). The rapid-sequence protocols were identical, except for the dose of midazolam. Both crews used 0.1 mg/kg, but one crew had a maximum dose of 5 mg imposed. This meant that patients over 50 kg received lower doses of midazolam; they also had a higher incidence of hypotension. This relation was also present in patients with traumatic brain injury, implying that cerebral perfusion could be compromised at a critical time in those without dosage restriction.

Midazolam depresses both cardiovascular and respiratory function, especially in elderly patients (14). As little as 0.01 mg/kg can obtund the response to hypoxia and hypercapnia (15). The simultaneous use of opiates (such as fentanyl) commonly produces hypoxia (16).

Hypertension and tachycardia during coronary angiography can cause significant problems. In a double-blind, randomized, placebo-controlled study during coronary angiography in 90 patients, midazolam with or without fentanyl under local anesthesia provided better hemodynamic stability than placebo (11).

Respiratory

Intranasal midazolam is a successful route of administration for sedating children. However, it can cause nasal burning, irritation, and lacrimation (17). In a study of an alternative route of administration, namely inhalation via a nebulizer, bronchospasm developed in two of the 10 patients studied. This formulation of midazolam has a pH of 3.0, and this was thought to be the reason it caused bronchospasm.

Nervous system

Two premature neonates, who already had epileptic manifestations related to severe hypoxic ischemic encephalopathy, developed seizures (one tonic and the other tonic-clonic) within a few seconds of receiving intravenous midazolam (0.15 μg/kg) for sedation (18). In one, the seizure recurred after rechallenge on the same day. Benzodiazepines occasionally cause tonic seizures, especially after intravenous administration to children with Lennox–Gastaut syndrome. This seems to be the first report related to midazolam in newborns.

Involuntary epileptiform movements have been described in three of six premature infants given midazolam for sedation (19). The infants had been born at 24–26 weeks gestation, were aged 23–32 days, and weighed on average 671 g. They were given midazolam 100 μg/kg by slow bolus injection for sedation and then had accentuated myoclonic jerks resembling clonic seizures within 5 minutes. In all cases it was the first dose of midazolam and the cardiorespiratory parameters remained normal. The abnormal movements resolved within 5–10 minutes. There has also been a report of convulsions caused by midazolam in two preterm infants (20). They were of 26 and 28 weeks gestation and were given midazolam 100 and 150 μg/kg intravenously before tracheal intubation. Both were successfully treated with flumazenil 10 μg/kg.

The safety of midazolam in very low birth-weight neonates is being questioned. In 200 children weighing 3–15 kg premedicated with rectal midazolam 0.5 or 1.0 mg/kg before minor surgery, the incidence of hiccups was 22% and 26% respectively (21). The mean age of children with hiccups was 6 months and of children without hiccups 20 months. Intranasal ethyl chloride spray was 100% successful in treating the hiccups. The incidence of hiccups was related to age but not dose. The effectiveness of ethyl chloride was postulated to be via cold nasopharyngeal stimulation.

© 2006 Elsevier B.V. All rights reserved.

The effects of sevoflurane and halothane anesthesia, including the effect of midazolam 0.5 mg/kg premedication, on recovery characteristics have been studied in 100 children aged 6 months to 6 years undergoing myringotomy (22). Children who received sevoflurane had about 50% faster recovery times and discharge-home times than those who received halothane. However, sevoflurane without midazolam premedication was associated with 67% postoperative agitation compared with 40% in the premedicated group. Midazolam delayed early recovery times by about 5 minutes, but had no effect on discharge times. In view of the very high incidence of postoperative agitation in the control group midazolam was seen as an effective premedicant.

Midazolam can cause paradoxical reactions, including increased agitation and poor cooperation (23,24). Often other drugs are required to continue the procedure successfully. Reversal of these reactions by flumazenil, a benzodiazepine antagonist, has been reported.

Sevoflurane often causes postoperative delirium and agitation in children, and this may be severe. The effect of intravenous clonidine 2 μg/kg on the incidence and severity of postoperative agitation has been assessed in a double-blind, randomized, placebo-controlled trial in 40 boys who had anesthetic induction with sevoflurane after oral midazolam premedication (25). There was agitation in 16 of those who received placebo and two of those who received clonidine; the agitation was severe in six of those given placebo and none of those given clonidine.

The effect of a single bolus dose of midazolam before the end of sevoflurane anesthesia has been investigated in a double-blind, randomized, placebo-controlled trial in 40 children aged 2–7 years (26). Midazolam significantly reduced the incidence of delirium after anesthesia. However, when it was used for severe agitation, midazolam only reduced the severity of agitation without abolishing it.

In the presence of acute neurological injuries, midazolam produces a high risk of raised intracranial pressure (27), and the risk of airway obstruction (28) is a further concern.

Recovery after propofol or midazolam has been compared in two studies (29,30). Memory was significantly impaired by midazolam, an effect that was reminiscent of the problems experienced with short-acting oral benzodiazepine hypnotics, such as triazolam.

Psychological, psychiatric

Midazolam can cause an unpleasant state of dysphoria if surgical stimuli are applied to the patient, who may nevertheless appear calm and untroubled. Amnesia is also routinely produced and can be beneficial. Delayed recovery of cognitive function occurs after the use of benzodiazepines as premedication (31).

There was a variety of significant nervous system adverse effects in six of 104 patients who underwent transesophageal echocardiography, including aggression, euphoria, depression, and intense hiccups (32). These effects occurred despite careful titration and relatively low doses of intravenous midazolam (mean 4.8 mg), and were generally reversible with intravenous flumazenil 0.25–0.5 mg.

Hematologic

Fat emulsions affect coagulation and fibrinolysis (33). In 36 patients undergoing aortocoronary bypass operations with midazolam/fentanyl- or propofol/alfentanil-based anesthesia, factor XIIa concentrations and kallikrein-like activity were about 30% higher in the propofol group. The authors suggested that there had been stronger activation of the contact phase at the start of recirculation and stronger fibrinolysis in the propofol group. They also found more hypotension in the propofol group, which they assumed to be due to release of kallikrein, resulting in release of bradykinin. Propofol has not been proven to cause increased perioperative bleeding.

In a 40-month-old boy a withdrawal syndrome with neurological symptoms was accompanied by thrombocytosis, which peaked at 1230×10^9/l (34). Recovery from the withdrawal syndrome was accompanied by normalization of the platelet count. The relevance of this change in platelet count was not clear. The boy had also been given fentanyl, and the authors suggested that the combination of midazolam with fentanyl should be used with caution.

Urinary tract

The conjugates of the main metabolite of midazolam, α-hydroxymidazolam, accumulate in renal insufficiency. In five patients with severe renal insufficiency (creatinine clearance 7 ml/minute or less), in whom prolonged sedation after midazolam was immediately reversed by flumazenil, there were high serum concentrations of glucuronidated α-hydroxymidazolam, even at times when the concentrations of the unconjugated metabolite and midazolam itself were low (35). Glucuronidated α-hydroxymidazolam is about one-tenth as potent as midazolam and unconjugated α-hydroxymidazolam, and accumulation of the conjugated metabolite in renal insufficiency may be important.

Body temperature

Midazolam premedication causes exaggerated perioperative hypothermia in 15 elderly surgical patients compared with 15 young patients (36). The same group also showed that atropine prevents midazolam-induced core hypothermia in 40 elderly patients (37). The thermoregulatory effects of benzodiazepine agonists and cholinergic inhibitors oppose each other, and the combination leaves core temperature unchanged.

Long-Term Effects

Drug withdrawal

The withdrawal of an infusion of midazolam, used as sedation in intensive care units, is associated with occasional severe and bizarre behavioral disturbances, particularly in children (38). These are similar in nature to the withdrawal effects seen with other short-acting benzodiazepines.

© 2006 Elsevier B.V. All rights reserved.

Susceptibility Factors

Age

The pharmacology and adverse effects of midazolam in infants and children have been reviewed (4). The optimal dose of intramuscular midazolam for preoperative sedation has been studied in a double-blind prospective study of 600 patients who were age-stratified (39). The patients received intramuscular atropine 0.6 mg and one of five doses of midazolam 15 minutes before induction of anesthesia. For the age groups 20–39, 40–59, and 60–79 years, the optimal sedative and amnesic effects of midazolam were 0.10, 0.08, and 0.04 mg/kg respectively. The frequency with which the undesirable adverse effects of reduced blood pressure, oxygen desaturation, oversedation, loss of eyelash reflex, and tongue root depression occurred increased with age, and optimal doses for a low incidence of adverse effects were 0.08, 0.06, and 0.04 mg/kg in the same age groups respectively.

Drug Administration

Drug administration route

Midazolam nasal spray 2 mg/kg has been compared with a citric acid placebo for conscious sedation in children undergoing painful procedures (40). Citric acid was added to the placebo, so that the sensation of nasal burning caused by midazolam did not unblind the observers. Parents and nurses judged the procedure to be more comfortable with midazolam, but the children rated the discomfort of the procedure similar in the two groups. Anxiety was significantly reduced by midazolam. There was nasal discomfort in 43% of the midazolam group. The authors concluded that midazolam intranasal spray effectively reduces anxiety, but that its use may be limited by nasal discomfort.

Drug–Drug Interactions

Antifungal azole derivatives

The pharmacokinetics and pharmacodynamics of midazolam are significantly affected by antifungal azoles. The effects of fluconazole (400 mg loading dose followed by 200 mg/day) on the kinetics of midazolam have been studied in 10 mechanically ventilated adults receiving a stable infusion of midazolam (41). Concentrations of midazolam were increased up to fourfold after the start of fluconazole therapy; these changes were most marked in patients with renal insufficiency. During the study, the ratio of α-hydroxymidazolam to midazolam progressively fell. The authors concluded that in ICU patients receiving fluconazole, reduction of the dose of midazolam should be considered if the degree of sedation is increasing.

In a study of the effects of itraconazole 200 mg/day and rifampicin 600 mg/day on the pharmacokinetics and pharmacodynamics of oral midazolam 7.5–15 mg during and 4 days after the end of the treatment, switching from inhibition to induction of metabolism caused an up to 400-fold change in the AUC of oral midazolam (42).

In an in vitro study of midazolam biotransformation using human liver microsomes, midazolam metabolism was competitively inhibited by the antifungal azoles ketoconazole, itraconazole, and fluconazole, and the antidepressant fluoxetine and its metabolite norfluoxetine (43). The degree of inhibition was consistent with the inhibition reported in pharmacokinetic studies, and suggests that in vitro assay is useful for predicting significant interactions.

Diltiazem

Diltiazem caused a 43% mean increase in the half-life of midazolam in 30 patients who underwent coronary artery bypass grafting (44). Similar effects were observed with alfentanil. The proposed mechanism was diltiazem-induced inhibition of benzodiazepine metabolism by CYP3A. Patients taking diltiazem had delayed early postoperative recovery as a result.

Drugs that influence CYP3A

Midazolam is selectively metabolized by CYP3A4, with which several drugs interact, influencing its pharmacokinetics and pharmacodynamics.

Itraconazole, an inhibitor of CYP3A, and rifampicin, an inducer of CYP3A, altered the pharmacokinetics and pharmacodynamics of oral midazolam in nine healthy volunteers (42). The half-life was prolonged from 2.7 to 7.6 hours by itraconazole and reduced to 1.0 hour by rifampicin. These effects were still present, although less marked, at 4 days after withdrawal of itraconazole and rifampicin. Similarly, after acute administration, the period of drowsiness was increased from 76 to 201 minutes with itraconazole and fell to 35 minutes with rifampicin; the effects were again less marked 4 days after withdrawal.

The protease inhibitor saquinavir, propofol, and fluconazole (41,45,46) increased the systemic availability and peak plasma concentrations and prolonged the half-life of midazolam, thus increasing its sedative effects. The dosage of midazolam should be reduced in patients taking these drugs.

Grapefruit juice reduced the metabolism of midazolam; prolonged sedation can be expected in some circumstances (47).

Chronic administration of glucocorticoids, which induce CYP3A4, reduces the sedative effect of midazolam by increasing its clearance; higher doses are therefore required for sedation (48).

Fentanyl

Several adverse effects have been reported with the combined use of fentanyl and midazolam, including chest wall rigidity, making ventilation with a bag and mask impossible (SEDA-16, 79). In neonates, hypotension can occur (SEDA-16, 80), and respiratory arrest in a child and sudden cardiac arrest have been reported (SEDA-16, 80). However, in one study there were no cardiac electrophysiological effects of midazolam combined with fentanyl in subjects undergoing cardiac electrophysiological studies (SEDA-18, 80).

© 2006 Elsevier B.V. All rights reserved.

Glucocorticoids

Chronic administration of glucocorticoids, which induce CYP3A4, reduces the sedative effect of midazolam by increasing its clearance; higher doses are therefore required for sedation (48).

Grapefruit juice

Grapefruit juice reduced the metabolism of midazolam; prolonged sedation can be expected in some circumstances (47).

Halothane

Midazolam produced marked reduction of the MAC of halothane in humans at lower serum concentrations than required to cause sleep (49).

Isoflurane

The effects of the combination of midazolam and isoflurane on memory were studied in a randomized, double-blind study in 28 volunteers (50). Midazolam 0.03 mg/kg or 0.06 mg/kg combined with isoflurane 0.2% almost completely abolished explicit and implicit memory, but there were more variable effects on the level of sedation. The duration of the deficit averaged 45 minutes. The study was remarkable for the very low doses required to abolish memory, owing to synergy of the combination of midazolam and isoflurane and abolition of memory at subhypnotic doses with this combination. However, the subjects did not undergo surgery, so caution must be exercised in extrapolating the result to surgical patients, because painful stimuli increase the dosage required to abolish memory.

Macrolides

Interactions of macrolide antibiotics with midazolam are clinically important. Increases in serum concentration, AUC, and half-life, and a reduction in clearance have been documented (51). These changes can result in clinical effects, such as prolonged psychomotor impairment, amnesia, or loss of consciousness (52).

Erythromycin potentiates the effects of oral midazolam (SEDA-17, 125). Either midazolam should be avoided in patients taking erythromycin or the dose should be reduced by 50–75% (53,54).

Nitrous oxide

The combination of midazolam with nitrous oxide produced retrograde amnesia in 21 women undergoing elective cesarean section (55). All had spinal anesthesia. After delivery the patients received intravenous midazolam, average dose 94 μg/kg, and inhaled nitrous oxide 50%. At the end of surgery, flumazenil was given in 0.1 mg increments until the patient awoke. Another nine women were given only nitrous oxide inhalation after delivery. Of the women who received midazolam and nitrous oxide, 33% could not recall their baby's face, while all of the women not given midazolam could. The results suggest that midazolam plus nitrous oxide can produce retrograde amnesia not reversed by flumazenil.

Pethidine

Rectal pethidine is not advised in children, owing to enormous variability in systemic availability (SEDA-18, 82). When used for sedation in children undergoing esophagogastroduodenoscopy, hypoxia with dysrhythmias was more likely to occur with a combination of pethidine and diazepam than with pethidine and midazolam (SEDA-18, 81).

Rifampicin

In a study of the effects of itraconazole 200 mg/day and rifampicin 600 mg/day on the pharmacokinetics and pharmacodynamics of oral midazolam 7.5–15 mg during and 4 days after the end of the treatment, switching from inhibition to induction of metabolism caused an up to 400-fold change in the AUC of oral midazolam (42).

Saquinavir

Saquinavir substantially potentiates the effects of midazolam by raising its blood concentrations, and this suggests that a parallel interaction could occur with other protease inhibitors (and no doubt certain other benzodiazepines) in similar combinations (46).

Midecamycin

See also Macrolide antibiotics

General Information

The reported rates of adverse events among 1565 patients treated with midecamycin 900–1800 mg/day are similar to the rates with other macrolides (1). The adverse events profile is also similar, but precise data are not available. In 12 053 Japanese children under 15 years, the rate of adverse events was 0.54% (2). There were adverse events in 0.97% of very young children (under 1 year). These adverse events affected mainly the skin and the gastrointestinal tract. However, this very low rate of adverse events must be interpreted with caution, since lower dosages (21–40 mg/kg/day) were used than are typically prescribed (50 mg/kg/day) (1).

Some drug interactions can be caused by weak induction of cytochrome P450 by midecamycin (3).

Drug–Drug Interactions

Carbamazepine

The half-life of carbamazepine given as a single daily dose (13% increase) and the AUC were significantly affected (4), whereas the trough concentrations and mean AUCs in nine patients treated with carbamazepine 400, 600, or 1200 mg/day increased only minimally (5).

Ciclosporin

Midecamycin 1600 mg/day increased the steady-state concentration of ciclosporin two-fold (6).

Nicoumalone

Midecamycin did not significantly change the pharmacokinetics of acenocoumarol (nicoumalone) in six volunteers (1).

Theophylline

The pharmacokinetics of theophylline were not significantly affected by midecamycin (7).

Midodrine

General Information

Midodrine is a prodrug, whose active metabolite is relatively selective for vascular postjunctional alpha$_1$-adrenoceptors and therefore increases peripheral resistance by arteriolar constriction, with some venoconstriction in capacitance vessels (1). It has minimal activity in the central nervous system, since it does not cross the blood–brain barrier. It can be given orally and has a systemic availability of over 90% by this route. The half-life of the active deglycinated metabolite is relatively short (2–3 hours). The dosage range is 2.5–10 mg tds, and is usually toward the upper end of this range.

Midodrine has been extensively tested in several of the orthostatic hypotension syndromes, including: neurogenic hypertension due to autonomic neuropathies (2,3); neurocardiogenic syncope (4–8); the controversial syndrome of orthostatic hypotension and tachycardia that may be associated with chronic fatigue (9,10); the hypotension seen during hemodialysis (11); and hypotension due to neuroleptic drugs (12).

Few of the above-mentioned studies have systematically addressed problems of safety and adverse effects, but on the whole the effects described are predictable from the adrenergic properties of the drug and are dose-related. The most common adverse effect, in up to 15% of patients, is piloerection, with or without paresthesia especially of the scalp and face, most commonly in the form of pruritus.

In a 4-week, double-blind, placebo-controlled study in 97 patients with orthostatic hypotension aged 22–86 years (mean age 61 years) midodrine 2.5, 5, or 10 mg was given three times a day for 4 weeks (5). Midodrine 10 mg significantly increased standing systolic blood pressure by

22 mmHg and improved the following symptoms of orthostatic hypotension compared to placebo: dizziness/light-headedness, weakness/fatigue, syncope, low energy, impaired ability to stand, and feelings of depression. The overall adverse effects were mainly mild to moderate. One or more adverse effects were reported by 22% of the placebo group compared with 27% of the midodrine-treated group. Scalp pruritus/tingling, which was reported by 10 of 74 (13.5%) of those given midodrine, was most frequent. Other reported adverse effects included supine hypertension (8%) and feelings of urinary urgency (4%).

Organs and Systems

Cardiovascular

Supine hypertension occurs in up to 3% of subjects, although it is not clear how the underlying pathology of the hypotension influences the likelihood of this reaction.

Nervous system

- A 33-year-old schizophrenic woman took midodrine 4 mg/day because of postural hypotension due to risperidone 6 mg/day (13). She developed an acute dystonic reaction, which recurred several times on rechallenge, and the dose of risperidone had to be halved to minimize the hypotension.

Mifepristone

General Information

Mifepristone (RU-486) has become best known as an abortifacient. It is a potent antagonist at progesterone receptors and glucocorticoid receptors. The abortifacient effect is thought to be primarily due to blockade of endometrial progesterone receptors, but mifepristone also impedes the production of human chorionic gonadotropin and progesterone in the placenta. When given in a single dose of 10 mg/kg by mouth to induce menses, heavy bleeding was reported in some cases (1).

Whatever the adverse effects of mifepristone, the risks have to be looked at realistically and compared with those of the alternatives available to a particular woman in particular circumstances. Particularly in rural areas in developing countries, the risks of surgical and non-professional abortion are high, whereas, as has been shown in a study in rural India, a regimen of mifepristone plus misoprostol can be used as effectively and safely, through family planning clinics and country hospitals, as in a European environment (2).

Observational studies

The effective oral doses of mifepristone are 100–600 mg, and at any dose the bulk of recipients abort. Of 150 healthy women who received the higher dose, 131 attained a complete abortion. Three women reported bleeding for more than 2 weeks after abortion; 16 women had a reduced hemoglobin concentration of under 11 g/dl, justifying iron therapy. Other adverse effects were uterine contractions and pelvic pain ($n = 4$), transient asthenia ($n = 3$), and nausea ($n = 2$) (3). These findings seem to be typical, even though dosage schemes have varied; as little as 100 mg orally has been used successfully with similar adverse effects (SED-12, 1037) (4).

Placebo-controlled studies

In a double-blind, randomized, controlled trial, 896 healthy women requesting a medical abortion (57–63 days gestation, mean age 25 years) were randomized to a single oral dose of mifepristone 200 mg or 600 mg, both followed in 48 hours by gemeprost 1 mg vaginally (5). The complete abortion rates were similar with the lower and higher doses of mifepristone (92 versus 92%). The

© 2006 Elsevier B.V. All rights reserved.

incidences of adverse effects were similar, with the exception of nausea at 1 week, which was less frequent in the low-dose group (3.6 versus 7.6%).

Organs and Systems

Electrolyte balance

Severe hypokalemia has been attributed to long-term mifepristone (6).

- An extremely ill 51-year-old man with Cushing's syndrome, due to an ACTH-secreting pituitary macroadenoma, which had failed to respond to conventional surgical, medical, and radiotherapeutic approaches, responded dramatically in the short-term and long-term to high-dose mifepristone (up to 25 mg/kg/day) for 18 months. However, she developed severe hypokalemia, attributed to excessive cortisol activation of mineralocorticoid receptors; it responded to spironolactone.

This case shows the potential need for concomitant mineralocorticoid receptor blockade when mifepristone is used to treat Cushing's syndrome, since mineralocorticoid concentrations can rise markedly, reflecting corticotropin disinhibition.

Reproductive system

Long-term mifepristone is primarily used as a means of treating uterine myomas, endometriosis (25–100 mg/day), and possibly inoperable meningiomas (200 mg/day) or inoperable Cushing's syndrome. While it is primarily regarded as an antiprogestogen, some of these uses reflect its antiglucocorticoid and antiproliferative effects. However, there are also data to suggest that, acting as an antiprogestogen, mifepristone can promote an unopposed estrogen milieu, and can thus have a proliferative effect on the endometrium.

- An adolescent girl with Cushingoid features and osteoporosis took mifepristone 400 mg/day for its antiglucocorticoid effect in an attempt to prevent further bone loss (7). Her striae, weight gain, and buffalo hump markedly improved, and further bone loss was halted. However, with each of the two 6-month courses of mifepristone (9 months apart) she developed massive simple endometrial hyperplasia and a markedly enlarged uterus. This reverted to normal after withdrawal of mifepristone.

The authors suggested that interval pelvic imaging may be advisable in women who take long-term mifepristone.

Drug Administration

Drug dosage regimens

There has sometimes been reluctance to use higher doses of mifepristone, because of a supposedly greater risk of severe adverse effects. However, in a randomized comparison of a single oral dose of mifepristone (either 200 mg or 600 mg) followed 48 hours later by oral misoprostol 400 μg the two regimens produced identical results as regards the induction of abortion and the incidence of adverse effects (8).

The optimal dose of mifepristone to secure an abortion without excessive adverse effects is not known. In a study in nearly 900 women there was no appreciable difference between oral doses of 200 or 600 mg, followed after 48 hours by gemeprost 1 mg vaginally (5). The similarity of adverse reactions with the lower and higher doses of mifepristone has been confirmed by others (9). However, in another study mifepristone 0.5 mg, which has sometimes been recommended on supposed safety grounds, was not sufficient to induce abortion (10). The frequencies of various adverse effects of mifepristone in effective doses have emerged from various studies. In one study nausea, vomiting, or diarrhea in women using a standard regimen occurred in 68%, 36%, and 20% respectively (11); these risks are not considered to be problematic. The combination of oral mifepristone and vaginal misoprostol is also effective and safe, has few serious adverse effects, and is well accepted by women (12).

Milrinone

See also Phosphodiesterase type III, selective inhibitors of

General Information

Milrinone is an inhibitor of phosphodiesterase type III. Although the long-term oral use of such inhibitors is associated with an increase in mortality (SEDA-17, 217), milrinone has been used intravenously in patients with heart failure, both for short-term and longer-term therapy (SEDA-21, 196) (SEDA-22, 203) (SEDA-23, 109). It has been suggested to be particularly useful in tiding patients over while they are waiting for definitive treatment.

- A 48-year-old man with an inflammatory aneurysm of the ascending aorta and severe heart failure due to massive aortic regurgitation was given a continuous intravenous infusion of milrinone 0.5 micrograms/kg/minute (1). His pulmonary arterial pressure fell and his symptoms improved over 7 weeks while he was taking corticosteroids. The diseased tissue was successfully replaced at operation and the milrinone was tapered uneventfully.

The authors suggested that continuous milrinone infusion may be suitable for patients with surgically correctable inflammatory cardiovascular diseases complicating severe heart failure in whom maintenance of optimal hemodynamics is necessary for several weeks before operation.

The disappointing results with positive inotropic drugs in treating acute and chronic heart failure may be due to the fact that they increase both systolic and diastolic calcium concentrations in the myocardium (2).

Observational studies

There has been a study of the use of intermittent intravenous milrinone in 10 patients with end-stage congestive heart failure (3). Some hemodynamic benefit was obtained, but this was an open uncontrolled study and firm conclusions are impossible. There was also some improvement in the quality of life. The drug was well tolerated and only one patient had an increase in dysrhythmias (an increased frequency of ventricular extra beats).

On the premise that phosphodiesterase inhibitors also inhibit the production of cytokines, milrinone has been used in the treatment of nine patients with the systemic inflammatory response syndrome and compared with seven patients with congestive heart failure (4). In both groups milrinone significantly altered cardiac index, pulmonary capillary wedge pressure, and left ventricular stroke work index. In the patients with cardiac failure it also reduced systemic vascular resistance index, and the dose of adrenaline had to be increased substantially during milrinone infusion to counteract vasodilatation.

Placebo-controlled studies

OPTIME-CHF (5) was a randomized, placebo-controlled study in which 951 patients (mean age 65 years; 92% with baseline NYHA class III or IV; mean left ventricular ejection fraction 23%) with acute exacerbations of chronic heart failure in 78 community and tertiary care hospitals in the USA were randomly assigned to a 48-hour infusion of either milrinone (0.5 micrograms/kg/minute initially for 24 hours) or saline (6). The median number of days in hospital for cardiovascular causes within 60 days after randomization did not differ significantly between patients given milrinone (6 days) or placebo (7 days). Sustained hypotension requiring intervention (11 versus 3.2%) and new atrial dysrhythmias (4.6 versus 1.5%) were more common in the patients who received milrinone. There was no difference in hospital mortality (3.8 versus 2.3%), 60-day mortality (10 versus 8.9%), or the composite incidence of death or readmission (35 versus 35%). The authors concluded that these results do not support the routine use of intravenous milrinone as an adjunct to standard therapy in patients with an exacerbation of chronic heart failure.

Comparative studies

In a randomized, open, parallel-group study of the hemodynamic effects of milrinone and glyceryl trinitrate in 119 patients with advanced decompensated heart failure, milrinone was significantly more effective than glyceryl trinitrate (7). Adverse effects caused the withdrawal of milrinone in three of the 58 patients who took it; one had ventricular extra beats, one had renal insufficiency, and one had hypokalemia. Headache was the most common adverse effect in both groups, but was less common in those who took milrinone (12 versus 29%).

In a randomized, open study of milrinone and dobutamine in 120 patients with low cardiac output after cardiac surgery, the two drugs were roughly comparable in efficacy (8). Adverse events were more frequent with dobutamine (77%) than with milrinone (58%). With milrinone cardiovascular adverse events were the most common, including hypertension (13%), hypotension (20%), bradycardia (13%), new atrial fibrillation (5%), and tachycardia (8%). Other adverse events included hemorrhage and oliguria. Adverse events required withdrawal from the study in 20 patients who took milrinone.

Organs and Systems

Cardiovascular

The main limitations of the short-term use of milrinone is the risk of hypotension and ventricular dysrhythmias (9–12) and sudden death has occurred (10). Acute exacerbation of chronic heart failure has also been reported (13).

In a retrospective view of 63 patients who received intravenous milrinone for more than 24 hours for advanced cardiac failure, the mean dose was 0.43 microgram/kg/minute and the mean duration of therapy 12 (range 1–70) days (14). After 24 hours of therapy there was significant improvement in pulmonary artery pressure, pulmonary capillary wedge pressure, and cardiac index. Because of the nature of the study, which was not placebo-controlled, it is impossible to be sure what events could have been attributed to the milrinone. However, the authors reported five cases of asymptomatic, nonsustained ventricular tachycardia, six of symptomatic ventricular tachycardia, and three deaths, one in ventricular tachycardia and two in heart failure. There was no difference in the incidence of these adverse events in patients who received milrinone for more than 7 days compared with the others.

Milrinone can cause tachycardia, partly because of its vasodilatory effects and partly perhaps by a direct effect on the heart.

- A 74-year-old man had a tachycardia of 145/minute during infusion of milrinone after an operation for repair of an abdominal aortic aneurysm (15). The tachycardia was controlled by esmolol on one occasion and more impressively by metoprolol on a second occasion. However, the hemodynamic effects of milrinone were not altered by beta-blockade.

Presumably the beneficial effects of beta-blockade in this case were non-specific, since milrinone does not affect beta-adrenoceptors.

Of 19 children (12 infants and 7 children aged 1–13 years) who were given either two boluses of 25 micrograms/kg followed by an infusion of 0.5 microgram/kg/minute, or a bolus of 50 micrograms/kg followed by a bolus of 25 micrograms/kg followed by an infusion of 0.75 microgram/kg/minute, two infants developed junctional ectopic tachycardia during infusion of milrinone.

Vasopressin has been used to treat hypotension due to milrinone. In seven patients with congestive heart failure who developed hypotension (systolic arterial pressure below 90 mmHg), vasopressin 0.03–0.07 units/minute increased the systolic arterial pressure to 127 mmHg (16). This effect was due to peripheral vasoconstriction, since the systemic vascular resistance increased from 1112 to 1460 dyne.s/cm^5 with no change in cardiac index. Urine output also improved significantly. In three patients in whom milrinone caused hypotension, vasopressin (0.03–0.07 U/minute) increased the systolic arterial pressure from 90 to 130 mmHg and reduced the dosages of catecholamines that were being used (17). The authors hypothesized that vasopressin may have inhibited the milrinone-induced accumulation of cyclic AMP in vascular smooth muscle.

Fluid balance

In one series fluid retention was very common with milrinone (10).

Hematologic

Falls in platelet counts have been seen with milrinone (18) and it can cause thrombocytopenia (SEDA-20, 174). Of 19 children (12 infants and 7 children aged 1–13 years) who were given either two boluses of 25 micrograms/kg followed by an infusion of 0.5 microgram/kg/minute, or a bolus of 50 micrograms/kg followed by a bolus of 25 micrograms/kg followed by an infusion of 0.75 microgram/kg/minute, 11 developed thrombocytopenia, defined as a platelet count below 100×10^9/l, during milrinone infusion (19). Of these, two infants required a platelet transfusion. By comparison, in 128 patients who did not receive milrinone the incidence of thrombocytopenia was 25%, significantly lower than in those given milrinone. The occurrence of thrombocytopenia increased with increasing duration of infusion.

Susceptibility Factors

Renal disease

In six patients with severe congestive heart failure and renal insufficiency being treated with continuous venovenous hemofiltration, the pharmacokinetics of milrinone 0.25 mg/kg/minute by continuous intravenous infusion were different from those that have been previously reported in patients with normal renal function, with a prolonged half-life and a raised mean steady-state concentration, suggestive of reduced clearance (20). The half-life of milrinone was 20 hours, compared with reported half-lives of around 3 hours.

Drug Administration

Drug administration route

Inhaled milrinone has been used to treat patients with pulmonary hypertension after cardiac surgery (21). Milrinone produced a significant dose-related reduction in pulmonary vascular resistance in nine patients. There were no systemic adverse effects.

Miltefosine

General Information

Miltefosine is an alkylphospholipid that affects cell-signaling pathways and membrane synthesis; it was originally developed as an oral antineoplastic agent but is now licensed for use in visceral leishmaniasis in India (1,2).

Observational studies

In an open, multicenter trial in 120 patients, aged 12–50 years, who took 50, 100, or 150 mg/day of miltefosine for 4 or 6 weeks, there was an initial parasitological cure in all cases (3). Six patients had clinical and parasitological relapses by 6 months after initial treatment. There was a 97% cure rate with miltefosine 100 mg/day. Gastrointestinal adverse effects were frequent (in 62%) but mild to moderate in intensity, and no patient discontinued therapy as a result. In one patient, treatment was withdrawn because of raised aspartate transaminase activity, and in 12 others the aspartate transaminase activity increased to 100–150 U/l during treatment. In one patient, treatment was withdrawn because of a raised creatinine concentration.

Comparative studies

Miltefosine has been compared with the most effective standard treatment, amphotericin, in a randomized, open comparison in India, in which 299 patients, aged 12 years or over, received oral miltefosine (50 or 100 mg) and 99 patients received intravenous amphotericin deoxycholate (1 mg/kg every other day to a total of 15 injections) (4). Vomiting and diarrhea were more common with miltefosine. However, the effects were mild in almost all cases, and only 3–4% of patients needed antiemetic drugs in both groups. One patient who took miltefosine withdrew because of gastrointestinal intolerance and one developed Stevens–Johnson syndrome.

Second-Generation Effects

Fertility

Miltefosine caused infertility in male rats, but not in 211 men (4).

Minocycline

See also Tetracyclines

General Information

Minocycline, in common with doxycycline, is more lipophilic than other tetracyclines. It is well absorbed after oral administration. Its half-life is 16–18 hours. Its higher affinity for fatty tissues improves its effectiveness and changes its adverse effects profile. Local gastrointestinal irritation and disturbance of the intestinal bacterial flora occur less often than with the more hydrophilic drugs, which have to be given in higher oral doses for sufficient absorption.

Nevertheless, its toxic effects are similar to those of other tetracyclines and arise from accumulation in fatty tissues. Accumulation in a third compartment and the resulting long half-life may contribute to an increased incidence of various toxic adverse effects during long-term treatment, even if lower daily doses are used. This seems also to be the case for pigmentation disorders and possibly for neurological disturbances (1).

Minocycline is predominantly eliminated by the liver and biliary tract (70–90%). Therefore, no change in dose is needed in patients with impaired renal function. However, it should be considered that hepatic elimination of doxycycline might be accelerated by co-administration of agents that induce hepatic enzymes.

Adverse effects of minocycline are reported far more often than adverse effects of other tetracycline derivatives. Whatever the mechanisms underlying this larger number of reports might be, they continue to appear. With increasing use of minocycline in acne and other conditions, adverse reactions may become increasingly common; early recognition is important to prevent further deterioration, to hasten recovery, and to avoid invasive investigations and treatment (2). The authors of this review recommended that safer alternatives be considered in the treatment of acne.

Organs and Systems

Respiratory

Minocycline and nicotinamide therapy for bullous pemphigoid have been associated with severe pneumonitis (3).

Nervous system

The syndrome of pseudotumor cerebri consists of symptoms and signs of raised intracranial pressure in the absence of neuroimaging or cerebrospinal fluid abnormalities. Most cases are idiopathic, but several drugs have been implicated as causative or contributory.

The first description of minocycline-related pseudotumor cerebri was published in 1978 (4). Further data have been published concerning 12 patients who developed pseudotumor cerebri after taking standard doses of minocycline for acne vulgaris (5). Nine developed symptoms within 8 weeks of starting minocycline therapy. Minocycline was withdrawn, and none of the patients developed recurrences for at least 1 year afterwards. However, three patients had substantial residual visual field loss.

It seems reasonable to assume that the mechanisms may be similar to that postulated for tetracyclines, which reduce cerebrospinal fluid absorption, possibly by an effect on cyclic adenosine monophosphate at the arachnoid villi (6). Minocycline crosses the blood–brain barrier more effectively than other tetracyclines, because of its greater lipid solubility. Therefore, a physician who prescribes minocycline should keep his eye on the patient's eyes.

Mouth and teeth

Staining of permanent teeth by tetracyclines takes place during tooth development by well-documented mechanisms. Tetracycline forms a complex with calcium orthophosphate during calcification, which then darkens with exposure to light. With minocycline, however, the staining occurs after eruption in previously normal-colored, fully mineralized adult teeth. For example, adult-onset tooth discoloration coincident with minocycline administration occurred in four of 72 patients (7).

There are at least four theories about the mechanisms of this adverse effect.

1. That minocycline attaches to the acquired pellicle glycoproteins (the "extrinsic theory") (8). This in turn etches the enamel, and cycles of demineralization and remineralization occur. It oxidizes on exposure to air or as a result of bacterial activity, and the final product is insoluble black quinine.
2. That minocycline, bound to plasma proteins, is deposited in collagen-rich tissues, such as pulp, teeth, and bones (the "intrinsic" theory). Minocycline is then slowly oxidized over time with exposure to light (9,10).
3. That a breakdown product of minocycline chelates with iron to form insoluble complexes (7,11).
4. That minocycline is deposited in dentine during dentinogenesis, accelerating or changing the process (12).

Whatever the mechanism(s) might be, staining of adult dentition occurs in 3–6% of patients who take long-term minocycline 100 mg/day (8,13). The onset of discoloration can occur at any time from 1 month to many years after the start of treatment (11,13).

The importance of avoiding permanent staining of the teeth cannot be over-emphasized, as many patients with acne are already prone to negative psychological effects. Minocycline should therefore be prescribed only with great care.

© 2006 Elsevier B.V. All rights reserved.

Liver

Hepatotoxicity associated with minocycline has been reviewed, covering data reported to the WHO Centre for International Drug Monitoring, which had recorded 8025 reactions to minocycline, of which 493 were reactions involving the liver (14). The authors stated that fields available to define indications for use, time of treatment, and outcome subsequent to the reactions were seldom completed. They therefore concentrated on more complete records in patients known to have used minocycline for acne. Patients taking minocycline for reasons other than acne or those given intravenous minocycline were excluded. Altogether, 65 patients were then commented on; 58% were women and 94% were aged under 40 years. Briefly, two types of hepatic reactions were recognized: autoimmune hepatitis associated with lupus-like symptoms occurring after 1 year or more of exposure to minocycline, and hypersensitivity reactions associated with eosinophilia and exfoliative dermatitis occurring within 35 days of therapy.

The authors stated that they did not have any clear information about the absolute and relative risks of hepatitis, whether these were hypersensitivity reactions or autoimmune hepatitis, in patients taking minocycline for varying lengths of time, and that a study of the comparative rates of hepatitis in people exposed to minocycline compared with those not exposed is required. In the meantime, new reports of severe hepatic reactions to minocycline continue to appear (15–17), including one case of autoimmune hepatitis requiring liver transplantation in a woman who had used minocycline 50–200 mg/day for 3 years (17). Another case of liver transplantation has previously been reported in patients with hepatic failure after minocycline therapy (18).

Some patients consider drugs to treat a common dermatological disease such as acne vulgaris to be cosmetics rather than medications. Safer alternatives than minocycline should be considered in the treatment of acne.

Pancreas

Minocycline has been associated with acute pancreatitis (19).

Skin

Long term minocycline often results in pigmentation of skin, nails, bones, thyroid, mouth, and eyes. The bones of the oral cavity are probably the most frequently affected sites of pigmentation. On the skin, the blue-black pigmentation develops most frequently on the shins, ankles, and arms. Other patterns include pigmentation that either is generalized and symmetrical or develops at sites of inflammation. The pigmentation is often permanent when sites other than the skin and oral mucosa are involved (20,21). The pigment is a product of an oxidation reaction. In an experimental rat study, pigmentation of the thyroid gland was prevented by ascorbic acid (9). Laser treatment was successfully used in two cases (22,23).

Fixed drug eruptions are characterized by solitary or multiple, round or oval, erythematous patches of variable size; some of them develop into bullae or superficial erosions. Characteristically they appear in the same site each time the responsible drug is given, usually 30 minutes to 8 hours after administration, and with itching or burning as the first symptoms. Over a period of 1–2 weeks they fade, often with crusting and scaling, followed by hyperpigmentation, which can persist for months.

Antimicrobial drugs, especially co-trimoxazole, ampicillin, and tetracyclines, can cause fixed drug eruptions (24), and cases have been attributed to minocycline (25). There is usually no cross-reactivity (26). However, a case of fixed drug eruption has been reported after minocycline in a patient with a previous eruption due to doxycycline (27).

- A 48-year-old man with urethritis took doxycycline 100 mg bd and developed a fixed drug eruption on the glans penis. Doxycycline was withdrawn and the eruption healed with symptomatic treatment. Eight months later he took minocycline 100 mg/day for rosacea. A few hours after having taken the first tablet he became aware of oval erythematous patches on the glans, prepuce, and scrotum. The patches rapidly became violaceous and developed into superficial erosions. He stopped taking minocycline and the lesions faded.

According to the authors, this is the first report of a fixed drug eruption after minocycline in a patient with a previous eruption due to doxycycline. They advised clinicians to be aware of this potential cross-reactivity when prescribing these two drugs.

A generalized pustular eruption was reported in a patient with acne treated with minocycline (28). Skin prick tests with minocycline were positive at 48 hours.

Immunologic

Immunoallergic reactions have been reported with minocycline and include lupus-like syndrome, autoimmune hepatitis, eosinophilic pneumonia, hypersensitivity syndrome, a serum sickness-like illness (29), and Sweet's syndrome (SEDA-21, 262) (SEDA-22, 271). Over 60 minocycline-induced cases of lupus-like syndrome and 24 cases of minocycline-induced autoimmune hepatitis were found in a review of the literature (30). In 13 patients, both disorders co-existed. These patients had symmetrical polyarthralgia/polyarthritis, raised liver enzymes, and positive antinuclear antibodies; they were also generally antihistone-negative, and only two patients had p-ANCA antibodies. Minocycline-related lupus can also occur in adolescents (31).

Lupus-like syndrome

Drug-induced lupus is a well-known phenomenon, although the mechanisms are unclear. The diagnostic features should include no prior history of systemic lupus erythematosus (SLE) before the start of treatment, at least one clinical feature of SLE, a positive antinuclear antibody during sustained drug therapy, and dramatic symptomatic improvement after drug withdrawal. Since 1970, at least 49 drugs have been reported to be associated with drug-related lupus (32), of which hydralazine and procainamide have been claimed to the most commonly implicated. However, new reports on minocycline-induced lupus continue to appear (33–35) and it is possible that minocycline is now the most common cause.

© 2006 Elsevier B.V. All rights reserved.

In a retrospective nested case-control study in 27 688 young patients with acne, 7136 had used minocycline, of whom 29 had the lupus-like syndrome (36). Minocycline was associated with an 8.5-fold risk of the lupus-like syndrome. The effect was greater in longer-term users, but the absolute risk of developing lupus-like syndrome seemed to be relatively low.

Minocycline-induced lupus usually occurs some months, or even years, after the start of therapy, and it usually resolves when the drug is withdrawn. The diagnosis can easily be overlooked, especially in patients with rheumatoid arthritis (37). It would always be wise to follow the recommendation that a patient's antinuclear antibody be checked before starting minocycline and when drug-induced lupus is suspected.

In a retrospective review of drug safety databases, minocycline was the only tetracycline derivative that caused drug-induced lupus (SEDA-22, 268) (38). The authors proposed that the propensity of minocycline to cause drug-induced lupus may be due to the presence of a functional group that is easily oxidized to a reactive metabolite. However, the chemically modified tetracycline CMT-3, which has also reportedly caused a lupus-like syndrome (39), lacks this group, so another theory is needed.

- A 16-year-old girl, who had taken minocycline for acne for more than 2 years, developed a severe cough with paroxysms (40). She had also a recent history of joint pain with swelling and stiffness, fever, general weakness, and weight loss of 9 kg. She had been treated as an outpatient for presumed pneumonia with multiple antibiotics, but developed progressive dyspnea. Pulmonary lupus was suspected, and minocycline was withdrawn. She was treated with an initial 3-day course of intravenous methylprednisolone 20 mg tds, and then prednisone 40 mg bd for 2 weeks. She improved very rapidly, and the prednisone was gradually reduced over 7 weeks.

According to the authors, the patient fulfilled all the criteria for a diagnosis of drug-induced lupus-like syndrome, that is no history of lupus erythematosus before minocycline therapy, the presence of antinuclear antibodies, at least one clinical feature of lupus erythematosus, and prompt recovery after withdrawal of minocycline. She also had positive antihistone antibodies, compatible with drug-induced lupus-like syndrome.

- A 54-year-old woman with a 2-week history of low-grade fever, dry cough, and dyspnea was given levofloxacin for a presumed community-acquired pneumonia (41). Five days later she developed severe respiratory failure and was mechanically ventilated and given antibiotics (imipenem and clarithromycin). Microbiological examination of tracheobronchial aspirates was negative for pathogenic organisms, as were serological tests for common agents of atypical pneumonia. She progressively improved and was taken off the ventilator after 6 days and discharged about 10 days later, but 14 days later was readmitted with rapidly progressive pulmonary failure requiring mechanical ventilation. It then transpired that 2 weeks before the first episode of respiratory failure, she had started to take oral minocycline for acne vulgaris and had started to take it again 24 hours before the second episode. The minocycline was stopped and she was given intravenous methylprednisolone. She improved rapidly, and for 12 months after minocycline withdrawal she remained free of respiratory symptoms.

It is a good rule of thumb that patients who develop minocycline-induced lupus should never be rechallenged with minocycline, as symptoms tend to recur (34,42,43). If minocycline is used to treat rheumatoid arthritis, the patient should be followed very carefully, as worsening arthritis may be erroneously attributed to the underlying disease. It should also be emphasized that in the search for a cause of joint pains, minocycline should always be considered (44).

Autoimmune hepatitis

In a review of relevant American and European literature, hepatitis and drug-induced lupus were reported in 66 cases after minocycline therapy, mostly after long-term treatment for acne (45).

- Minocycline-induced hepatitis with antinuclear, antimitochondrial, and antismooth muscle antibodies has been reported in a 19-year-old black West Indian woman who had been treated for acne for two years with oral minocycline (50 mg/day) and topical benzoyl peroxide (5%) (46).
- Seven patients (17–22 years old) developed symptoms of arthralgia and arthritis after having taken minocycline 50–100 mg bd for 6–36 months for acne vulgaris (47). Increased titers of perinuclear ANCA were detected in all seven, five had fluorescent antinuclear antibodies, two had antihistone autoantibodies, and one had anticardiolipin antibodies. Symptoms resolved in five patients on withdrawal; the other two were treated with corticosteroids and also achieved remissions.

Autoimmune hepatitis has also been reported (48).

- Three adolescents taking therapeutic doses of minocycline for 12–20 months met the 1993 International Autoimmune Hepatitis Group criteria for autoimmune hepatitis. All had hypogammaglobulinemia and positive antinuclear antibody and antismooth muscle antibody titers. Two underwent liver biopsy that showed severe chronic lymphoplasmocytic inflammation, necrosis, and fibrosis. All other causes of liver disease were excluded. One patient had resolution of symptoms after withdrawal of the drug, while two required immunosuppressive therapy.

Necrotizing vasculitis of the skin and uterine cervix has been reported in a patient taking minocycline (49).

- A 35-year-old woman developed an asymptomatic, erythematous, subcutaneous nodule on the anterior aspect of her left leg. She had been taking minocycline 50–100 mg bd for acne for 2 years, and her only other medication was an oral contraceptive. A presumptive diagnosis of erythema nodosum was made. The nodule was injected twice with triamcinolone acetonide and she was given indometacin 50 mg tds but continued to take minocycline. Some weeks later, after a routine gynecological examination, pathological examination

© 2006 Elsevier B.V. All rights reserved.

of a cervical biopsy showed necrotizing arteritis of the cervix. A biopsy of the pretibial nodule showed a necrotizing vasculitis with fibrinoid necrosis of the vessel walls and thrombosis. Her serum transaminase activities were increased, and an antinuclear antibody test was positive at 1:60 with a nucleolar pattern. Minocycline was withdrawn, and over the next 3 months her liver function tests normalized, the antinuclear antibody became negative, and the pretibial nodule and uterine cervix vasculitis resolved. There was no recurrence over the next 2 years.

Serum sickness

A serum sickness-like reaction clinically similar to classical serum sickness can result from the administration of a number of non-protein drugs, such as tetracyclines, penicillins, cephalosporins (50). Minocycline has been reported to cause serum sickness (29,51).

- A 16-year-old girl taking minocycline for acne developed typical symptoms of serum sickness after 14 days. Minocycline was withdrawn and her symptoms resolved after a short course of systemic steroids for 5 days.
- An 18-year-old woman developed typical symptoms of serum sickness after taking minocycline 50 mg/day for 10 days for acne. Her symptoms resolved gradually after minocycline was withdrawn.

The authors reviewed some other cases of serum sickness after the use of minocycline. They suggested that the syndrome is under-reported, either because of unawareness that it can be an adverse effect or lack of willingness of physicians to document the event.

Polyarteritis nodosa

Two cases of biopsy-proven cutaneous polyarteritis nodosa with positive perinuclear antineutrophilic cytoplasmic antibodies have been reported with long-term use of minocycline for acne vulgaris (50–100 mg/day for 44 months and 100 mg/day for 65 months) (52). In one of the cases, involvement was not restricted to medium-size vessels alone. In both cases the vasculitis disappeared after a short course of prednisone (40 mg/day) and withdrawal of minocycline. Rechallenge was not performed. P-ANCA is usually found in microscopic polyangiitis, a vasculitis of smaller arteries, and its significance in polyarteritis nodosa is not clear.

Susceptibility Factors

Renal disease

Minocycline is almost completely eliminated via the liver and the biliary tract and is therefore safe in patients with pre-existing renal insufficiency.

Drug Administration

Drug administration route

The use of minocycline as an agent for inducing chemical pleurodesis has been reported in only a few patients and there is little information regarding its adverse effects. In a retrospective study, 51 patients with primary spontaneous pneumothorax treated by video-assisted thoracoscopic surgery followed by instillation of minocycline hydrochloride 7 mg/kg into the pleural space through a thoracostomy tube were compared with 51 who underwent surgery only (53). Chest pain was a common complaint after minocycline pleurodesis, but the total doses of analgesics were comparable. The rate of prolonged air leaks was significantly lower after minocycline (7 versus 18%). Patients treated with minocycline had shorter periods of postoperative chest drainage and hospitalization. The ipsilateral recurrence rate was also significantly lower (2.9 versus 9.8%).

Drug–Drug Interactions

Phenothiazines

Black galactorrhea was described in a breastfeeding woman during treatment with minocycline and a phenothiazine (54).

Minoxidil

General Information

Minoxidil (2,4-diamino-6-piperidinopyrimidine-3-oxide) is a potent vasodilator effective in severe hypertension irrespective of the cause. Isolated case reports have been published of hair growth in areas of male pattern baldness in patients treated with oral minoxidil, therefore topical minoxidil has been used for the treatment of alopecia areata and alopecia androgenica, with some success.

The pattern of adverse vasodilator effects with minoxidil is similar to, but more severe than, that of hydralazine and fluid retention can be troublesome.

Topical minoxidil stimulates new hair growth and arrests loss of hair in androgenic alopecia. Minoxidil is poorly absorbed through the skin (less than 4%) (1), and plasma concentrations of minoxidil are far less than 10% of the mean minoxidil concentration present 2 hours after oral ingestion of 5 mg, the lowest dose for the treatment of hypertension (2). Its adverse effects after topical application are therefore usually limited to the application site on the scalp. They include irritant contact dermatitis, allergic contact dermatitis, and exacerbation of seborrheic dermatitis. These effects are seen in 5.7% of patients who use a 5% solution and in 1.9% of those who use a 2% formulation (3).

Therapeutic studies

The results with a 2% solution of minoxidil are variable, and experience has suggested that higher concentrations may be more effective. Topical twice-daily minoxidil 2% and 5% have therefore been compared for 48 weeks in a double-blind, randomized, placebo-controlled, multicenter trial in 393 men (aged 18–49 years) with androgenic alopecia (4). The higher concentration of minoxidil was significantly more effective than both the lower concentration and placebo in terms of change from baseline in non-vellus hair count, patient rating of scalp coverage and treatment benefit, and investigator rating of scalp coverage; the response to treatment occurred earlier with 5% minoxidil. However, there was more pruritus and local irritation with 5% minoxidil.

Organs and Systems

Cardiovascular

Minoxidil can cause pericardial effusion (5).

- A 52-year-old man with a history of chronic hypertension presented with worsening dyspnea and leg edema. He had been taking minoxidil for 10 years. The cardiac silhouette was markedly enlarged. Echocardiography and computed tomography showed a large pericardial effusion. Minoxidil was withdrawn and the effusion resolved within 1 month.

A hypertensive crisis occurred in one patient after withdrawal of topical minoxidil (SEDA-16, 158).

Skin

Local adverse effects of topical minoxidil (usually in an alcohol–propylene glycol base) include dryness, irritation, pruritus, contact allergy (SEDA-11, 139), and photocontact allergy (SEDA-11, 139).

Leukoderma has been reported in two men from India who used 2% minoxidil lotion for 2–3 months to treat baldness (6). The depigmentation was localized to the scalp. Other possibilities of leukoderma were ruled out, as was vitiligo. There was repigmentation of the leukodermic area within 3 months of minoxidil withdrawal in both cases.

Hair

A particular feature of minoxidil is excessive hair growth (7), which occurs in about 70% of patients who take oral minoxidil, usually within 2 months of the start of therapy. Severe hypertrichosis, unacceptable even to men, has complicated the otherwise successful antihypertensive treatment of six patients after renal transplantation, for which ciclosporin was also used. Since hypertrichosis has also been described with ciclosporin, there may be an additive pharmacodynamic interaction (8).

Topical minoxidil has been used to treat women with androgenic alopecia. Severe hypertrichosis of the face and the limbs occurred in three women after 2–3 months of treatment with 5% topical minoxidil (9). The hypertrichosis disappeared from the face and arms within 1–3 months of withdrawal and from the legs after 4–5 months.

Immunologic

A "polymyalgia syndrome," characterized by fatigue, anorexia, weight loss, and severe pain in the shoulders and the pelvic girdle, was attributed to minoxidil in four men (10).

In 11 patients allergic to topical minoxidil lotion, patch tests showed that four were positive to minoxidil itself (11). Propylene and butylene glycol are used as solvents for minoxidil in topical formulations. Nine of the 11 patients appeared to have positive patch tests to propylene glycol and one of the 11 reacted to its alternative butylene glycol.

- A 57-year-old man developed a pigmented contact dermatitis after using topical minoxidil 5% for 2 years (12). Patch tests were negative with the European standard series and with a textile and finishes series, but positive with minoxidil 5% on days 3 and 7. However, withdrawal of the minoxidil did not lead to improvement after 10 months.
- A 24-year-old woman with androgenic alopecia became sensitized to topical minoxidil after using minoxidil 4% with retinoic acid in a propylene glycol base (13). She subsequently also became sensitized to saw palmetto (*Serenoa repens*), a topical herbal extract commonly promoted for the treatment of hair loss.
- Allergic contact dermatitis occurred in a 54-year-old man who had used 1% minoxidil on the scalp for 8 months (14). He had positive patch tests to minoxidil in alcohol, but not to minoxidil in petrolatum, piperidine, pyrimidine, or diaminopyrimidine.

© 2006 Elsevier B.V. All rights reserved.

The authors of the last report suggested that the whole structure of minoxidil is required for sensitization and that propylene glycol in the formulation of minoxidil that is used therapeutically increases the penetration of minoxidil into the skin, enhancing the risk of a reaction.

Long-Term Effects

Drug withdrawal

A hypertensive crisis occurred in one patient after withdrawal of topical minoxidil (SEDA-16, 158).

Second-Generation Effects

Teratogenicity

Caudal regression syndrome is a rare anomaly, a continuum of congenital malformations ranging from isolated sacral agenesis to absence of the lumbosacral spine and major visceral anomalies. While the exact cause of this syndrome is unclear, maternal diabetes, genetic factors, teratogens, and vascular anomalies that alter blood flow have been hypothesized to play a role. A case has been attributed to maternal minoxidil exposure (15).

A fetus had an extremely hypotrophic caudal body pole, aplasia of the lower spine, and complete renal agenesis diagnosed in the second trimester by ultrasound. The mother had used minoxidil solution to prevent hair loss for 4 years before and during gestation. She had also taken co-trimoxazole during the first trimester. She was not diabetic and had no history of familial genetic disorders.

Drug Administration

Drug administration route

Despite the poor transdermal absorption of minoxidil, in 7 out of 30 non-hypertensive patients treated with 3% minoxidil solution twice daily, there was a "significant" fall in blood pressure (16).

Some patients using minoxidil solution had increased hair growth outside the area of drug application (SEDA-18, 175), which suggests a systemic effect (17).

The sudden death of a patient using topical minoxidil (18) was probably not drug-related but due to cardiovascular disease and hypertension. Nevertheless, in patients who are known to be hypertensive and who are also receiving other antihypertensive medication extra caution is warranted when topical minoxidil is used (19).

Smoking intolerance possibly related to topical minoxidil has been observed rarely (20).

Drug overdose

In some countries, an extra-strength solution of minoxidil is available over the counter for hair regrowth treatment in men. Ingestion of a large dose in a suicide attempt has been reported (21).

- A 26-year-old woman took 60 ml of minoxidil solution 5% and 1 hour later developed hypotension (75/40 mmHg) and tachycardia (130/minute). She was alert and oriented and physical examination was unremarkable. She was given a saline infusion, oral activated charcoal, and sorbitol, and had worsening hypotension (40 mmHg systolic) and bradycardia (20/minute), developed chest pain and T wave inversion on the electrocardiogram, and lost consciousness. Atropine and dopamine restored a heart rate of 120/minute, but she remained hypotensive (54/36 mmHg). Her blood ethanol concentration was 5.64 mmol/l and other toxicological screening tests were negative. The addition of phenylephrine up to a dose of 200 μg/minute restored her systolic blood pressure to 90–100 mmHg.

Mirtazapine

See also Antidepressants, second-generation

General Information

The antidepressant mirtazapine is pharmacologically similar to mianserin. It has a slightly weaker blocking action at α_1-adrenoceptors, and this is claimed to give it a dual mode of action, increasing the release of both noradrenaline and serotonin (1). It is claimed to have a more rapid onset of action than some SSRIs, but this may be due to its prominent sedative effect, which improves insomnia from the start of treatment.

Mirtazapine is extensively metabolized in the liver, mainly by CYP1A2, CYP2D6, and CYP3A4. With once-daily dosing, steady-state concentrations are reached after 4 days in adults and 6 days in elderly people.

In major depression, the efficacy of mirtazapine is comparable to that of amitriptyline, clomipramine, doxepin, fluoxetine, paroxetine, citalopram, and venlafaxine.

In placebo-controlled trials the most common adverse effects of mirtazapine were dry mouth (25%), drowsiness (23%), increased appetite (11%), and weight gain (10%) (SEDA 21, 13).

Organs and Systems

Psychological, psychiatric

Some patients appear to develop manic symptoms in response to some antidepressants but not to others. Psychosis was reportedly triggered by mirtazapine in a patient taking long-term levodopa (2) and in another patient hypomania occurred.

- A 45-year-old woman had a long history of dysthymia and depression. She had taken many antidepressants, including tricyclics, SSRIs, amfebutamone, and venlafaxine. She had no history of mania or hypomania. She took sertraline 250 mg/day, with only a transient response, and mirtazapine 15 mg/day was added. Within 4 days she developed clear symptoms of hypomania, with euphoric mood, mild grandiosity, pressure of speech, increased energy, and a reduced need for sleep. Mirtazapine was withdrawn and sertraline continued; within 3 days the hypomanic symptoms had remitted. The depressive disorder then re-emerged (3).

Unlike most other antidepressants, mirtazapine does not inhibit the reuptake of monoamines, but instead blocks inhibitory α_2-adrenoceptors. It is conceivable that this pharmacological mechanism led to hypomanic symptoms in this patient.

Hematologic

During clinical trials two of 2796 patients (0.08%) developed neutropenia, but both recovered after withdrawal. No other cases were detected in postmarketing surveillance of 13 500 patients in the Netherlands (SEDA-21, 14).

Liver

Mirtazapine has been associated with increases in liver enzymes (SEDA-21, 14).

Drug–Drug Interactions

Fluoxetine

In patients who do not respond to SSRI treatment, the addition of mirtazapine is an increasingly popular option. Mirtazapine is an α_2-adrenoceptor antagonist, so its acute pharmacological effects predominantly involve potentiation of noradrenergic function. This might be expected to enhance the serotonergic actions of SSRIs.

- A 48-year-old woman unresponsive to fluoxetine (20–40 mg/day for 8 weeks) was given additional mirtazapine (30 mg/day) (4). Over the next month her depression remitted, but after taking the combined treatment for 7 weeks she slept less, spent more, and was more sociable than usual. She was also argumentative and agitated. Mirtazapine and fluoxetine were withdrawn and valproate introduced as a mood stabilizer. Within 2 weeks her mood had settled but she subsequently became depressed again.

The manic episode here could have been due to mirtazapine alone or to the combination of fluoxetine and mirtazapine. The case also demonstrates the common clinical observation that when an antidepressant treatment has apparently caused mania, withdrawal of antidepressant therapy often results in re-emergence of depressive symptoms, even when mood stabilizer treatment has been introduced.

Misoprostol

See also Prostaglandins

General Information

Misoprostol, an analogue of PGE_1, is licensed for use in the management of gastroduodenal ulceration. It is an effective myometrial stimulant of the pregnant uterus and is used for the induction of labor and as abortifacient, both alone and in combination with other substances (for example mifepristone). It provides an effective alternative to gemeprost, the most widely used prostaglandin pessaries in combination with mifepristone.

Vaginal misoprostol is more effective and better tolerated than oral misoprostol for induction of first and second trimester abortions after the administration of mifepristone (1,2). It is more effective than either gemeprost or sulprostone combined with mifepristone for induction of first trimester abortion, although uterine rupture has been reported (3).

Intramuscular methotrexate 50 mg/m^2 followed by intravaginal misoprostol was effective in the induction of first trimester abortion. Adverse events following the administration of misoprostol included nausea (12%), vomiting (8.1%), diarrhea (7.4%), and fevers/chills (3.4%) (4).

Observational studies

A single intravaginal dose of misoprostol 800 micrograms can obtain an abortion. The success rate has been assessed in 102 pregnant patients with amenorrhea for less than 42 weeks (5). After 1 day and 3 days of administration the abortion rates were 72 and 87% respectively. A second dose 7 days later increased the cumulative rate to 92%. The main complaints were pain (85%), nausea (21%), and headache (18%). Similar results were obtained in 2295 pregnant women (up to 56 days of gestation), who took a single oral dose of mifepristone (200 mg) and were randomized to self-administer misoprostol 800 micrograms/day at home for 1, 2, or 3 days (6). Complete abortion rates were 98, 98, and 96% among those who took misoprostol for 1, 2, and 3 days respectively. There were similar frequencies of adverse effects in all groups (cramping, nausea, fever/chills, dizziness, vomiting, headache, and diarrhea).

Misoprostol has been used to induce abortions in 150 adolescents (age range 12–17 years) at gestations of 63–84 days (7). They received vaginal misoprostol 800 micrograms/day to a maximum of three doses. Complete abortion occurred in 84%. Adverse effects were more frequent in these adolescents than in adult women, and included nausea (31%), vomiting (41%), diarrhea (48%), dizziness (19%), headache (17%), a subjective feeling of fever (26%), flushing (16%), and chills (49%).

The efficacy and tolerability of sublingual misoprostol has been evaluated in an uncontrolled trial in China in 50 women who requested medical abortions at up to 12 weeks of gestation (8). All received three doses of misoprostol 600 micrograms sublingually 3-hourly, and two more doses of 600 micrograms sublingually if an abortion did not occur. The overall complete abortion rate was 86% and the mean number of doses of misoprostol required was four. There was no significant change in hemoglobin concentration and the median duration of vaginal bleeding was 15 days. Lower abdominal pain, fatigue, diarrhea, fever, and chills were the most common adverse effects, and they occurred more often (from 70 to 100%) than in studies in which repeated doses of vaginal misoprostol were used.

Comparative studies

Different prostaglandins

Extra-amniotic dinoprost ($PGF_{2\alpha}$) and intracervical misoprostol have been compared for termination of pregnancy in 40 women at 16–24 weeks of gestation (9). All the women given dinoprost aborted within 28 hours and 16 within 20 hours; termination of pregnancy was complete in 13 cases. With misoprostol, all the women aborted within 20 hours, 18 within 13 hours; termination of pregnancy was complete in 17 cases. The mean time to induction of abortion was 16 hours for extra-amniotic dinoprost and 10 hours for intracervical misoprostol (significantly quicker). The incidence of prostaglandin-associated pyrexia, vomiting, and diarrhea was significantly higher with dinoprost. Abdominal pain was similar in the two groups.

Oxytocin

Misoprostol and oxytocin have been compared in three trials during vaginal and cesarean delivery. The first trial included 663 women (mean age 25 years, mean parity 2) with uncomplicated vaginal deliveries (10). They were randomized to receive two tablets of misoprostol (total dose 400 micrograms, dissolved in saline 5 ml and given as a micro-enema) or oxytocin (10 IU intramuscularly), with a double-dummy technique. There were no significant differences between the groups in mean hemoglobin and hematocrit, volume of blood loss, or duration of third-stage labor. Shivering (38 versus 15%) and an increased mean temperature were significantly more common among those who received misoprostol.

The second trial included 60 women who were randomized to oral misoprostol (400 micrograms) or intravenous oxytocin (10 IU) during cesarean section (11). Estimated blood loss was 545 ml (95% CI = 476, 614) in those given misoprostol and 533 ml (95% CI = 427, 639) in those given oxytocin. The hemoglobin concentration and hematocrit were similar in the two groups.

The third trial included 2058 patients (mean age 28 years, 53% nulliparous) with a singleton pregnancy, a low risk of postpartum hemorrhage, and vaginal delivery (12). They were randomly assigned to either intramuscular Syntometrine 1 ml (oxytocin 5 units plus ergometrine 0.5 mg) or oral misoprostol 600 micrograms. There were no significant differences between the two groups in mean blood loss, the incidence of postpartum hemorrhage, or the fall in hemoglobin concentration. The need for oxytocic medication was higher with misoprostol, but manual removal of the placenta was required more often. Shivering (30 versus 9.9%) and transient pyrexia (temperature over 38°C, 8.5 versus 1.3%) were more common with misoprostol.

© 2006 Elsevier B.V. All rights reserved.

Misoprostol could be an alternative to oxytocic drugs in reducing postpartum blood loss.

Placebo-controlled studies

Oral misoprostol 400 micrograms has been compared with placebo in the routine management of the third-stage of labor. In this study shivering was a specific adverse effect of oral misoprostol in the puerperium (19 versus 5%; RR = 3.69; 95% CI = 2.05, 6.64) (13).

A systematic review of the use of misoprostol for induction of labor has been published (14). The meta-analysis included all randomized clinical trials registered in the Cochrane Pregnancy and Childbirth Group. Vaginal misoprostol was associated with increased uterine hyperstimulation, both without fetal heart changes (RR = 1.67; CI = 1.30, 2.14) and with associated fetal heart rate changes (RR = 1.45; CI = 1.04, 2.04). There was also an increase in meconium-stained amniotic fluid (RR = 1.38; CI = 1.06, 1.79).

General adverse effects

The most common adverse effects during misoprostol use in labor include pyrexia (temperature over 38°C), shivering, postpartum hemorrhage, nausea, vomiting, diarrhea, hot flushes, headache, and vertigo. When it is used in the first or second trimesters for pregnancy termination, its adverse effects include fever, chills, vomiting, diarrhea, moderate and severe abdominal pain, profuse bleeding, dysfunctional uterine bleeding, dizziness, and headache.

Organs and Systems

Body temperature

Severe hyperthermia has been reported after misoprostol (15).

- A 31-year primigravida had a missed abortion after 12 weeks of amenorrhea and was admitted for evacuation of the uterus. Preoperative cervical priming was done with intravaginal misoprostol 600 micrograms. Within 30 minutes of insertion of the misoprostol tablets she had chills and rigors, felt unwell, and started to have lower abdominal cramps. She was febrile (39.5°C) and her pulse rate was 90/minute. The undissolved misoprostol tablets were removed digitally and her vagina was douched. Ice sponging lowered her temperature. A rectal suppository of diclofenac 25 mg and an intramuscular injection of promethazine 25 mg were given. Her temperature remained high at 38°C for 3 hours and normalized after 5 hours.

Second-Generation Effects

Pregnancy

Cervical laceration associated with misoprostol has been reported in a 33-year-old woman who received four doses of vaginal misoprostol (total dose 100 micrograms) for labor induction. Uterine rupture has occurred during induction of labor with misoprostol, usually in women who have had a previous cesarean section (16,17). Uterine dehiscence occurred in one and uterine rupture in three of 48 women with prior cesarean sections treated with intravaginal misoprostol 50 micrograms for cervical ripening (18). In comparison, uterine rupture occurred in one of 89 women who had an oxytocin infusion and none of 24 patients who received intravaginal alprostadil.

- Transvaginal misoprostol for induction of labor caused uterine rupture in a 26-year-old woman with a previous low transverse cesarean delivery (19).
- In two cases, disruption of prior uterine incisions occurred after misoprostol (20).
- In two cases, uterine rupture occurred after inappropriate use (21). In one case the dose of 200 micrograms was too high. In the other case oxytocin was started 5 hours after the second misoprostol tablet, while the usual recommendation is to wait at least 12 hours. One patient had also had a previous dilatation and curettage for spontaneous abortion, which is a predisposing factor for uterine rupture in labor.

Seven pregnant women who had uterine rupture after intravaginal administration of misoprostol for induction of labor (SEDA-23, 436) had all undergone cesarean section in previous pregnancies (22).

- The first four women (aged 26–36 years) underwent induction of labor at 37–40 weeks of gestation. They received 1–2 doses of intravaginal misoprostol 25 micrograms; three of the women then received intravenous oxytocin. Soon after the first woman began pushing, there was fetal heart rate deceleration and the fetal head could not be palpated in the vagina. Emergency laparotomy showed that the baby was free in the abdominal cavity and the woman had a bladder defect. The bladder and uterine defects were repaired successfully and the mother received a transfusion of packed erythrocytes.
- In the second case, there was sudden fetal bradycardia. Laparotomy showed a large clot overlying the previous uterine incision. Dissection through the hematoma showed complete separation of the uterine incision. After delivery, the uterine rupture site and a cervical laceration were successfully repaired.
- The third woman had sudden-onset severe abdominal pain and fetal decelerations were detected. Emergency laparotomy showed complete separation of the uterine scar; both the fetus and the placenta were free in the abdominal cavity. The uterine defect was repaired and the woman recovered. However, the baby subsequently died.
- The fourth woman began to have extreme pain and fetal bradycardia then occurred. Uterine rupture from the previous incision was found at emergency cesarean section, with the baby's arm extending through the lacerated area. The uterine defect was successfully repaired.
- Uterine rupture also occurred in another three women (ages not stated) after misoprostol (dosages not stated) was used to induce labor. One underwent cesarean section because labor did not progress. During the procedure, the fetal hand and head were outside the uterine cavity (maternal and fetal outcome not stated).

© 2006 Elsevier B.V. All rights reserved.

- The other two women underwent emergency cesarean deliveries because of fetal bradycardia. Both had complete uterine wall separation; one had a stellate laceration involving the previous incision, and the other had a hematoma associated with the scar disruption. Outcomes were good in both cases.

In view of these cases, the authors recommended that there be a moratorium on the use of misoprostol in the setting of a scarred uterus until the relative risks have been thoroughly investigated in appropriately controlled trials.

Uterine rupture has also been associated with misoprostol (200 micrograms vaginally) during second trimester termination of pregnancy. Occasionally, uterine rupture can occur in women who have not had a previous cesarean section, as happened in two women, one of whom had a normal delivery and the other curettage after abortion (23).

Misoprostol is not approved by the FDA for any obstetric indication. In 2000, the manufacturers GD Searle distributed a "Dear Health Care Provider" letter in the USA, emphasizing the fact that misoprostol, by any route of administration, is not intended for the induction of labor or as a cervical ripening agent before termination of pregnancy (24). Searle has become aware of instances in which misoprostol was used for such purposes, in spite of its being specifically contraindicated for use during pregnancy. The following serious adverse events have been reported after such off-label use: maternal or fetal death; uterine hyperstimulation; uterine rupture or perforation requiring surgical repair, hysterectomy, or salpingo-oophorectomy; amniotic fluid embolism; severe vaginal bleeding; retained placenta; shock; fetal bradycardia; and pelvic pain. Searle does not intend to study or support the use of misoprostol for pregnancy termination or labor induction. The company is therefore unable to provide complete risk information for misoprostol when it is used for such purposes. Furthermore, the effects of misoprostol on the later growth, development, and functional maturation of children who are exposed to it during induction of labor have not been established.

Teratogenicity

The common phenotypical effects of exposure of the fetus to misoprostol in utero have been defined in 42 infants who were exposed to misoprostol during the first 3 months of gestation, and then born with congenital abnormalities (25). Equinovarus with cranial nerve defects occurred in 17 infants. Ten children had equinovarus as part of more extensive arthrogryposis. The most distinctive phenotypes were arthrogryposis confined to the legs (five cases) and terminal transverse limb defects (nine cases), with or without Möbius' syndrome. The most common dose of misoprostol was 800 (range 200–16 000) micrograms. Deformities attributed to vascular disruption were found in these children. The authors suggested that the uterine contractions induced by misoprostol cause vascular disruption in the fetus, including brainstem ischemia. Information on the effects of taking misoprostol during pregnancy should be made more widely available, to dissuade women from misusing the drug. Additional information on the risk associated with continuing a pregnancy to term after a failure of mifepristone and prostaglandin has been provided (26).

Data from Brazil, where misoprostol has been used orally and vaginally as an abortifacient, have suggested a relation between the use of misoprostol by women in an unsuccessful attempt to terminate pregnancy and Möbius' syndrome (congenital facial paralysis) in their infants (27). The frequencies of misoprostol use during the first trimester by mothers of infants in whom Möbius' syndrome was diagnosed and mothers of infants with neural-tube defects have been compared. There were 96 infants with Möbius' syndrome and 96 with neural-tube defects. The mean age at the time of the diagnosis of Möbius' syndrome was 16 (range 0.5–78) months and the diagnosis of neural-tube defects was made within 1 week of birth in most cases. Of the mothers of the infants with Möbius' syndrome, 47 had used misoprostol in the first trimester of pregnancy, compared with three of the mothers of the infants with neural-tube defects (OR = 30; 95% CI = 12, 76). Of the mothers of the infants with Möbius' syndrome, 20 had taken misoprostol only orally (OR = 39; CI = 9.5, 159), 20 had taken misoprostol both orally and vaginally, three had taken it vaginally, and four did not report how they had taken it. The authors concluded that attempted abortion with misoprostol is associated with an increased risk of Möbius' syndrome in infants.

In another case-control study in Brazil, 93 cases of prenatal exposure to misoprostol and 279 controls were recruited (28). Vascular disruption defects (transverse terminal limb reductions, Möbius and/or Poland sequences, hypoglossia–hypodactyly sequence, arthrogryposis, intestinal atresia, hemifacial microsomia, microtia, and porencephalic cyst) were identified in 32 exposed infants compared with only 12 controls.

In another case-control study in Brazil, congenital anomalies were compared in 34 misoprostol-exposed children and 4639 unexposed controls (29). Misoprostol exposure significantly increased the risk of arthrogryposis (OR = 8.5; 95% CI = 2, 37), hydrocephalus (OR = 4.2; CI = 1.5, 12), terminal transverse limb reduction (OR = 12; CI = 3.5, 41), and limb constriction ring or skin scars (OR = 40; CI = 11, 153). There were 13 different defects not previously described in the misoprostol-exposed cases, but only holoprosencephaly and bladder exstrophy significantly exceeded the expected number.

Mothers who used misoprostol during pregnancy as an abortifacient had an increased risk of having a baby with congenital anomalies (OR = 2.4; 95% CI = 1.0, 6.2), as reported in a case-control study in Fortaleza, Brazil (30). Multiple malformations have been described associated with the use of misoprostol (31).

- A 23-year-old woman took oral misoprostol 600 micrograms/day twice when she was 7 weeks pregnant to induce an abortion. At 12 weeks she developed a *Varicella* infection. At 15 weeks, ultrasound showed a fetus of 14.5 weeks size with several abnormalities. After amniocentesis at 17 weeks, an elective abortion was performed. The fetus had amputation deformities at the proximal interphalangeal joints of four fingers, with

© 2006 Elsevier B.V. All rights reserved.

distal fusion of the proximal finger stumps by thin strands of tissue; the index finger was normal. The left leg had an amputation deformity at the mid-tibial/fibular level. There was an omphalocele. Histological examination of the placenta showed an absence of amnion on the chorionic surface, with reactive changes in the superficial chorionic stroma and "vernix granulomas" on the chorionic surface. These findings are diagnostic of early amnion rupture. There were no features of *Varicella* embryopathy.

Möbius' syndrome in association with congenital central alveolar hypoventilation has been described in Brazil (32).

Misoprostol-induced arthrogryposis has been reported in 15 Brazilian patients (33).

Mitomycin

See also Cytostatic and immunosuppressant drugs

General Information

Mitomycin is an alkylating agent that is used intravenously to treat upper gastrointestinal and breast cancers and by direct instillation to treat superficial bladder tumors. Its main adverse effects are thrombocytopenia and leukopenia. Rare but severe adverse effects are hemolytic–uremic syndrome, pneumonitis, and cardiac failure.

Organs and Systems

Respiratory

Biopsy-proven mitomycin pneumonitis occurred in five of 44 patients who were given mitomycin in conjunction with low-dose doxorubicin 20 mg/week (1). The picture was of pulmonary infiltrates clinically and radiologically, progressive dyspnea, and hypoxia, and improvement with glucocorticoids. The mean total dose of mitomycin that had been given in the five patients was 89 mg. Mitomycin-induced interstitial pneumonitis occurs in 2–38% of cases (2,3) and at cumulative doses of 20 mg/m^2 or greater, although doses up to 30 mg/m^2 have been used safely. It is characteristically of slow-onset (3).

A fatal case of mitomycin C-induced pneumonitis has been reported in a radiotherapy/chemotherapy trial in 43 patients (4). The dose was 8 mg/m^2 on days 1 and 29, radiotherapy and vindesine being given on the intervening days.

Urinary tract

Hemolytic–uremic syndrome has often been described in patients treated with mitomycin (5–7). Up to 1990 the United States National Cancer Registry received 85 reports of cancer-associated hemolytic–uremic syndrome and 84 had received a cumulative dose of 60 mg mitomycin or more as part of their treatment (8).

Hemolytic–uremic syndrome presents as a Coombs-negative microangiopathic hemolytic anemia, thrombocytopenia, and renal insufficiency, and the outcome is often fatal. The underlying pathology is thought to be vascular endothelial damage. It occurs 4–7 months after the start of chemotherapy. Blood transfusion can cause clinical deterioration in those affected (9). Histology of the kidney in the hemolytic–uremic syndrome caused by mitomycin shows mesangial proliferative glomerulonephritis with partial thickening and/or splitting of the basement membrane. On electron microscopy there is accumulation of non-homogeneous material in the subendothelial spaces. Neither immunoglobulin nor complement deposition is found (10). Treatment with hemodialysis and immunosuppressive drugs is not always successful. Plasmapheresis is commonly used (11). Prophylactic glucocorticoids can reduce the severity and prevent hemolytic–uremic syndrome in patients receiving mitomycin (12). Erythropoietin is also reportedly beneficial (13).

Mitomycin when administered intravesically causes cystitis of variable severity, which can lead to mucosal ulceration in the worst cases. However, there has also been a report of bladder fibrosis and loss of function in a 74-year-old man who had received 20 mg/week for 8 weeks (14).

Ten cases of bladder wall calcification have been reported after intravesicular administration of mitomycin. These lesions can resemble tumor recurrence in the bladder, and biopsy is advocated to distinguish between the two (15).

Skin

There have been several reports of erythematous blistering skin eruption of the palms and soles affecting patients treated with intravesical mitomycin. This has been attributed to contact dermatitis, but more widespread skin involvement and an association with eosinophilic interstitial cystitis suggest that it may be a more generalized allergic reaction (16–20).

Local extravasation of mitomycin causes inflammation and ulceration, starting within 7–10 days and lasting several weeks. In four cases the onset of tissue necrosis was delayed several weeks or months after exposure (21,22). In one case, ulceration seemed to have been precipitated by drinking ethanol, and in another by exposure to the sun.

Three cases of allergic dermatitis have been described after intravesical mitomycin (23). A type IV hypersensitivity reaction was demonstrated on patch-testing. Six cases of purpuric allergic drug eruption from intravesicular mitomycin have been reported (24).

Mitotane

See also Cytostatic and immunosuppressant drugs

General Information

Mitotane is an inhibitor of intramitochondrial synthesis of pregnenolone and cortisol, used to produce a chemical adrenalectomy in the treatment of adrenal carcinoma and Cushing's disease and syndrome. Its unwanted effects include increased transaminase and alkaline phosphatase activities, reduced leukocyte, platelet and erythrocyte counts, and myasthenia (1).

Organs and Systems

Sensory systems

A pigmentary retinopathy with macular edema and abnormal electroretinography has been attributed to mitotane (2).

Endocrine

Because it inhibits glucocorticoid synthesis, mitotane can cause acute hypoadrenalism (3).

Metabolism

Mitotane 1–5 g daily for 4 weeks was associated with the development of hypercholesterolemia in three cases; the effect had not reverted to normal 3 months later (4).

Hematologic

Pancytopenia has been attributed to mitotane (5).

In six of seven patients with adrenocortical cancer taking mitotane for 1–2 weeks the bleeding time became prolonged; four had platelet aggregation responses compatible with an aspirin-like defect (6).

Liver

All of 10 patients taking mitotane for Cushing's syndrome had rises in either gamma-glutamyl transpeptidase or alanine transaminase, with a maximum increase six times basal value (7). The only variable that correlated with hepatic increase was the body mass index. In contrast, the severity of the disease, alcohol intake, and other biological characteristics did not correlate with transaminase rises.

In six patients with Cushing's syndrome, including one pregnant woman, who took mitotane 0.5 g/week, there was adrenocortical insufficiency requiring hormone replacement in one patient. The only other significant adverse effect was a reversible increase in gamma-glutamyl transpeptidase activity (8).

Mivacurium chloride

See also Neuromuscular blocking drugs

General Information

Mivacurium chloride is a non-depolarizing muscle relaxant, a benzylisoquinolinium diester compound with a duration of approximately twice that of suxamethonium. In vitro (1), it is metabolized to a significant extent by plasma cholinesterase, and minimally by acetylcholinesterase. The rate of metabolism in vitro is directly related to plasma cholinesterase activity. In pooled human plasma the rate of hydrolysis of mivacurium was 70% that of suxamethonium. Its half-life is 5–10 minutes compared with 2–5 minutes for suxamethonium. The in vitro hydrolysis of mivacurium by purified human plasma cholinesterase occurs at 88% of the rate for suxamethonium (2). There was a poor correlation between the duration of action of bolus doses of mivacurium and the plasma cholinesterase activity in individual patients (2), a finding that has also been reported by others (3). However, the average infusion rate to maintain around 95% blockade in individual patients correlated significantly with the patients' plasma cholinesterase activities (4). While metabolites have been detected in both urine and bile, mivacurium seems to depend principally on ester hydrolysis for its plasma clearance, so that reduced activity of plasma cholinesterase is likely to result in a prolonged duration of action.

Organs and Systems

Cardiovascular

Benzylisoquinolinium compounds have a tendency to evoke histamine release, the main source of the cardiovascular changes seen with mivacurium. These have been reported as minimal up to and including twice the ED_{95} dose in several studies (3,5–7). At higher dosages (0.2 mg/kg and over) transient hypotension, often associated with facial flushing and lasting only some 2–5 minutes, which correlated significantly with increases in plasma histamine, has been described (5). Reducing the speed of injection to 30 or 60 seconds reduced the degree of hypotension to insignificant levels. Similar findings in 50% of patients given doses of 0.2 and 0.25 mg/kg have been described elsewhere (3). In yet another series, mean arterial pressure fell by more than 20% (24–61%) in seven of 15 patients given rapid bolus injections of 0.2–0.25 mg/kg (6). Pretreatment with oral antihistamines has been suggested as an additional option to reduce histamine-related adverse effects after administration of high-dose mivacurium (8).

In patients scheduled for coronary artery bypass grafting or valve replacement (7), significant hypotension was seen in two patients (out of 27 given higher doses), even when mivacurium was injected slowly (over 60 seconds); the mean arterial pressure fell by 24 and 50% after the injection of 0.2 and 0.25 mg/kg respectively. Beta-blockers, calcium channel blockers, and nitrates were not discontinued preoperatively in this study. The authors concluded that "doses larger than 0.15 mg/kg are probably unnecessary and may contribute to hemodynamic instability at least in cardiac patients."

Susceptibility Factors

Genetic factors

Prolonged neuromuscular blockade, up to several hours duration, has been reported in patients with abnormal plasma cholinesterase activity, who were either homozygous for the atypical gene or the silent gene or heterozygous for the atypical and the silent genes (9–12). This is a particular problem if mivacurium is used for ambulatory anesthesia, after which the patient is expected to return home, since facilities for postoperative ventilatory support may not be available. As patients with atypical cholinesterase are usually not detected by preoperative screening, it has been suggested that the patient's response to mivacurium should be tested by using a very low initial dose. However, complete paralysis for nearly 5 hours has recently been observed after a test dose of mivacurium 14 μg/kg in a patient with atypical serum cholinesterase as diagnosed by standard phenotyping and DNA sequencing (13). The authors concluded that neuromuscular monitoring and facilities for long-term ventilation should always be available when mivacurium is used.

Renal disease

The duration of mivacurium-induced neuromuscular blockade was prolonged in patients with kidney disease (SEDA-17, 25) (14,15). These results are probably due to reduced plasma cholinesterase activity.

Hepatic disease

The duration of mivacurium-induced neuromuscular blockade was prolonged in patients with liver disease (SEDA-17, 25) (16). These results are probably due to reduced plasma cholinesterase activity.

Drug–Drug Interactions

Bambuterol

Bambuterol has been reported to alter the metabolism of mivacurium (17). Bambuterol has a dose-dependent inhibitory effect on plasma cholinesterase activity and prolongs the effects of suxamethonium. Bambuterol 10 mg was given to 28 patients 2 hours before an elective operation requiring general anesthesia. The patients given bambuterol had a 67–97% fall in plasma cholinesterase activity, leading to reduced clearance of mivacurium. This resulted in a shorter onset and a 3- to 4-fold prolongation of action of the neuromuscular blockade produced by standard doses of mivacurium.

General anesthetics

Inhalation anesthetics potentiate the neuromuscular blocking action of mivacurium, as with other nondepolarizing relaxants. With isoflurane (3) and enflurane (18) the ED_{95} is reduced by about 25% and the duration of action is somewhat prolonged, although the extent of this is not clear. Halothane has much less of an effect (19,20).

Mizolastine

See also Antihistamines

General Information

Mizolastine is a second-generation antihistamine, a benzimidazole derivative (SEDA-19, 175) (SEDA-20, 163) (SEDA-21, 176). The effectiveness of mizolastine has been demonstrated by the inhibition of histamine-induced weal and flare and in clinical trials with patients with rhinitis or urticaria (1).

© 2006 Elsevier B.V. All rights reserved.

Organs and Systems

Cardiovascular

Erythromycin and ketoconazole both increase mizolastine plasma concentrations and patients with hepatic or renal impairment have altered pharmacokinetics of mizolastine, indicating the need for caution in its use in such individuals (2).

Nervous system

Initial studies with mizolastine strongly suggested that it was free of significant sedative effects in the lower range of clinically useful doses, but a dose of 40 mg was sufficient to produce general behavioral impairment. Subsequently, investigations using tests simulating driving performance showed that even a dose of 10 mg was sufficient to impair performance in divided attention tasks 6 hours after intake and to reduce tracking speed significantly; although direct examination of driving performance showed no changes, these specific measures suggest that caution is justified in using the drug when driving vehicles, particularly because individual sensitivity to such effects of antihistamines varies.

Psychological, psychiatric

Mizolastine in doses up to 10 mg does not differ from placebo with regard to cognitive function and psychomotor performance, but in higher doses, there is dose-dependent impairment (SEDA-19, 175).

Susceptibility Factors

Renal disease

Patients with renal impairment have altered pharmacokinetics of mizolastine, indicating the need for caution in its use in such individuals (2).

Other features of the patient

Patients with hepatic impairment have altered pharmacokinetics of mizolastine, indicating the need for caution in its use in such individuals (2).

Drug–Drug Interactions

Alcohol

Mizolastine did not potentiate the effects of ethanol on psychomotor and driving performance (SEDA-20, 163), but did affect tracking speed and performance in divided attention tests.

Erythromycin

Erythromycin increases mizolastine plasma concentrations (2).

Ketoconazole

Ketoconazole increases mizolastine plasma concentrations (2).

Mizoribine

General Information

Mizoribine is an immunosuppressive agent that inhibits de novo purine biosynthesis and affects both humoral and cell-mediated immunity. It has been used as an alternative to azathioprine in transplant patients, with a reduced incidence of leukopenia and hepatotoxicity.

Mizoribine is mostly well tolerated when it is used to treat different renal diseases, such as vasculitis, lupus nephritis, or nephritic syndrome (1–3). However, hemorrhagic enteritis and erosive changes in the intestinal mucosa have been found in dogs, and similar adverse effects have been reported in humans (4).

Organs and Systems

Endocrine

There has been a single case report of inappropriate secretion of antidiuretic hormone (SIADH) attributed to mizoribine (5).

A 74-year-old man with rheumatoid arthritis developed nausea and headache 1.5 months after starting to take mizoribine. His serum sodium concentration fell to 118 mmol/l, but his urinary sodium excretion was normal and there was no hypotension or hemoconcentration. His serum antidiuretic hormone concentration was raised at 0.59 pg/ml in spite of a reduced serum osmolality to 254 mosm/kg. He had no organic disease likely to cause SIADH. Despite infusion of hypertonic saline, his serum sodium concentration did not return to normal. Shortly after mizoribine withdrawal, his serum sodium increased from 128 to 139 mmol/l and his plasma osmolality from 265 to 287 mosm/kg.

Additional predisposing factors in this case were the patient's age and difficulty in micturition because of benign prostatic hyperplasia.

Metabolism

In a double-blind, placebo-controlled, multicenter study of mizoribine in 197 children aged 2–19 years with frequently relapsing nephrotic syndrome, transient

© 2006 Elsevier B.V. All rights reserved.

hyperuricemia was the most common adverse event, occurring in 16% (6).

Moclobemide

See also Monoamine oxidase inhibitors

General Information

Moclobemide was the first selective inhibitor of monoamine oxidase (MAO) type A to become commercially available. It binds reversibly to the enzyme, considerably shortening the duration of its effect. Both of these characteristics reduce the risk of hypertensive crisis (1,2).

The adverse effects of moclobemide have been well reported in several studies, mainly comparisons of moclobemide with standard antidepressants. The consensus has been that moclobemide produces fewer anticholinergic effects and less orthostatic hypotension and dizziness than clomipramine or imipramine. The main problems reported early on were insomnia, agitation, and paresthesia (3–9). The most common adverse effects in controlled trials have been insomnia and nausea (SEDA-18, 15).

In a multicenter comparison of moclobemide, amitriptyline, and placebo, gastrointestinal discomfort, headache, and dizziness occurred in over 20% of moclobemide-treated patients; insomnia was also common (10). In healthy volunteers there were no effects of moclobemide on psychomotor performance. Acute confusion and agitation was reported in one patient who dropped out of a clinical trial owing to this adverse effect (SEDA-16, 7). Hypomania was attributed to moclobemide in two cases (SEDA-17, 16). Aggressive behavior and mild manic symptoms were described in severely depressed patients, refractory to other treatments, who took moclobemide (SEDA-18, 15).

In a controlled multicenter study of 115 in-patients with relatively severe depression, moclobemide was better tolerated but had a weaker therapeutic effect than clomipramine. Nine of the patients taking moclobemide withdrew owing to worsening of depression and suicidality, although it is possible that the dosage of moclobemide (400 mg/day) was inadequate (SEDA-18, 15).

Organs and Systems

Cardiovascular

There have been two reports of single cases of a rise in blood pressure after moclobemide: in one there was a 40 mmHg increase in systolic pressure after one dose only (8), while the other report referred only to "episodes of hypertension" without further comment (4). Interactions were not suggested in either case.

In a prospective drug utilization study in 13 741 patients who received the reversible type A MAO inhibitor moclobemide in a variety of settings, including general practice, psychiatric out-patients, and psychiatric in-patients, there were few episodes of hypertension (0.11%; 95% CI = 0.06, 0.18%) or hypotension (0.04%; 95% CI = 0.02, 0.10%) and episodes were mostly associated with underlying cardiovascular disease (11). These findings suggest that moclobemide in usual therapeutic doses carries a low risk of producing significant changes in blood pressure relative to conventional MAO inhibitors.

Endocrine

A number of antidepressant drugs, particularly SSRIs, can increase plasma prolactin concentrations, although galactorrhea is uncommon. In a prescription event monitoring survey of about 65 000 patients, compared with SSRIs, moclobemide was associated with a relative risk of galactorrhea of 6.7 (95% CI = 2.7, 15) (12). However, this was substantially less than the risk associated with the dopamine receptor antagonist risperidone (relative risk compared with SSRIs 32; 95% CI = 14, 70). Nevertheless, the data suggest that moclobemide may be more likely to cause galactorrhea than other antidepressant drugs.

Liver

Hepatotoxicity has been associated with moclobemide, including fatal intrahepatic cholestasis in an 85-year-old

© 2006 Elsevier B.V. All rights reserved.

woman 7 days after switching to moclobemide from fluoxetine (13).

Sexual function

Most conventional antidepressants lower sexual desire and performance. However, the reversible type A selective MAO inhibitor moclobemide produced intense pathological sexual desire in three men with organic brain disease (two with strokes and one with idiopathic Parkinson's disease) (14). In one man, the hypersexuality was associated with features of pathological jealousy in a paranoid state, but in the other two increased sexuality was an isolated symptom. One of these patients, who had been impotent after the stroke, resorted to telephone sex services, a most uncharacteristic behavior for him. In all cases, the hypersexuality remitted when moclobemide was withdrawn. There have been two previous case reports of moclobemide-induced hypersexuality in women without organic brain disease. This must be a rare adverse effect, but it is possible that in the cases reported here the organic brain disease may have contributed.

There are many other ways in which SSRIs can interfere with sexual function, for example by causing loss of sexual interest and erectile difficulties. In an open, prospective study of 1000 Spanish patients taking a variety of antidepressants, there was an overall incidence of sexual dysfunction of 59% (15). The highest rates, 60–70%, were found with SSRIs (including fluvoxamine) and venlafaxine. The lowest rates were found with mirtazepine (24%), nefazodone (8%), and moclobemide (4%). Spontaneous resolution of this adverse effect was uncommon – 80% of subjects had no improvement in sexual function over 6 months of treatment.

Second-Generation Effects

Lactation

Moclobemide was measured in the milk and plasma of six nursing mothers after single oral doses of moclobemide 300 mg, 3–5 days after delivery (16). The milk plasma ratio was 0.72 and the estimated dose of moclobemide to the infant was at most 1.2% of the weight-adjusted maternal dose.

Drug Administration

Drug overdose

Overdoses of moclobemide alone have been considered less toxic than overdoses of tricyclic antidepressants. Intoxication with moclobemide (0.95–2 g) produced symptoms of drowsiness, disorientation, and hyporeflexia (17,18). Fatal moclobemide overdose when the compound is taken alone is extremely rare (19).

Drug–Drug Interactions

Alprazolam

A 44-year-old man developed the serotonin syndrome after taking moclobemide and alprazolam for 1 year (20). The symptoms developed after 4 days of extreme heat, which was thought to have contributed.

Citalopram and clomipramine

Five fatal cases of serotonin syndrome after combined overdoses of moclobemide with citalopram and moclobemide with clomipramine have been reported (SEDA-18, 16). Several cases of this syndrome have been reported in patients taking moclobemide with drugs that potentiate serotonin function (21–28).

Co-beneldopa

In healthy subjects given co-beneldopa and moclobemide, no hypertension was noted, but the combination was poorly tolerated, headache and insomnia commonly being reported (SEDA-18, 16).

Dextromethorphan

Four healthy volunteers taking moclobemide (600 mg/day for 9 days) had reduced clearance of dextromethorphan, a marker of hepatic CYP2D6 activity (29). These findings suggest that at the higher end of its therapeutic dosage range, moclobemide inhibits the metabolism of drugs that are substrates for CYP2D6, for example antipsychotic drugs and tricyclic antidepressants (SEDA-14, 22).

Indirect sympathomimetics

Moclobemide increased the pressor effect of ephedrine in healthy volunteers, who also had more adverse effects including light-headedness and palpitation (SEDA-18, 16). Thus, moclobemide can potentiate the effect of indirect sympathomimetics; such combinations should be used with caution.

Rizatriptan

Rizatriptan is a 5-$HT_{1B/1D}$ receptor agonist that is metabolized by MAO type A. In 12 young healthy volunteers, moclobemide (300 mg/day for 4 days) potentiated the hypertensive effect of acute rizatriptan (10 mg orally) (30). This was associated with a significant increase in the AUC of rizatriptan and its *N*-monodesmethyl metabolite (by 2.2 and 5.3 times respectively). The authors suggested that moclobemide and rizatriptan should not be given together.

Selegiline

Patients taking moclobemide can usually eat a normal diet, since there is no significant potentiation of tyramine. However, the combination in high doses (20 mg or more) of selegiline and moclobemide potentiates the pressor effects of tyramine (presumably because of simultaneous inhibition of both MAO type A and MAO type B), and a tyramine-free diet is needed if the two drugs are used together (SEDA-20, 6).

© 2006 Elsevier B.V. All rights reserved.

SSRIs

The combination of conventional MAO inhibitors with serotonin-potentiating agents, such as SSRIs, is contraindicated, because of the risk of the serotonin syndrome. Moclobemide may be less likely to cause this interaction, although both case reports and clinical series have suggested that some patients have suffered significant adverse effects consistent with serotonin toxicity (SEDA-20, 6) (SEDA-21, 10). After steady-state therapy with the SSRI fluoxetine (20–40 mg/day for 23 days), 12 subjects took fluoxetine plus moclobemide (600 mg/day) and 6 took fluoxetine and placebo (31). There was no difference in the rates of adverse effects between the two groups and no evidence of serotonin toxicity, although fluoxetine inhibited the metabolism of moclobemide. The authors suggested that patients can be safely switched from fluoxetine to moclobemide without the need for the currently advised 5-week washout (which is necessary to allow the long-acting fluoxetine metabolite, norfluoxetine, to be eliminated). However, case reports have suggested that some patients can develop serotonin toxicity when moclobemide is combined with SSRIs (23,25,28) or clomipramine (26), so great caution is still needed in clinical practice. Overdoses of moclobemide and SSRIs can cause serious and sometimes fatal serotonin toxicity (SEDA-18, 16).

Tyramine

Moclobemide in conventional doses (300–600 mg/day) does not significantly potentiate the pressor effects of oral tyramine, and special dietary restrictions are therefore not usually necessary. However, higher doses of moclobemide are sometimes used to treat patients with resistant depression. Moclobemide 900 mg/day and 1200 mg/day have been compared with placebo in 12 healthy volunteers (32). Neither dose of moclobemide significantly potentiated the pressor effect of 50 mg of tyramine, which has been estimated to be the upper limit of dietary tyramine content, even of large meals containing substantial amounts of cheese. However, one subject taking moclobemide 1200 mg/day had an increase in systolic blood pressure of over 30 mmHg. Individuals have rather different sensitivities to the pressor effects of oral tyramine challenge, and the number studied in this series was small. Accordingly, clinical extrapolation might not be straightforward. Patients taking conventional doses of moclobemide are sometimes advised to restrict their intake of cheese or other tyramine-containing foods, and this advice is clearly prudent if subjects take higher doses.

Venlafaxine

Interactions of moclobemide with venlafaxine, a potent serotonin re-uptake inhibitor, have been reported (25,33).

- A 34-year-old man took 2.625 g of venlafaxine (therapeutic dose 75–375 mg/day) and 3 g of moclobemide, plus an unknown amount of alcohol 1 hour before being admitted to hospital. Within 20 minutes of arrival his conscious level deteriorated and he had increased muscle tone, with clonus in all limbs. He was treated with intubation, paralysis, and ventilation, and sedated with midazolam and morphine. He regained consciousness after 2 days.

This case report confirms the serious consequences of combined overdosage of moclobemide with drugs that potentiate brain serotonin function (see also the monograph on SSRIs).

Modafinil

General Information

Modafinil is a benzhydrylsulfinylacetamide wake-promoting agent for oral administration (1). It selectively targets neuronal pathways in the sleep/wake centers of the brain. It is well absorbed and its half-life is about 12–15 hours, which largely reflects the half-life of its levorotatory enantiomer. It is metabolized, mainly in the liver, by amide hydrolysis with lesser contributions from CYP-mediated oxidation, and. less than 10% of the dose is excreted as unchanged drug.

In controlled clinical trials, modafinil reduced excessive daytime sleepiness in patients with narcolepsy (2).

In an open, randomized, crossover study in healthy men, concomitant administration of single oral doses of modafinil (200 mg) and dexamfetamine (10 mg), each given separately, produced a slight increase in blood pressure and the cardiovascular effects were more pronounced after concomitant administration (3). These changes were considered not to be clinically relevant and would not necessarily preclude short-term administration of the two drugs together. The most frequent adverse events with modafinil or dexamfetamine were headache, dizziness, insomnia, and dry mouth.

Modafinil was effective in narcolepsy in a 9-week, randomized, placebo-controlled, double-blind, 21-center trial in 271 patients (4). During treatment withdrawal, the patients did not have symptoms associated with amphetamine withdrawal. Nausea and rhinitis were significantly more common in the treatment group; in contrast, in a previous multicenter study in the USA there was a higher incidence of headache (5). Modafinil was also effective in the treatment of somnolence due to pramipexole in a patient with Parkinson's disease (6).

Once-daily modafinil for an average of 4.6 weeks has been evaluated in an open trial in 11 children aged 5–15 years with ADHD (7). This pilot study, with non-blinded ratings, a small number of subjects, and a short duration of treatment, showed significant improvement. Adverse events were responsible for drug withdrawal in one child. The most common adverse event was delayed onset of sleep or sleep disruption, which, in two of three cases, responded to a reduction in dosage. No patient taking modafinil lost weight or had a reduced appetite. A larger-scale, double-blind, placebo-controlled study will be needed to further substantiate the efficacy and safety of modafinil.

In a 9-week, single-blind, placebo-controlled pilot study in 72 patients with multiple sclerosis who took modafinil 200 mg/day for 2 weeks, there was significant improvement in fatigue compared with placebo run-in treatment (8). The most frequent adverse effects were headache, nausea, and anxiety, and these were rated as either mild or moderate.

Long-Term Effects

Drug dependence

The abuse potential of modafinil is very low and differs from that of methylphenidate (9). The data suggest that the subjective effects of modafinil may be similar to those of drugs such as phenylpropanolamine or caffeine, although a direct comparison with these drugs would be required to draw adequate conclusions. Furthermore, modafinil cannot be injected intravenously or smoked, and its once-daily dosing in the management of excessive daytime sleepiness in patients with narcolepsy suggests that it does not carry the same public health or safety concerns for abuse as amphetamines, since drugs that have a long half-life have less of a tendency to produce a "rush" and hence are less likely to be abused. However, the effects of social responses to the availability of

© 2006 Elsevier B.V. All rights reserved.

modafinil can only be determined by post-marketing surveillance.

Drug–Drug Interactions

General

In vitro, modafinil caused reversible inhibition of CYP2C19 in human liver microsomes (1). It also caused a small, but concentration-dependent, induction of CYP1A2, CYP2B6, and CYP3A4 and inhibition of CYP2C9 activity in primary cultures of human hepatocytes. In clinical studies of interactions of modafinil with methylphenidate, dexamfetamine, warfarin, ethinylestradiol, and triazolam, the only substantive interactions were with ethinylestradiol and triazolam, apparently through induction of CYP3A4, primarily in the gastrointestinal tract (1). The results suggested that modafinil can affect the pharmacokinetics of drugs that are metabolized by certain CYP isozymes. Compounds that induce or inhibit CYP activity are unlikely to have major effects on the pharmacokinetics of modafinil.

Clozapine

Clozapine toxicity occurred after modafinil administration to reverse sedation associated with clozapine (10).

- A 42-year-old man with schizophrenia, taking haloperidol, quetiapine, divalproex, gabapentin, benzatropine, and lorazepam, was given clozapine 25 mg at bedtime titrated to 400 mg/day over 13 days. His non-psychotropic medications included levothyroxine, furosemide, potassium, and docusate sodium. All other psychotropic drugs were tapered and withdrawn by day 69. On day 70 the serum clozapine concentration was 761 ng/mL. Because of persistent psychotic symptoms, the dose of clozapine was increased to 450 mg/day on day 77, but this resulted in severe sedation. He was given modafinil 100 mg/day on day 82, titrated to 300 mg/day by day 101; this produced slight improvement in sedation. On day 116 he complained of dizziness, had an unsteady gait, and fell twice. He was afebrile and tachycardic but had a normal blood pressure; his blood oxygen saturation was 86%. His serum clozapine concentration on day 112 was 1400 ng/ml. Clozapine and modafinil were withdrawn. His gait disturbance and hypoxemia resolved. Clozapine 100 mg/day was restarted on day 121 and increased to 300 mg/day by day 122. The clozapine concentration 21 days later was 1236 ng/ml and 5 weeks later 960 ng/ml.

It is possible that inhibition of CYP2C19 by modafinil interfered with clozapine clearance in this case (11). Despite the potential of modafinil for reversing clozapine-associated sedation (12), caution is required when prescribing this drug combination.

Dexamfetamine

The potential for an interaction of modafinil with dexamfetamine, each at steady state, has been investigated in an open, randomized study in 32 healthy subjects (13). All took modafinil orally once daily for 28 days (200 mg on days 1–7 and 400 mg on days 8–28). On days 22–28, half of them also took dexamfetamine 20 mg orally 7 hours after modafinil. The steady-state pharmacokinetics of modafinil and its metabolites, modafinil acid and modafinil sulfone, were unaltered by low-dose dexamfetamine. Adverse events (abdominal pain, headache, and insomnia) were similar in the two groups and mild or moderate in nature. In another open, randomized, crossover study in healthy men, concomitant administration of single oral doses of modafinil (200 mg) and dexamfetamine (10 mg) showed no clinically significant pharmacokinetic interaction (3). Some patients with narcolepsy may require a change from dexamfetamine to modafinil, and arguably such a transition can be made without any washout period.

Mofebutazone

See also Non-steroidal anti-inflammatory drugs

General Information

Adverse reactions to mofebutazone are similar to those of the parent drug, phenylbutazone, and include skin reactions, including epidermal necrolysis and bullous drug eruption (1). Gastrotoxicity, hepatotoxicity, nephrotoxicity, edema, headache, and hematological adverse effects (SED-9, 145) (2) have been described.

Molsidomine

See also Antianginal drugs

General Information

Molsidomine is a vasodilator that acts as a nitric oxide donor and has been used in angina pectoris, heart failure, and after myocardial infarction.

In a multicenter, randomized, double-blind, crossover, placebo-controlled study of the efficacy of two regimens of molsidomine in 90 patients with stable angina, beneficial effects on exercise load did not seem to be reduced by 6 weeks of continuous therapy, suggesting lack of tolerance (1). The most frequently reported adverse effect of molsidomine was headache, as for all other nitric oxide donors.

Monoamine oxidase inhibitors

General Information

All available monoamine oxidase (MAO) inhibitors (excepting moclobemide, toloxatone, brofaromine, and selegiline) act via a "suicide" mechanism, by causing long-lasting, irreversible, competitive inhibition of mitochondrial MAO, which persists until new enzyme is manufactured (1). Most of these drugs also produce a non-specific reduction in the activity of hepatic drug-metabolizing enzymes.

Table 1 lists the MAO inhibitors that are already available or under investigation. These compounds fall into different chemical categories, including compounds that have the following properties: antidepressant (moclobemide), antihypertensive (pargyline), antineoplastic (procarbazine), and antimicrobial (furazolidone).

Antidepressant drugs of various classes (tricyclics, MAO inhibitors, SSRIs) have broad efficacy in generalized anxiety and in panic disorder, but SSRIs are now the treatments of choice (2,3). Selegiline has been used to treat Parkinson's disease. Other drugs that have MAO inhibitory activity, but are not used as such, include debrisoquine, linezolid, and isoniazid.

The monoamine oxidase inhibitors epitomize cyclical fashions in drug use and the impact of adverse effects. They were the first psychotropic drugs for which a clear biochemical action was defined. Early excitement was quickly tempered by reports of liver toxicity with the hydrazine derivatives, leading to synthesis of the cyclopropylamine drug, tranylcypromine, which in turn elicited the food and drug interactions that led to an overall decline in popularity.

Then in the 1980s there was a reappraisal of the benefit-to-harm balance of the MAO inhibitors. This spawned both a search for safer and more selective or rapidly reversible enzyme inhibitors (including moclobemide, toloxatone, and brofaromine), as well as a review and retrial of the older compounds.

The scientific underpinnings of this renaissance have been reviewed (4). Much of the earlier work was conducted using inadequate doses of phenelzine, whose efficacy was later validated using adequate drug concentrations (to produce 85% or more enzyme inhibition) (5). A review of eleven studies conducted in 1963–1982 that compared MAO inhibitors and tricyclic compounds showed that in three studies there was no difference, four favored tricyclic antidepressants, and in three MAO inhibitors were superior (6). The three studies that favored MAO inhibitors were among the four most recently conducted (all since 1979). An article in 1985 entitled "Should the use of MAO be abandoned?" (7) was accompanied by commentaries from six British and US experts in psychopharmacology. The consensus was clearly in favor of continued use, with the recognition that even if a specific responder is difficult to define there are individuals who respond when all other drugs have failed. No clear-cut clinical or metabolic features distinguish such individuals; an earlier claim that the clinical response and susceptibility to adverse effects might be influenced by genetically determined rapid or slow acetylation of phenelzine was not confirmed by a review of seven studies (8).

There have been many studies of the efficacy and toxicity of selective inhibitors of MAO type A (SEDA-16, 7) (SEDA-17, 16) (SEDA-18, 16).

The adverse effects of the MAO inhibitors include hepatocellular damage, similar to that which led to the withdrawal of the earlier hydrazine derivatives, hypotension, often a pronounced adverse effect (possibly due to the accumulation of a pseudotransmitter normally

Table 1 Monoamine oxidase (MAO) inhibitors that have been studied or are currently commercially available for treating depression or for other purposes (rINNs except where stated)

Compound	Structure	Comments
Fenoxypropazine Iproniazid Mebanazine Pheniprazine Pivhydrazine	Hydrazines	These drugs are earlier compounds that caused liver damage; they are obsolete
Nialamide	Hydrazine	Little used today
Phenelzine (pINN)	Hydrazine	Widely used
Isocarboxazid	Hydrazine	Similar to phenelzine
Tranylcypromine	Cyclopropylamine	Most amphetamine-like High propensity for interactions with foods and drugs
Pargyline	Propinylbenzylamine	Used for hypertension
Furazolidone	Nitrofuran	Antimicrobial (giardiasis)
Procarbazine	Methylhydrazine	Antineoplastic
Clorgiline	Propylamine	Type A MAO inhibitor (serotonin/noradrenaline)
Selegiline	Propinylamine	Type B MAO inhibitor (phenylethylamine)
Moclobemide	Benzamide	Type A MAO inhibitor
Toloxatone	Oxazolidinone	Type A MAO inhibitor
Brofaromine	Piperidine	Type A MAO inhibitor

metabolized by MAO), and autonomic disturbances, such as dryness of the mouth, sweating, constipation, and weight gain.

Differences between MAO inhibitors in adverse effect profiles are poorly substantiated, and are confounded by different usage patterns and drug potencies. The selective MAO inhibitors are considered in other monographs.

Comparative risks of monoamine oxidase inhibitors and tricyclic antidepressants

MAO inhibitors suffered a long period of disfavor, largely because of their troublesome interactions. Their risks still exceed those of the tricyclic compounds, but some experienced clinicians feel that they can be used safely, provided appropriate precautions are taken.

Of particular interest is a chart review of 198 patients, aged 19–64, treated in a university research clinic by psychiatrists who specialized in the pharmacological treatment of affective disorders (9). Most of the patients (130) had atypical depression and participated in a 6- or 12-week double-blind comparison of phenelzine, imipramine, and placebo, with further follow-up. The authors selected 14 adverse effects generally considered to cause "serious medical risk or subjective discomfort great enough to require drug discontinuation." There were serious adverse effects in 14% of the patients taking placebo, 27% of those taking imipramine, 43% of those taking tranylcypromine, and 64% of those taking phenelzine; 38% had two or more serious adverse effects and all but one was taking phenelzine. The differences between imipramine and phenelzine were highly significant. By 33 weeks under half of the patients taking imipramine had had a serious adverse effect, compared with over 90% of those taking phenelzine. Adverse effects were sufficiently severe to require withdrawal in 45%. None of the 14 selected adverse effects was more common in the patients taking imipramine. The serious adverse effects that were more common in patients taking phenelzine included hypomania (10%), hypertensive crisis (8%), weight gain over 15 pounds (8%), and anorgasmia and impotence (22%). In a second article the authors discussed these adverse effects in detail (10). Of the eleven patients who had hypertensive crises, six had eaten tyramine-containing foods "despite meticulous dietary review and cautioning," and three had taken ephedrine-containing medications; four obtained emergency medical treatment in local hospitals and a fifth developed coma with intracranial bleeding due to an unsuspected aneurysm.

Organs and Systems

Cardiovascular

When MAO is inhibited, the concentrations of noradrenaline, dopamine, and serotonin increase in the central nervous system and heart. The concentrations of the precursors of these amines (dihydroxyphenylalanine and 5-hydroxytryptophan) are greatly increased. The effects are similar to those of the postganglionic blocking amines: postural hypotension occurs and cardiac output is reduced, possibly due to the accumulation of a pseudotransmitter.

Hypotension

The hypotensive effects of the MAO inhibitors differ from those of the tricyclic antidepressants, inasmuch as the former affect supine as well as orthostatic blood pressure. This was confirmed both in a study (11) involving tranylcypromine and in an evaluation of blood pressure changes in 14 patients taking phenelzine averaging 65 mg/day for at least 3 weeks (12). The drug-free mean supine systolic blood pressure was 127 mmHg and it fell significantly (mean drop 5 mmHg) by the end of the first week. By contrast, an increase in the orthostatic drop from the mean predrug baseline of 2 mmHg did not reach significance until the end of the second week of treatment, after which the blood pressure continued to fall. Two patients developed profound orthostatic falls of up to 50 mmHg

© 2006 Elsevier B.V. All rights reserved.

after more than 2 weeks of treatment. In one patient the hypotension and related symptoms (light-headedness and ataxia) improved with fludrocortisone, but not in the other, who required drug withdrawal. The authors commented that because orthostatic hypotension can develop late, cautious long-term monitoring is required.

Hypertension

Hypertensive crises usually occur when MAO inhibitors are combined with other drugs or foods that cause interactions (see next subsection).

Autopotentiation of hypertensive effects

In a few cases, a hypertensive crisis appears not to have been provoked by known drug or dietary precipitants (13). From a review of 12 reports of spontaneous hypertension in patients taking tranylcypromine or phenelzine, it has emerged that a family history of hypertension may be a risk factor (SEDA-18, 14). A significant increase in supine blood pressure without similar changes in standing blood pressure after the administration of tranylcypromine has also been described (SEDA-17, 17).

Cardiac arrhythmias

MAO inhibitors can cause bradycardia. A report of two cases of interactions of monoamine oxidase inhibitors with beta-blockers (nadolol and metoprolol) is of interest, and several possible mechanisms were discussed (14).

Nervous system

Autonomic nervous system

A carefully controlled 3-week comparison of phenelzine (up to 90 mg/day, mean 77 mg) and imipramine (up to 150 mg/day, mean 139 mg) showed no significant difference between the drugs in the incidence of dry mouth, blurred vision, constipation, and urinary hesitancy (15).

Central nervous system

Insomnia and daytime somnolence and fatigue have been reported with tranylcypromine, phenelzine, and isocarboxazid (SEDA-16, 8) (SEDA-17, 16). In a comparison of phenelzine and imipramine (15) there were important and significant differences between the drugs: 19% of the patients taking phenelzine reported drowsiness compared with none of those taking imipramine; moreover, 18 patients taking phenelzine had to be withdrawn, compared with one taking imipramine (who developed urinary retention). Central nervous system toxicity was also reported after an abrupt switch from phenelzine to isocarboxazid (SEDA-17, 17).

Parkinsonism

The MAO inhibitors can be used in patients who have Parkinson's disease, for two reasons. First, this is a disorder in which depression is common. Secondly, the selective type B inhibitor selegiline was originally thought to benefit patients with parkinsonism, possibly by increasing brain dopamine concentrations (16).

However, a recent long-term study has shown higher death rates in patients with early mild Parkinson's disease taking combined selegiline and levodopa compared with those taking levodopa alone. The authors concluded that the combination of selegiline with levodopa offers no advantage to patients with early mild Parkinson's disease, and that although selegiline may help symptoms in advanced Parkinson's disease it is best avoided in patients with postural hypotension, frequent falls, confusion, and dementia (17).

Dystonias

Two Italian neurologists have described current theories about the pathophysiology of levodopa-associated motor fluctuations and the use of inhibitors of MAO type B, inhibitors of catechol-*O*-methyl transferase, and modified-release levodopa in minimizing this problem (18).

- Dystonia has been described in a 65-year-old woman who had taken tranylcypromine 10 mg bd for 3 days. She had major long-term depression that had failed to respond to other agents. The dystonia abated 48 hours after withdrawal but recurred on rechallenge (19).

Neuromuscular function

The tendency for MAO inhibitors to produce symptoms related to neuromuscular excitability, the serotonin syndrome, has been recognized in cases of overdose (SEDA-10, 18) and in interactions with other antidepressants or tryptophan (SEDA-10, 16, 17) (20). The authors of a thorough review of the preclinical and clinical literature have drawn attention to these phenomena, which occur at therapeutic doses with a MAO inhibitor alone, and have speculated that the mechanism is related to a combination of increased serotonergic tone and central disinhibition of alpha motor neuron-mediated spinal activity (21). They discussed ten previous reports of myoclonus, hyperreflexia, muscle twitching, and increased muscle tone in patients taking MAO inhibitors. These neuromuscular effects appear to occur in up to 15% or more of patients, and are more likely when tryptophan is given in combination. They usually appear after 10–14 days. Tolerance does not occur, but the effects may abate or disappear with dosage reduction. Symptoms predominate during sleep and are often associated with muscle or joint pains.

Endocrine

The syndrome of inappropriate secretion of antidiuretic hormone (SIADH) (22) may be the mechanism of action underlying cases of peripheral edema that have been described (SEDA-2, 12) (SEDA-6, 28). Diuretics are not helpful, but dosage reduction produces relief (23).

A number of antidepressant drugs, particularly selective serotonin re-uptake inhibitors (SSRIs), can increase plasma prolactin concentrations, although galactorrhea is uncommon. In a prescription-event monitoring survey of about 65 000 patients, compared with SSRIs, moclobemide was associated with a relative risk of galactorrhea of 6.7 (95% CI = 2.7, 15) (24). However, this was substantially less than the risk associated with the dopamine receptor antagonist risperidone (relative risk compared with SSRIs 32; 95% CI = 14, 70). Nevertheless, the data suggest that moclobemide may be more likely to cause galactorrhea than other antidepressant drugs.

Hematologic

Leukopenia and agranulocytosis are well-recognized complications of treatment with tricyclic antidepressants and have been reported with some second-generation compounds. In a report of leukopenia in a patient taking phenelzine attention was drawn to five other unpublished cases and to previous published reports involving isocarboxazid, tranylcypromine, and tryptamine (25).

Liver

The early reports of hepatotoxicity with iproniazid led to the synthesis of non-hydrazine inhibitors, and a report from 19 French drug surveillance centers (26) has reaffirmed the frequency and severity of this adverse effect. There were 91 cases of hepatitis due to all antidepressants (11 with iproniazid) over 5 years. Cytolytic reactions occurred in 11 patients treated with iproniazid; 5 died. There was a high titer of antimitochondrial antibodies (M6) in five patients.

Skin

Photosensitivity to MAO inhibitors must be most unusual, but one well-authenticated report has been published (27).

Sexual function

Impotence and delayed ejaculation in men and difficulty in achieving orgasm in two women have been reported with a variety of MAO inhibitors used to treat narcolepsy (28), phobic anxiety (29), and depression (30–32). Sexual symptoms are often dose-related and there is a delicate interplay between psychic and pathophysiological influences. In men with premature ejaculation this effect may even be considered therapeutic.

Immunologic

Rashes have been reported, but their relation to drug ingestion is poorly substantiated. The hepatocellular damage caused by hydrazine derivatives is probably mediated by an immunological mechanism.

Body temperature

Hyperthermia and labile blood pressure, perhaps due to an interaction of clomipramine, phenelzine, and chlorpromazine has been described in one patient (SEDA-17, 17).

Long-Term Effects

Drug withdrawal

The literature on a withdrawal syndrome (SEDA-10, 17) has been expanded by further reports. One of these (33) involved the development of an acute toxic delirium 3 days after withdrawal of phenelzine, and another (34) concerned patients who became manic after withdrawal of isocarboxazid. A withdrawal state similar to that caused by withdrawal from amphetamines has been described after withdrawal of tranylcypromine (SEDA-16, 8) (SEDA-18, 14).

In principle it should be possible to switch from one conventional MAO inhibitor to another without a washout period. However, there have been reports that patients who switched from phenelzine to tranylcypromine had hypertensive reactions, with disastrous consequences (35). Whenever possible, a 2-week washout period when switching from a conventional MAO inhibitor to tranylcypromine seems advisable.

Second-Generation Effects

Pregnancy

Little is known about the use of MAO inhibitors during pregnancy and the postpartum period. There is a literature review along with a case report of phenelzine exposure throughout pregnancy and the postpartum period (36).

Lactation

There are some reports of the excretion of MAO inhibitors in breast milk (37,38).

Susceptibility Factors

Age

Because of the concern expressed about the use of tricyclic antidepressants in elderly people, MAO inhibitors have been studied in this population (39). Patients with dementia benefited in mood (but not cognition), and some non-demented patients also improved. Adverse effects were considered less frequent or troublesome than those due to tricyclic compounds, although one patient taking tranylcypromine became paranoid and another taking phenelzine developed a choreiform movement disorder. The fact that MAO concentrations increase with age supports the use of these drugs in the elderly, but their hypotensive effects and interactions with other drugs and foods suggest that they should be used with extreme caution in people who are exposed to polypharmacy and whose comprehension of and attention to warnings may be impaired.

Other features of the patient

It is inadvisable to give MAO inhibitors to schizophrenic patients, even when they seem to be anergic or depressed, since they may precipitate a psychotic crisis. It is also difficult to ensure that such patients respect the necessary dietary restrictions, that is, avoidance of tyramine-containing foods.

Drug Administration

Drug overdose

The fatal effects of antidepressants in England, Scotland, and Wales during 1975–1984 and 1985–1989 have been compared in retrospective epidemiological studies (40,41). The fatality index (deaths per million prescriptions) for individual drugs or groups of drugs was used to give an indication of the relative effects of the different drugs. There were 24 deaths due to tranylcypromine, 33

© 2006 Elsevier B.V. All rights reserved.

due to phenelzine, and 3 due to isocarboxazid. The fatality index for tranylcypromine was significantly higher than the mean for all antidepressants, while that for the other MAO inhibitors was lower. The majority of all deaths from antidepressant poisoning were due to two tricyclic drugs (amitriptyline and dosulepin), and they, as well as the entire group of older tricyclic antidepressants, had a fatality index significantly higher than the mean (41). It must of course be kept in mind that the fatality index of a drug is influenced by many factors other than its inherent toxicity, including dosage, differences in severity of illness and suicidal tendencies, and prescription for indications other than depression.

The minimum fatal dose of non-selective MAO inhibitors is about 5–10 times the maximum daily dose, although individuals have been reported to survive such amounts. Symptoms of overdosage can be initially mild and deceptive, but can progress over 24 hours to include agitation, tremor, alternating low and high blood pressure, severe muscle spasms, hyperpyrexia, and convulsions. Symptomatic treatment has included the beta-blocker practolol (10 mg intravenously, repeated after 2 hours) and muscle relaxants with assisted respiration (42), which may help reduce pyrexia by abolishing excessive muscle activity. Active elimination techniques are unhelpful, according to a comprehensive review of antidepressant overdosage (43).

In one patient who took 900 mg of phenelzine, there was a marked excess of urinary and plasma catecholamines, analogous to pheochromocytoma, and the patient was successfully managed with alpha-adrenoceptor antagonists (44). In another patient, who probably took about 2000 mg of phenelzine, hyperpyrexia was prominent and responded to dantrolene sodium (45). The authors noted clinical similarities to malignant hyperpyrexia and neuroleptic malignant syndrome.

Drug–Drug Interactions

General

Problems with non-selective irreversible MAO inhibitors arise for two reasons: the large number of amines that are substrates for the enzyme and the fact that these drugs also inhibit non-specific drug-metabolizing enzymes in the liver. Together, these two actions produce a lengthy list of interactions with other substances, the effects of which can be enhanced or prolonged, both during treatment with a MAO inhibitor and for up to 2 weeks afterwards, owing to the irreversible nature of the enzyme inhibition (Table 2).

Amines that serve as substrates include both natural and synthetic ephedrine congeners contained in prescribed and proprietary formulations, and amines such as tyramine, which occur naturally in a variety of protein-containing foods, in which amines are produced by bacterial decarboxylation of amino acids. When these "indirectly acting" amines are ingested, they are normally destroyed by MAO in the intestine or liver; however, after treatment with a MAO inhibitor they gain access to the systemic circulation, resulting in release of noradrenaline from sympathetic nerve terminals. If the amount ingested is sufficient, symptoms similar to those of pheochromocytoma occur, with a paroxysmal increase in blood pressure, sudden severe occipital headache, and cardiac irregularities. In rare instances, fatal cerebral hemorrhage or cardiac failure have occurred. The actions of MAO inhibitors on non-specific hepatic drug-metabolizing enzymes potentiate the effects of a large number of drugs, including narcotic analgesics, barbiturates, and anesthetics. This can complicate elective or emergency surgery in patients taking these antidepressants, with occasional fatal results.

A cause-and-effect relation for interactions between non-selective MAO inhibitors and other substances is often difficult to establish, for two reasons (46). First, MAO inhibitors act by forming an irreversible bond with an enzyme that is continuously being resynthesized. The degree of enzyme inhibition therefore varies with the dosage and duration of treatment, and can persist to some degree for up to 2 weeks after withdrawal. Secondly, any

protein food that contains decarboxylating bacteria can convert amino acids to amines such as tyramine, phenylethylamine, and histamine, and the amine composition of foodstuffs is variable and unpredictable; for example, identical-looking pieces of cheese can vary 100-fold in tyramine content. The diversity and number of substances (listed in Table 2) and unpredictability in the occurrence of adverse effects have contributed to the unpopularity of the MAO inhibitors as therapeutic agents.

Two facts simplify the understanding and use of these drugs.

(1) The interactions listed in Table 2 fall into three categories:

   (a) hypertensive crisis due to the release and potentiation of catecholamines similar to that experienced in pheochromocytoma;
   (b) a serotonin syndrome, caused by excess serotonin availability in the nervous system;
   (c) exacerbation or prolongation of the normal actions of the object drug (sedation or coma due to alcohol, anesthetics, or opioid analgesics; atropine-like central toxicity due to tricyclic antidepressants).

   The consequences of the hypertensive interaction are variable. Many individuals remain unaware of relatively minor increases in blood pressure. However, if the rise is large and rapid (an increase of 30 mmHg or more in systolic pressure within 20 minutes), the patient experiences a sudden severe occipital headache and palpitation, which may be associated in rare instances with subarachnoid hemorrhage or cardiac failure, if the cerebral vasculature or cardiac musculature are already weakened.

   The serotonin syndrome is characterized by three or more of the following symptoms: confusion, hypomania, agitation, myoclonus, hyper-reflexia, hyperthermia, shivering, sweating, ataxia, and diarrhea (47). It is most often seen in patients taking a combination of drugs that increase serotonin availability by different mechanisms. Drug combinations that have been reported to cause the serotonin syndrome have been reviewed and the pathophysiology of the syndrome discussed (45). It is probably mediated by stimulation of 5-HT_2 receptors. In most reported cases the drug combination associated with the syndrome included a MAO inhibitor (see Table 2). The syndrome is rare, although it has been reported more often during the past few years, and is often due to a combination of a MAO inhibitor and a selective serotonin re-uptake inhibitor. In most cases the symptoms are mild and resolve rapidly after drug withdrawal and supportive therapy. It must, however, be borne in mind that this syndrome can be fatal, and if combinations of serotonergic drugs are used they should be used with great caution.

(2) A second factor that can improve the use of these drugs is adequate patient education. Patients must be aware of the name and nature of the drug they are taking and its potential to interact with proscribed foods and prescribed or over-the-counter medications. In addition, patients should understand what symptoms to expect when an interaction occurs, such as unexpected drowsiness (after alcohol or other drugs) or a sudden severe headache (within 2 hours of a meal or medication). Because of the many variables involved, foods or medications that are taken with impunity on one occasion can interact dangerously on another. The director of a British counselling service has reported that of 119 patients taking MAO inhibitors who experienced problems, 35 reported hypertensive crises, 4 fatal (48). Despite warnings, these patients had eaten amine-containing foodstuffs or taken over-the-counter cold remedies. MAO inhibitors should not be prescribed unless the patient is able to understand such instructions and repeat them after explanation; compliance can be confirmed at subsequent inquiry. Those who take multiple medications, who have difficulty with comprehension or compliance (such as the elderly), or who are frightened by such explanations should not be given these drugs.

   The management of a patient who experiences these drug interactions depends on their nature. For symptoms due to exacerbation or prolongation of drug effects, specific or supportive measures (cardiovascular or respiratory) may be indicated. In the case of a hypertensive crisis, symptoms usually abate within 1–2 hours, as the blood pressure falls. If hypertension is seen early, or if it persists or recurs, it can be treated with parenteral phentolamine or chlorpromazine, but the danger of causing hypotension should be weighed carefully.

   The combination of central nervous system stimulants with MAO inhibitors in treatment-resistant depressed patients has been reported (49). However, this use should be restricted to patients in whom there is careful monitoring by specialists, because of the potential for hypertensive crisis.

Buspirone

The combination of buspirone with a MAO inhibitor can cause the serotonin syndrome (50).

Etamivan

Etamivan is contraindicated in patients taking MAO inhibitors (51).

Fenfluramine

Fenfluramine can produce an acute confusional state if it is given together with a MAO inhibitor (SED-9, 9).

Fluoxetine

The problem of the long half-life of fluoxetine, which leads to interactions with MAO inhibitors, even after withdrawal, has been discussed previously (SEDA-13, 12), and caused the manufacturer to circulate a warning to that effect.

Ginseng

Interactions of antidepressants with herbal medicines have been reported (52). Herbal medicines are widely used for their psychotropic properties and patients

© 2006 Elsevier B.V. All rights reserved.

sometimes take herbal formulations in addition to conventional psychotropic drugs, such as antidepressants. Ginseng has been reported to cause mania, tremor, and headache in combination with conventional MAO inhibitors.

Isoniazid

Isoniazid inhibits MAO, and during isoniazid treatment the ingestion of several kinds of cheese can cause flushing, palpitation, tachycardia, and increased blood pressure (53). Similar symptoms occur with isoniazid after the ingestion of skipjack fish (*Thunnidae*) (53). The symptoms, notably headache, palpitation, erythema, redness of the eyes, itching, diarrhea, and wheezing, are thought to be caused mainly by the high histamine content of this fish. The undesirable effects that occur when MAO inhibitors are taken together with isoniazid resemble the symptoms seen after the simultaneous ingestion of these foods.

Lithium

Interactions of lithium with antidepressants have been reviewed: tricyclic antidepressants and MAO inhibitors—no serious problems; SSRIs—a few reports of the serotonin syndrome (54).

Nefazodone

Co-administration of nefazodone with a MAO inhibitor or SSRI can cause the serotonin syndrome (55).

Neuroleptic drugs

Additive hypotensive effects can occur when a MAO inhibitor is combined with an antipsychotic drug (56). However, the combination can be beneficial in treating the negative symptoms of schizophrenia (57).

Opioids

The interactions of MAO inhibitors with opioids, which can lead to sudden and fatal reactions, have been reviewed (SEDA-18, 14).

Dextromethorphan is metabolized by CYP2D6 to dextrorphan, which binds to phencyclidine receptors and is thought to account for the toxic effects of hallucinations, tachycardia, hypertension, ataxia, and nystagmus. Individuals who are slow metabolizers, those who take long-acting dextromethorphan formulations, and those who take serotonin re-uptake inhibitors or MAO inhibitors are at increased risk of adverse effects.

Phenylephrine

Patients taking medications with pressor effects, such as MAO inhibitors, tricyclic antidepressants, and anticholinergic agents, should be monitored closely if phenylephrine is used (SEDA-16, 542).

Sumatriptan

On theoretical grounds sumatriptan should not be used with a MAO inhibitor (58).

Trazodone

Trazodone is related to nefazodone but probably potentiates 5-HT neurotransmission less. Trazodone is often added to MAO inhibitors and SSRIs at low doses (50–150 mg/day) as a hypnotic, but such combinations can rarely provoke the serotonin syndrome.

- The serotonin syndrome occurred in a 60-year-old woman when the addition of trazodone 50 mg/day to nefazodone 500 mg/day caused confusion, restlessness, sweating, and nausea after the third day of treatment (59). The symptoms settled quickly on withdrawal of both antidepressants.

Monobactams

See also Beta-lactam antibiotics

General Information

In the monobactams there is no second ring fused to the beta-lactam ring. However, the highly active compounds of this group do, as a rule, contain the aminothiazole side chain, known to be associated with good antimicrobial activity and beta-lactamase stability in cephalosporins (1). Aztreonam, marketed in 1984, was the first monobactam.

© 2006 Elsevier B.V. All rights reserved.

Other compounds, such as carumonam, pirazmonam, and tigemonam, have been developed (2), but so far only aztreonam is widely used. Monobactams are almost exclusively active against Gram-negative bacteria, and their clinical usefulness lies particularly in their antipseudomonal activity.

Like 6-aminopenicillanic acid for the penicillins and 7-aminocephalosporanic acid for the cephalosporins, 3-aminomonobactamic acid is the basic compound for the monobactam family.

In clinical trials the safety profile of aztreonam was similar to or better than that of other more conventional beta-lactam antibiotics, in adult patients with both normal renal function (3,4) and impaired renal function (5). These findings have been confirmed in children (6).

Organs and Systems

Hematologic

In a child with typhoid fever, severe leukopenia and neutropenia necessitated withdrawal of aztreonam (150 mg/kg/day) on the 10th day, followed by recovery (7). In another case there was myelosuppression (mainly neutropenia) possibly caused by aztreonam after 10 days of treatment; it resolved within 1 week of withdrawal (8). However, acute reversible neutropenia has been otherwise reported in under 0.1% of patients taking aztreonam (6).

Three of twenty-eight patients taking high-dose aztreonam (300 mg/kg/day) for cystic fibrosis developed mild and transient thrombocytopenia (9).

Liver

The frequency of liver function test abnormalities in patients taking monobactams does not differ from the frequencies in patients taking other beta-lactam antibiotics (3,6,9).

Urinary tract

- Acute renal insufficiency associated with a skin rash and eosinophilia has been reported in a 70-year-old man after 9 days of treatment with aztreonam (10).

However, significant nephrotoxicity has not been documented in trials.

Skin

Aztreonam was the suspected cause of toxic epidermal necrolysis in two patients undergoing bone marrow transplantations (11). Graft-versus-host disease seemed a less likely diagnosis of the cutaneous manifestations.

Immunologic

Aztreonam has minor immunogenicity in animals and was associated with a 2% incidence of all presumably immunologically mediated drug reactions in early phase I and II trials (12).

When *Escherichia coli* was co-cultured with mouse peritoneal macrophages and exposed to aztreonam and ceftazidime, there was enhanced secretion of TNF-alpha; imipenem did not do this (13). Both aztreonam and ceftazidime enhanced LPS release from *E. coli* while imipenem did not, consistent with the observed differences in TNF-alpha release. All three antibiotics increased *E. coli*-induced expression of inducible nitric oxide synthase (iNOS), as assessed by both mRNA and protein.

Negligible cross-reactivity has been reported in both animal and human studies involving hapten inhibition, skin tests, and treatment of penicillin-allergic patients with therapeutic doses of aztreonam (12,14–19). Aztreonam therefore seems to be a safe alternative for patients with penicillin allergy. However, the numbers of safely treated patients reported are still small, and immediate type hypersensitivity to aztreonam has been reported in patients with penicillin allergy (20–23).

Several cephalosporins, for example ceftazidime, have the same aminothiazole side chain as aztreonam. Sensitization with either drug involving side chain-specific antibodies may therefore predispose to allergy to the other. However, clinical data on this problem are currently not available.

Monoclonal antibodies

General Information

Human monoclonal antibody immunotherapy in clinical medicine has been an exciting prospect for some time, and increasing numbers of such antibodies have gradually become available (1,2).

An illustration of the potential of human monoclonal antibodies was provided by the HA-1A antibody, a human monoclonal IgM specific for the core/lipid A part of endotoxin. Among 291 patients with Gram-negative bacteremia treated with this antibody there was a significant reduction in mortality (3). Since then other patient groups have been treated, and apart from local urticaria, flushing, and mild transient hypotension, no adverse reactions were noted (4,5). No patient has developed antibodies to HA-1A. Although the initial results seem promising, more trials are needed to substantiate the therapeutic efficacy of HA-1A.

Numerous investigators have reported and reviewed the clinical application of monoclonal antibodies in various areas, including organ transplantation, neoplastic diseases, severe sepsis, and chronic inflammatory diseases. Collectively, these antibodies generally did not produce major adverse effects. The rapid development of antibodies against murine monoclonal antibodies is one of the most important clinical limitations to their therapeutic use, but the development of humanized (chimeric human/murine) monoclonal antibodies has improved their safety. Monoclonal antibodies have also been used in non-immune mediated diseases, such as cancer, septic shock, reperfusion, and as antiplatelet drugs. Treatment of neoplastic diseases with monoclonal antibodies is theoretically attractive. Unfortunately none of the monoclonal antibodies available at present has been demonstrated to be strictly tumor-specific, and binding of antibody to normal cells has been shown to be the major unknown factor for toxicity (6).

Monoclonal antibodies that are dealt with in separate monographs are abciximab, alemtuzumab, anti-CD4 antibody, basiliximab, daclizumab, edrecolomab, gemtuzumab ozogamicin, ibritumomab, muromonab-CD3, omalizumab, palivizumab, rituximab, and trastuzumab.

Nomenclature

Modern international non-proprietary drug names have two parts. The suffix, or stem, tells you what group the drug belongs to, ideally chosen to reflect its pharmacological action. For instance, -vastatin denotes HMG Co-A reductase inhibitors (-stat- often being used for enzyme inhibitors); -olol denotes beta-blockers (but beware stanozolol); and -mycins are antibiotics. The prefix is chosen at will. It might reflect the structure or source of the drug (for example diclofenac, virginiamycin), the inventor's love of opera or the cinema (for example, mimimycin, rifampicin (7)), or just whimsy.

The monoclonal antibodies have a prefix and three substems. All, with one exception (muromonab), end in -mab for monoclonal antibody. The penultimate syllable (or substem) indicates the animal source and the prepenultimate syllable indicates the target (Table 1). The prefix (one or two syllables) is chosen at random. Finally, if

Table 1 The components of the names of monoclonal antibodies

Prepenultimate syllable (general target)	Prepenultimate syllable (specific tumor target)	Penultimate syllable (species source)
-ba(c)- = bacterium	-co(l)- = colon	-a- = rat
-ci(r)- = cardiovascular	-go(t)- = gonad (testis)	-e- = hamster
-le(s)- = infectious lesions	-go(v)- = gonad (ovary)	-i- = primate
-li(m)- = immunomodulation	-ma(r)- = mammary	-o- = mouse
-vi(r)- = virus	-me(l)- = melanoma	-u- = human
-pr(o) = prostate		-abo- = rat-mouse hybrid
-tu(m)- = tumor (unspecified)		-xi- = chimeric
		-zu- = humanized

© 2006 Elsevier B.V. All rights reserved.

the antibody is conjugated to a toxin, an extra word is added; aritox, for example, denotes the A chain of ricin.

For example, trastuzumab can be parsed as follows: tras-tu-zu-mab. The -zu- denotes a humanized antibody and the -tu- a tumor target. If you wanted to show that it targets the breast specifically, you could call it tramazumab.

Uses

The uses of some monoclonal antibodies are listed in Table 2.

Several anti-human T cell monoclonal antibodies have undergone preliminary trials in the treatment of renal allograft rejection. Most of these monoclonal antibodies were not effective than muromonab (1). T10B9, an anti-human pan-T lymphocyte monoclonal antibody, had similar efficacy but caused less fever, severe infection, respiratory, gastrointestinal, or neurological symptoms than muromonab (SEDA-22, 409). Other monoclonal antibodies, such as chimeric anti-CD7 and murine anti-ICAM-1 (CD54; enlimomab), were devoid of adverse effects or produced only minimal and transient adverse effects (SED-13, 1134).

Anti-CD4 monoclonal antibodies, for example OKT4A, BF-5, cM-T412 (clenoliximab, keliximab), are continuously being investigated, although in small numbers of patients, after transplantation or in chronic inflammatory diseases, such as rheumatoid arthritis (SEDA-20, 340) (SEDA-21, 379) (2,8,9). Significant clinical immunomodulation has sometimes been obtained, with only transient and self-limiting, first-dose effects, namely headache, fever and chills, gastrointestinal disorders, hypotension, and tachycardia (SEDA-21, 379). Whereas most other adverse effects were not specifically associated with these monoclonal antibodies, mild skin eruptions and transient increases in hepatic enzymes, with one reversible case of liver failure, have been attributed to B-F5, a murine IgG1 CD4 monoclonal antibody (10).

Various monoclonal antibodies have been developed to be used as carrier molecules or as immunoconjugates to target drugs, enzymes, isotopes, or toxins to tumor cells. Some of the available data have been summarized (11), but there is still insufficient evidence of clinical benefit.

Table 2 Some monoclonal antibodies and their uses

Monoclonal antibody	Uses
Abciximab	Prevention of ischemic cardiac complications during percutaneous coronary interventions; short-term prevention of myocardial infarction
Afelimomab	Treatment of sepsis
Alemtuzumab	Chronic lymphocytic leukemia
Apolizumab	Chronic lymphocytic leukemia
Basiliximab	Prevention of acute renal allograft rejection
Clenoliximab	Rheumatoid arthritis
Daclizumab	Prevention of acute renal allograft rejection
Edrecolomab	Adjuvant therapy for cancer after colorectal surgery
Efalizumab	Treatment of severe plaque psoriasis
Enlimomab	Burns; stroke; prevention of acute rejection and delayed onset of graft function in cadaveric renal transplantation
Epratuzumab	Non-Hodgkin's lymphoma
Gemtuzumab	CD33-positive acute myelogenous leukemia
Infliximab	Rheumatoid arthritis; ankylosing spondylitis; Crohn's disease
Inolimomab	Prevention of graft rejection
Keliximab	Rheumatoid arthritis
Muromonab	Prevention of acute renal allograft rejection
Natalizumab	Acute relapse in multiple sclerosis; Crohn's disease
Odulimomab	Prevention of ischemic renal damage during kidney transplantation
Omalizumab	Prevention of allergic asthma and seasonal rhinitis
Palivizumab	Prevention of respiratory syncytial virus infection
Rituximab	Chemotherapy-resistant advanced follicular lymphoma; diffuse non-Hodgkin's lymphoma
Trastuzumab	HER2 receptor-positive breast cancer
Visilizumab	Treatment of glucocorticoid-refractory acute graft-versus-host disease

Rodent monoclonal antibodies

Compared with the therapeutic use of human monoclonal antibodies, the use of rodent (mouse or rat) monoclonal antibodies in vivo is disadvantageous because the xenogeneic antibody can induce immune responses that will mitigate the effectiveness of the antibody and/or cause adverse reactions in the recipient. Thus, the authors of one report concluded that antimouse immunoglobulin responses in human patients have limited the usefulness of murine monoclonal antibodies in more than half of those treated (12). The formation of human antimouse antibodies has been described both when murine monoclonal antibodies are used as a diagnostic tool in vivo and when they are used therapeutically (13–16).

Common adverse effects of treatment with murine monoclonal antibodies include fever, chills, and malaise in 21–23% of cases and urticaria and pruritus in 15–18% (17).

The murine monoclonal antibody muromonab directed against the CD3 structure on T lymphocytes has proved to be an important therapeutic agent with potent immunosuppressive actions, and its extensive use provides examples of the adverse effects of rodent monoclonal antibodies. It is used to reverse acute rejection episodes in kidney, heart, liver, or pancreas allografts and for graft-versus-host disease in bone marrow transplant recipients, when glucocorticoids have failed, or to avoid ciclosporin nephrotoxicity and the inconvenience of polyclonal anti-lymphocyte globulins (18). Despite its efficacy in over 90% of cases, muromonab causes a number of adverse effects, such as fluid retention and acute pulmonary edema (19), while marked early adverse effects include fever, chills, nausea, vomiting, headache, and hypotension, the last being attributed to systemic vasodilatation.

Other rodent monoclonal antibodies against cell membrane markers (CD molecules) have been described. The adverse effects of such antibodies can be ascribed to the general adverse effects of a heterologous protein, or to effects of the cell-targeting mechanisms (for example cell lysis).

General adverse effects

Although the adverse effects of most monoclonal antibodies were very few or benign, the possibility of more severe or unusual late complications should be

© 2006 Elsevier B.V. All rights reserved.

considered, as illustrated by several case reports. In one patient, both immediate and delayed injection site reactions were noted after injections of a type I recombinant human interleukin-1 receptor (rhu IL-1RI), and positive cutaneous tests and specific IgE antibodies strongly suggested an immune-mediated allergic reaction (20).

Severe migratory polyarthritis with fever, an urticarial rash, and renal involvement have been reported after the first dose of CAMPATH-1G, a rat antihuman monoclonal antibody reactive against CDw52 antigens, used before marrow transplantation in a 25-year-old patient (21). In patients with renal transplants or rheumatoid arthritis, alemtuzumab, a humanized monoclonal antibody directed against the CDw52 antigen found on lymphocytes, produced only mild to moderate first-dose symptoms, such as fever and rigors, nausea and vomiting, bone pain, dyspnea, and headache (SED-13, 1134) (SEDA-20, 380). By contrast, there was a high incidence of severe lymphopenia associated with infectious complications during the intravenous administration for low-grade lymphoma (22). Finally, several patients with rheumatoid arthritis treated with infliximab (a chimeric monoclonal anti-TNF-alfa antibody) or CDP-571 (a human anti-TNF-alfa antibody) developed various autoantibodies (23). Although there were no clinical consequences in these patients, the possible delayed development of overt autoimmune diseases should still be considered.

The mechanisms of adverse effects of monoclonal antibodies include sensitization due to the xenogeneic nature of the product, specific suppression of physiological functions, and secondary activation of inflammatory cells or mediators, which might be characterized by the cytokine release syndrome, as observed with muromonab-CD3 or rituximab (24). Although sensitization may be frequent, its clinical relevance is still limited, with only rare cases of allergic reactions. Although this has been strongly debated with muromonab-CD3 (orthoclone) (SED-14, 1309), the available information on the risk of infections or cancers with other monoclonal antibodies is still limited, but does not suggest an increased risk.

Monosodium glutamate

General Information

Monosodium glutamate, the sodium salt of the amino acid L-glutamic acid, is used as a flavor enhancer in a variety of foods. Average individual daily intake in developed countries is 0.3–1.0 g/day.

The use of monosodium glutamate has been controversial over the past 35 years because of reports of adverse reactions in people who have eaten foods that contain it.

The Chinese restaurant syndrome (Kwok's syndrome)

A triad of symptoms, numbness at the back of the neck radiating to both arms and the back, general weakness, and palpitation, after eating a Chinese meal, referred to collectively as the Chinese restaurant syndrome, was first described by Kwok in 1968 (1). It was suggested that monosodium glutamate triggered these symptoms, which were later extended to include headache, flushing, tingling, weakness, stomachache, visual disturbances, nausea, vomiting, and tightness or pain in the chest.

- A 36-year-old man developed severe weakness, palpitation, and sweating 30 minutes after eating wonton soup (2). He had a ventricular tachycardia, which converted to normal rhythm soon after the administration of intravenous lidocaine.

Many similar reports, most of them anecdotal, were published after the original observation, followed by clinical studies of varying degrees of rigor in experimental design, ranging from uncontrolled open challenges to double-blind, placebo-controlled studies. Challenges in subjects who reported adverse reactions to monosodium glutamate included relatively few subjects and failed to show significant reactions to monosodium glutamate. The results of surveys and of clinical challenges with monosodium glutamate in the general population showed no evidence of untoward effects. In a multicenter, double-blind, placebo-controlled challenge study in 130 subjects, large doses of monosodium glutamate given without food elicited more symptoms than placebo in individuals who believed that they reacted adversely to monosodium glutamate (3). However, the frequency of responses was low and the responses were inconsistent, not reproducible, and not observed when monosodium glutamate was given with food. Some have suggested that the syndrome is more likely in the presence of vitamin B_6 (pyridoxine) deficiency (4).

In a questionnaire survey, 43% of 3222 respondents associated unpleasant symptoms with specific foods and eating environments; however, only 1–2% reported symptoms characteristic of the Chinese restaurant syndrome, and only 0.19% associated the characteristic symptoms with consumption of Chinese food (5). Most respondents who were aware of the syndrome and most of those who believed they had experienced it reported non-specific symptoms.

L-glutamic acid and its ammonium, calcium, monosodium, and potassium salts were evaluated by the Joint FAO/WHO Expert Committee on Food Additives (JECFA) in 1988 (6). Because human studies had failed to confirm involvement of monosodium glutamate in the Chinese restaurant syndrome or other reactions, the JECFA classified glutamic acid and its salts under the heading "acceptable daily intake (ADI) not specified." The Scientific Committee for Food (SCF) of the European Commission reached a similar conclusion in 1991, and the conclusions of a subsequent review by the Federation of American Societies for Experimental Biology (FASEB) and the Federal Drug Administration (FDA) did not discount the existence of a sensitive subpopulation but otherwise concurred with the evaluations of JECFA and the SCF.

Organs and Systems

Nervous system

Research on the role in the nervous system of the glutamates has raised questions about the safety of monosodium glutamate (7). Glutamate is an amino acid neurotransmitter in the brain, and there are glutamate-responsive tissues in other parts of the body as well. Abnormal function of glutamate receptors has been linked with certain neurological diseases, such as Alzheimer's disease and Huntington's chorea. Injection of glutamate in laboratory animals has resulted in damage to nerve cells in the brain, but consuming glutamate in food does not have this effect. Although people normally consume dietary glutamate in large amounts, and the body can make and metabolize glutamate efficiently, the results of animal studies conducted in the 1980s raised the question of whether monosodium glutamate and possibly some other glutamates can harm the nervous system.

However, the 1995 report from the FASEB, an independent body of scientists, helped to put these safety concerns into perspective and reaffirmed the FDA's belief that monosodium glutamate and related substances are safe food ingredients for most people when eaten in usual amounts.

Montelukast

See also Leukotriene receptor antagonists

General Information

Montelukast is a leukotriene receptor antagonist. It has been taken by about 2500 patients in over 40 clinical trials. Its adverse events have not been significantly different from those of placebo.

Montelukast is extensively metabolized to 21- and 36-hydroxylated and dicarboxylic acid metabolites, which are excreted in the bile. The steady-state plasma concentrations of these metabolites are below the limit of detection in adults and children. In vitro studies have shown that high concentrations of montelukast inhibit CYP3A4 and CYP2C9, but in clinical studies the recommended dose of 10 mg/day did not interfere with metabolism of important cytochrome P450 substrates, such as warfarin (1).

The efficacy and safety of montelukast in 689 asthmatic children under 5 years have been studied in an international, multicenter, randomized study (2). The patients were randomly assigned to 12 weeks of treatment with placebo ($n = 228$) or montelukast 4 mg as a chewable tablet ($n = 461$). There were no clinically relevant differences between the groups in the overall frequencies of adverse effects, individual adverse effects, or the frequency of laboratory adverse effects, especially raised serum transaminase activities. Asthma was more frequent in the placebo group. The withdrawal frequency was similar in the two groups. Accidental ingestion of montelukast up to dosages 18 times the recommended daily dose of 4 mg was generally well tolerated. The authors concluded that montelukast is well tolerated in this specific group of preschool children.

The safety and tolerability of montelukast in patients aged 6 years or more have been evaluated in a meta-analysis of pooled data from 11 multicenter, randomized studies and five long-term extension studies (3). In 3386 adults (aged 15–85 years) and 336 children (aged 6–14 years), the overall incidence of clinical and laboratory adverse events was similar among patients taking montelukast and placebo. There were no clinically important differences in individual adverse events between the two treatment groups. There were no dose-related adverse effects of montelukast up to dosages 20 times the recommended daily dose of 10 mg.

Drug Administration

Drug overdose

Since montelukast is a relatively new drug, few data are available on unintentional poisoning. This makes it difficult to determine which dosages require aggressive decontamination or simple monitoring. Acute montelukast overdose with doses up to at least 150 mg/day have been reported in children. In most of the reports no adverse events were reported; when they occurred, symptoms included thirst, somnolence, mydriasis, hyperkinesia, and abdominal pain. In two cases of unintentional poisoning with montelukast there were no symptoms in a 3-year-old child who took 80 mg or in a 5-year-old child who took 135 mg (4).

In adults, montelukast doses up to 20- to 90-fold greater than the recommended dose (10 mg/day), given for longer than 1 week, were well tolerated and no unexpected adverse events occurred (5).

Moracizine

See also Antidysrhythmic drugs

General Information

Moracizine (moricizine) has Class I antidysrhythmic actions that cannot be easily further subclassified. Its pharmacology, clinical pharmacology, clinical uses, adverse effects and interactions have been reviewed (1–3).

In a retrospective study of 85 patients with recurrent atrial fibrillation (mean left atrial size 46 mm, mean left ventricular ejection fraction 0.51), 69 of whom had structural heart disease, moricizine (mean dose 609 mg/day) was withdrawn because of unacceptable adverse effects in six patients: frequent ventricular extra beats and short runs of non-sustained ventricular tachycardia ($n = 2$); significant widening of the QRS complex ($n = 1$); first-degree heart block ($n = 1$); a significant rise in liver enzymes ($n = 1$); and a severe rash ($n = 1$) (4). Six patients developed transient adverse effects that resolved spontaneously without withdrawal: brief self-limiting episodes of atrial flutter ($n = 2$); a small increase in blood pressure ($n = 1$); generalized weakness and tremor ($n = 2$); and reduced appetite ($n = 1$).

© 2006 Elsevier B.V. All rights reserved.

Organs and Systems

Cardiovascular

The overall risk of dysrhythmias with moracizine seems to be similar to that of other antidysrhythmic drugs, at around 10% (5), although lower rates have been reported. In CAST-II (the Cardiac Arrhythmia Suppression Trial) moracizine increased mortality in patients with asymptomatic ventricular dysrhythmias after myocardial infarction (6).

There have been anecdotal reports of conduction defects (SEDA-17, 225).

Moracizine has little or no effect on hemodynamics, but it sometimes has adverse hemodynamic effects and can exacerbate heart failure (SEDA-17, 225).

Hematologic

Moracizine has an anti-aggregatory effect on platelets, and thrombocytopenia has been reported (7).

Liver

Moracizine can cause increased serum bilirubin concentrations and serum transaminase activities (7).

Susceptibility Factors

Hepatic disease

Moracizine is cleared by the liver, and dosages should be reduced in liver disease (8).

Drug–Drug Interactions

Cimetidine

Cimetidine inhibits the metabolism of moracizine, but the effect is probably clinically unimportant (9).

Diltiazem

Moracizine is an enzyme inducer; it increases the rate of clearance of diltiazem (10). Conversely, diltiazem caused a doubling of the AUC of moracizine (10) in healthy volunteers.

Phenazone (antipyrine)

Moracizine is an enzyme inducer; it increases the rate of clearance of phenazone (antipyrine) (11).

Theophylline

Moracizine is an enzyme inducer; it increases the rate of clearance of theophylline (12).

Morniflumate

See also Non-steroidal anti-inflammatory drugs

General Information

Morniflumate is an NSAID that is widely prescribed in some countries as an antipyretic analgesic in children.

Organs and Systems

Immunologic

- A 4-year-old girl developed angioedema and urticaria 30 minutes after receiving rectal morniflumate. Her signs and symptoms resolved in 48 hours. Skin prick and intradermal tests to morniflumate were negative, but rechallenge with rectal administration caused a recurrence (1).

Morphine

See also Opioid analgesics

General Information

Morphine and its two glucuronides may have neuroexcitatory effects and affinity for non-opioid receptors (glycine and/or *N*-methyl-D-aspartate), effects that will not be antagonized by naloxone. Furthermore, these other opioid effects may be related to the mechanism of some adverse effects, including hyperalgesia, allodynia, and myoclonus, which are increasingly being reported after high doses of morphine, but which do not seem to occur after methadone, fentanyl, sufentanil, or ketobemidone (1).

Morphine is the benchmark "step 3" opioid analgesic based on the WHO's concept of an analgesic ladder (2). Revised recommendations for the use of morphine in cancer pain have been published by the European Association for Palliative Care's Expert Working Group on Opioid Analgesics (3). In summary, oral morphine is still the opioid of first choice for moderate to severe cancer pain, every 4 hours for normal-release morphine and 12- or 24-hourly for modified-release morphine. If patients are not able to take morphine orally the preferred alternative is subcutaneous infusion, especially in patients who require continuous parenteral morphine. A small proportion of patients develop intolerable adverse effects with oral morphine, and a change to an alternative opioid (for example hydromorphone, oxycodone, methadone, transdermal fentanyl) or a change in the rate of administration should be considered. If despite optimal use of systemic opioids and non-opioids a patient still has intolerable adverse effects or inadequate analgesia, spinal (epidural or intrathecal) administration of an opioid analgesic in combination with a local anesthetic or clonidine should be considered.

In a randomized, double-blind study in 94 patients with acute renal colic, morphine had equal analgesic efficacy to pethidine and a similar adverse effects profile (4).

Managing the adverse effects of morphine

The strategies used in managing the adverse effects of oral morphine have been reassessed in another special article compiled by the Expert Working Group of the European Association of Palliative Care Network (5). Factors that predict opioid adverse effects include:

(1) *Drug-related factors* There is little evidence suggesting that any one opioid agonist has a substantially better adverse effects profile than any other.
(2) *Route-related factors* There is limited evidence to suggest differences in adverse effects associated with specific routes of systemic administration.
(3) *Patient-related factors* There is evidence to suggest that there is interindividual variability in sensitivity to opioid-related adverse effects; the variables include genetic susceptibility, the presence of co-morbidity, and age.
(4) *Dose-related factors* A dose-response relation is most evident with the CNS adverse effects of sedation, cognitive impairment, hallucinations, myoclonus, and respiratory depression, although there is still interindividual variability in dose responsiveness to these effects; nausea and vomiting are common at the start of therapy but are then unpredictable.
(5) *Starting doses and escalation* The adverse effects of morphine, especially cognitive impairment, occur transiently and abate spontaneously; there are no reports of a relation between the starting dose of morphine or dose escalation and the occurrence of nausea, vomiting, or delirium.
(6) *Drug interactions* Adverse effects of concurrent medications may be synergistic or cumulative with those associated with opioids.

The reviewers also stressed the importance of differentiating opioid-related adverse effects from other causes of co-morbidity that might mimic opioid-induced adverse effects. Examples include cerebral metastases, stroke, metabolic changes, septicemia, bowel obstruction, and iatrogenic factors (other drugs or radiotherapy).

Four different approaches to the management of opioid adverse effects were described in the review:

(1) *Dosage reduction* A reduction in the dosage of the systemic opioid is usually enough to relieve adverse effects. If dosage reduction is accompanied by loss of pain control, a non-opioid analgesic (for example an NSAID) can be added. Specific therapy, such as radiotherapy, chemotherapy, or surgery, that targets the cause of the pain can be helpful, as can a regional anesthetic or neuroablative intervention (for example celiac plexus blockade in patients with pancreatic cancer).
(2) *Symptomatic management of the adverse effects.*
(3) *Opioid rotation.*
(4) *Switching the route of administration.*

The reviewers also examined the symptomatic management of specific adverse effects and commented that most approaches are based on cumulative anecdotal evidence and that there have been few prospective evaluations of the efficacy and toxicity of these approaches over a long period of use. Polypharmacy adds to the burden of adverse effects and drug interactions.

Nausea and vomiting

The authors of two related double-blind, randomized, placebo-controlled studies of the use of dexamethasone prophylaxis for nausea and vomiting after epidural morphine for postcesarean or posthysterectomy analgesia concluded that 5 mg of dexamethasone is an effective dose (6,7). Meanwhile, ADL 8-2698, a trans-3-4-dimethyl-4 piperidine that is a novel opioid antagonist, produced improved gastrointestinal transit time (peripherally mediated opioid activity) without affecting centrally mediated opioid analgesia (8). This contrasts with naloxone or nalmefene, which tend to antagonize central opioid effects, resulting in withdrawal symptoms in up to 50% of patients when used to treat constipation.

Intravenous droperidol 1.25 mg and intravenous dexamethasone 8 mg, given at the end of cesarean section, have been compared in reducing the incidence of nausea and vomiting caused by epidural morphine 3 mg in 120

© 2006 Elsevier B.V. All rights reserved.

women in a randomized, double-blind, placebo-controlled study (9). The incidence of nausea and vomiting was 18% with dexamethasone, 21% with droperidol, and 51% with saline. About 11–13% of the women who were given dexamethasone or droperidol required rescue antiemetic therapy compared with 41% in the saline group. The incidence of pruritus was similar among the three groups (26–42%). Six women (16%) given droperidol reported restlessness compared with none in the other two groups.

Pruritus

The effectiveness of intravenous ondansetron in preventing intrathecal morphine-induced pruritus has been investigated in a randomized, double-blind, placebo-controlled study in 60 consecutive women undergoing cesarean section (10). All were given spinal anesthesia with bupivacaine and intrathecal morphine 0.15 mg and then randomly divided into three groups. Group 1 received intravenous saline injections as placebo, group 2 received diphenhydramine 30 mg intravenously, and group 3 received ondansetron 0.1 mg/kg intravenously. Group 3 had a significantly lower incidence of pruritus (25%) than both group 1 (85%) and group 2 (80%), with no difference in postoperative pain scores between the groups.

In another randomized, double-blind study, 140 patients undergoing cesarean section had anesthesia with epidural bupivacaine 100 mg and adrenaline to which was added morphine 2 mg and droperidol 0, 1.25, 2.5, or 5.0 mg (11). Previous evidence had suggested that intravenous droperidol reduces morphine-induced pruritus, but that the effect disappeared when the dose was increased from 2.5 mg to 5.0 mg (12). However, in this study, epidural droperidol caused a dose-dependent reduction in morphine-induced pruritus even at a dose of 5 mg.

Myoclonus

Gabapentin has been used to treat morphine-induced myoclonus in a 54-year-old patient with gallbladder cancer (13). Effective pain control was maintained with morphine 300 mg, but after 24 hours the patient developed generalized muscular movements while asleep. Gabapentin 300 mg bd produced complete resolution of symptoms after 12 hours. In another case gabapentin 600 mg/day was used to treat a 1-month history of spontaneous jerking of both wrists after an increase in the dose of morphine to 120 mg/day; the myoclonus disappeared over the next 24 hours (8,13).

Organs and Systems

Cardiovascular

Adverse cardiac effects due to morphine are rare. They comprise inappropriate heart rate responses to hypotension, rather than conduction defects. They are not especially associated with inferior myocardial infarction, as was previously thought (SED-11, 142) (14).

Respiratory

Non-cardiogenic pulmonary edema occurred in three cancer patients, all of whom had received rapidly escalating doses of morphine over a short period (15).

Nervous system

A patient with Guillain–Barré syndrome experienced shock with morphine sulfate (16).

- A 69-year-old woman developed interscapular pain after a mild respiratory infection. Non-opioid analgesics were ineffective, so she was given modified-release morphine 10 mg. On day 4 she had rapidly progressive weakness in her legs and on day 5 she was found unconscious with no detectable blood pressure. She recovered with naloxone 0.8 intravenously. Her paralysis persisted. Nerve conduction studies confirmed slowed neurotransmission. Further investigation excluded other potential causes and Guillain–Barré syndrome was diagnosed.

The episode of unconsciousness was attributed to opioid toxicity in a patient in whom autonomic dysfunction may already have been present. It was suggested that opioid analgesics should be used with caution in patients with Guillain–Barré syndrome, because of the risk of hypotension consequent on autonomic dysfunction.

High doses of chronic morphine can cause hyperalgesia or allodynia (pain caused by a stimulus that does not normally provoke pain) (17).

- A 9-month-old girl with an inoperable and partially resected astrocytoma of the hypothalamus had morphine-induced allodynia, and became extremely distressed during routine care, such as nappy changing, feeding, and washing. The allodynia resolved after the dosage of morphine was reduced from 6950 μg/kg/hour to 280 μg/kg/hour.

Intravenous patient-controlled administration of morphine (total 56 mg in 9 hours) was associated with downbeat nystagmus in a 61-year-old man with a Grade 3 adenocarcinoma of the gastro-esophageal junction and a previous small cerebellar infarct (18). Withdrawal of the analgesia led to complete resolution of all signs and symptoms within 12 hours.

Psychological, psychiatric

Hallucinations have been described after the use of morphine in various dosage forms; in one series, patients experienced adequate pain relief and no further hallucinations or nightmares when changed to oxycodone (19). Delusions and hallucinations have been reported in a patient who was also taking dosulepin (20). Restlessness, vomiting, and disorientation were described in two male patients over 60 years of age taking modified-release morphine for relief of pain in advanced cancer (21).

Endocrine

Morphine can cause prolactin release (22); this effect is not antagonized by naloxone.

© 2006 Elsevier B.V. All rights reserved.

Mouth and teeth

There is a clear association between the administration of morphine and dry mouth (23).

Gastrointestinal

Nausea and vomiting are frequent adverse effects associated with the use of PCA opioids. Droperidol and tropisetron may reduce the incidence and severity of nausea and vomiting caused by morphine (SEDA-19, 84).

Morphine reduces the rate of transient lower esophageal sphincter relaxation in patients with reflux disease, thus reducing the number of reflux episodes; the effect was reversed by naloxone (SEDA-22, 12).

Biliary tract

Morphine can cause choledochal sphincter spasm, especially if there is a previous history of cholecystectomy (24).

- A 60-year-old man received intramuscular morphine 10 mg with scopolamine 0.4 mg as premedication and 40 minutes later complained of sharp right upper quadrant pain radiating to the back. The symptoms were identical to the gallbladder pain he had experienced in the past and for which he had had a cholecystectomy 25 years before. He had complete relief from intravenous naloxone 0.9 mg.

Skin

A purpuric rash has been reported in a patient taking morphine (25).

Death

- A 14-year-old boy with infectious mononucleosis was given intravenous morphine 10 mg for pain relief with good effect, but 2 hours later was found unresponsive, lying on his back, and not breathing (26). An autopsy showed marked bilateral tonsillar enlargement with considerable narrowing of the upper airway. The blood morphine concentration was 0.08 μg/ml.

The coroner concluded that the morphine had contributed to respiratory compromise and death.

Long-Term Effects

Drug withdrawal

Acute opioid withdrawal syndrome apparently precipitated by naloxone following epidural morphine has been reported (27).

- A 28-year-old nulliparous woman with no history of opioid exposure underwent elective cesarean section with epidural anesthesia. On delivery she received morphine 2 mg epidurally. At 8 hours after delivery she complained of pruritus and received naloxone 0.14 mg intravenously in fractional doses. After 2 minutes she felt warm in her legs, trunk, and face. Pruritus resolved and analgesia was maintained. After 5 minutes she began to shiver in a waxing and waning pattern every 2 minutes. She was restless and agitated and had tachypnea, lacrimation, and rhinorrhea. Her symptoms resolved in 40 minutes.

Previous reports of opioid withdrawal on single exposure have been described after the administration of intramuscular morphine in healthy individuals. This case suggests that opioid dependence can occur after acute exposure to morphine by the epidural route too. An alternative explanation (28) is that the stress of labor may have led to increased endogenous opioid activity, particularly B-endorphin, and that the antagonistic effect of naloxone on the endogenous opioid system contributed to the clinical effects in this patient. Moreover, the authors pointed out that many symptoms characteristic of the classic opioid withdrawal syndrome were not present in the patient.

Second-Generation Effects

Pregnancy

In a double-blind, randomized, controlled study of analgesia in labor, the addition of morphine 150 μg to an intrathecal combination of fentanyl (25 μg) and bupivacaine (2.5 mg) significantly prolonged analgesia to more than 4 hours without increasing opioid-related adverse effects (29).

Susceptibility Factors

Genetic factors

Accumulation of morphine-6-glucuronide is a risk factor for opioid toxicity during morphine treatment. However, it does not occur in all patients with renal insufficiency, which is the most common reason for accumulation of morphine-6-glucuronide; this suggests that other risk factors can contribute to morphine-6-glucuronide toxicity.

- Two men, aged 87 and 65 years, both with renal insufficiency, took oral morphine 30 mg/day for pain management (30). While the 65-year-old tolerated morphine well despite a high plasma morphine-6-glucuronide concentration of 1735 nmol/l, the 87-year-old had severe sleepiness and drowsiness, even though the plasma morphine-6-glucuronide concentration was only 941 nmol/l.

The patients were screened for genetic polymorphisms in the OPRM1-gene (coding for μ opioid receptors), P glycoprotein, and other candidate genes that code for transporters that may play an important role in determining the central nervous system concentration of morphine or morphine-6-glucuronide. The 65-year-old patient was a homozygous carrier of the mutated G118 allele of the μ opioid receptor gene, which has previously been related to reduced glucuromorphine potency (a protector gene). In contrast, the 87-year-old patient was a homozygous carrier of the wild-type allele A118. This observation implies that a single nucleotide polymorphism, the G118 allele, has a protective effect against morphine-6-glucuronide toxicity.

© 2006 Elsevier B.V. All rights reserved.

Age

Children

Of 44 children undergoing major genitourinary or lower abdominal surgery in a randomized, single-blind study, 24 were given morphine 0.1 mg/kg epidurally and 20 were given the same dose intravenously immediately after intubation (31). Postoperatively PCA boluses were administered to both groups. Both techniques provided sufficient pain relief. Of the children given epidural morphine, one required treatment for pruritus and seven vomited more than once, compared to none in those given intravenous morphine.

A study of PCA in children suggested that the pharmacokinetics of morphine are similar to those in adults, with the exception of young infants (32).

Neonates with reduced capacity for glucuronidation may have reduced efficacy of morphine, because of reduced renal excretion of morphine-6-glucuronide.

In a 7-year, retrospective, multicenter, observational study, 95 children aged 1–19 years with cancer pain and treated with long-acting morphine were investigated for adverse effects and age-dependent analgesic effects (33). The adverse effects most frequently reported were constipation (10 patients at the beginning of treatment, 20 patients during the course of therapy, and 3 patients at the end of data collection), followed by vomiting (five, eight, and two patients), and nausea (two, six, and three patients), especially in children aged 7 years or more. Some of the children repeatedly complained of pruritus (five, eleven, and two patients). There were no cases of respiratory depression. Oral long-acting morphine proved to be safe and effective, even in very young patients with a history of malignancy.

There have been another two studies of the analgesic effect of intrathecal morphine in children (34,35). In a prospective, double-blind study, 30 children (aged 9–19 years) scheduled for spinal fusion were randomly allocated to a single dose of saline or intrathecal morphine 2 or 5 μg/kg; after surgery, a PCA device provided access to additional intravenous morphine (34). The doses of 2 and 5 μg/kg had similar analgesic effectiveness and adverse effects profiles (nausea, vomiting, pruritus). There were no episodes of severe respiratory depression. Low-dose intrathecal morphine supplemented with PCA morphine provides better analgesia than PCA morphine alone.

In a smaller prospective, open, uncontrolled study, 12 children (3–6 years of age) were given either intermittent intrathecal morphine 5 μg/kg qds or a continuous infusion of a mixture of bupivacaine (40 μg/kg/hour) and morphine (0.6 μg/kg/hour) for intense postoperative pain after selective dorsal rhizotomy (35). The bupivacaine/morphine mixture provided better analgesia with fewer adverse effects. The incidence of pruritus was 83% with morphine compared with 33% with bupivacaine/morphine. Otherwise the adverse effects were similar.

Elderly people

Morphine, as an intravenous bolus of 2 or 3 mg every 5 minutes until pain relief or adverse effects occurred, was given to 875 patients who were under 70 years old and 175 patients who were over 70 years old in a prospective, uncontrolled, non-blinded study (36). The total dose of morphine was not significantly different between the groups. There was no significant difference in the incidence of morphine-related adverse effects, the number of sedated patients, and the number of patients in whom dose titration had to be stopped. The results only applied to the immediate and short-term postoperative periods and the patients studied had a variety of surgical procedures unrelated to age. The results suggested that intravenous morphine can be safely given to elderly patients using the same protocol that is used in younger ones. The generalizability of this study is limited because the sample size was small.

Renal disease

There was a higher incidence of adverse effects of morphine in patients with renal insufficiency who receive opioids for some time (37), and in patients with hemolytic uremic syndrome who were given ketamine with subcutaneous morphine postoperatively (38).

Patients with renal insufficiency may experience a stronger and more prolonged effect, because of reduced renal excretion of morphine-6-glucuronide.

Hepatic disease

Morphine is extensively metabolized. Its main metabolite, morphine-3-glucuronide is without analgesic effects, while morphine-6-glucuronide (also called morphine glucuronide) is supposed to be more potent than morphine. In patients with cirrhosis, morphine clearance may be reduced and the half-life prolonged, and dosages should be reduced (SEDA-22, 101).

Other features of the patient

Myoclonus is more likely in patients taking psychotropic or non-steroidal anti-inflammatory drugs as adjunct analgesia (39).

Drug Administration

Drug additives

Low-dose intrathecal morphine (0.3 mg) plus 0.5% spinal bupivacaine and patient-controlled intravenous morphine (given as a 1 mg bolus with a 5-minute lockout period) has been compared with patient-controlled intravenous morphine alone in 38 patients undergoing knee surgery in a randomized, double-blind study (40). The former combination provided effective analgesia with a low and non-significant incidence of emesis, pruritus, and respiratory depression.

Drug dosage regimens

Oral morphine is more effective after repeated rather than single doses. This is probably due to penetration into the central nervous system of morphine-6-glucuronide, the active metabolite (41).

In a dose-response study of the effects of epidural morphine after cesarean section the quality of analgesia increased with the dose of morphine to a ceiling dose of 3.75 mg (42). Adverse effects were not dose-related.

© 2006 Elsevier B.V. All rights reserved.

Perioperative administration of morphine is another way of enhancing its analgesic properties during the transition from total remifentanil-based anesthesia to the postoperative period, when adequate analgesia is sometimes difficult.

In a randomized study in 245 patients undergoing abdominal or urological surgery the effect of perioperative morphine was evaluated (43). Patients were given a bolus of 0.15 or 0.25 mg/kg 30 minutes before the end of surgery. The results suggested that intraoperative morphine administration did not preclude the need for more morphine in the immediate postoperative period. The 0.25 mg/kg dose was slightly more effective but caused more respiratory depression.

Drug administration route

The practical administration of morphine has been reviewed in relation to dose (initial dose with titration and rescue), formulations (indication and costs), routes of administration, and adverse effects (44).

There is a similar frequency of adverse effects between buccal and intramuscular morphine, as well as intramuscular and intravenous infusions.

Two novel routes for the administration of morphine or bupivacaine (intraperitoneal and interpleural) have been studied for the provision of analgesia after laparoscopic cholecystectomy (SEDA-20, 79).

Some patients developed severe local toxicity during the subcutaneous administration of morphine sulfate (and of hydromorphone) via portable pumps (SEDA-16, 82).

Intramuscular morphine has been compared with epidural morphine or epidural sufentanil, both with bupivacaine, in 90 patients undergoing major abdominal surgery (45). Both epidural regimens gave significantly better postoperative analgesia at rest and during movement. The incidence of adverse effects did not differ significantly between the groups, although the intraoperative requirement for ephedrine or dopamine was higher for the epidural group. Itching was significantly less in the intramuscular morphine group than the epidural groups (7 versus 69%) but nausea and vomiting were equally common.

The systemic availability of morphine from an aerosol is low (about 10%). A nasal solution containing morphine and chitosan, a linear polysaccharide, has been tested in a pilot study in healthy volunteers and patients with cancer (46). The formulation was well tolerated and could be a useful delivery system for morphine.

In a double-blind, randomized, uncontrolled study in 150 women to compare intrathecal morphine 100 micrograms plus ketoprofen, intrathecal morphine 200 micrograms, or epidural morphine 3 mg, postoperative nausea or vomiting occurred in 16, 28, and 26% respectively (47). The incidence of itching was least in those given intrathecal morphine 100 micrograms. The results were unequivocal and did not justify preferring any one of the techniques as better or safer.

In a double-blind, randomized study in 60 patients undergoing elective knee arthroscopy, direct intrasynovial injection of morphine 1 mg provided better long-term analgesia (12–24 hours) than intra-articular morphine 1 mg, with no adverse effects (48).

Intrathecal

Intrathecal morphine provides adequate postoperative analgesia in orthopedic surgery, but commonly causes urinary retention, pruritus, and nausea and vomiting. Finding the optimal dose of analgesic effect with minimal adverse effects is still the main objective of most papers published on morphine (49,50).

In a randomized, double-blind study in 143 patients scheduled for total hip surgery the optimal dose of intrathecal morphine was as low as 0.1 mg (51). The patients were allocated to four groups depending on the dose of morphine used (0.025, 0.05, 0.1, and 0.2 mg). The incidence of pruritus, nausea and vomiting, and urinary retention, and the consumption of antiemetics did not differ among the groups.

The use of intrathecal morphine (52) in the management of chronic non-malignant pain has been reported. Eighty-eight patients were originally evaluated followed by 67 patients 6 months later. At the time of follow-up, mean pain relief was 60%, with 74% of respondents reporting increased activity. There were frequent reports of opioid adverse effects, including sexual dysfunction and menstrual disturbances. The reported adverse effects in descending order of frequency were: excessive sweating (62%), weight gain (52%), difficulty in concentrating, thinking, and memory (48%), nausea and vomiting (42%), arthralgia (25%), peripheral edema (25%), and pruritus (21%). Despite these adverse effects, most of the patients expressed satisfaction with intrathecal opioid therapy. The results were limited owing to the retrospective nature of the study, differing rates of response to specific questions, and the lack of objective measures.

Drug–Drug Interactions

Diclofenac

Although spinal morphine provides effective analgesia, different ways of managing and minimizing its troubling adverse effects are constantly sought. Diclofenac, a non-steroidal anti-inflammatory drug, improves the analgesia provided by epidural morphine and may allow dosage reduction. In an investigation of this drug combination, intrathecal morphine was administered either regularly or on demand to 120 women undergoing cesarean section in doses of 0.1 mg, 0.05 mg, or 0.025 mg with diclofenac 75 mg intramuscularly (53). Severe pruritus was significantly more common in those who received morphine 0.1 mg and there was a trend toward less vomiting with smaller doses. There was no respiratory depression. The results suggested that the adverse effects of intrathecal morphine are dose-dependent and that there was no advantage in using doses of morphine larger than 0.25 mg.

Droperidol

A prospective, randomized, double-blind study of 97 women investigated whether droperidol alleviated the adverse effects of epidural morphine after cesarean section (54). All groups received morphine 5 mg epidurally on delivery, accompanied by no droperidol, or droperidol 2.5 mg epidurally, or droperidol 2.5 mg intravenously. Pruritus occurred in 70% of patients, starting at 6 hours

© 2006 Elsevier B.V. All rights reserved.

after epidural morphine, peaking at 17 hours, and with no significant difference between the different treatment regimens. Nausea and vomiting were significantly reduced by intravenous droperidol, but not by epidural droperidol. The authors concluded that droperidol acts systemically to counter the adverse effects of epidural morphine but is not entirely effective, and they suggested that its failure to alleviate pruritus may have been due to the fact that they used larger doses of morphine than some other investigators.

Propofol

Subhypnotic doses of propofol (20 mg) given to 120 women receiving intrathecal morphine after cesarean section had no significant effect on pruritus (55). Higher success rates have been reported for propofol with non-obstetric patients, suggesting that labor-related factors may perpetuate this adverse effect.

Rifampicin

The metabolism of morphine is enhanced by rifampicin, resulting in loss of analgesic effects of morphine (56).

Tricyclic antidepressants

Clomipramine, amitriptyline, and probably other antidepressants that potentiate the serotonergic system, enhance the analgesic effect of morphine.

Interference with Diagnostic Tests

Therapeutic doses of morphine can alter the blood activities of amylase, lipase, lactate dehydrogenase, creatine phosphokinase, and leucine aminopeptidase, BSP retention, and urine glucose concentration (Benedict's) (57–59).

Moxifloxacin

See also Fluoroquinolones

General Information

Moxifloxacin is an 8-methoxyquinolone with enhanced potency against important Gram-positive pathogens, notably *Streptococcus pneumoniae* (penicillin-resistant and penicillin-susceptible strains), and class activity against Gram-negative bacteria. Its activity is not affected by beta-lactamases. Moxifloxacin may therefore represent a promising alternative for treatment of respiratory tract infections (1).

Dosage adjustment is not required for patients of advanced age or those with renal or mild hepatic impairment (2).

© 2006 Elsevier B.V. All rights reserved.

Drug interactions with moxifloxacin have been reviewed (3–6).

Observational studies

In a phase I trial, single-dose pharmacokinetics of moxifloxacin have been reported after oral administration of 50–800 mg in 45 healthy Caucasian men. Moxifloxacin was well tolerated (7). There were no serious adverse events, dropouts, or deaths. Only weakness was reported more often in the active treatment group. Other adverse events in subjects taking the active treatment included *Herpes simplex* labialis and an ear disorder. There were no changes in laboratory parameters, electrocardiograms, electroencephalograms, or findings on physical examination. Mean maximum concentrations of moxifloxacin in plasma ranged from 0.29 μg/ml (50 mg dose) to 4.73 μg/ml (800 mg dose) and were reached 0.4–4 hours after drug administration (MICs at which 90% of isolates of penicillin-resistant *Streptococcus pneumoniae* were inhibited were below 0.125 μg/ml). Plasma concentrations fell in a biphasic manner: within 4–5 hours, they fell to 30–55% of the C_{max}. A terminal half-life of 11–14 hours accounted for most of the AUC. Protein binding was about 48%. There was partial tubular reabsorption. No major active metabolites were detected. Concentrations in saliva were higher than in the plasma during the absorption phase, whereas in the terminal phase there was a constant saliva:plasma concentration ratio of 0.5–1.

In an open, randomized, crossover study, the absolute systemic availability of a single 100 mg dose of moxifloxacin was 0.92 in 10 healthy men (mean age 29 years) (8). There was no evidence of active tubular secretion. Both the oral and intravenous formulations were well tolerated, with five reported possible or probable drug-related adverse events, including headache, nausea, and localized urticaria.

In a prospective, uncontrolled, unblinded, phase III trial in 254 patients with community-acquired pneumonia diagnosed by culture or serologically, moxifloxacin (400 mg/day orally for 10 days) produced a bacteriological response of 91% (9). Drug-related adverse events were reported in 33% of patients; nausea (9%), diarrhea (6%), and dizziness (4%) were the most common adverse events.

Moxifloxacin (400 mg/day orally for 7 days) in 12 healthy men significantly reduced the normal oropharyngeal microflora (alpha-hemolytic streptococci and *Neisseriae*), whereas the number of Gram-negative anerobic bacteria increased markedly; however, no new colonizing moxifloxacin-resistant strains were isolated (10). Moxifloxacin caused a significant reduction in enterococci and enterobacteria, while the numbers of staphylococci, streptococci, *Bacillus* species, and *Candida albicans* were unaffected. There was no impact on peptostreptococci, lactobacilli, *Veillonella*, *Bacteroides*, or fusobacteria, but bifidobacteria and *Clostridia* decreased during moxifloxacin administration. The microflora normalized after 35 days (11).

In a multicenter, prospective, double-blind, randomized trial in 455 patients with community-acquired pneumonia oral moxifloxacin 200 mg/day or 400 mg/day for 10 days resulted in a bacteriological response of 91% (12). Most adverse events, possibly or probably related to moxifloxacin, were generally mild or moderate and were mostly related to the digestive system: diarrhea, nausea, and abdominal pain with 200 mg/day; diarrhea, liver function abnormalities, and nausea with 400 mg /day. The drugs were withdrawn because of adverse events in seven of 229 patients taking 200 mg/day, and 11 of 224 taking 400 mg/day.

Organs and Systems

Cardiovascular

Moxifloxacin blocks the rapid-component delayed-rectifier potassium channel in the heart, and thus prolongs the QT_c interval by 6 minutes after oral administration and 12 minutes after intravenous administration (13). Moxifloxacin carries a greater risk of QT interval prolongation than ciprofloxacin, levofloxacin, and ofloxacin (14), and although the risk of moxifloxacin-induced torsade de pointes is expected to be minimal when the drug is given in the recommended dosage (400 mg/day) (15), moxifloxacin should be used with caution in patients with prodysrhythmic conditions and avoided in patients taking antidysrhythmic drugs, such as quinidine, procainamide, amiodarone, and sotalol (3).

- A man developed a hypertensive crisis and transient left bundle branch block with QT interval prolongation after taking moxifloxacin (16).
- Sinus tachycardia (120/minute) associated with moxifloxacin has been reported in a 49-year-old man about 45 minutes after he took a single 400 mg dose of moxifloxacin (17).

The underlying mechanism may have been vasodilatation, either directly or indirectly, owing to release of histamine, with reflex tachycardia. These effects have been described for other fluoroquinolones.

Nervous system

Syncope has been reported after the use of moxifloxacin (18).

Gastrointestinal

The most common adverse effects of moxifloxacin are gastrointestinal disturbances (nausea, diarrhea), which are usually mild to moderate in intensity and do not force patients to discontinue treatment (19,20). The frequency of nausea and vomiting is higher than the frequency of diarrhea and abdominal pain (21). Moxifloxacin caused nausea in 7.2% and diarrhea in 5.7% of patients (19).

In a prospective pharmacokinetic study in 12 healthy men the most frequent adverse events, possibly or probably related to moxifloxacin, were generally mild or moderate and were mostly diarrhea, nausea, and abdominal pain (22).

Liver

- A 69-year-old man who took moxifloxacin 400 mg/day for 5 days developed cholestasis (20).

© 2006 Elsevier B.V. All rights reserved.

Skin

Moxifloxacin has a low propensity for causing phototoxic reactions relative to other fluoroquinolones (2,3).

Immunologic

In vitro, moxifloxacin has immunomodulatory activity through its capacity to alter the secretion of IL1-α and TNF-α by human monocytes (23).

Moxifloxacin can cause anaphylactic reactions (24).

A case of simultaneous drug allergies has been reported (25).

- A 32-year-old woman had a generalized urticaria 15 minutes after taking co-amoxiclav and 1 year later developed a non-pruritic micropapular rash some hours after taking moxifloxacin 400 mg.

Drug–Drug Interactions

Antacids

The systemic availability of moxifloxacin is markedly reduced by the co-administration of antacids that contain magnesium or aluminium, unless administration occurs 2 hours before or 4 hours after moxifloxacin (19,26). An interval of 2 hours before or 4 hours after taking antacids ensures that the effect of the interaction is not clinically relevant.

Digoxin

There was no clinically relevant effect of moxifloxacin on the pharmacokinetics of digoxin in combination steady-state conditions (4).

Epoetin

- A 76-year-old man with low-risk myelodysplastic syndrome had a major erythroid response to combination therapy with epoetin and moxifloxacin (27). The immunomodulatory effects of moxifloxacin may have explained the synergy with epoetin.

Iron

Iron salts impair the absorption of moxifloxacin (26).

Probenecid

Concomitant administration of probenecid did not affect the elimination of moxifloxacin (4).

Ranitidine

The systemic availability of moxifloxacin was not affected by concurrent administration of ranitidine (4).

Sucralfate

Drugs that contain sucralfate impair the absorption of moxifloxacin (26).

Theophylline

Moxifloxacin did not affect the pharmacokinetics of theophylline or vice versa (28).

© 2006 Elsevier B.V. All rights reserved.

Warfarin

Moxifloxacin had no effect on the pharmacokinetics of warfarin in combination steady-state conditions (4)

Food–Drug Interactions

The effect of food on the pharmacokinetics of moxifloxacin was not clinically important (29). In another study dairy products had no effect on moxifloxacin kinetics (30).

Moxisylyte

General Information

Moxisylyte is an alpha-adrenoceptor antagonist with vasodilatory activity (1). It is used orally in the treatment of peripheral vascular disease and by intracavernosal injection in erectile dysfunction.

Organs and Systems

Liver

Three cases of hepatitis have been reported with moxisylyte in separate publications from France in 1991 (SEDA-17, 163).

Reference

1. Marquer C, Bressolle F. Moxisylyte: a review of its pharmacodynamic and pharmacokinetic properties, and its therapeutic use in impotence. Fundam Clin Pharmacol 1998; 12(4):377–87.

Moxonidine

General Information

Moxonidine is a selective agonist at imidazoline I_1 receptors in the rostroventrolateral medulla and has very little alpha$_2$-adrenoceptor agonist activity. It has similar efficacy to other antihypertensive drugs. Its safety has been evaluated in a number of individual studies and in a systematic review of randomized trials (1).

Unlike clonidine, moxonidine does not appear to cause sedation or to impair psychomotor performance or cognitive function. However, possible potentiation of the effect of benzodiazepines can occur. There is no evidence of a withdrawal syndrome or rebound hypertension associated with sudden withdrawal.

Organs and Systems

Mouth

Dryness of the mouth occurs in about 10% of patients who take moxonidine, but it is usually mild and occurs early in therapy. The effect is dose-dependent but shows no tendency to accumulate over time. This effect is consistent with an action of mildly inhibiting salivary flow.

Liver

- Cholestatic hepatitis occurred in an 83-year-old man after 9 months of continuous therapy with moxonidine. No autoantibodies were detected and liver biopsy showed features compatible with drug-induced inflammatory intrahepatic cholestasis. The patient recovered fully and his biochemical data normalized 8 weeks after withdrawal.

In a postmarketing surveillance program none of more than 20000 patients developed cholestatic hepatitis (2).

Drug Administration

Drug formulations

Whereas moxonidine appears to be generally well tolerated in hypertension, in congestive heart failure it was

© 2006 Elsevier B.V. All rights reserved.

prematurely withdrawn because of adverse outcomes on survival in a major trial, the MOXCON trial, in patients with NYHA class II-IV heart failure who were treated with modified-release moxonidine 0.5–3.0 mg/day or placebo (3). An interim analysis of the first 2000 patients enrolled showed that 53 patients taking moxonidine, compared with 29 taking placebo, died in the first 6 months and the trial was stopped prematurely. Excess mortality in the moxonidine arm appeared to be related to sudden death. The reason for this adverse outcome has to be fully elucidated. Although it has not been established that moxonidine caused a higher mortality rate, it is no longer being used in patients with heart failure. From the large database available there is no concern with regard to any adverse effect on survival with the immediate-release formulation used in hypertension.

Drug–Drug Interactions

Lorazepam

When co-administered with lorazepam 0.4 mg, moxonidine increased impairment of attentional tasks (choice, simple reaction time and digit vigilance performance, memory tasks, immediate word recall, delayed word recall accuracy, and visual tracking). These effects should be considered when moxonidine is co-administered with lorazepam, although they were smaller than would have been produced by a single dose of lorazepam 2 mg alone (4).

Mupirocin

General Information

Mupirocin is an antibiotic that inhibits bacterial protein synthesis by binding to isoleucyl transfer RNA synthetase. It is primarily bacteriostatic at low concentrations, but is bactericidal in the high concentrations and can have activity against organisms reported to be relatively resistant in vitro.

In a randomized, double-blind, placebo-controlled trial, 97 of 2012 patients treated with mupirocin reported adverse effects, such as rhinorrhea and itching at the site of application (1).

Spontaneous rupture of polyurethane peritoneal catheter has been attributed to mupirocin ointment (2).

- An 84-year-old man with diabetic nephropathy and end-stage renal disease began continuous ambulatory peritoneal dialysis and over the next year had four episodes of exit-site infection and peritonitis and used mupirocin ointment. The exit-site catheter became dilated and during an episode of infection for which he used mupirocin on 6 successive days, a longitudinal rupture developed in the peritoneal catheter, which was removed. The peritoneal liquid contained *Escherichia coli* and *Proteus mirabilis* and the catheter tip contained *E. coli* and *Enterobacter cloacae*. He was treated with ciprofloxacin, without complications, and after 1 month a new peritoneal catheter was inserted.

Organs and Systems

Skin

Mupirocin ointment can occasionally cause allergic contact dermatitis (3).

Long-Term Effects

Drug tolerance

Resistant *Staphylococcus aureus* can emerge during treatment with mupirocin.

In 149 patients undergoing chronic peritoneal dialysis, *S. aureus* was isolated from 26 patients, 25 from the nares, axillae, or groins and one from the catheter exit site (4). So-called "high-level" mupirocin-resistant organisms (minimum inhibitory concentration 256 mg/ml or more) were isolated from four patients. Methicillin-resistant organisms (MRSA) were not detected. One patient with high-level mupirocin-resistant organisms had peritonitis due to *S. aureus*, resulting in treatment failure and catheter loss.

Of 36 patients undergoing continuous ambulatory peritoneal dialysis (mean age 55 years; 21 men), who had been applying mupirocin to the catheter exit site once weekly for an average of 3.1 years before the start of the study, three were nasal carriers of *S. aureus*, and there was only one mupirocin-resistant organism (5). Once-weekly application of mupirocin at catheter exit sites led to comparable rates of colonization by mupirocin-resistant *S. aureus* as did thrice-weekly or more frequent application.

Muramyl tripeptide

General Information

The antitumor properties of muramyl tripeptide are thought to be related to its immunoenhancing effects, in particular on the monocyte/macrophage system. Its most common adverse effect is a flu-like syndrome, usually during the first administration. In one trial in nine patients, four had mild to moderate respiratory distress, two of whom had pre-existing asthma and symptoms suggestive of asthma exacerbation (1).

Muromonab–CD3

See also Monoclonal antibodies

General Information

Muromonab–CD3 (orthoclone, OKT3) is a murine monoclonal antibody targeted against the human CD3-receptor–T cell complex. This powerful immunosuppressive agent is used in the treatment of acute transplant rejection. Its use during initial rejection prophylaxis is subject to debate because excessive immunosuppression can increase the risk of infections and secondary malignancies (1). Renal transplant patients with a high risk of rejection have been suggested as possible candidates for muromonab prophylaxis (2). Excessive immunosuppression and unexpected over-activation of the immune system are the main adverse effects.

Cytokine release syndrome

A complex of acute systemic symptoms referred to as the "cytokine-release syndrome" is the most typical adverse effect of muromonab (3). A flu-like reaction is the key component of this complex syndrome, including fever, chills, headache, myalgia, tachycardia, and gastrointestinal symptoms. Other systemic and severe manifestations of the syndrome include acute pulmonary edema and neurological, renal, and hematological disorders. Symptoms occur within 1 hour after the initial doses of muromonab and last for several hours. A lower incidence and less severity were observed after subsequent doses (4). The cytokine-release syndrome was also less frequent after low doses or a 2-hour infusion of muromonab (instead of conventional doses or single bolus infusion) and it was thought to be more severe and of longer duration in patients with moderate-to-severe graft rejections (5–9).

Considerable efforts have been made to prevent or control the cytokine-release syndrome and its consequences (10). High-dose methylprednisolone (8 mg/kg) given before muromonab remains the basis of prophylaxis, and two separate doses are more effective than a single bolus (11). In a retrospective comparison of 345 renal transplant patients, other investigators found that the use of diltiazem allowed a reduction in the dosage of methylprednisolone, reduced nephrotoxicity, and reduced both delayed graft function and postoperative intragraft thrombosis (12). Indometacin, even at low doses, has also been successfully used without impairing rejection reversal or renal function (13). In contrast, prophylaxis with pentoxifylline was not supported in one carefully controlled study (14).

Although the release of a wide range of cytokines was increased after muromonab administration, tumor necrosis factor alfa and interleukin-6 were suggested to play a pivotal role, and monoclonal anti-TNF-alfa antibody administration reduced the acute clinical symptoms (15). A role for the activation of complement and neutrophils was also suggested.

Several humanized CD3 antibodies have been produced and tested, with the aim of reducing the adverse effects associated with the murine orthoclone antibody. The first results in renal transplant patients were encouraging, with promising clinical results, no evidence of antiglobulin response, and no or very few and minimal adverse effects attributable to various humanized monoclonal CD3 antibodies (16,17). In particular, careful patient monitoring failed to identify any significant cytokine release syndrome.

Organs and Systems

Cardiovascular

Cardiovascular manifestations are usually observed during the cytokine-release syndrome. They mostly included tachycardia and transient hypertension or hypotension (4). Fluid overload or volume depletion can also play a role. Chest pain or severe dysrhythmias are infrequent (18).

Muromonab has been thought to exert procoagulant activity and activate fibrinolysis, probably as a result of TNF-alfa release of other cytokines and cellular adhesion to the vascular endothelium (19,20). Accordingly, retrospective studies have pointed to an increased risk of intragraft thromboses with thromboses in the renal artery, renal vein, or glomerular capillaries, or thrombotic microangiopathy, leading to a higher incidence of rejection episodes in patients receiving high or conventional doses of muromonab (19,21). Among 231 kidney transplant

© 2006 Elsevier B.V. All rights reserved.

recipients who received muromonab prophylaxis, intragraft thromboses were found in 13 (5.6%), and the use of very high-dose methylprednisolone (30 mg/kg) was suggested to be a major risk factor (22). In contrast, and despite the evidence of procoagulant activity, some investigators have failed to identify evidence that muromonab increases the risk of thromboembolic complications (20,23).

Respiratory

Dyspnea and pulmonary edema sometimes develop during the cytokine-release syndrome. Pulmonary toxicity was mostly observed in patients who had fluid retention and weight gain before receiving muromonab. The incidence has been markedly reduced by the formulation of guidelines for management (3). Cytokine release and complement activation with further neutrophil activation and pulmonary vascular endothelium damage were suggested to be involved (24).

Nervous system

Self-limiting and benign central nervous system manifestations mimicking those of aseptic meningitis, that is fever, headache, nuchal rigidity, cognitive disorders, and photophobia, were observed in 3–10% of patients who received muromonab (3). The symptoms were usually delayed for 2–3 days and resolved spontaneously despite continuation of treatment. More severe neurological disorders requiring withdrawal have been observed in up to 7% of patients (25). The various reported symptoms consisted of slowly reversible diffuse encephalopathy with mental changes, neurosensory hallucinations, tinnitus with reversible hearing loss, transient hemiparesis, cerebral infarction, generalized or focal seizures, cortical blindness, psychotic symptoms, obtundation, and coma (SED-13, 1132) (SEDA-21, 380) (25). Diabetes and severely impaired renal function were possibly significant risk factors (SEDA-19, 353) (SEDA-21, 380). Neurotoxic symptoms were supposedly mediated by cytokine release and potentiated by uremic toxins. Raised concentrations of tumor necrosis factor alfa in the cerebrospinal fluid were suggested to play a major role in muromonab-induced aseptic meningitis and encephalopathy (26).

Muromonab-induced aseptic meningitis is relatively common and is usually benign, with prompt recovery despite continuation of treatment.

- In a 28-year-old man the clinical features of aseptic meningitis were prolonged over 1 month after the administration of muromonab, and persistent severe headaches resolved only after several aspirations of cerebrospinal fluid (27).

This case was described as a syndrome of headache with neurological deficits and CSF lymphocytosis (HaNDL syndrome).

Sensory systems

Eyes

Spontaneously reversible mild conjunctivitis and episcleritis have been noted in 75 and 10% of patients respectively.

Diffuse anterior scleritis responding to an increased dosage of prednisone was mentioned in one patient (28).

Isolated visual loss (persistent in one patient) shortly after muromonab administration is rare (SEDA-20, 340) (29).

Ears

Ototoxicity from muromonab has been described, but the incidence is unknown (SEDA-21, 380). Audiograms performed before and 48–72 hours after administration of muromonab showed sensorineural hearing loss of at least 15 db in five of seven renal transplant patients (30). A third audiogram 2 weeks after muromonab treatment showed amelioration or complete recovery in all four of the patients who were tested.

Hematologic

Acute thrombocytopenia has been reported in one patient (SEDA-21, 380).

Liver

Hepatitis has been attributed to cytokine release from muromonab (31).

- A 31-year-old man underwent renal transplantation for end-stage renal disease secondary to hypertension. He was given basiliximab for induction immunosuppression. At 13 months after transplantation he had evidence of transplant rejection. His creatinine concentration rose acutely from 83 to 165 μmol/l over 1 week. This was his first rejection episode (Banff IIa). There was no evidence of viral infection. He received muromonab with conventional prophylaxis (antihistamines, paracetamol, and corticosteroids) to reduce the severity of cytokine release. This was his first exposure to muromonab. Initially he complained of fever and nausea, and the following day he was somnolent and had right upper quadrant tenderness. Liver function tests, which had been normal on the day of admission, were abnormal. Hepatitis serology showed positive hepatitis B core antibody (IgM and IgG), positive hepatitis A antibody, negative hepatitis surface antigen, and negative hepatitis C antibody. The hepatitis B core antibody (IgM and IgG) had been positive before transplantation 16 months before. Muromonab was withdrawn and he showed signs of clinical and chemical improvement. Rejection was successfully treated with glucocorticoids and antithymocyte globulin.

Urinary tract

Spontaneously reversible increases in serum creatinine concentrations occurred in 8–18% of muromonab-treated patients, and were thought to have resulted from inhibition of renal prostaglandin synthesis and release of cytokines (32,33). There were no adverse consequences on short-term graft survival or graft function (32).

Isolated cases of hemolytic-uremic syndrome have been reported (SED-13, 1133) (SEDA-21, 380).

© 2006 Elsevier B.V. All rights reserved.

Immunologic

An antibody response to muromonab has been detected in 40% of patients undergoing a 14-day induction regimen of muromonab 5 mg/day (10). It has been suggested that the incidence of antimuromonab antibodies depended on the immunosuppressive regimen, but this was based on a retrospective study in a limited number of patients (SEDA-22, 409). Furthermore, sensitization was not relevant in most patients. Only raised IgG anti-idiotypic antibodies in high enough titers (over 1:1000) significantly neutralize the binding of muromonab to the CD3 receptor and reduce clinical efficacy, thus precluding further muromonab administration.

Antimuromonab IgE antibodies have been identified after 10–25 days of treatment in six of 181 patients, and only in those with high titers of antimuromonab IgG antibodies (34). Immediate IgE-mediated anaphylactic reactions, namely anaphylactic shock, bronchospasm, urticaria, have been rarely reported and have sometimes been difficult to differentiate from the cytokine-release syndrome (35,36). Late-onset reactions after the first week of treatment, including cutaneous erythema, a fall in blood pressure, or serum sickness-like reactions, are infrequent (37).

Rare anaphylactic reactions with antimuromonab IgE antibodies have been reported (SED-14, 1309). Anaphylactoid reactions to muromonab can also occur (38).

- A 15-year-old girl underwent uneventful renal transplantation. On the third postoperative day she received her first dose of muromonab for a presumptive diagnosis of graft rejection. Despite premedication with diphenhydramine, paracetamol, and high-dose methylprednisolone, within 20 seconds after intravenous muromonab, she developed shortness of breath, digital paresthesia, facial edema, laryngeal stridor, reduced oxygen saturation, and a fall in blood pressure. She recovered after intubation and appropriate vasopressor administration, but required transplant nephrectomy for hemorrhagic and coagulative necrosis of the transplanted kidney.

This acute reaction was supposedly mediated by nonimmunologic mast cell degranulation, as screening for IgE antimuromonab antibodies was negative.

As with other potent immunosuppressive drugs, muromonab has been suspected to increase the risk of infections. Multiple possible biases in studies of the incidence of muromonab-associated infections have been discussed (3); there were no differences among patients who received muromonab compared with those who received other immunosuppressive regimens. Since then, several other investigators have reported their findings, indicating that this debate continues.

In patients with renal transplants, the overall incidence of infections during the first three posttransplantation months was significantly higher in one trial of patients treated with prophylactic muromonab or ciclosporin (39), but there was no significant difference in the severity of infections in another similar trial (40). Both studies failed to identify any adverse impact of infectious episodes on patient survival. In a comparison of prophylactic ATG-Fresenius with muromonab there were more common minor infections (for example, cutaneous mycosis, *Herpes simplex* virus infections) in the muromonab arm, but a similar incidence of life-threatening or severe infections (41). In contrast to these findings, a large retrospective study showed a significantly higher incidence of infection-related deaths among patients who received muromonab for induction therapy compared with those who did not receive muromonab (42). However, renal graft survival was significantly improved in patients treated with muromonab, and there were no subsequent viral deaths after the routine use of appropriate anti-infectious prophylaxis.

In patient with liver transplants (43,44) or heart transplants (45), retrospective studies have shown that muromonab treatment is an additional or independent risk factor for symptomatic cytomegalovirus infections in cytomegalovirus-seropositive patients or in recipients of cytomegalovirus-seropositive donors, suggesting that cytomegalovirus prophylaxis should be implemented in these patients. It has also been suggested that early muromonab administration in the posttransplant period increases the likelihood of invasive cytomegalovirus disease after liver transplantation (46). In contrast, other investigators failed to show an increased incidence of cytomegalovirus infections after muromonab versus triple drug therapy in heart transplant patients (47). Based on a retrospective study of 154 liver transplant patients, muromonab was suggested as a risk factor for *Pneumocystis jiroveci* pneumonia (48).

These results suggest that the incidence and severity of infections is more likely to be related to the degree of immunosuppression than to the effect of an individual drug.

Long-Term Effects

Tumorigenicity

As expected from its pronounced immunosuppressive activity, muromonab is a significant risk factor for secondary neoplasia, especially when high doses, increased treatment duration, sequential courses, or early retreatment are used (49). Whether the increased risk of neoplasia after muromonab-based immunosuppression is due to the drug itself or reflects the overall degree of immunosuppression is a matter of debate, and conflicting results have emerged. Several retrospective or controlled studies did not show more frequent malignancies after muromonab compared with other immunosuppressive regimens (50–52). On the other hand, the rate of non-Hodgkin's lymphomas was higher in kidney and heart transplant recipients who received muromonab prophylaxis rather than antithymocyte/antilymphocyte globulin (53). Using data from the manufacturers and the literature, the rate of malignancies after muromonab was estimated to be 0.57% (54), but potential under-reporting strongly limited the validity of this estimation. Although the roles of high cumulative doses or repeated courses as risk factors are not definitely proven, it is usually recommended not to exceed 14 days of treatment with cumulative doses of 70 mg (3).

An analysis of the Australia and New Zealand Dialysis and Transplant Registry (7953 patients with 9460 renal

© 2006 Elsevier B.V. All rights reserved.

transplants) has confirmed that immunosuppression with polyclonal and monoclonal muromonab antibodies independently increases the risk of virus-mediated cancer (55). The increased risk was about 60% for non-Hodgkin's lymphoma and 75% for non-Hodgkin's lymphoma plus, in women, carcinoma of the cervix, vagina, and vulva.

Muzolimine

See also Diuretics

General Information

Muzolimine is a diuretic with a long duration of action, slightly more effective than furosemide. In Germany muzolimine was withdrawn 2 years after its introduction.

Organs and Systems

Nervous system

Of 29 patients with chronic renal insufficiency treated with high doses of muzolimine, five developed a neurological syndrome very similar to multiple sclerosis (1). Other reports of severe neurotoxicity with muzolimine have appeared (SEDA-16, 225).

MW-2884

See also Non-steroidal anti-inflammatory drugs

General Information

MW-2884 (10-methoxy-4*H*-benzo-(4,5)-cycloheptathiophene-4-glindene acetic acid) is an inhibitor of monokine release. In 12 patients with rheumatoid arthritis it caused gastrointestinal disturbances, temporary liver function impairment, and allergic skin reactions. One patient stopped taking it because of severe urticaria (1).

Mycophenolate mofetil

General Information

Mycophenolate mofetil, the morpholinoethyl ester of mycophenolic acid (rINN), is an antimetabolite that interferes with the synthesis of nucleic acids and selectively inhibits the proliferation of T and B lymphocytes. It has been used to treat psoriasis and to prevent acute renal allograft rejection in combination with ciclosporin and glucocorticoids.

Uses

In 16 renal transplant patients with suspected ciclosporin nephrotoxicity, the addition of mycophenolate allowed safe reduction in the dosage of ciclosporin, with subsequent improvement in renal function and arterial blood pressure over 6 months (1). It might allow the rapid withdrawal of glucocorticoids in patients taking ciclosporin or tacrolimus, and therefore reduce the incidence of glucocorticoid-induced post-transplant diabetes, hypercholesterolemia, and hypertension (2). There have been several reports of patients with ciclosporin-associated thrombotic microangiopathy/hemolytic-uremic syndrome in whom mycophenolate was successfully substituted (3,4).

When mycophenolate replaced ciclosporin in 17 renal transplant patients with ciclosporin nephropathy, serum creatinine concentrations fell by a mean of 26% (5). There were no cases of acute allograft rejection. Adverse effects of mycophenolate were not mentioned.

There were beneficial effects on blood pressure, lipid profile, and glomerular hemodynamics by switching from ciclosporin to mycophenolate in an open study in 17 renal transplant patients with stable renal function who took ciclosporin and prednisone in two steps (6). In step I mycophenolate was added and the dose of ciclosporin was progressively reduced to produce one-third of the original trough concentration; this took about 20 weeks. In step II, ciclosporin was gradually withdrawn over 6 weeks. During step I, two patients dropped out, one with severe diarrhea which reversed after mycophenolate withdrawal and one with biopsy-proven acute rejection, with recovery after mycophenolate withdrawal and an increase in the dose of ciclosporin. During step II there was no acute rejection. At 1 year after the end of the study, two patients had stopped taking mycophenolate, one because of recurrent upper airway infections (probably not related to mycophenolate) and one because of Kaposi's sarcoma of the leg. In the last case a possible role of mycophenolate could not be ruled out (SEDA-24, 429).

Mycophenolate has also been studied in various chronic inflammatory disorders, such as rheumatoid arthritis, pemphigus vulgaris, and psoriasis. In 70 patients with chronic active Crohn's disease, mycophenolate plus glucocorticoids produced benefit on disease activity comparable to azathioprine plus glucocorticoids (7). Two of the 35 patients randomized to mycophenolate had significant adverse effects that required drug withdrawal, namely rashes and vomiting.

General adverse effects

In three pivotal clinical trials of mycophenolate mofetil in kidney transplant recipients, adverse effects were in accordance with the known antiproliferative effect of mycophenolate, namely gastrointestinal disorders, leukopenia, and opportunistic infections, in particular cytomegalovirus tissue invasive disease (SED-13, 1130) (SEDA-20, 346). Nephrotoxicity was not observed in clinical trials, and renal function significantly improved in six patients converted to mycophenolate for ciclosporin nephrotoxicity (8).

In one patient, mycophenolate mofetil was putatively involved in a constellation of symptoms that included fever, exudative pharyngitis, adynamic ileus, electrolytic abnormalities, and myocardial dysfunction, which resolved on withdrawal (SEDA-20, 346).

Organs and Systems

Respiratory

Interstitial pneumonitis with severe respiratory failure has been reported in two patients (SEDA-21, 389) (SEDA-22, 418). One patient improved after mycophenolate mofetil was withdrawn, but interstitial fibrosis was found on serial lung biopsies. The other patient died from respiratory failure 3 months later. Although other drugs may have been involved in these two patients, one other reported case with recurrence of respiratory failure on each rechallenge of mycophenolate is particularly convincing.

There was a dry cough in five of 45 patients taking mycophenolate, associated with dyspnea and hypoxia in one patient and asthma exacerbation in another (9). As the symptoms reversed only after mycophenolate mofetil withdrawal, the authors suggested that dry cough and dyspnea should be considered as early symptoms of pulmonary toxicity.

© 2006 Elsevier B.V. All rights reserved.

Hematologic

There was a dose-related increase in the incidence of leukopenia in the three pivotal trials.

Abnormalities of neutrophil morphology have been reported with mycophenolate.

- In two transplant patients, changes in circulating neutrophils (nuclear hypolobulation and abnormal clumping of nuclear chromatin) were identified after 4–5 months of treatment with mycophenolate (10). A bone marrow aspirate in one patient showed hypocellularity, abnormal clumping of chromatin beyond the promyelocyte stage, and almost no segmented neutrophils. These morphological abnormalities preceded the appearance of peripheral neutropenia in both patients and normalized after mycophenolate withdrawal.

The authors suggested that neutrophil dysplasia had resulted from inhibition of guanosine nucleoside synthesis.

Gastrointestinal

Mycophenolate mofetil often causes gastrointestinal disorders, most commonly a dose-related diarrhea and more rarely esophagitis, gastritis, duodenal or colonic ulceration, and gastrointestinal hemorrhage (SEDA-22, 418). Diarrhea can be extremely severe for various reasons, such as inappropriate dosage in low-weight patients, renal insufficiency, drug interactions (for example with sulfinpyrazone) interfering with the renal tubular excretion of mycophenolate metabolites. That was the case in two patients who had frequent diarrhea with significant weight loss and electrolyte disturbances requiring parenteral nutrition (SEDA-21, 389).

Pooled data from the tricontinental and the US studies in kidney transplant patients showed incidences of diarrhea of 31 and 36% in patients taking 2 and 3 g/day respectively (11). In a retrospective study, 29% of 109 mycophenolate-treated patients had diarrhea that required hospitalization and 12% developed upper intestinal symptoms (gastritis, esophagitis) (12). Frequent dosage reduction was necessary and only 28% of patients were still taking full doses after 1 year.

Gastrointestinal toxicity was confirmed to be the most frequent adverse effect (53%) in 120 pancreas transplant patients who received a triple immunosuppressive regimen consisting of mycophenolate, tacrolimus, and prednisone (13). As a result, conversion from mycophenolate to azathioprine at 1 year was mostly due to gastrointestinal toxicity, which was significantly more frequent in recipients of pancreas transplantation alone (49%) compared with recipients of pancreas transplantation after previous kidney transplantation (26%) or recipients of simultaneous pancreas and kidney transplants (14%). In another study in 120 kidney transplant patients randomized to receive tacrolimus and prednisone with or without mycophenolate, there was a high rate of mycophenolate withdrawal (43%) during the first 6 months, mostly because of gastrointestinal toxicity (14). In both of these studies, the withdrawal rate was higher than in the pivotal trials in kidney transplant patients (4–10% after 6 months) (11). As both studies used a combination of tacrolimus plus mycophenolate rather than mycophenolate plus ciclosporin, a synergistic effect on the gastrointestinal tract, or more probably higher serum concentrations of mycophenolic acid due to an interaction with tacrolimus, could have contributed (SEDA-21, 390) (SEDA-22, 421).

The mechanism of gastrointestinal toxicity is not well understood.

- A 42-year-old woman with a renal transplant taking triple immunosuppression (azathioprine, ciclosporin, and glucocorticoids) was converted after 7 years from azathioprine plus ciclosporin to mycophenolate (2 g/day) because of ciclosporin nephrotoxicity (15). Within 2 months she had developed severe persistent watery diarrhea (5–10 stools/day) and lost 7 kg over 2 months. Investigations ruled out an infectious cause and there were features of duodenal villous atrophy on histological examination. Diarrhea disappeared after mycophenolate withdrawal and two subsequent duodenal biopsies showed improvement 2 months later and further complete recovery 6 months later.

This report suggests that loss of normal villous structure is one of the possible mechanisms of mycophenolate-induced severe diarrhea.

Diarrhea is the most commonly reported adverse effect in patients with transplants taking mycophenolate. In 26 renal transplant recipients with persistent afebrile diarrhea (daily fecal output over 200 g), prospectively investigated for infections and morphological and functional integrity of the gastrointestinal tract, all but one had an erosive enterocolitis; 70% had malabsorption of nutrients, which contributed to the diarrhea (16). In about 60% an infectious origin was demonstrated and successfully treated with antimicrobial drugs without changing the immunosuppressive regimen. In about 40% there was no infection but a Crohn's disease-like pattern of inflammation. These patients also had less pronounced malabsorption of bile acids but a significantly faster colonic transit time, which correlated with trough concentrations of mycophenolic acid. Withdrawal of mycophenolate was associated with allograft rejection in one-third of these patients.

Ischemic colitis has also been attributed to mycophenolate (17).

- A 49-year-old woman taking ciclosporin, prednisolone, and mycophenolate developed acute refractory rejection 4 days after renal transplantation. After an unsuccessful glucocorticoid pulse, her immunosuppressive regimen was successively changed to muromonab and tacrolimus with mycophenolate maintenance. Twelve days after transplantation she had abdominal pain and watery/bloody diarrhea. Colonoscopy showed multiple ulcers with mucosal injection and colon edema. A biopsy suggested ischemic colitis and cytomegalovirus infection was ruled out. Her symptoms persisted until mycophenolate was withdrawn and further colonoscopy showed complete resolution.

Patients with inflammatory bowel disease unresponsive to azathioprine or intolerant of it may benefit from mycophenolate mofetil. Of 12 patients so treated, three had minor adverse effects (headache, nausea, arthralgia). Three with ulcerative colitis developed rectal bleeding while taking mycophenolate mofetil. Histological features of the mucosa were highly

© 2006 Elsevier B.V. All rights reserved.

suggestive of drug-induced bleeding. Enterohepatic recycling results in high colonic concentrations of mycophenolic acids, which may have a direct toxic effect on the epithelium (18).

Liver

In two renal transplant patients, serum bilirubin concentrations increased to 46 and 63 μmol/l within 3–7 days of mycophenolate treatment, and further increased to 98 μmol/l in one patient after the dose was increased (19). The bilirubin concentration returned to normal or pretreatment values after withdrawal or dosage reduction. Although both patients also received ciclosporin, which has been associated with hyperbilirubinemia, the temporal relation and a possible dose-dependent effect favored a causative role of mycophenolate.

Skin

Mycophenolate-induced eczema has been reported (20).

- A 45-year-old woman with a liver transplant began to take mycophenolate mofetil (2 g/day) before planned ciclosporin withdrawal. After 3 days she developed pruritus and a bullous eruption on her hands and feet. The lesions improved after mycophenolate was withdrawn, but soon reappeared after readministration of a lower dose (500 mg/day). A skin biopsy showed dyshidrotic eczema and a skin test with mycophenolate mofetil produced recurrence.

Hair

Alopecia has been noted in two patients converted from ciclosporin to mycophenolate (SEDA-22, 418).

- Onycholysis with blisters and loose toenails has been observed in a 45-year-old man who took tacrolimus, prednisone, and mycophenolate for 3 weeks after renal transplantation (21). The lesions improved after withdrawal and recurred after two subsequent re-exposures.

Immunologic

Transplant rejection

In a randomized study, 14 patients with liver transplants were given calcineurin inhibitors and 14 were given mycophenolate mofetil monotherapy (22). Those who were given mycophenolate had reversible episodes of acute graft rejection and there were no such episodes in those who were given calcineurin inhibitors.

In 11 patients with orthotopic liver transplants who had adverse effects from ciclosporin or tacrolimus, mycophenolate mofetil monotherapy for 1 year was successful. This was followed by a randomized, controlled trial in 18 patients, of whom nine were given mycophenolate mofetil (23). Five patients completed the 3 month trial. Of these, two had an episode of acute rejection, one after 2 months and one after 3 months, which did not respond to the reintroduction of tacrolimus and intravenous glucocorticoids. One had a glucocorticoid-responsive episode of severe acute rejection after 3 weeks. The other two patients had normal liver function tests after 2 weeks and 2 months respectively, when the trial was stopped. Mycophenolate mofetil allows a reduction of the dose of calcineurin inhibitor, with a low risk of rejection and improvement in renal function. However, it is associated with an unacceptable risk of acute rejection.

Infection risk

The role of mycophenolate in the occurrence of opportunistic infections is debated. In a retrospective comparison of 358 simultaneous pancreas plus kidney transplant patients who received a ciclosporin-based immunosuppressive regimen, the rate of opportunistic infections was similar in patients treated with mycophenolate ($n = 109$) and azathioprine ($n = 249$) (12). However, very few patients taking mycophenolate were available for long-term comparison. In contrast, another retrospective comparison of 135 renal transplant patients (69 for prophylactic treatment and 66 for rescue therapy) showed that the combination of mycophenolate, tacrolimus, and prednisone ($n = 49$) produced fewer rejection episodes, but a significantly higher incidence of infectious episodes than the combination of mycophenolate, ciclosporin, and prednisone (24). In another randomized trial of 120 renal transplant patients, there was a significantly higher rate of asymptomatic or symptomatic cytomegalovirus infection in patients who took mycophenolate, tacrolimus, and prednisone than in patients who took tacrolimus plus prednisone (20 versus 5%) (14). Overall, both of these studies suggest that mycophenolate plus tacrolimus has a more potent immunosuppressive effect, with an increased risk of infections (and theoretically lymphoproliferative disorders), as the counterpart of a possible greater effect on acute rejection prophylaxis.

Bacterial infections

- Staphylococcal septicemia complicated by endocarditis has been reported in a 50-year-old woman after 5 months of treatment with mycophenolate for atopic dermatitis (25).

As the skin of most patients with atopic dermatitis can be colonized with *Staphylococcus aureus*, the authors suggested caution in using mycophenolate, which can also cause leukopenia. This patient had previously taken ciclosporin and azathioprine, which were ineffective, but without apparent infectious complications. A specific role of mycophenolate is therefore debatable and the occurrence of bacterial septicemia may have been purely coincidental.

Mycobacterium hemophilum is a pathogen that is found in immunosuppressed patients, such as those with malignancy, AIDS, and organ transplants. Systemic lupus erythematosus can make patients more susceptible to infection.

- A 25-year-old Chinese woman with systemic lupus erythematosus had a disease course characterized by multiple flares involving the kidneys, central nervous system, and gastrointestinal tract (26). She was given mycophenolate mofetil and multiple courses of antibiotics, with a poor response. After about 9 months she developed a recurrent right leg cellulitis. Two initial skin biopsies yielded negative bacterial and mycobacterial cultures, but histopathology of the muscle of

© 2006 Elsevier B.V. All rights reserved.

her right thigh showed acid-fast bacilli and culture subsequently grew *M. hemophilum*.

The authors concluded that this complication had been due to late diagnosis, multiple antibiotics, and immunocompromise. These points must be taken into consideration when treating a patient with mycophenolate mofetil.

Virus infections

Cytomegalovirus

The role of mycophenolate in the rate and severity of cytomegalovirus infection in transplant patients has been debated (SEDA-23, 407) and is difficult to evaluate in otherwise immunosuppressed patients. Whereas there was a dose-related increase in the incidence of cytomegalovirus disease in the three pivotal trials, a later analysis did not confirm that mycophenolate mofetil is specifically associated with an increased risk of cytomegalovirus infection, and suggested that over-immunosuppression rather than mycophenolate mofetil per se was the main contributing factor (SEDA-22, 418) (27–29).

- Severe cytomegalovirus pancolitis has been reported in a 59-year-old man taking only mycophenolate and prednisone for Wegener's granulomatosis (30).

In a retrospective study of 84 cytomegalovirus-seronegative renal transplant patients who received a kidney from a cytomegalovirus-seropositive donor without cytomegalovirus prophylaxis, the incidence of primary cytomegalovirus infection was similar in the 24 patients who took mycophenolate plus ciclosporin and prednisone, compared with the 60 patients who took ciclosporin and prednisone alone (31). However, the incidence of cytomegalovirus disease was nearly twice as high in the mycophenolate group (67 versus 30%), but with no difference in the severity of the disease. The authors speculated that the more frequent incidence of symptomatic cytomegalovirus disease might have been due to some specific effects of mycophenolate on the primary immune response to cytomegalovirus.

Mycophenolate mofetil has been compared with azathioprine in combination with ciclosporin and glucocorticoids in 65 children after kidney transplantation (32). The main adverse effects of this treatment were infections of the urinary tract and the upper respiratory tract, abdominal pain, and diarrhea. Opportunistic infections with cytomegalovirus or cytomegalovirus syndrome occurred in 20% within the first 6 months and tissue-invasive cytomegalovirus disease in 3.1%. These results were similar to those in adults.

Varicella

A retrospective study in 19 children with renal transplants identified three who developed disseminated varicella, despite a prior history of chickenpox in two and pretransplant varicella vaccination in one (33). The clinical disease was mild and responded promptly to oral aciclovir. Although this was based on very few patients, the incidence of 16% was thought to be unexpectedly higher than that reported in historic controls (0.7–1.9%), and might have resulted from the higher degree of immunosuppression achieved with mycophenolate mofetil.

Herpes simplex

To evaluate whether mycophenolate mofetil is effective in treating moderate to severe atopic dermatitis, an open pilot study was conducted in 10 patients (34). There were no serious adverse effects, but one patient had to discontinue treatment because he developed *Herpes simplex* retinitis, which resolved after treatment with aciclovir. Although there is no direct evidence that mycophenolate mofetil is a major cause of *Herpes* retinitis, in this patient it seems likely that it was due to immunosuppression. In contrast, in vivo and in vitro mycophenolate mofetil strongly potentiates the antiherpetic effects of aciclovir, ganciclovir, and penciclovir (35). It is probably therefore enough to give antiviral therapy only when clinical signs of *Herpes* infection occur.

Fungal infections

There have been two cases of intestinal microsporidiosis (36) and one case of *Nocardia asteroides* brain abscess (37) in adults taking mycophenolate mofetil.

Body temperature

- Isolated and intermittent drug fever with a spiking pattern has been attributed to mycophenolate in a 41-year-old man with a renal transplant (38). The relation to treatment was confirmed by the exclusion of numerous infectious causes, the persistence of fever despite ciclosporin withdrawal, subsidence of fever after mycophenolate withdrawal, and the absence of further episodes of fever during follow-up.

Long-Term Effects

Tumorigenicity

- Kaposi's sarcoma recurred 4 months after starting mycophenolate in a 58-year-old renal transplant patient who 7 years before had had similar lesions that reversed on withdrawal of ciclosporin (39).
- Kaposi's sarcoma has been reported after a mean of 7 months of treatment in three renal transplant patients whose immunosuppressive regimen included mycophenolate mofetil (40).

The investigators of the second case found that the incidence of Kaposi's sarcoma in patients taking regimens containing mycophenolate mofetil was 0.8% (3/371 patients) compared with 0.1% in patients not taking it (2/1464). It was suggested that mycophenolate mofetil might increase the susceptibility to Kaposi's sarcoma.

Second-Generation Effects

Pregnancy

- A 33-year-old woman was given a living related donor kidney transplantation during the first trimester, followed by mycophenolate mofetil, tacrolimus, and prednisone (41). The mother did well, except for mild pre-eclampsia and mild renal insufficiency. The child was born prematurely during the 36th week. The only teratogenic effects detected were hypoplastic nails and a short fifth finger.

Susceptibility Factors

Age

The adverse effects of mycophenolate mofetil in children have been reviewed retrospectively in 24 renal transplant patients (mean age 14 years) switched from azathioprine to mycophenolate mofetil a mean of 4.8 years after transplantation (42). The mean dose of mycophenolate mofetil was 560 mg/m^2. After a mean of 9.6 months, 13 had to discontinue treatment because of adverse effects, namely severe and partially reversible anemia (10 patients, of whom three required transfusions), neutropenia ($n = 1$), and diarrhea ($n = 2$). The anemia was normocytic and normochromic in nine patients, and such a high incidence of severe anemia was unexpected from the available adult data. Although patients who discontinued treatment had a lower pretreatment-calculated creatinine clearance, this was not significant and probably not the major cause of anemia. The author speculated that the anemia resulted from a disproportionately high unbound plasma concentration of mycophenolate mofetil, due to reduced protein binding and impaired renal clearance.

Drug–Drug Interactions

Ciclosporin

In 52 patients taking mycophenolate mofetil 1 g bd, prednisone, and ciclosporin to a target blood concentration of 125–175 ng/ml for 6 months after transplantation, withdrawal of ciclosporin resulted in almost a doubling of mycophenolic acid trough concentrations (43).

Tacrolimus

Patients taking tacrolimus have higher mycophenolate mofetil plasma trough concentrations than patients taking ciclosporin (44). Compared with the combination of ciclosporin plus mycophenolate mofetil, tacrolimus plus similar doses of mycophenolate produced significantly higher serum concentrations of mycophenolic acid, resulting in a greater degree of in vitro immunosuppression (SEDA-21, 390).

Myeloid colony-stimulating factors

See also Individual agents

General Information

Around 10 glycoprotein myeloid hemopoietic growth factors or colony-stimulating factors (CSFs) have so far been identified and purified; their genes have been cloned and active recombinant proteins have been produced. Recombinant factors produced by yeast or mammalian cells are glycosylated, as they are in their native state, whereas those expressed in bacterial systems are not. Glycosylation may be clinically relevant with regard to the efficacy and antigenicity of the molecule, although antibody formation has not been observed, even after prolonged therapy (1). Most clinical studies with CSFs have hitherto been performed with granulocyte-macrophage colony-stimulating factor (GM-CSF) and granulocyte colony-stimulating factor (G-CSF), although clinical trials of other colony-stimulating factors have also been initiated in a number of centers. GM-CSF leads to a dose-related sustained increase in peripheral neutrophil numbers, with a delayed increase in circulating monocytes and eosinophils. The effect of G-CSF appears to be more restricted to neutrophils. Multi-CSF (IL-3) stimulates the production of all types of leukocytes, as well as platelets and reticulocytes (2).

Both granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF) have been extensively investigated for the treatment of chemotherapy-induced neutropenia, reducing the duration of neutropenia after bone marrow transplantation, or mobilizing peripheral blood progenitor cells after myelosuppressive chemotherapy (3). Other clinical uses are indicated in the monographs on the individual growth factors.

© 2006 Elsevier B.V. All rights reserved.

Two reviews have examined the available data on the effects of hemopoietic growth factors on the duration of neutropenia and mortality in drug-induced agranulocytosis, which mostly consists of isolated case reports or small series of patients (4,5). The authors reached contrasting opinions, suggesting that hemopoietic growth factors might or might not be of interest in patients with severe drug-induced agranulocytosis. Adverse effects were noted in 13 of 118 case reports (4). Although most of them were benign, pulmonary toxicity or acute respiratory distress syndrome occurred in a few patients.

Comparative studies

There were no major differences in the adverse effect profiles in 42 patients with breast cancer randomized to filgrastim (G-CSF) or molgramostim (GM-CSF) (SEDA-22, 407). There were no significant differences in the adverse effects profiles and severity of adverse effects in 181 patients with cancers randomized to receive filgrastim (G-CSF) or sargramostim (GM-CSF) for chemotherapy-induced myelosuppression (6).

The effects and the safety of a 5-day regimen of G-CSF ($n = 9$) or GM-CSF ($n = 8$) have been compared (7). Most patients complained of flu-like symptoms in both groups (six and seven respectively), but rash at the injection site was observed only in four patients treated with GM-CSF. In the G-CSF group, there was a fall in platelet count (below 150×10^9/l) in five patients, raised serum lactic dehydrogenase activity, and raised uric acid concentrations; three patients required transient treatment with allopurinol.

The frequency and severity of adverse effects associated with the prophylactic use of filgrastim or sargramostim have been assessed in a retrospective review of the medical records of 490 cancer patients from ten centers (8). Sargramostim-treated patients had significantly more frequent non-infectious fever, fatigue, diarrhea, injection site reactions, edema, and dermatological adverse effects, whereas skeletal pain was more frequent with filgrastim. In addition, switching to the alternative treatment was more frequent in the sargramostim group (18% of patients) than in the filgrastim group (none of the patients). The authors tried to minimize selection bias, but the strength of the results was limited by the retrospective nature of the study.

Susceptibility Factors

Age

Guidelines for the appropriate use of hemopoietic growth factors in children have been proposed by a panel of European experts, who carefully summarized the potential indications and recommendations, and concluded that adult guidelines are applicable to children in most cases (9). The authors considered that growth factors should be used in children for only a limited number of circumstances: prophylaxis or treatment in low-risk patients treated with chemotherapy, routine use in aplastic anemia, and mobilization of peripheral blood progenitor cells in healthy pediatric donors.

Myristicaceae

See also Herbal medicines

General Information

There are three genera of the family of Myristicaceae:

- *Horsfieldia*
- *Myristica* (nutmeg)
- *Virola* (virola).

Myristica fragrans

Myristica fragrans (nutmeg) has long been a highly desired spice. In the seventeenth century physicians claimed that a nutmeg pomander was a cure for the bloody flux and the sweating sickness, later called the black plague, and nutmeg was also supposed to have aphrodisiac properties (1). Mace, the dried shell of the nutmeg, is used as a spice; it should not be confused with

chemical Mace, which is a form of tear gas containing 1% chloracetophenone (CN) gas in a solvent of sec-butanol, propylene glycol, cyclohexene, and dipropylene glycol methyl ether; some formulations also include oleoresin *Capsicum* (from peppers).

Myristicin is methoxysafrole, the principal aromatic constituent of the volatile oil of nutmeg. Myristicin is also found in several members of the carrot family (Apiaceae, formerly Umbelliferae), such as *Petroselinum crispum* (parsley) (2). Safrole is a mutagenic and animal carcinogenic monoterpenoid. It is the major component of oil of sassafras, and lesser quantities occur in essential oils from cinnamon, mace, nutmeg, and star anise. Some of its known or possible metabolites have mutagenic activity in bacteria and it has weak hepatocarcinogenic effects in rodents. Experiments in mice have suggested the possibility of transplacental and lactational carcinogenesis. The carcinogenic effect is primarily mediated by the formation of 1′-hydroxysafrole, followed by sulfonation to an unstable sulfate that reacts to form DNA adducts; these metabolites are formed by CYP2C9 and CYP2E1, the latter contributing three-fold more to the metabolic clearance than the former (3).

Adverse effects

Asthma has been attributed to nutmeg (4).

- A 27-year-old man developed rhinitis and asthma 1 year after starting to prepare a certain kind of sausage, having a previous allergy to coconut, banana, and kiwi and allergic rhinitis to horses, cats, dogs, and cows. There was a positive immediate skin prick test with paprika (dry powder of *Capsicum annuum*), coriander (*Coriandrum sativum*), and mace (shell of *M. fragrans*) at concentrations of 10%. There were specific IgE antibodies to paprika, coriander, and mace.

Large doses of nutmeg seed can cause nausea, vomiting, flushing, dry mouth, tachycardia, nervous system stimulation possibly with epileptiform convulsions, miosis, mydriasis, euphoria, and hallucinations (5).

- A 16-year-old youth who had taken nutmeg for recreational purposes developed a number of neurological symptoms and signs along with non-specific electrocardiographic changes and anticholinergic-type symptoms (6).

Among 55 patients with suspected contact dermatitis, skin patch tests that were positive at concentrations of both 10% and 25% were most common with ginger ($n = 7$), nutmeg ($n = 5$), and oregano ($n = 4$); other spices produced no responses or one positive response (7). Positive reactions at only one concentration were more likely at 25%: nutmeg ($n = 5$), ginger and cayenne ($n = 4$), curry, cumin, and cinnamon ($n = 3$), turmeric, coriander, and sage ($n = 2$), oregano ($n = 1$), and basil and clove ($n = 0$).

Contact allergy has been reported with mace (8).

Nutmeg is sometimes abused for its hallucinogenic potential; less than one tablespoon can be enough to produce severe symptoms similar to those seen in anticholinergic poisoning (9,10). It can also cause psychosis, both acute (11,12) and chronic (13).

- A 13-year-old girl took 15–24 g of nutmeg in gelatin capsules over 3 hours and smoked two joints of marijuana (14). She developed bizarre behavior and visual, auditory, and tactile hallucinations, nausea, gagging, hot/cold sensations, and blurred vision, followed by numbness, double, and "triple" vision, headache, and drowsiness. There was nystagmus, muscle weakness, and ataxia. She received activated charcoal 50 g and recovered within 2 days.

Deaths from acute poisoning have been reported (15).

Myrrh

General Information

Myrrh is an oleo gum resin obtained from the stem of *Commiphora molmol*, a tree that grows in north-east Africa and the Arabian Peninsula. In mice, myrrh showed no mutagenic effects and was a potent cytotoxic drug against solid tumor cells (1). The antitumor potential of *Commiphora molmol* was comparable with that of cyclophosphamide. Studies in hamsters suggested an antischistosomal activity of myrrh (2).

© 2006 Elsevier B.V. All rights reserved.

Observational studies

Facioliasis

The efficacy of myrrh has been studied in seven patients aged 10–41 years (five men, two women) with fascioliasis and 10 age- and sex-matched healthy volunteers (3). Myrrh was given orally in the morning on an empty stomach in a dosage of 12 mg/kg/day for 6 days. All the patients were passing *Fasciola* eggs in their stools (mean 36 eggs per gram of stool). The symptoms and signs of fascioliasis resolved during treatment with myrrh, and *Fasciola* eggs could not be demonstrated in the stools 3 weeks and 3 months after treatment. Antifasciola antibody titers became negative in six of the seven patients. There were no adverse effects.

Schistosomiasis

The efficacy and adverse effects of myrrh and the most effective dosage schedule have been studied in 204 patients (169 men and 35 women) with schistosomiasis aged 12–68 years and 20 healthy non-infected age- and sex-matched volunteers (2). The patients were divided into two groups: 86 patients with schistosomal colitis and 118 with hepatosplenic schistosomiasis, further divided into two subgroups—77 patients with compensated disease and 41 with decompensated disease. All but 12 had received one or more courses of praziquantel. The dosage of myrrh was 10 mg/kg/day for 3 days on an empty stomach 1 hour before breakfast. A second course of 10 mg/kg/day for 6 days was given to patients who still had living ova in rectal or colonic biopsy specimens. The response rate to a single course of myrrh was 92% in 187 patients. The cure rates were 91, 94, and 90% in patients with schistosomal colitis, compensated hepatosplenic schistosomiasis, and decompensated hepatosplenic schistosomiasis respectively. The cure rate was less in patients who had previously taken praziquantel and in patients with impaired liver function. *Schistosoma hematobium* infection was the most responsive ($n = 4$, cure rate 100%), followed by mixed infections ($n = 29$, cure rate 93%). Those infected with *Schistosoma mansoni* had the lowest cure rate ($n = 171$, cure rate 91%). There was no impairment of liver function after treatment with myrrh. In contrast, liver function tests significantly improved in patients with impaired liver function. There were no significant effects of myrrh on the electrocardiogram. Adverse effects of myrrh were reported in 24 of the 204 patients. Giddiness, somnolence, or mild fatigue were the most common (2.5%), and all other adverse effects were minor and less frequent. None of the healthy volunteers reported any adverse effects, nor were there any significant changes in liver or kidney function. A second course of myrrh resulted in a cure in 13 of the 17 patients who did not respond to a single course.

Myrtaceae

See also Herbal medicines

General Information

The family of Myrtaceae (Table 1) includes guava and various types of gums.

Eucalyptus species

Eucalyptus oil has been used in different medications to relieve symptoms of asthma and rhinitis and is a constituent of cold remedies and ointments designed to be rubbed on to the chest or applied around and even into the nostrils (Vicks Vaporub, Obat Madjan, etc.). Applied to the skin it acts as a rubefacient and counterirritant, but substantial concentrations of volatile oil can be inhaled from the skin. Eucalyptus oil has also been used systemically to treat asthma.

Adverse effects

Fever and headache occurred in a heavy consumer of eucalyptus extract (1).

Respiratory
Asthma can be exacerbated by eucalyptus (2).

- In a 30-year-old woman the symptoms of asthma and rhinoconjunctivitis were exacerbated by eucalyptus pollens and by ingestion of an infusion containing eucalyptus. There were specific IgE antibodies to eucalyptus pollens but not to common aeroallergens.

Eucalyptus oil has been reported to cause vocal cord dysfunction (3).

- A 46-year-old woman with vocal cord dysfunction associated with exposure to eucalyptus underwent inhalation challenges consisting of water, ammonia, pine oil, and a combination of eucalyptus (dried leaves) and ammonia. Vocal cord dysfunction occurred within minutes of exposure to eucalyptus.

Skin
Contact urticaria has been ascribed to eucalyptus pollen (4).

Drug overdose
Eucalyptus oil has caused death in doses of up to 560 ml in adults and 15 ml in children.

- A 73-year-old woman who deliberately took 200–250 ml of eucalyptus oil was found unconscious in her home after she had vomited and had been incontinent of urine and feces. Despite intensive treatment she developed pneumonitis and aspiration pneumonia to which she ultimately succumbed (5).

In a telephone survey of 109 parents or guardians of children under 5 years who had been involved in actual or suspected ingestion of eucalyptus oil, 90 incidents had involved vaporizer solutions, 15 eucalyptus oil formulations, and the remainder other medicinal products containing eucalyptus oil (6).

In a retrospective analysis of case histories of 109 children admitted to the Royal Children's Hospital, Melbourne, between 1 January 1981 and 31 December 1992 with a diagnosis of eucalyptus oil poisoning, there were clinical effects in 59%; 31 had depression of consciousness, 27 were drowsy, three were unconscious after taking known or estimated volumes of 5–10 ml, and one was unconscious with hypoventilation after taking an estimated 75 ml (7). Vomiting occurred in 37%, ataxia in 15%, and pulmonary disease in 11%. No treatment was given to 12%; ipecac or oral activated charcoal was given to 21%, nasogastric charcoal to 57%, and gastric lavage without anesthesia to 4% and under anesthesia to 6%. All recovered.

Of 42 children with oral eucalyptus oil poisoning, 33 were entirely asymptomatic (8). This group included all of the four children who were reported to have taken more than 30 ml of eucalyptus oil. Only two of the others had symptoms or clinical signs on presentation to hospital. No child required advanced life support. There was no correlation between the amount of eucalyptus oil taken and the presence of symptoms.

Systemic eucalyptus oil toxicity can result from topical application.

- A 6-year-old girl presented with slurred speech, ataxia and muscle weakness progressing to unconsciousness following the widespread application of a home remedy for urticaria containing eucalyptus oil. Six hours after removal of the topical preparation her symptoms had resolved and there were no long-term sequelae (9).

Administrative route
Systemic effects of eucalyptus oil applied locally have been reported (9).

- A 6-year-old girl was treated with a home-made concoction mainly containing 50 ml of eucalyptus oil (consisting of 80–85% cineole oil) for pruritus. As the mixture seemed to relieve her symptoms, the parents applied it more and more generously to the girl's skin. She subsequently developed symptoms of intoxication: slurred speech, unsteady gait, and drowsiness. Eventually she lost consciousness and was unrousable. She was admitted to hospital, where several tests were negative, but her urine sample contained components of eucalyptus oil. She made a full recovery within 24 hours after withdrawal of the external herbal treatment.

Melaleuca species

The undiluted essential oil from the leaves of *Melaleuca alternifolia* (tea tree), which contains the sesquiterpene viridiflorene and the monoterpenoids eucalyptol, limonene, and terpinen-4-ol, has been used as a topical natural cure for bacterial and fungal skin infections.

Adverse effects
Nervous system

- A 23-month-old boy became confused and was unable to walk 30 minutes after ingesting less than 10 ml of T36-C7, a commercial product containing 100% tea tree oil (10). His condition improved and he was asymptomatic within 5 hours of ingestion.

Skin
Tea tree oil can have adverse effects on the skin (11). Several patients developed an allergic contact dermatitis (12), which was most commonly caused by the constituent d-limonene (13). Internal use of half a teaspoonful of the oil can result in a dramatic rash (14), whereas half a teacup can induce coma followed by a semiconscious state with hallucinations (15). Less than 10 ml is sufficient to produce serious signs of toxicity in small children.

- In one case, allergic contact dermatitis to tea tree oil presented with an extensive erythema multiforme-like reaction (16). However, a skin biopsy from a target-like lesion showed a spongiotic dermatitis without the features of erythema multiforme. Five months after treatment with systemic and topical glucocorticoids, patch testing elicited a 3+ reaction to old, oxidized tea tree oil, a 2+ reaction to fresh tea tree oil, a 2+ reaction to colophony, a 1+ reaction to abitol, and a 1+ reaction to balsam of Peru.

Of 1216 patients who were patch tested, 14 with eczema had used products (creams, hair products, and essential oils) containing tea tree oil (17). They were patch tested for a standard panel of allergens, topical emulgents, perfumes, plants, topical medications, metal, gloves, topical

© 2006 Elsevier B.V. All rights reserved.

disinfectants and preservatives, dental products, and rubber derivatives. Seven patients had allergic contact dermatitis due to tea tree oil. Two of them also had delayed type IV hypersensitivity toward fragrance-mix or colophony, suggesting the possibility of cross-reactions or allergic group reactions caused by contamination of the colophony with the volatile fraction of turpentines.

Immunologic

Of 1017 subjects, 16 had positive skin tests to *Melaleuca quinquenervia* pollen extract (18). Six of them were subjected to double-blind nasal challenge with the pollen extract and four to single-blind bronchial challenge; 11 received 34 different *Melaleuca* odor challenges (blossoms, bark, and leaves) through a closed system for up to 30 minutes. Four inhaled an odor from cajeput oil (derived from *Melaleuca* leaves) for 1 hour. One of six nasal challenges and one of four bronchial challenges were positive. All the odor challenges with blossoms, bark, leaves, and cajeput oil were negative. A radioallergosorbent test for *Melaleuca* pollen extract correlated with the skin test results. The authors concluded that the *Melaleuca* tree is not a significant source of aeroallergens and explained the few positive results on the basis of cross-reactivity with pollen extracts from a proven aeroallergen, *Bahia* grass pollen.

Syzygium aromaticum

Syzygium aromaticum (clove) is used as an aromatic spice.

Adverse effects

Of about 1000 patients with occupational skin diseases, five had occupational allergic contact dermatitis from spices (19). They were chefs, or workers in kitchens, coffee rooms, and restaurants. In all cases the dermatitis affected the hands. The causative spices were garlic, cinnamon, ginger, allspice, and clove. The same patients had positive patch test reactions to carrot, lettuce, and tomato.

Nabumetone

See also Non-steroidal anti-inflammatory drugs

General Information

Nabumetone is a naproxen derivative, whose efficacy is related to its active metabolite, 6-methoxy-2-naphthylacetic acid. Not unexpectedly, a study in 2000 patients, mostly treated for more than 6 months, elicited an adverse events pattern similar to the other derivatives of this class of NSAIDs (SEDA-13, 81). Adverse effects were reported in 18% of patients and 10% stopped taking the drug because of adverse reactions. Diarrhea was the most common problem (13%) followed by abdominal pain (9.9%), dyspepsia (9.3%), nausea (7.8%), and flatulence (4.7%). Ten ulcers were detected. Nervous system reactions, skin rashes, edema, unspecified eye disorders, and liver function test abnormalities all occur (1).

A postmarketing surveillance study in 10 800 patients with osteoarthritis and rheumatoid arthritis, who were followed up at 12 months, reported that 12% of patients discontinued the drug because of adverse events; 11 serious events may have been related to nabumetone and seven of these were gastrointestinal hemorrhage (2). In 6148 patients treated with nabumetone in long-term trials, the 3-month cumulative incidence of clinically detected perforations, ulcers, and bleeding was 0.1% and the 6-month incidence was 0.2% (3).

Organs and Systems

Metabolism

Nabumetone-induced pseudoporphyria has been described (SEDA-16, 11) (SEDA 22, 117), and a further five cases in four adults and a child have been reported (4–6).

Gastrointestinal

Being a non-acidic compound and a weak inhibitor of prostaglandin synthesis, nabumetone was designed as a prodrug that could be administered without causing gastric damage. This theoretical advantage still awaits confirmation. Although there was no gastrointestinal toxicity in animals, in humans gastric problems with NSAIDs are not primarily a local effect but are exerted systemically, so a metabolite formed after gastric passage could still cause gastric problems. Again, although radiochromium evaluation of gastrointestinal blood loss in healthy volunteers and endoscopic studies in patients with rheumatoid arthritis showed that nabumetone provokes less gastric damage than naproxen, the usual defects of such studies limit their clinical relevance (SEDA-13, 81). The same applies to the preliminary results of a long-term study in patients with osteoarthritis and rheumatoid arthritis, which also showed that nabumetone is less gastrotoxic than naproxen, but it was not possible to exclude the possibility that the dosage was lower than was needed for optimal efficacy (7).

Susceptibility Factors

Age

After repeated once-daily doses, nabumetone accumulates in elderly patients but not in others; it is therefore wise to reduce the dose in elderly patients.

Drug–Drug Interactions

Warfarin

Concomitant therapy with warfarin and NSAIDs is of concern, owing to the potential for increasing bleeding.

- In a 72-year-old man the concomitant use of nabumetone and warfarin led to an increased international normalized ratio and hemarthrosis (8).

Previous reports suggested a lack of interaction of nabumetone with warfarin, but close monitoring is advisable when these two drugs are co-administered.

Naftidrofuryl

General Information

Naftidrofuryl is a complex acid ester of diethylaminoethanol, with direct vasodilatory properties and antagonistic effects on 5-HT (via 5-HT_2 receptors) and bradykinin. It also causes an intracellular increase in ATP concentrations, improves cellular oxidative metabolism (by activating succinate dehydrogenase), and reduces blood and plasma viscosity and fibrinogen concentrations.

Naftidrofuryl has been marketed in Europe for over 20 years for the treatment of peripheral and cerebrovascular diseases and for senile dementia (1). A few placebo-controlled studies have reported increases in

© 2006 Elsevier B.V. All rights reserved.

walking distance in patients with claudication, but no substantial hemodynamic improvement. Subjective improvement with naftidrofuryl was also noted in patients with Raynaud's phenomenon, but it had variable effects on digital blood flow and pressure during cold provocation. In patients with an acute ischemic stroke there was better neurological progress, leading to a shorter stay in hospital in some but not all studies. Several double-blind trials have reported improvements in the deficits associated with mild senile organic brain syndrome.

Oral naftidrofuryl (300–600 mg/day) was generally well tolerated in controlled trials: gastrointestinal complaints were as frequent with placebo as with the drug. Esophageal ulceration has been ascribed to naftidrofuryl in a few patients. Rare cases of reversible liver dysfunction have been reported.

Parenteral naftidrofuryl was withdrawn from the market following reports of severe adverse effects with intravenous or intra-arterial bolus injections, including intracardiac conduction defects, epileptic seizures, severe anaphylactic reactions, and acute renal insufficiency secondary to deposition of oxalate crystals in the tubules (SED-12, 473) (SEDA-17, 244).

Nalbuphine

See also Opioid antagonists

General Information

Nalbuphine is a partial opioid agonist structurally similar to naloxone. Like naloxone it is an antagonist at $OP_3(\mu)$ receptors, whilst achieving analgesia via an agonist effect at $OP_2(\kappa)$ receptors.

Nalbuphine was approximately equianalgesic with morphine (1) and its hemodynamic and respiratory effects were not statistically significantly different from those of morphine (SEDA-14, 69). Other studies have shown that this also applies to other organ systems. However, unlike morphine, nalbuphine has a "ceiling" effect on respiratory depression, a low incidence of dysphoric effects, and a low addiction potential. Ten patients with a history of cardiac or orthopedic problems who received intravenous nalbuphine (6–20 mg) required additional doses of morphine (15–70 mg) to relieve pain (2). However, this report was not supported by objective physiological measures or recognized pain scores.

Nalbuphine has similar efficacy and incidence of adverse effects to tramadol and paracetamol (acetaminophen) (3). Dysrhythmias and coughing occurred more often with nalbuphine than fentanyl (4).

Cardiac dysrhythmias, hypertension, agitation, nausea, and vomiting occurred when nalbuphine was given to four patients to reverse fentanyl-induced respiratory depression (SEDA-16, 89).

In a double-blind, placebo-controlled study in 24 elderly patients scheduled for elective total hip replacement who were randomized to either intrathecal morphine 160 μg or nalbuphine 400 μg postoperatively, when the pain score was greater than 3 cm on a visual analogue scale, nalbuphine produced significantly faster onset and shorter duration of analgesia (5). Both opioids produced adequate maximal pain relief in all patients. The adverse effects profile was unremarkable in both groups.

Intravenous nalbuphine 3 mg ($n = 101$) has been compared with intravenous propofol 20 mg ($n = 90$) in a double-blind, randomized study, to determine efficacy in the treatment of intrathecal morphine-induced pruritus after cesarean delivery 10 minutes after the drug was administered (6). Nalbuphine was significantly more effective, especially in cases of moderate but not severe pruritus. Adverse effects such as reduced analgesia and increased nausea, vomiting, sedation, and dizziness were not significantly different between the two groups.

Organs and Systems

Respiratory

Although similar respiratory depression occurs with morphine and nalbuphine after single doses, on cumulative dosing there appears to be a ceiling effect with nalbuphine, which may also occur with respect to analgesic efficacy (7). Considerable respiratory depression requiring prolonged monitoring has been reported in children (SEDA-16, 89).

Neuromuscular function

Psychomotor performance and subjective effects seems to be dose-related (SEDA-22, 104).

Psychological, psychiatric

- A 53-year-old man with no past psychiatric history was found by the police walking aimlessly, unclothed, and responding to auditory hallucinations (8). He had slurred speech and generalized tremors. Lumbar puncture, a CT head scan, and urine drug screen were all normal. He responded to risperidone 1 mg bd with dramatic improvement after 2 days. He reported chronic use of nalbuphine, with recent increased use.

Gastrointestinal

The effects of nalbuphine and morphine on gastrointestinal function have been compared in 17 volunteers. Nalbuphine 10 mg prolonged gastric emptying to a greater extent than nalbuphine 5 mg or morphine 5 mg, which were about equal in their effects (9). However, another study (10) showed that nalbuphine produced significantly less inhibition of gastrointestinal activity than morphine.

© 2006 Elsevier B.V. All rights reserved.

Biliary tract

The effect of nalbuphine 20 mg intravenously on biliary tract pressure was examined in 10 patients undergoing surgery for symptomatic cholelithiasis. There was a statistically significant rise in pressure 30 minutes after the administration of nalbuphine, but this did not have any apparent deleterious effects (11). Others have suggested that nalbuphine reverses opioid-induced spasm of the sphincter of Oddi (SEDA-17, 88).

Long-Term Effects

Drug dependence

The development of dependence is unlikely at doses within the usual analgesic range (12).

Second-Generation Effects

Fetotoxicity

Transplacental transfer of nalbuphine was measured in eight mothers who underwent cesarean section and were given nalbuphine 200 μg/kg intravenously along with thiopental and suxamethonium. The umbilical cord/maternal vein ratio was 1.4:1 at delivery, which occurred at 2–10 minutes after nalbuphine injection. Mean Apgar scores at 1 minute were 6.6 and 8.5 at 5 minutes and did not correlate with either the serum nalbuphine concentration or the time between injection of nalbuphine and delivery (13).

Three neonates, whose mothers who had received nalbuphine during labor, developed apnea and cyanosis, which required ventilation within 3 minutes of birth (14,15).

Bradycardia and bradypnea have been reported in babies whose mothers were given nalbuphine a few hours before delivery (SEDA-16, 89).

A case of fetal sinusoidal rate pattern with nalbuphine has been reported (SEDA-17, 87).

Drug Administration

Drug dosage regimens

In a randomized, double-blind, multicenter comparison of three different intrathecal doses of nalbuphine (0.2, 0.8, or 1.6 mg) and a single intrathecal dose of morphine (0.2 mg) for postoperative pain relief after cesarean section in 90 parturients, intrathecal nalbuphine 0.8 mg provided rapid and effective analgesia, with minimal adverse effects but a shorter duration of action, reinforcing morphine's position as an analgesic that provides long-lasting analgesia (16).

Nalidixic acid

General Information

Nalidixic acid, the first quinolone, first introduced in 1962, is now only rarely used and has been supplanted by the fluoroquinolones. It is almost completely absorbed from the gastrointestinal tract and is rapidly eliminated by the kidneys, resulting in urinary concentrations 4–6 times higher than plasma concentrations. There are better drugs to treat urinary tract infections.

© 2006 Elsevier B.V. All rights reserved.

General adverse effects

The adverse effects of nalidixic acid tend to be toxic rather than allergic. Nervous system toxicity is predominant, including disturbances of sensory perception and benign intracranial hypertension, which is nearly exclusively found in babies and young children. Gastrointestinal toxicity and skin reactions also occur. Immunological and hypersensitivity reactions mainly affect the skin. Drug fever is rare. Hematological and hepatic reactions are very rare. Tumor-inducing effects have not been reported but require further study, since nalidixic acid, as a DNA gyrase inhibitor, damages DNA (1,2). Fluorinated derivatives, but not nalidixic acid, induced unscheduled DNA synthesis in vitro but not in vivo. While specific fluoroquinolones, such as CP-115,953, have cytotoxic effects on eukaryotic cancer cells, the fluoroquinolones designed specifically as antimicrobial agents have extremely low toxicity against eukaryotic cells. This is due to a marked reduction in the affinity for eukaryotic topoisomerases versus prokaryotic topoisomerases (3,4).

Organs and Systems

Nervous system

Benign intracranial hypertension (pseudotumor cerebri) mainly affects babies, especially during the first 3 months of life. Occasionally even older children can be affected, especially when inordinately high doses are used (5). Very rarely, it occurs in adults with renal insufficiency. In infancy, impaired nalidixic acid elimination (due to underdeveloped glucuronidation), overdosage, or prolonged treatment may be responsible. Metabolic acidosis is usually important in adults (6).

The syndrome includes headache, nausea and vomiting, dizziness, tinnitus, papilledema, and visual disturbances caused by scotoma or optic nerve damage. In babies, the first symptoms appear during the first 3 days of treatment; while in older children and adults symptoms may not appear before a second or even later exposure. In adults, peripheral paresis or severe pyramidal and extrapyramidal symptoms, occasionally followed by a transitory psychosis, have been observed (7).

After withdrawal, most symptoms usually subside quickly. Papillary edema and ocular palsy recede more slowly, the latter not always completely.

Functional short-lasting phenomena, such as sensations of over-bright lights, blurred vision, altered color perception, or difficulty in focusing, are dose-dependent and have been observed in about 7% of cases (8). They begin 30–60 minutes after drug intake and subside within 20 minutes to 3 hours.

Convulsions without benign intracranial hypertension have been reported (9). Affected patients usually had preexisting cerebral disease or had taken very high doses. Normal doses in otherwise healthy persons can exceptionally provoke convulsions.

Uncharacteristic general symptoms, such as headache, dizziness, drowsiness, insomnia, or restlessness, can occur (10).

Sensory systems

Occasional cases of tinnitus have been attributed to nalidixic acid (8).

Psychological, psychiatric

Disturbances of body perception, hallucinations, confusion, confabulation, and depression can rarely occur with nalidixic acid (11).

Endocrine

Hyperglycemia associated with convulsions has been observed after the use of high single doses of nalidixic acid (7,12).

Metabolism

Nalidixic acid can cause metabolic acidosis in infants (13). This has also been seen in older children and adults with renal insufficiency and can result from disturbed lactate metabolism. Extreme overdosage can cause metabolic acidosis in subjects with normal renal function (12,14).

Hematologic

Rarely, hemolytic anemia associated with glucose-6-phosphate dehydrogenase deficiency has been precipitated by nalidixic acid (15,16).

Rarely hemolytic anemia in neonates has been attributed to nalidixic acid in breast milk (15).

Gastrointestinal

Nausea, vomiting, and occasionally diarrhea or abdominal pain occur in about 8% of patients taking nalidixic acid (17).

Liver

Cholestatic hepatitis has been reported in patients taking nalidixic acid (18).

Skin

Skin reactions occur in about 5% of patients taking nalidixic acid (19), including urticaria, erythematous or maculopapular rashes, isolated pruritus, purpura, lesions resembling pityriasis rosea, erythema multiforme, or exfoliative dermatitis. Except for the latter, they usually run a benign course.

Phototoxic reactions occur in animals given nalidixic acid after exposure to light (20) and have been reported in patients taking nalidixic acid, with blistering (21,22). Sometimes the lesions develop only several days after nalidixic acid withdrawal. The eruptions can persist for several months after withdrawal.

Musculoskeletal

Large doses of nalidixic acid cause degenerative inflammatory damage in the large weight-bearing joints in animals, and occasionally arthritis, arthralgia, or myalgia occur in humans (17). However, three retrospective controlled studies showed no evidence of nalidixic acid-associated arthropathy in children (23,24).

© 2006 Elsevier B.V. All rights reserved.

Long-Term Effects

Drug tolerance

Salmonella typhimurium DT104 is usually resistant to ampicillin, chloramphenicol, streptomycin, sulfonamides, and tetracycline. An outbreak of 25 culture-confirmed cases of multidrug-resistant *S. typhimurium* DT104 has been identified in Denmark (25). The strain was resistant to the above-mentioned antibiotics and nalidixic acid and had reduced susceptibility to fluoroquinolones. A swineherd was identified as the primary source (26). The DT104 strain was also found in cases of salmonellosis in Washington State, and soft cheese made with unpasteurized milk was identified as an important vehicle of its transmission (27).

Mutagenicity

The genotoxic effects of nalidixic acid (400 mg bd for 10 days) and metronidazole (250 mg tds for 10 days) have been investigated in a prospective randomized study in 20 patients with *Trichomonas vaginalis* infections (28). Evaluation was by the sister-chromatid exchange test, in which an increased number of exchanges in lymphocytes reflects mutagenic action. Metronidazole had no effect but there was a significant increase with nalidixic acid.

Second-Generation Effects

Teratogenicity

In a case-control surveillance of congenital abnormalities in 22 865 women who had neonates or fetuses with congenital abnormalities, and 38 151 pregnant women who had neonates without any defects, treatment with nalidixic acid during pregnancy was associated with an increased risk of pyloric stenosis (29). Nalidixic acid should be avoided during pregnancy.

Lactation

Very small amounts of nalidixic acid pass into the breast milk. Use during lactation should therefore also be avoided. Rare cases of hemolytic anemia in the newborn have been related to nalidixic acid ingested through breast milk (15).

Drug Administration

Drug overdose

In 18 children with nalidixic acid intoxication, most of whom were aged under 1 year, the clinical effects were neurological disorders of alertness, hypertensive cranial syndrome, and neuronal damage; some had a metabolic acidosis (30). Treatment included gastric lavage, correction of acid-base balance, and control of convulsions.

- A woman survived ingestion of nalidixic acid 32 g despite developing lactic acidosis, hyperglycemia, convulsions, and abnormal behavior (12). The maximum recorded plasma concentration of nalidixic acid was 185 μg/ml and the half-life was 3.2 hours. Carboxynalidixic acid was demonstrated in the plasma.
- A woman developed a severe metabolic acidosis and coma after taking nalidixic acid 28 g (14). She was given sodium bicarbonate 600 mmol and developed a respiratory alkalosis with secondary tetany. She recovered consciousness 9 hours later and the acid–base disturbance resolved after 60 hours.

Drug–Drug Interactions

Urine alkalinizing compounds

Alkalinization of the urine increases the excretion of nalidixic acid (31).

Warfarin

Nalidixic acid can displace warfarin from its plasma albumin binding sites, briefly enhancing its anticoagulant effect (32).

Interference with Diagnostic Tests

Glucose measurements

If reducing agents are given with nalidixic acid, glycosuria and hyperglycemia can be mimicked by the presence of nalidixic and glucuronic acid compounds in blood and urine (33).

Ketosteroids

Urine concentrations of C17-ketosteroids (but not of C17-hydroxysteroids) can be falsely raised by nalidixic acid (34).

Nalmefene

See also Opioid antagonists

General Information

Nalmefene is a pure opioid antagonist, which is structurally similar to naloxone and naltrexone.

Drug studies

Reversal of opioid-induced adverse effects

In a comparison of the efficacy of naloxone and nalmefene in reversing opioid-induced sedation, vertigo and nausea were observed with nalmefene (1). Three of six healthy male volunteers given nalmefene 0.4 mg/70 kg complained of paresthesia in the midthoracic region (2).

In a randomized, placebo-controlled, double-blind study 120 women undergoing lower abdominal surgery were randomized to receive nalmefene 15 micrograms, nalmefene 25 micrograms, or saline intravenously at the end of surgery (3). The total consumption of morphine and the subsequent adverse effects profiles were recorded. Those given nalmefene used significantly less antiemetic and antipruritus medications during the subsequent 24-hours without a change in the quality of analgesia.

Stroke

The Cervene Stroke Study Investigation Group conducted a phase III study to assess the efficacy and safety of nalmefene (Cervene) in patients with acute ischemic strokes and also the safety of combined recombinant tissue plasminogen activator and nalmefene in a subset of patients (4). It was a randomized, placebo-controlled, double-blind study of a 24-hour infusion of nalmefene on 368 patients who received 60 mg nalmefene administered as 10 mg bolus over 15 minutes and then a 50 mg infusion over 24 hours or placebo. Even though nalmefene appeared safe and well tolerated, the study failed to find any benefit in stroke patients treated with nalmefene within six hours.

Pruritus

The role of opioid antagonists in the treatment of pruritus in cholestatic liver disease has been reviewed (5). Their use is based on the theory that implicates opioid neurotransmission as the cause of itching in this condition, and it has been observed that opioid antagonists, while providing relief from itching in patients with cholestasis, also cause symptoms similar to those seen in the opioid withdrawal syndrome. It has therefore been suggested that

© 2006 Elsevier B.V. All rights reserved.

patients with cirrhosis are chronically exposed to increased concentrations of endogenous opiate receptor agonists.

In 11 patients with cirrhosis-induced pruritus, nalmefene led to relief of itching within 1 month, sustained at 3 and 6 months. However, the first two patients had severe withdrawal reactions that took 3 days to subside. In the light of this experience, the trial was modified so that patients received oral nalmefene 5 mg bd with a gradual increase in dosage over 7–10 days to 20–40 mg/day, and clonidine was administered simultaneously for the first 7 days of nalmefene therapy. Despite these precautions, all patients had withdrawal reactions, including anorexia, nausea, colicky abdominal pain, sweating, tremor, and occasionally visual or auditory hallucinations. These developed within 1 hour of nalmefene therapy and diminished within 2–3 days, despite continuation of nalmefene. This review included reports of two other studies, available in abstract form only, but which appear to have reported a lower incidence of withdrawal symptoms precipitated by nalmefene, although the dose of drug used also appeared to have been lower.

In 14 patients with cholestatic liver disease, oral nalmefene was started at a dose of 2 mg bd and increased until symptomatic relief of pruritus was obtained (6). Five patients were reported to have a transient opioid withdrawal-like reaction that did not preclude continuing with treatment. Other adverse events associated with nalmefene therapy included: perception of pins and needles ($n = 4$), anxiety and depression ($n = 2$), abdominal cramps and nausea ($n = 2$), insomnia ($n = 3$), depersonalization ($n = 2$), and changes in mood ($n = 2$); difficulties in visual focusing, dizziness, chronic goose bumps, mental "fuzziness," anorexia, and nightmares were each reported by one patient only. Of the cases of depersonalization, one occurred after the first dose while the other occurred in the first 2 weeks of therapy. There were no consistent changes in biochemistry with nalmefene. Several patients had a "breakthrough" of pruritus, which was managed by upward adjustment of dose. The authors suggested that this can be explained if nalmefene initially displaced pruritus-mediating ligands from opioid receptors, but then induced an increased density of receptors because of reduced agonist–receptor interactions, allowing further binding of pruritus-mediating ligands to receptors. In a few other patients, exacerbations of pruritus after long-term control on maintenance therapy may have been attributable to the development of tolerance toward nalmefene.

Organs and Systems

Cardiovascular

Pulmonary edema has been described after nalmefene (SEDA-22, 104).

Long-Term Effects

Drug abuse

When nalmefene was given to six men with history of drug abuse, the adverse effects reported were agitation, irritability, muscle tension, and a feeling of hangover (SEDA-17, 88).

Susceptibility Factors

Age

The efficacy and safety of intravenous nalmefene 0.1 mg/ml has been studied in an open trial in 115 children given fentanyl (7). An initial dose of 0.25 microgram/kg (maximum 10 microgram) was infused over 15 seconds, and another dose of 0.25 microgram/kg (maximum 10 micrograms) was given if there was no response after 1.75 minutes. Further doses were given every 2 minutes until a response occurred or a maximum dose of 1 micrograms/kg (maximum 40 micrograms) was reached. Nalmefene was effective and safe, especially in a mean dose of 0.55 microgram/kg; the median number of doses was two. The limitations of this study included the small study sample and the use of a short-acting opioid, fentanyl, so that re-sedation was unlikely even without the use of an antagonist.

Naloxone

See also Opioid antagonists

General Information

Naloxone is an opioid antagonist devoid of pharmacological activity, except for its reversal of opioid effects.

As naloxone is widely believed to be innocuous, large maintenance doses of opioids are commonly used, in the belief that reversal can be safely achieved at the end of anesthesia.

© 2006 Elsevier B.V. All rights reserved.

Drug studies

Placebo-controlled studies
In a randomized, double-blind study in 40 patients with moderate to severe acute traumatic brain injury, intravenous naloxone, 0.3–4.8 mg/kg/day for 10 days, reduced morbidity and mortality (1).

Reversal of opioid adverse effects
According to the results of one study, it might be expected that in every 1000 patients with drug overdose treated with naloxone, 4–30 serious complications, such as convulsions, asystole, pulmonary edema, and violent behavior, can be expected (SEDA-21, 92).

The use of naloxone has been studied in an open study in 43 patients having combined thoracic epidural and general anesthesia for subtotal gastrectomy, who were randomly assigned to receive a bolus dose of epidural morphine 3 mg followed by a continuous infusion of 3 mg in 0.125% bupivacaine 100 mg with either no naloxone ($n = 18$) or naloxone 0.208 μg/kg/hour ($n = 25$) for 48 hours (2). The time to the first postoperative passage of flatus and feces (indicating restoration of bowel function) and pain intensity (using a visual analogue scale) were assessed. The results suggested that naloxone 0.208 μg/kg/hour adequately reverses hypomotility induced by epidural morphine.

The preliminary results of two pilot schemes to provide take-home naloxone to opiate users have suggested that this provision can save lives (3). This observation needs corroboration by a prospective case-control study of adequate sample size and response rate, with the ability to collate objective data robust enough for analysis (4).

There was complete resolution of a unilateral neurological deficit associated with anesthesia along with complete resolution of postoperative unilateral EEG evidence of ischemia when naloxone was given to reverse residual opioid effects (5).

Pruritus
In a randomized, double-blind, controlled trial in pruritus in cholestatic liver disease, naloxone was effective in most patients, but five had an increase in mean scratching activity during naloxone therapy, three patients had anxiety, and one developed withdrawal symptoms (6).

Stroke
The efficacy and toxicity of a naloxone loading dose of 4 mg/kg followed by 2 mg/kg per day was evaluated in 36 patients with acute stroke (7). The most common adverse effects were nausea and vomiting, which were easily controlled. The most serious effects were bradycardia and hypotension, which occurred in response to the loading dose. One patient developed hypotension and two developed focal seizures, which were ipsilateral to the affected hemisphere; one had myoclonus.

In another study, the safety of naloxone in much higher doses was studied in 38 patients with acute ischemic stroke (SEDA-16, 87). They were given a loading dose of 160 mg/m^2 over 15 minutes followed by a 24-hour infusion at a rate of 80 mg/m^2/hour. There was nausea and/or vomiting in 26 patients, 3 patients had behavioral changes, and in 7 patients naloxone was withdrawn because of adverse effects. The authors concluded that although naloxone is relatively safe in the dosage used, its efficacy in ischemic stroke is unproven.

Tension headaches
Mild adverse effects, such as dizziness, nausea, coolness of the head, and abdominal pain, were reported when moderate doses of naloxone were given to patients with tension headaches (8).

Organs and Systems

Cardiovascular

Doses of naloxone over 1 pg/kg should be given with caution, especially to patients with hypertension. Massive release of catecholamines in response to pain after administration of naloxone can trigger left ventricular failure, partly by causing a shift in fluid from the intravascular to the interstitial space. Thus, alpha-blockers such as phentolamine have been postulated to be beneficial in its management (SEDA-17, 88). A fatal case of pulmonary edema followed the use of naloxone in a young man (9), although the causal link was disputed (10).

Severe hypertension and multiple atrial extra beats have been reported after the administration of naloxone, especially in patients with coronary heart disease (11).

Psychological, psychiatric

Behavioral effects have been noted after high doses of naloxone (2 and 4 mg/kg) in volunteers. Most subjects experienced an initial rush or buzz, tingling or numbness in the extremities, dizziness, a heavy head, and reluctance to move or initiate activities, which usually subsided within 15–30 minutes of administration. Transient sweating and yawning occurred later. Nausea and stomachache were often experienced and in two subjects persisted throughout the day, although in mild form. There were no pupillary changes or sleepiness. Increasing doses of naloxone were associated with increasingly impaired cognitive performance. Violent behavior has been reported after the use of naloxone to reverse sedation (SEDA-17, 88).

Endocrine

Marked changes in physiological functions can occur if naloxone is given when the endorphin system has been modified by opioids. Following the use of naloxone, a reduced plasma prolactin concentration was noted (12).

Second-Generation Effects

Fetotoxicity

Convulsions occurred in a baby born to an opioid-dependent mother. This case is unusual, as convulsions due to neonatal opioid withdrawal do not usually occur in the first 24 hours after delivery; it suggests that naloxone should be used with great caution in children born to opioid-dependent mothers (13).

© 2006 Elsevier B.V. All rights reserved.

Susceptibility Factors

Patients with pre-existing cardiac abnormalities are particularly susceptible to effects such as hypertension, pulmonary edema, atrial and ventricular dysrhythmias, and cardiac arrest, which can occur when naloxone is given to reverse opioid effects.

Drug Administration

Drug administration route

The authors of two review papers both concluded that there is no evidence that subcutaneous or intramuscular administration of naloxone is less effective in restoring respiration in patients with opioid overdose than the intravenous route (14,15).

Drug–Drug Interactions

Captopril

Following the use of naloxone the hypotensive effect of captopril was abolished (16).

Naltrexone

See also Opioid antagonists

General Information

Naltrexone is an orally-active long-acting pure opioid antagonist with no significant actions of its own. It antagonizes the actions of morphine-like drugs by preferentially binding to opioid receptors in the brain and other tissues, thereby displacing any opioid present and preventing the binding of any pure opioid agonist subsequently administered.

Naltrexone can be used on its own in detoxified individuals to discourage relapse.

The neurotoxic adverse effects of interferon alfa may be mediated by an action at opioid receptors, and naltrexone may antagonize some of this (SEDA-20, 83). Pruritus, probably mediated via enkephalins and opioids, may also be antagonized by naltrexone (SEDA-22, 104).

Gastrointestinal irritation and clinically insignificant increases in blood pressure are commonly reported. Fatigue, irritability, and reduced food intake are also reported.

Drug studies

Opioid dependence

Behavioral disturbances and aversive effects in particular have been observed when naltrexone has been used for treatment of opioid dependence; symptoms noted were loss of energy, gastrointestinal disturbances, and mental depression.

Alcohol dependence

When naltrexone was used in the treatment of alcohol dependence, 5–10% of patients discontinued treatment because of adverse effects (SEDA-20, 83).

A systematic review and meta-analysis of seven double-blind, randomized, placebo-controlled outpatient studies of naltrexone used in the treatment of alcohol dependence between 1976 and 2001 has shown that naltrexone was no more toxic than placebo and was not associated with a significantly greater number of withdrawals because of adverse effects (1). Naltrexone was more effective than placebo in reducing relapses to heavy

© 2006 Elsevier B.V. All rights reserved.

drinking and improving alcohol abstinence in the short term, considering that the studies lasted for only 12 weeks. Additional long-term follow-up studies, with the possibility of studying outcomes of naltrexone treatment programs after stopping the drug and with suitable comparison groups, are necessary. Similar results with similar conclusions were seen in a 12-week randomized controlled trial in 55 alcohol-dependent men treated with naltrexone 50 mg or placebo (2).

To examine the relation between adverse effects profiles, study retention, and treatment outcomes in alcohol-dependent individuals receiving naltrexone for relapse prevention, 92 subjects had their adverse effects monitored weekly and categorized as either neuropsychiatric or gastrointestinal (3). The neuropsychiatric adverse effects had little effect on medication compliance but reduced the length of study retention. In contrast, the gastrointestinal adverse effects significantly affected medication compliance but not study retention.

In an open, single-blind, randomized study, naltrexone (50 mg/day) and acamprosate (1665–1998 mg/day) were used for 1 year by 157 recently detoxified alcohol-dependent men with moderate dependence (4). The time to first relapse was 63 days (naltrexone) and 42 days (acamprosate); after 1 year, 41% of those given naltrexone and 17% of those given acamprosate had not relapsed. Adverse effects were more common with naltrexone and were worse during the first 2 weeks of treatment. They included nausea (25 versus 4%), abdominal pain (23 versus 4%), drowsiness (35 versus 2%), headache (13 versus 6%), and nasal congestion (23 versus 7%).

The Health Technology Board of Scotland has concluded that in people with alcohol dependence, naltrexone reduces drinking (5). In a multicenter, double-blind, placebo-controlled, 12-week study of naltrexone 50 mg/day in 202 patients with alcohol dependence naltrexone was well tolerated, with few adverse effects: abdominal pain (8.6%), headache (7.5%), nausea (6.5%), and dizziness (5.4%); there were no changes in liver function tests (6). However, those who took naltrexone did not have significant improvements in drinking history or fewer relapses.

Pruritus

Naltrexone 50 mg/day has been used to relieve pruritus in cholestatic liver disease in five patients (7). Pruritus scores fell, but two patients developed severe nausea, vomiting, light-headedness, or tremor, requiring withdrawal of treatment. The reviewers commented that these reactions may or may not have been related to opioid withdrawal and that the trial had had several design limitations. They pointed out that one concern relating to the chronic use of high-dose naltrexone is an asymptomatic rise in serum transaminases, although the doses used in this study have not been reported to produce liver function abnormalities.

Organs and Systems

Nervous system

Headache occurred in two children, and an opioid withdrawal syndrome occurred in one child during the first 3 days of treatment when naltrexone was given for protracted apnea in children with increased beta-endorphin concentrations in the cerebrospinal fluid (8).

Psychological, psychiatric

Panic attacks precipitated by naltrexone have been reported (9).

- A 29-year-old woman with bulimia nervosa and a family history of anxiety was enrolled in a trial of naltrexone (100 mg/day). She had no history of opioid use. Within hours of her first dose she experienced alarm, anxiety, chest discomfort, shortness of breath, a fear of dying, sweating, nausea, and derealization. She was unable to remain at home or to go out alone. For 3 days she continued to take naltrexone, with an increasing frequency of panic attacks. On day 4 she was treated with alprazolam (0.5 mg) but relapsed after further naltrexone. Withdrawal of naltrexone led to complete remission of symptoms.

This effect was attributed to an action of naltrexone in removing the endogenous opioid effect at OP_3 (μ) opioid receptors in the locus ceruleus and thus resulting in unchecked noradrenergic hyperactivity.

Acute psychosis secondary to the use of naltrexone has been reported (10).

- A 44-year-old physically healthy woman developed auditory and visual hallucinations and persecutory delusions. She had been given naltrexone hydrochloride 50 mg/day 3 days before the acute psychotic incident in order to prevent relapse of alcohol dependence. Her psychotic symptoms completely resolved 48 hours after withdrawal of naltrexone.

In studies of its use in treating alcohol, opioid, and nicotine dependence, naltrexone has not been reported to cause depression or dysphoria. Patients who complain of naltrexone-associated dysphoria often have co-morbid depressive disorders or depression resulting from opioid or alcohol withdrawal states (11). Co-morbid depression is not a contraindication to naltrexone. Small pilot studies have supported the use of naltrexone in combination with antidepressants for the treatment of patients with co-morbid depression. The risk of non-fatal overdose is significantly increased after naltrexone treatment, as a result of reduced tolerance, compared with patients taking substitution methadone (12).

Hematologic

Idiopathic thrombocytopenic purpura has been attributed to naltrexone (13).

Gastrointestinal

The risk factors for naltrexone-induced nausea have been studied in 120 alcohol-dependent patients in an open trial (14). After 5–30 days of abstinence, they received a bolus dose of naltrexone 25 mg followed by 50 mg/day for 10 weeks. Moderate to severe nausea was reported in 15%. The risk of nausea was significantly predicted by poor medication compliance, intensity of drinking during

© 2006 Elsevier B.V. All rights reserved.

treatment, short duration of abstinence, young age, and female sex.

Gastrointestinal adverse effects of naltrexone were also observed in 183 alcohol-dependent individuals who received either naltrexone or nefazodone (15). These adverse effects predicated early termination of naltrexone used to treat alcohol dependence (16).

Liver

Reversible hepatocellular injury has been reported with naltrexone in doses of up to 300 mg/day, which is five times that usually used for opioid blockade (SED-11, 147) (17). Five of twenty-six patients treated with naltrexone for obesity developed raised serum transaminase activities after 3–8 weeks of treatment. In another study in which 60 obese subjects received naltrexone for 8 weeks, there were abnormal liver function tests in six patients. Three patients failed to complete the course. Nausea and vomiting occurred within the first 24 hours of treatment but responded to a reduction in dose. There were also changes in mentation such as decreased mental acuity, depression, and anxiety, all of which resolved after withdrawal. This is significant, as adverse effects from naltrexone have previously been attributed to mild physical withdrawal syndromes.

Biliary tract

A woman with chronic cholestasis and disabling pruritus had severe but transient opioid withdrawal-like reactions after oral naltrexone 12.5 mg and 2 mg (18). This observation suggests the hypothesis that increased central opioidergic tone is a component of the pathophysiology of cholestasis.

Skin

Skin rashes have been attributed to naltrexone (SEDA-21, 92).

Musculoskeletal

Rhabdomyolysis has been attributed to naltrexone (19).

- A 28-year-old alcoholic was given naltrexone 50 mg/day on the eighth day of a detoxification regimen. On day 17 there was a marked rise in creatine kinase activity (2654 U/l) but no accompanying symptoms of myalgia, weakness, or chest pain. Naltrexone was withheld immediately. The creatine kinase peaked at over 18 000 U/l on day 19 and then fell to within the reference range by day 25. A diagnosis of rhabdomyolysis without accompanying renal insufficiency was suggested.

Long-Term Effects

Drug abuse

Three opiate-dependent individuals abused intravenous naltrexone, believing it to be diamorphine, and developed acute opiate withdrawal symptoms; they were managed with a combined regimen of diazepam, prochlorperazine, and hyoscine (20,21).

Drug Administration

Drug administration route

Six cases of complications loosely related to the use of naltrexone pellet implantation during the highly controversial rapid and ultra-rapid opioid detoxification procedures have been reported (22). These included pulmonary edema, prolonged opioid withdrawal states, drug toxicity, withdrawal from cross-dependence to alcohol and benzodiazepines, aspiration pneumonia, and death. The risk of these controversial procedures and of naltrexone in this novel delivery system are high; a robust scientifically validated program of research is needed to justify such treatment packages.

Drug–Drug Interactions

Clonidine

When naltrexone was given to a group of clonidine-detoxified opioid-dependent subjects, several complained of anorexia and weight loss (23).

Diazepam

The effects of naltrexone on diazepam intoxication were investigated in 26 non-drug-abusing subjects who received either naltrexone 50 mg or placebo and 90 minutes later oral diazepam 10 mg in a double-blind crossover trial (24). Naltrexone was significantly associated with negative mood states, such as sedation, fatigue, and anxiety, compared with placebo, while positive states (friendliness, vigor, liking the effects of diazepam, feeling high from diazepam) were significantly more common with placebo. Naltrexone significantly delayed the time to peak diazepam concentrations (135 minutes) compared with placebo (75 minutes), but there were no significant differences in the concentrations of nordiazepam, the main metabolite of diazepam, at any stage in the study.

Naphazoline

General Information

Naphazoline is used as a 0.05% intranasal solution. Local irritation, headache, and rebound effects can all occur, and rhinorrhea can follow prolonged use. It has been suggested that such effects are more common with naphazoline than with other decongestants.

Systemic adverse reactions have been reported with ocular administration in young children.

- When nasal drops containing naphazoline were given to an infant of 12 weeks, he had what was apparently severe depression of the nervous system, with pallor followed by apnea, then tachycardia with hypertension; the condition responded to treatment (1).

Although this reaction was unusual, all nasal decongestants should be regarded as contraindicated in young infants.

Naproxen

See also Non-steroidal anti-inflammatory drugs

General Information

Naproxen sodium, an arylalkanoic acid NSAID, was approved for over-the-counter marketing in January 1994.

The adverse effects of naproxen resemble those of ibuprofen. Any minor differences in frequency cannot be assessed with certainty. In 881 patients who had been followed for more than 3 years, only 8.9% dropped out because of adverse effects. In shorter studies, doses of up to 1.5 g/day produced no more adverse effects than lower or standard doses of other NSAIDs (1).

The safety profile of over-the-counter naproxen has been adequately evaluated, and the incidence of adverse events was similar to the incidence with placebo, ibuprofen, and paracetamol. There were no serious adverse reactions in these studies (SEDA-20, 93).

A comparative case-cohort study on the risk of gastrointestinal tract bleeding associated with naproxen or ibuprofen showed a low incidence of upper gastrointestinal tract bleeding with both drugs, but low-dose naproxen put patients at increased risk of gastrointestinal bleeding compared with low-dose ibuprofen (2). If properly advised, patients can use the over-the-counter formulations without serious risks; patients taking NSAIDs must swallow their tablets with large amounts of water while standing, at least 1 hour before retiring.

© 2006 Elsevier B.V. All rights reserved.

The safety and efficacy of NSAIDs for the relief of symptoms of the common cold have been insufficiently studied. Naproxen did not alter virus shedding or the serum-neutralizing antibody response in healthy young adults with experimental rhinovirus colds but had some beneficial effect on symptoms (SEDA-17, 113).

The fact that its half-life is unchanged in renal insufficiency can be therapeutically useful (3).

Piproxen

Piproxen is a piperazine derivative of naproxen; its adverse effects profile is similar to that of naproxen (4).

Organs and Systems

Respiratory

Eosinophilic interstitial pneumonitis has been reported (5); the incidence is greater with naproxen than ibuprofen, as shown by an FDA survey (SEDA-17, 112).

Exacerbation of asthma in sensitive patients is rare, but has been reported with naproxen (6–8).

Nervous system

Peripheral neuropathy has been reported in a patient with psoriatic arthropathy taking naproxen and hydroxychloroquine (SEDA-12, 87).

Aseptic meningitis has been attributed to naproxen in a healthy young man taking it for neck pain (SEDA-14, 95).

Worsening of parkinsonian symptoms has been described with naproxen (SEDA-19, 99).

Sensory systems

Eyes

Blurred vision, ocular discomfort, and lenticular and corneal changes were observed in a long-term study (1).

Ears

Hearing loss and tinnitus (sudden, bilateral, and permanent) have been associated with naproxen (9).

Psychological, psychiatric

Abnormalities in cognitive capacity and altered behavior have been described in elderly patients taking naproxen (SEDA-8, 107) (10).

Hematologic

Fatal aplastic anemia was reported in a patient taking naproxen as the only drug for 4 months (11). Cases of Coombs' positive and Coombs' negative autoimmune hemolytic anemia (12), agranulocytosis (SEDA-13, 82), and thrombocytopenia (SEDA-15, 102) have also been reported.

- Three men, aged 56, 57, and 71 years developed extensive purpuric hemorrhages involving their legs ($n = 3$), arms ($n = 2$), and abdomen ($n = 1$) 10–20 days after having taken naproxen 250 mg tds for musculoskeletal disorders (13). One patient also had gastrointestinal bleeding. They all had severe thrombocytopenia (platelet counts below 3×10^9/l). Naproxen was withdrawn and prednisone started. The platelet counts normalized within a week. The prednisone was withdrawn and the thrombocytopenia did not recur during follow up. Analysis of their sera showed the presence of IgG antibodies that recognized normal platelets in the presence of the metabolite naproxen glucuronide.

Gastrointestinal

By December 1995 the FDA had received 81 reports of esophageal symptoms and 7 had esophageal ulcers. No hemorrhages were reported (SEDA-22, 117).

Naproxen-induced gastrotoxicity has been reported with varying frequency (SED-9, 152) (1).

There were no differences in the incidence of middle and distal duodenum lesions (14). Esophageal ulceration with bleeding was reported in an elderly woman with esophageal dysmotility (SEDA-17, 112). Esophageal symptoms and esophageal ulcers were reported with naproxen sodium tablets (as opposed to capsules) for over-the-counter use (SEDA-22, 111). Naproxen did not cause reflux and had no significant effect on motility in healthy subjects (15).

Local adverse effects of naproxen suppositories include edema, erythema, and bleeding, which are usually mild.

Acute eosinophilic colitis has been described; it resolved rapidly when naproxen was withdrawn (16).

Liver

Abnormal liver function tests (SED-9, 152) (17) and hepatic injury have been associated with naproxen (18), but no definite cause–effect relation has been established.

Pancreas

Acute pancreatitis has been described in two young women taking naproxen for dysmenorrhea (SEDA-18, 105) (SEDA-20, 93).

Urinary tract

Interstitial nephritis, with rises in serum urea and creatinine, which fell after withdrawal, has been described after treatment for 3 months in adults (19) and in a young boy (SEDA-16, 111).

Oliguric renal insufficiency with the nephrotic syndrome and active interstitial nephritis has been described in a young woman with systemic lupus erythematosus taking intermittent long-term naproxen (SEDA-15, 102).

- A marathon runner, who had taken naproxen until 36 hours before the race, developed acute oliguric renal insufficiency that required hemodialysis 2 days afterwards (SEDA-12, 87).

The kidney can be affected in generalized hypersensitivity reactions to naproxen (3).

Skin

Acne has been reported in a woman with primary dysmenorrhea (20).

The skin can be affected in the course of generalized allergic reactions (21).

Bullous photodermatitis resembling porphyria cutanea tarda has been described in patients taking long-term treatment (SEDA-12, 87).

Hair loss can be induced by naproxen (SEDA-15, 102).

© 2006 Elsevier B.V. All rights reserved.

A photodermatitis, defined as pseudoporphyria, has been reported in 21 children with juvenile rheumatoid arthritis and one with systemic lupus erythematosus after prolonged treatment with naproxen (22) and in another four children with juvenile rheumatoid arthritis (23). This effect is rare, but since naproxen is widely used in juvenile rheumatoid arthritis, it is worth mentioning.

- Linear IgA bullous dermatosis occurred in a 69-year-old man (24). Long-term corticosteroid treatment caused gradual resolution.

Sexual function

Impotence and failure to ejaculate have been described, the latter with positive rechallenge (25).

In women, naproxen, like other NSAIDs, can interfere with menstruation; two young women had interrupted menstrual blood flow after taking the drug (SEDA-15, 102).

At high doses in mid-cycle, naproxen can inhibit ovulation and cause the so-called luteinized unruptured follicle syndrome (SEDA-16, 111).

Immunologic

Generalized reactions (26) include cutaneous necrotizing vasculitis (SEDA-5, 106) (SEDA-17, 113), nephritis, paralytic ileus, and angiitis with cutaneous, muscular, articular, and renal involvement (21).

- A leukocytoclastic vasculitis occurred in a 62-year-old woman with skin, peripheral nerve, and renal involvement (27). Long-term corticosteroid treatment caused gradually resolution.
- Exercise-induced anaphylaxis in a girl who had been taking naproxen for 3 weeks was confirmed by rechallenge (SEDA-21, 106).

Second-Generation Effects

Fetotoxicity

Pulmonary hypertension and severe protracted hypoxemia occurred in babies born to mothers who took naproxen to delay delivery (28). The babies also had disorders of blood clotting, renal function, and bilirubin metabolism. Necroscopy showed subarachnoid hemorrhage, gastric ulcers, and closed ductus arteriosus.

Susceptibility Factors

Age

In an analysis of nine double-blind, controlled studies, adverse reactions to naproxen in older and in younger subjects had similar incidences (29).

Drug Administration

Drug formulations

The suspension and modified-release tablets produce the usual pattern of adverse effects (SEDA-15, 101), although an enteric-coated formulation of naproxen in patients intolerant of NSAIDs caused fewer gastrointestinal adverse effects (SEDA-19, 99).

Drug overdose

Nothing more serious than nausea and indigestion have been reported after 25 g of naproxen (30), whereas 35 g caused an epileptic fit (31). Metabolic acidosis, loss of consciousness, seizures, and apnea have been reported after the ingestion of more than 10 g (32).

Drug–Drug Interactions

Diuretics

Naproxen reduces the actions of diuretics (SEDA-8, 107).

Methotrexate

Methotrexate alters naproxen kinetics and vice versa (33).

Methyldopa

Naproxen reduces the actions of methyldopa (SEDA- 8, 107).

Prebenecid

Naproxen inhibits the metabolism and renal excretion of probenecid, prolonging its half-life (34).

Propranolol

Naproxen reduces the actions of propranolol (SEDA-8, 107).

Nedocromil

General Information

Nedocromil sodium, a cromone similar to cromoglicate, is classified as an antiallergic drug (1). It is available for inhalation as a metered dose aerosol and is used prophylactically in asthma. Nedocromil is more potent than cromoglicate in inhibiting lung mast cell secretion and stabilizing neutrophils, eosinophils, and platelets; it affects nerve reflexes in the lung in a similar manner to cromoglicate (1). In a number of comparisons of inhaled nedocromil with cromoglicate there was no clinically significant difference between the drugs (2,3).

Nedocromil appears to be as safe as cromoglicate, with an absence of reports of truly severe adverse effects. Nausea (3.8% of patients) and headaches (4.8%) are the most commonly observed adverse effects. These adverse effects were mild and tended to abate during long-term therapy (SEDA-13, 135). Throat irritation is another frequent complaint with nedocromil therapy; less common adverse effects include tremor, chest tightness, production of yellow mucus and dizziness (SEDA-15, 2).

Nedocromil 2% ophthalmic solution is as effective as cromoglicate in allergic conjunctivitis and more effective in peak periods of pollen challenge (4). Headache was the most common adverse effect, but unpleasant taste and nasal congestion also occurred commonly. In cases of vernal keratoconjunctivitis, both cromoglicate (2%) and nedocromil (2%) eye-drops produced improvement without significant adverse effects (5).

Drug Administration

Drug administration route

Ocular irritation, burning, or stinging can occur with nedocromil eye-drops (6). Unpreserved 2% nedocromil sodium eye-drops and placebo were used for 6 weeks in a double-masked comparative study of 45 patients with contact lens-associated papillary conjunctivitis. There was significantly less itching in the nedocromil sodium group compared with placebo, and biomicroscopic assessment showed a significant difference in the amount of mucus on the upper tarsal surface in favor of nedocromil sodium by the end of the study. In the nedocromil group, however, 21 patients had adverse effects, especially taste changes and/or stinging on application of the drops (7).

When nedocromil eye-drops (2%) were used by 1552 patients, 5% noticed a distinctive taste; in another study, 14% of patients reported that nedocromil had a distinctive bitter taste (8). Minor irritation was frequently noted just after application of the drops (4).

Nefazodone

See also Antidepressants, second-generation

General Information

Nefazodone is a phenylpiperazine antidepressant, structurally related to trazodone, but it has less alpha$_1$-adrenoceptor antagonist activity and is therefore less sedative. It is a potent 5-HT$_2$ receptor antagonist at postsynaptic receptors, and a weak serotonin reuptake inhibitor. In trials it was more effective than placebo and comparable to imipramine.

Commonly reported adverse effects are dry mouth, weakness, somnolence, nausea, dizziness, constipation, light-headedness, amblyopia, and blurred vision (1,2).

Organs and Systems

Nervous system

Nefazodone is unusual amongst antidepressants in that it does not reduce and in fact may increase rapid eye movement (REM) sleep or dream sleep. In a controlled study in depressed patients nefazodone 400 mg/day increased REM sleep, while fluoxetine 20 mg/day produced the opposite effect (3). In addition, nefazodone increased sleep efficiency, while fluoxetine reduced it. The patients' subjective assessments of sleep improved more with nefazodone than with fluoxetine. However, the overall antidepressant effects of the drugs were similar. The function of REM sleep and its relation to depressive disorders is not clear, so it is uncertain whether preservation of REM sleep by nefazodone is likely to be of clinical consequence.

Three men (aged 28–63 years) had troublesome burning sensations, not clearly localized to any one area of the body, 3 days to 3 weeks after starting to take nefazodone (4). The episodes lasted for about 30 minutes and recurred several times each day. The symptoms responded to nefazodone withdrawal or dosage reduction. These unpleasant sensations appeared to be linked to nefazodone, but the mechanism was obscure.

Psychological, psychiatric

- A 55-year-old woman with no previous history of bipolar disorder became manic while taking nefazodone (5).

Metabolism

Hypoglycemia occurred in a 54-year-old woman with diabetes mellitus after she started to take nefazodone (6). She also reported weight loss of 5 pounds.

Liver

There have been several reports of serious hepatotoxicity associated with nefazodone, in some cases leading to liver failure.

- A 27-year-old man developed hepatitis (with raised bilirubin and liver enzymes) without overt jaundice after taking nefazodone 200 mg/day for 12 weeks (7). No other cause for the hepatitis could be established and the abnormal liver function tests settled 4 weeks after nefazodone withdrawal. They became abnormal again 1 week after nefazodone rechallenge and settled once again on withdrawal.
- Four women, aged 16–73 years, developed catastrophic liver failure while taking nefazodone (8,9). Nefazodone was given for 14–28 weeks before the onset of symptoms. The cases had similar histological appearances, with prominent centrilobular necrosis. Three died, one survived after liver transplantation, and one improved sufficiently to obviate the need for transplantation. The duration of nefazodone treatment before the onset of symptoms was 7–28 weeks. The patients had no history of liver disease and other causes were excluded as far as possible.
- An 80-year-old man developed acute fatal liver failure while taking nefazodone 50 mg/day (8).
- A 52-year-old man with a 10-day history of fatigue and jaundice had been taking nefazodone (300 mg/day) for depression for about 6 weeks. Biochemical investigations showed acute liver failure. Infective hepatitis and immune disorders were excluded. He failed to respond to medical treatment, and hepatic transplantation was performed. Histological examination of the liver showed parenchymal necrosis, particularly in centrilobular areas, together with lymphocytic infiltration (10).
- A 46-year-old woman developed fatigue and jaundice about 20 weeks after she started to take nefazodone (300 mg/day). She had raised liver enzymes and bilirubin concentrations. There was no evidence of infectious hepatitis or immune disorders. Liver biopsy showed ballooning degeneration and necrosis of hepatocytes with mixed inflammatory infiltrates. The nefazodone was withdrawn and corticosteroid treatment started. Within 4 months she recovered clinically and her liver function tests returned to normal (11).

These severe reactions, although rare, cause concern.

The cumulative incidence of hepatic adverse reactions associated with antidepressant treatment has been estimated through spontaneous reports to the Spanish Pharmacovigilance System (12). For classical tricyclic

© 2006 Elsevier B.V. All rights reserved.

antidepressants and SSRIs the estimated rate of adverse hepatic reactions was 1.28–4.00 per 100 000 patient years. However, the rate with nefazodone was much higher (29 per 100 000 patient years). This report supports concerns that nefazodone may be more hepatotoxic than other antidepressants. Significant hepatic reactions to nefazodone are relatively rare but can be serious.

Hair

Nefazodone was associated with hair loss in a 40-year-old woman after dose escalation from 100 to 200 mg (13).

Sexual function

Sexual adverse effects seem to occur less often with nefazodone than with SSRIs (SEDA 20, 9).

- A 48-year-old woman developed clitoral priapism on the first day of nefazodone treatment (100 mg) (14). The problem persisted for another day, after which she discontinued the nefazodone and the priapism subsided.

Clitoral priapism has been reported with other antidepressants, including SSRIs both alone and in combination with trazodone. In men, trazodone rather than nefazodone is occasionally associated with priapism (SEDA-21, 14).

Long-Term Effects

Drug withdrawal

Discontinuation of SSRIs causes significant withdrawal symptoms (SEDA-22, 12). Withdrawal reactions have been less often described after discontinuation of nefazodone.

- A 27-year-old man developed withdrawal symptoms (dizziness, nausea, vomiting, sweating, anxiety, insomnia, and restlessness) after nefazodone was abruptly withdrawn after 1 month (15).
- A 22-year-old woman gradually increased her dose of nefazodone to 400 mg/day over 3 weeks (16). One week later she abruptly discontinued treatment. About 48 hours later she began to have nausea, vomiting, fatigue, headache, myalgia, restlessness, dizziness, nightmares, emotional lability, and anxiety. These symptoms continued unabated for a further 48 hours, after which they remitted a few hours after nefazodone was restarted.

These symptoms are very similar to those of severe SSRI-induced withdrawal, as were those described in two further case reports (17,18). As with SSRIs, it seems prudent to withdraw nefazodone slowly and to be aware of the possibility of SSRI-like withdrawal symptoms.

Second-Generation Effects

Lactation

Nefazodone passes into the breast milk and has been reported to cause drowsiness and feeding problems in a breast-fed infant (19).

- The mother of a 7-week-old premature girl became depressed and was given nefazodone 300 mg/day. Two weeks later the infant became drowsy and lethargic and did not feed well. No medical condition was found to account for these symptoms and breast-feeding was stopped. The symptoms improved over the next 3 days. The concentrations of nefazodone in breast milk were about 10 times less than those in maternal plasma, and the total infant dose of nefazodone was calculated to be only 0.45% of the maternal dose.

In this case, nefazodone in the breast milk may have caused the infant's drowsiness and feeding problems, despite the fact that the transferred dose of nefazodone would have been very low, since the low gestational age of the infant might have been associated with impaired hepatic and renal clearance, making her susceptible to even very small quantities of nefazodone.

Drug Administration

Drug overdose

The outcomes of over 1300 cases of poisoning with nefazodone as a sole agent have been reported (20). Generally, the toxic effects were mild, consisting mainly of drowsiness, nausea, and dizziness. Clinical signs developed within 1–4 hours of ingestion and dissipated within the following 24 hours. The most serious toxic effect was hypotension, which occurred in 1.6% of cases. Bradycardia occurred in 1.4% of cases. Only one patient had a seizure and none required intubation. These data suggest that the toxicity of nefazodone in overdose is low. However, in suicide attempts, antidepressants are often ingested with other agents, particularly alcohol and other sedating drugs. This might increase the toxic effects of nefazodone, particularly with regard to respiratory depression.

Drug–Drug Interactions

Carbamazepine

In a controlled study in 12 healthy men the combination of carbamazepine and nefazodone led to increased plasma carbamazepine concentrations and substantially lowered plasma nefazodone concentrations (21). This interaction, which is due to inhibition of CYP3A4 by nefazodone, could lead to difficulties during treatment, since the risk of carbamazepine toxicity would have to be balanced against the loss of therapeutic effect of nefazodone. Except in special circumstances it is probably better to avoid the combination.

Clozapine

When nefazodone (400 mg/day for 3 weeks) was added to clozapine treatment in six patients with schizophrenia there was no significant change in plasma clozapine concentrations (22). This finding suggests that CYP3A4 does not play a major role in the metabolism of clozapine and that nefazodone may be a suitable adjunctive treatment for depression in clozapine-treated patients.

However, in another case the addition of nefazodone appeared to produce clozapine toxicity (23).

- A 40-year-old man had taken clozapine 450 mg/day and risperidone 6 mg/day for several years. Nefazodone

© 2006 Elsevier B.V. All rights reserved.

200 mg/day was added in an attempt to improve persistent negative symptoms, and after a week the dosage was increased to 300 mg/day. One week later, he reported anxiety and dizziness and was hypotensive. The combined concentrations of clozapine and its active metabolite norclozapine had increased from 309 ng/ml before nefazodone to 566 ng/ml. The nefazodone dosage was reduced to 200 mg/day and the anxiety, dizziness, and hypotension resolved over the next 7 days. At the same time plasma concentrations of clozapine and norclozapine fell to 370 ng/ml.

These results suggest that in some individuals CYP3A4 plays a significant role in the metabolism of clozapine and that the combination of nefazodone and clozapine should therefore be used with caution. It is possible that in this case concomitant treatment with risperidone may have increased the effect of nefazodone to reduce the clearance of clozapine.

Selective serotonin re-uptake inhibitors (SSRIs)

Concentrations of nefazodone and its metabolites can be increased by fluoxetine and paroxetine (SEDA-20, 9). Combinations of serotonin agents produce serotonin toxicity, and a case of serotonin syndrome occurred when nefazodone (200 mg/day) was combined with fluoxetine (40 mg/day) in a 50-year-old man (24). The toxic symptoms settled 3 days after withdrawal of both antidepressants.

Statins

Nefazodone can cause myositis and rhabdomyolysis in patients taking pravastatin and simvastatin (25). The postulated mechanism involves inhibition of CYP3A4, leading to reduced clearance of the HMG-CoA reductase inhibitors and muscle toxicity.

Substrates of CYP3A4

Nefazodone is a weak inhibitor of CYP2D6, but a potent inhibitor of CYP3A4, and increases plasma concentrations of drugs that are substrates of CYP3A4, such as triazolam, alprazolam, ciclosporin, astemizole, cisapride, terfenadine, and carbamazepine (26). Co-administration with terfenadine, astemizole, or cisapride should be avoided, because of the risk of cardiac dysrhythmias (SEDA-20, 9).

Terfenadine

Drugs that inhibit CYP3A4 inhibit the clearance of terfenadine, an antihistamine that can prolong the QT_c interval. This can cause potentially dangerous interactions. In a double-blind, placebo-controlled study of the effect of nefazodone (600 mg/day for 1 week) on the pharmacokinetics of terfenadine (120 mg/day for 14 days) and another antihistamine, loratadine (20 mg/day for 14 days), in 67 healthy volunteers, nefazodone significantly reduced the clearance of terfenadine and prolonged the mean QT_c interval (27). In addition, nefazodone produced a similar but smaller decrease in the clearance of loratadine and combined treatment also significantly increased the QT_c interval. This effect of nefazodone on the clearance of terfenadine is predictable, as is the increase in QT_c interval. Loratadine is also partly metabolized by CYP2D6, which probably explains the lesser effect of nefazodone on loratadine clearance. Loratadine by itself does not increase the QT_c interval significantly, but cardiotoxicity may be a possibility when it is combined with nefazodone.

Nefopam

General Information

Nefopam, an orphenadrine derivative, is a centrally acting non-opioid analgesic. Various adverse effects have been reported, including nausea, vomiting, epigastric pain, dizziness, drowsiness and mental confusion, hypotension, tachycardia, skin rashes, xerostomia, and urinary retention; some of these may be related to its anticholinergic properties (SEDA-11, 100). Its unsatisfactory adverse effects profile was confirmed in two studies of pain control in cancer and rheumatoid arthritis (SEDA-15, 104)

In one study, five of 33 patients (15%) stopped treatment because of the severity of adverse effects attributed to nefopam (1).

In an open trial 120 patients undergoing elective hepatic resection were randomized to receive postoperative intravenous patient-controlled analgesia with morphine either alone or in combination with nefopam (20 mg 4-hourly) or propacetamol (2 g 6-hourly) (2). Nefopam plus morphine was the most effective treatment. Adverse effects, especially sedation, were comparable in the three groups, but there was significantly more nausea in the morphine group and more sweating in the nefopam group (requiring early drug withdrawal in three cases). Tachycardia was seen more often in the nefopam group but did not reach significance.

Organs and Systems

Urinary tract

There have been 53 cases of reversible urinary retention, hesitancy, a poor stream, or dribbling reported to the UK Committee on Safety of Medicines.

Long-Term Effects

Drug abuse

Three cases of nefopam abuse have been reported (3). The patients had the same pattern of a history of chronic pain, concomitant anxiolytic and antidepressant drug therapy, and abuse of nefopam due to its primarily psychostimulant-like symptoms. The recommended dose of nefopam is 20 mg intramuscularly every 6 hours, with a maximum recommended dose of 120 mg/day. Daily consumption in the three patients was 120–1840 mg/day.

Susceptibility Factors

The UK Committee on Safety of Medicines received 12 reports of confusion and 22 of hallucinations and recommended that nefopam be used with caution in the elderly, in patients with symptoms of urinary retention, or in conjunction with other drugs that have anticholinergic activity (4).

Nelfinavir

See also Protease inhibitors

General Information

Nelfinavir is a non-peptidic inhibitor of the HIV protease. Its most prominent adverse effect is diarrhea, which occurs in up to one-third of individuals. However, the diarrhea is usually mild and can be controlled, if necessary, by antidiarrheal agents (1). Other adverse effects, including rash, nausea, headache, and weakness, are reported in under 5%.

Observational studies

In a multicenter, open, uncontrolled trial of protease inhibitors in conjunction with NRTIs for at least 96 weeks in 32 children, the pharmacokinetics of nelfinavir showed large interindividual differences (2). In all, 17 children suffered adverse events, most of which were mild and occurred early in treatment. The rate of drug-related adverse effects was 0.16 per patient-year in those taking nelfinavir.

© 2006 Elsevier B.V. All rights reserved.

Organs and Systems

Nervous system

Peripheral neuropathy has been reported with nelfinavir (3).

- In a 40-year-old HIV-positive patient nelfinavir 750 mg tds was added to existing combination therapy with stavudine, lamivudine, and loviride. He had taken various drugs during the 4 years before, including zidovudine, zalcitabine, didanosine, stavudine, loviride, ritonavir, and saquinavir. Zalcitabine had been withdrawn 3 years before because of pain and paresthesia in both feet after 4 weeks. Thereafter, he had persisting dysesthesia in the feet. One week after having started nelfinavir, this extended in both legs to the knees. He also had sharp pains in the Achilles tendons and bones and burning in the legs, which made walking impossible. He reduced the dosage to 1500 mg/day and felt an improvement within a few days; nelfinavir was then withdrawn, and his symptoms abated.

Although circumoral paresthesia has been a common adverse effect of ritonavir, peripheral neuropathy has not been previously reported with HIV-1 protease inhibitors. There has been a report of painful neuropathy in two patients who took ritonavir and indinavir respectively (4).

Gastrointestinal

The main adverse event that has been consistently reported with nelfinavir is diarrhea and loose stools in 20–30% of patients. The frequency with which diarrhea is truly dose-limiting is not yet clear, but clinical experience suggests that in many cases treatment can be continued in conjunction with non-specific antidiarrheal medication (SEDA-22, 317) (5,6).

Pancreas

Pancreatitis, if it occurs, can be serious; any doubt as to the causal link has been largely dispelled by a case in which there was positive rechallenge (7).

Urinary tract

Nelfinavir has been reported to cause urinary stones.

- A 37-year-old woman stopped taking indinavir and other antiretroviral drugs because of skin reactions and started to take nelfinavir and delavirdine (8). An unspecified time later she presented with right flank pain, due to nephrolithiasis with hydronephrosis. She was treated with lithotripsy, but 6 months later had another episode of flank pain with microscopic hematuria and crystalluria. There was a large urinary stone in the right renal pelvis and a smaller stone obstructing the ureter. The stone fragments contained nelfinavir 99% and indinavir 1%.

The authors pointed out that nelfinavir is normally only 1–2% excreted in the urine, and they postulated that the indinavir may have started a nidus on which the nelfinavir was subsequently deposited.

Skin

Three HIV-infected patients, who had all taken zidovudine, didanosine, and co-trimoxazole (for *Pneumocystis jiroveci* prophylaxis) for over 12 months, developed generalized urticaria 8–10 days after starting nelfinavir 750 mg tds. Withdrawal of nelfinavir and treatment with antihistamines resulted in the disappearance of the lesions within 4–6 days. One patient restarted nelfinavir 250 mg tds without consulting his physician and had similar symptoms within 5 days. Desensitization by using a dose escalation protocol was attempted in all three patients after withdrawal of nelfinavir. This was successful in two cases; the third patient prematurely discontinued desensitization on his own request. During desensitization two of the patients had mild and transient pruritus and rash, reinforcing the diagnosis of an allergic skin reaction (9).

Patients often develop rashes due to HIV infection or drug allergy. Sulfa desensitization is well documented, but desensitization to other medications is not as well studied. One patient taking nelfinavir developed a severe, pruritic rash; management included nelfinavir desensitization over 12 days (10).

Susceptibility Factors

Age

The pharmacokinetics of three doses of nelfinavir, 15, 30, and 45 mg/kg bd, have been studied in 22 neonates, who were also given stavudine and didanosine for 4 weeks after birth (11). Median values of C_{min} (μg/ml) at 1, 7, 14, and 28 days of age were respectively: 0.19, 1.21, 0.51, and 0.33 (15 mg/kg); 1.02, 3.18, 0.73, and 0.55 (30 mg/kg); and 0.67, 3.21, 0.70, and 0.73 (45 mg/kg). The median values of steady-state AUC (hours.μg/ml) at 14 and 28 days were respectively: 14 and 8.7 (15 mg/kg); 19 and 16 (30 mg/kg); and 23 and 19 (45 mg/kg). There were no serious adverse events. Thus, systemic exposure to nelfinavir fell after 7 days of age, perhaps because of hepatic enzyme maturation, autoinduction of nelfinavir metabolism, and/or changes in nelfinavir absorption. Because of the highly variable kinetics the authors suggested that plasma concentration monitoring was warranted to ensure adequate nelfinavir dosing in neonates.

In a multicenter trial, 128 children were randomly assigned to one of three regimens: zidovudine + lamivudine ($n = 36$), zidovudine + abacavir ($n = 45$), or lamivudine + abacavir ($n = 47$) (12). The children who were free of symptoms ($n = 55$) were also randomized to nelfinavir or placebo, while those with more advanced disease received open-label nelfinavir ($n = 73$). All 13 episodes of diarrhea occurred in those taking nelfinavir. Nelfinavir did not affect serum cholesterol or triglyceride concentrations and there were no cases of lipodystrophy. There were 24 serious adverse events; six were in the symptom-free children (all taking nelfinavir), but all were attributed to the NRTIs.
