The effects of smoked marijuana (3.95% tetrahydrocannabinol; up to three cigarettes per day) and oral dronabinol (2.5 mg tds) on the pharmacokinetics of nelfinavir 750 mg tds ($n = 34$) have been evaluated in a

© 2006 Elsevier B.V. All rights reserved.

randomised, placebo-controlled study in HIV-infected patients (13). At day 14, marijuana reduced the 8-hour AUC of nelfinavir by 10%, the C_{max} by 17%, and the C_{min} by 12%. However, none of these changes was significant. Dronabinol had no effects.

Methadone

Withdrawal symptoms in a 40-year-old man maintained on methadone, necessitating an increase in dosage, were attributed to nelfinavir (14).

Phenytoin

While one might expect nelfinavir to reduce blood concentrations of certain other drugs by inducing their metabolism, it has been suggested that it might actually increase circulating concentrations of simultaneously administered phenytoin (15). However, a Japanese case has suggested that phenytoin concentrations can indeed be reduced; when the two drugs were co-administered a patient previously stabilized on phenytoin had a generalized convulsion (16).

Statins

Since HMG CoA reductase inhibitors (statins) are partially or completely metabolized by CYP3A4, drug interactions with protease inhibitors can be expected. When nelfinavir was combined with atorvastatin and simvastatin, their AUCs increased by 74 and 505% respectively (17). As myopathy and rhabdomyolysis are concentration-related, simvastatin is contraindicated with any protease inhibitor, not just nelfinavir. Based on the data, the starting dose of atorvastatin should be reduced by about 50%.

Tacrolimus

An interaction of nelfinavir with the macrolide immunosuppressant tacrolimus has been reported in a patient co-infected with HIV and hepatitis C virus who had undergone orthotopic liver transplantation (18). The dose of tacrolimus had to be reduced to a 70th of the normal dose to avoid adverse effects. Nelfinavir serum concentrations were not affected by tacrolimus. The authors suggested that this effect had resulted from inhibition of the metabolism of tacrolimus, because both compounds are substrates of CYP3A4.

Neuraminidase inhibitors

General Information

The major drawbacks of older drugs for the treatment of influenza (amantadine and rimantadine) include lack of activity against influenza B, a considerable frequency of adverse effects, and probably a higher likelihood of resistance. With the recent development of inhibitors of the viral neuraminidase, a more specific class of drugs has been added to the antiviral armamentarium. After the description of the crystal structure of the viral neuraminidase, a surface glycoprotein, specific inhibitors were designed. Two derivatives of sialic acid, the natural substrate of the neuraminidase, are currently in use, oseltamivir (rINN) and zanamivir (rINN). These drugs were designed to bind strongly to a conserved region of the cleavage site of the virus, which resulted in a class of compounds with limited risk of viral resistance. In fact, resistance is rare during the use of these drugs (1).

Oseltamivir is administered as an oral capsule and zanamivir by inhalation. Inhaled zanamivir has fewer adverse effects than oral oseltamivir, but there are concerns about its use in young and elderly patients, who are generally unable to achieve the inspiratory flow rate needed to ensure adequate lung deposition (2). Oral oseltamivir is more convenient and easier to administer, but needs to be given with food to lower the frequency of gastrointestinal adverse effects.

Oseltamivir

Oseltamivir (GS4104) is an ester prodrug, whose active metabolite (GS4071) is a potent selective inhibitor of influenza virus neuraminidase, to which it is rapidly hydrolysed by hepatic carboxylesterases. The metabolite is then completely excreted by the kidneys by filtration and secretion. In animals oseltamivir had a wide safety margin, with no evidence of teratogenicity or adverse effects on fertility. Oseltamivir has also been studied in the treatment and prevention of influenza A and B, but published results are sparse. To date it has been well tolerated. Headache was the most frequent complaint and mild to moderate gastrointestinal adverse effects (nausea, diarrhea) have been described (3).

Zanamivir

Zanamivir has poor oral systemic availability. Intranasal administration slightly increases its availability, but in mice strongly reduced viral replication (4). In vitro, zanamivir does not significantly inhibit human lysosomal neuraminidases, and so the potential for severe adverse effects is low (5).

Zanamivir has been evaluated in the prevention and treatment of influenza A and B, and was effective against both viruses. In placebo-controlled trials, the adverse events profile, including local nasal irritation, did not differ significantly between zanamivir and placebo (3,6–8). Phase II and III clinical studies have shown that zanamivir by inhalation, either orally or combined orally and intranasally, slightly shortened the duration and severity of influenza symptoms and in high-risk patients reduced the risk of complications (1,9). Typical doses are 10 mg by oral inhalation and 6.4 mg by intranasal inhalation. Dosing frequency is 2–6 times/day. Zanamivir is well tolerated. In placebo-controlled studies its toxicity profile was similar to placebo.

A review of the use of zanamivir in 6000 patients in clinical studies has confirmed its favorable safety profile (10). To date there is still an optimistic impression that the adverse reactions pattern is no different from that of placebo and that interactions are also unlikely, since it does not inhibit cytochrome P450 (11).

Observational studies

In 730 residents of nursing homes who took oseltamivir prophylaxis for a median of 9 days (range 5–12), adverse effects were identified in 30 (4.1%), of whom 20 had one adverse effect and 10 had two (12). The most common adverse effects were diarrhea ($n = 12$), nausea or vomiting ($n = 7$), cough ($n = 5$), and confusion ($n = 4$).

In seven patients with influenza (three type A and four type B) after allografting, inhaled zanamivir (10 mg bd) was used until excretion of virus ceased (median duration 15, range 5–44, days); there was rapid resolution of the influenza and no adverse effects attributable to zanamivir (13).

Organs and Systems

Respiratory

Zanamivir is administered by inhalation of a powder in a lactose vehicle. It can cause bronchospasm (14).

- A 63-year-old man with oxygen-dependent chronic obstructive pulmonary disease was given zanamivir because of an exacerbation attributed to influenza. Shortly after each inhalation of the drug he reported increasing respiratory difficulty and wheezing. After 3 days he developed respiratory distress, hypoxia, and wheezing, and was treated with bronchodilators, glucocorticoids, and antibiotics.

Patients taking zanamivir are advised to stop using it if bronchospasm occurs, and those with underlying lung disease are advised to have a fast-acting bronchodilator to hand. The bronchospasm can be reduced in frequency by using an inhaled β_2-adrenoceptor agonist before zanamivir. Proper drug deposition depends on flow rate and inhaler technique, so young and elderly patients may not be the best to treat in this way (2,15).

Gastrointestinal

Upper gastrointestinal effects (nausea or nausea with vomiting) have been reported more often in those taking oseltamivir in placebo-controlled studies (16,17). Despite this mild gastrointestinal intolerance, withdrawal rates have been low.

The oral capsule of oseltamivir can be used in any patient who can swallow. However, it must be given with food, to reduce the frequency of nausea and gastrointestinal discomfort. Of 695 children aged 1–12 years, 14.3% had vomiting compared with 8.5% of those

© 2006 Elsevier B.V. All rights reserved.

who took placebo; otherwise oseltamivir was well tolerated (18).

In a meta-analysis of trials, there was a reduction in the duration of symptoms of about 1 day (19). Oseltamivir caused significantly more gastrointestinal symptoms (dyspepsia or nausea) than placebo; the effect increased with dose. Similarly, zanamivir caused significantly more gastrointestinal symptoms than placebo (OR = 2.6; 95% CI = 1.6, 4.2).

Drug–Drug Interactions

Amoxicillin

In healthy subjects amoxicillin had no effect on the pharmacokinetics of oral oseltamivir (20).

Cimetidine

In healthy subjects cimetidine had no effect on the pharmacokinetics of oral oseltamivir (20).

Probenecid

In healthy subjects probenecid completely blocked the renal secretion of the active metabolite of oseltamivir after oral administration, increasing its AUC 2.5 times (20). In vitro studies of the metabolite on the human renal organic anionic transporter I (hOAT1) were investigated in Chinese hamster ovary cells stably transfected with the transporter. The metabolite was a low-efficiency substrate for hOAT1 and a very weak inhibitor of hOATl-mediated transport of *para*-aminohippuric acid. Probenecid inhibited the transport of the metabolite, *para*-aminohippuric acid, and amoxicillin via hOAT1.

Neuroleptic drugs

General Information

Since the introduction of chlorpromazine in the early 1950s, a large number of phenothiazines with neuroleptic properties have been discovered; they include fluphenazine, perphenazine, prochlorperazine, and thioridazine. Several other chemical structures with similar therapeutic properties have also been introduced, including the butyrophenones (such as haloperidol and droperidol) and the thioxanthenes (such as flupenthixol). In recent years the so-called atypical neuroleptic drugs (such as clozapine, olanzapine, and risperidone) have also become available. They have less affinity for dopamine receptors in the basal ganglia than the typical neuroleptic drugs, and therefore cause fewer extrapyramidal adverse effects. The range of usefulness of these agents includes the treatment of schizophrenia (to treat acute episodes and in long-term maintenance treatment), mania, certain organic psychoses, certain depressive states, and a variety of lesser indications. They have also been used to treat autism (1) and psychosis in patients with dementia (2).

Equipotent doses of neuroleptic drugs are listed in Table 1.

General adverse reactions

Neuroleptic drugs can produce a variety of adverse effects in several organ systems. Extrapyramidal reactions and sedation are common; less common are seizures, unwanted behavioral effects, and tardive dyskinesia. Most neuroleptic drugs have anticholinergic effects and commonly produce dry mouth, blurred vision, and constipation. Postural hypotension is common. These effects usually disappear when the drug is stopped or the dosage is reduced.

Table 1 Equipotent doses of neuroleptic drugs (all rINNs)

Drug	Dose (mg)
Typical neuroleptic drugs	
Chlorpromazine	100
Chlorprothixene	100
Fluphenazine hydrochloride	2
Haloperidol	2
Loxapine	10
Mesoridazine	50
Molindone	10
Perphenazine	10
Prochlorperazine	15
Pimozide	1
Thioridazine	100
Tiotixene	5
Trifluoperazine	5
Trifluoperazine	25
Atypical neuroleptic drugs	
Aripiprazole	6
Clozapine	50
Olanzapine	4
Quetiapine	80
Risperidone	1
Ziprasidone	20

Non-specific, usually reversible, cardiographic changes have been reported, but their relation to myocardial toxicity has not been confirmed. Sudden death related to cardiac arrest cannot be fully explained on the basis of the administration of neuroleptic drugs. Weight gain is a common adverse effect. Breast engorgement and galactorrhea can occur in women and even in men. Amenorrhea, gynecomastia, hyperglycemia, hypoglycemia, raised growth hormone, inappropriate ADH secretion, and disturbance of sex hormones have been reliably documented, although they are unusual.

The contraindications to neuroleptic drug therapy include coma, the presence or withdrawal of high doses of other CNS depressants (alcohol, barbiturates, narcotics, etc.), serious hematological conditions (for example bone-marrow suppression), and a previous history of hypersensitivity reactions for example jaundice or severe photosensitivity. Since neuroleptic drugs cause sedation, they can impair mental or physical abilities (including reaction times), especially during the first few days of therapy. A large number of substances can interact with neuroleptic drugs (SED-14, 153) (3).

Hypersusceptibility reactions

Neuroleptic drugs infrequently produce allergic reactions. There are no reports of anaphylactic reactions, but various skin reactions, for example rashes, photosensitivity, and dermatitis, can be viewed as delayed forms of hypersensitivity. Jaundice and blood dyscrasias (hemolytic anemia, agranulocytosis) are rare and may be types of allergic reactions.

Tumorigenicity

Since neuroleptic drugs raise prolactin concentrations, there is concern that this may increase the risk of breast cancer. Although studies have failed to show an association, it would be best to avoid neuroleptic drugs in a patient with a hormone-dependent breast tumor.

Effects on fertility

Amenorrhea and infertility were consequences of the effects of typical neuroleptic drugs and of risperidone. Clinicians should be aware that patients changed from these agents to drugs like olanzapine, quetiapine, or clozapine are therefore at risk of pregnancy (4).

A project group at the Swedish Council on Technology Assessment in Health Care has analysed more than 2000 published manuscripts about neuroleptic drugs (5). They concluded that neuroleptic drug therapy is often accompanied by serious, sometimes permanent, adverse effects. Hence, neuroleptic drugs should be reserved for patients with severe psychoses. Agitated and demented elderly patients should not be treated with neuroleptic drugs unless they have pronounced psychotic symptoms. Nor should neuroleptic drugs be used in young mentally retarded patients and other children and adolescents, except in those with severe autism, Tourette's syndrome, or schizophrenia. In fact, in patients with schizophrenia

© 2006 Elsevier B.V. All rights reserved.

there is increased mortality, and the involvement of neuroleptic drug treatment has been investigated (6).

Severe adverse events associated with neuroleptic drug treatment are epileptic seizures, QT interval prolongation, myocarditis associated with clozapine, neuroleptic malignant syndrome, hypothermia, respiratory arrest, and pulmonary embolism associated with clozapine. To minimize these potential risks, practical prescribing guidelines have recently been proposed (SEDA-21, 42); they recommend careful titration of therapy, checking for a history of cardiac disorders, seizures, neuroleptic malignant syndrome, and hypotension, and regular monitoring for known adverse effects.

Further comparisons of the main features of typical and atypical neuroleptic drugs have emerged (SEDA-22, 45) (7). The review by the Collaborative Working Group on Clinical Trial Evaluations has addressed adverse effects extensively (8). The authors stressed that atypical neuroleptic drugs cause fewer extrapyramidal signs and may have a lower risk of causing tardive dyskinesia than typical neuroleptic drugs. The adverse effects of the atypical drugs of which one should be aware are the following (listed with the drug(s) most likely to cause them):

(a) orthostatic hypotension (clozapine, olanzapine, quetiapine);
(b) myocarditis (clozapine);
(c) pulmonary embolism (clozapine);
(d) seizures (clozapine);
(e) anticholinergic effects (clozapine, olanzapine);
(f) increased prolactin (risperidone);
(g) weight gain (clozapine, olanzapine);
(h) hepatic changes (clozapine, risperidone);
(i) agranulocytosis (clozapine).

Drug interactions can be dangerous or fatal and should be avoided. Patients' individual concerns and health needs must be taken into account when selecting a drug. The atypical drugs, it is said, would be better first-line drugs for patients with specific health concerns.

The Collaborative Working Group has also drawn attention to the interpretation of certain results from clinical trials with novel neuroleptic drugs (8). It has been stated, for instance, that when extrapyramidal signs are not significantly different from those with placebo, it does not necessarily mean that a new neuroleptic drug absolutely lacks extrapyramidal effects. Patients who enter studies of new neuroleptic drugs may have been previously treated with traditional neuroleptic drugs, and extrapyramidal symptoms may have persisted from this prior drug treatment.

A comparison of patients' and prescribers' beliefs about the adverse effects of neuroleptic drugs has been carried out (9). Psychiatrists' estimates of prevalence, but not of distress, correlated significantly with patients' reports. The authors concluded that the apparent lack of understanding of which adverse effects are most likely to cause distress to patients can adversely affect the therapeutic alliance between prescribers and patients.

Patients with good adherence to therapy have a higher incidence of adverse effects (10). Logistic regression analysis identified four factors that discriminate adherent ($n = 48$) from non-adherent ($n = 30$) patients: the course of the illness, the employment status of a key relative, age at onset of the illness, and the presence or absence of adverse effects.

Several atypical neuroleptic drugs are currently considered to be first-line therapies for schizophrenia. However, choosing one can be difficult, because head-to-head comparisons are just beginning to appear and most published trials are comparisons with typical neuroleptic drugs, particularly haloperidol. Several reviews (11,12) and clinical comparisons (13,14) of atypical neuroleptic drugs have been published; a meta-analysis of the efficacy and extrapyramidal effects of the new neuroleptic drugs olanzapine, quetiapine, and risperidone, compared with typical neuroleptic drugs and placebo, deserves particular attention (15). Only randomized, double-blind, controlled trials in patients with schizophrenia or schizophrenia-like psychoses were selected. Combining all Brief Psychiatric Rating Scale (BPRS) comparisons between all neuroleptic drugs and placebo resulted in a mean effect size of 0.25 (CI = 0.22, 0.28; $n = 2477$), which is only a moderate treatment effect. Quetiapine (six studies; $n = 1414$) was as effective as haloperidol. Risperidone (nine studies; $n = 2215$) and olanzapine (four studies; $n = 2914$) were statistically superior to haloperidol. However, the latter two effect sizes (0.06 and 0.07) were very small. The new neuroleptic drugs and placebo were associated with similar use of antiparkinsonian medications, and all were clearly superior to haloperidol in this respect; risperidone had the weakest effect (effect size 0.09 versus placebo and 0.12 versus haloperidol). Many of the trials used relatively high doses of haloperidol, favoring the occurrence of extrapyramidal signs.

Special subgroups have been considered in different studies. Agitated and demented elderly patients should not be treated with neuroleptic drugs, unless they have pronounced psychotic symptoms (SEDA-23, 48). Since some studies have reported the lack of a documented diagnosis associated with the use of neuroleptic drugs, a drug utilization study using a chart review has been carried out in Canada to discover the pattern of use of neuroleptic drugs in a long-term care facility (16). Neuroleptic drugs were prescribed for 86 (19%) of 446 patients from four units of a 360-bed nursing home, mainly for agitation ($n = 21$); their mean age was 84 years and the mean length of time they had been receiving neuroleptic drugs was 37 (7–263) months. The authors thought that this was of definite concern, given the modest benefit that has been observed during long periods of treatment in such patients and the risk of tardive dyskinesia and other adverse effects.

In the light of evidence from large, randomized, double-blind trials, the authors of a thorough review of the role of atypical neuroleptic drugs in the treatment of psychosis and agitation associated with dementia have concluded that low-dose risperidone (0.25–1.5 mg/day) can be used as first-line treatment (17).

A further comprehensive review on the use of atypical neuroleptic drugs in older adults has also been published (18).

Comparisons of neuroleptic drugs

Comparisons of different typical drugs

Amisulpride versus typical neuroleptic drugs

In an extensive review of 19 randomized studies for the Cochrane Library ($n = 2443$), most of the trials were small and of short duration (19). Compared with typical

© 2006 Elsevier B.V. All rights reserved.

neuroleptic drugs, the pooled results of a total of 14 trials suggested that amisulpride was more effective in improving global state ($n = 651$), general mental state ($n = 695$), and the negative symptoms of schizophrenia ($n = 506$). Amisulpride was as effective as typical neuroleptic drugs in relieving positive symptoms. It was less likely to cause at least one general adverse event ($n = 751$), to cause one extrapyramidal symptom ($n = 771$), or to require the use of antiparkinsonian drugs ($n = 851$). There were no clear differences in other adverse events compared with typical drugs. Amisulpride also seemed to be more acceptable than typical drugs, as measured by early withdrawal ($n = 1512$) than typical drugs, but this result may have been overestimated owing to publication bias, which could not be excluded with certainty.

A further meta-analysis of 10 randomized controlled clinical trials of amisulpride in "acutely ill patients" ($n = 1654$) was supported in part by a grant from Sanofi-Synthélabo, the marketing authorization holder (20). Amisulpride was significantly better than typical neuroleptic drugs by about 11% on the BPRS. In four studies in patients with "persistent negative symptoms," amisulpride was significantly better than placebo ($n = 514$), but there was no significant difference between amisulpride and typical drugs (only three studies; $n = 130$). Low doses of amisulpride (50–300 mg/day) were not associated with significantly more use of antiparkinsonian drugs than placebo ($n = 507$), and usual doses caused fewer extrapyramidal adverse effects than typical neuroleptic drugs ($n = 1599$). In four studies in acutely ill patients, significantly fewer patients taking amisulpride dropped out compared with patients taking typical drugs, mainly because of fewer adverse events; in three small studies with conventional neuroleptic drugs as comparators there was only a trend in favor of amisulpride in this regard.

Amisulpride versus flupenthixol

In a randomized, double-blind, multicenter comparison of amisulpride 1000 mg/day ($n = 70$) and flupenthixol 25 mg/day ($n = 62$) for 6 weeks, the two drugs significantly improved the acute psychotic symptoms to a similar extent (21). The total numbers of dropouts were 19 with amisulpride and 25 with flupenthixol. Adverse effects accounted for 8.6 and 18% respectively of the totals. Amisulpride caused significantly fewer extrapyramidal adverse effects. Apart from the extrapyramidal adverse effects, there were treatment-related adverse events in 87% of the patients given amisulpride and 92% of those given flupenthixol. Prolactin concentrations were higher with amisulpride.

Amisulpride versus haloperidol

Fixed doses of amisulpride (100, 400, 800, and 1200 mg/day) and haloperidol (16 mg/day) have been compared in a 4-week, double-blind, randomized trial in 319 patients with acute exacerbations of schizophrenia (22). Amisulpride 400 mg/day and 800 mg/day was effective in treating the positive symptoms of schizophrenia, with fewer extrapyramidal adverse effects than haloperidol, which was associated with the highest proportion of extrapyramidal symptoms. The incidence of extrapyramidal symptoms in patients treated with amisulpride increased with increasing dose (31%, 42%, 45%, and 55% for 100, 400, 800, and 1200 mg/day respectively). The rate of withdrawals due to adverse events was higher with haloperidol (16%) than with amisulpride (0%, 5%, 3%, and 5% respectively).

The long-term safety and efficacy of amisulpride in subchronic and chronic schizophrenia have been assessed in an open, multicenter study in 489 patients randomly allocated to amisulpride (mean dose 605 mg/day; $n = 370$) or haloperidol (mean dose 14.6 mg/day; $n = 119$) for 12 months (23). Improvement in mean total score on the BPRS was significantly greater with amisulpride than with haloperidol. The proportion of patients with at least one treatment-emergent adverse event was similar in the two groups, 69% with amisulpride and 70% with haloperidol, but extrapyramidal symptoms occurred more often with haloperidol (41%) than with amisulpride (26%); endocrine disorders occurred in 4% of those taking amisulpride and 3% of those taking haloperidol. Amenorrhea (6 versus 0%) and weight increase (11 versus 4%) were more frequent with amisulpride. There were serious adverse events in 10% of the patients taking amisulpride and 7% of those taking haloperidol.

Atypical versus typical drugs

There is no clear evidence that atypical neuroleptic drugs are more effective or better tolerated than typical neuroleptic drugs. It has therefore been suggested that typical neuroleptic drugs can be used in the initial treatment of schizophrenia, unless the patient has previously not responded to these drugs or has unacceptable extrapyramidal adverse effects, based on a meta-analysis of 52 randomized comparisons of atypical neuroleptic drugs with typical neuroleptic drugs (12 649 patients) or alternative atypical neuroleptic drugs (24). After correction for the higher than recommended doses of typical neuroleptic drugs that are used in some trials, there was a modest advantage of atypical neuroleptic drugs in terms of extrapyramidal adverse effects, but the differences in efficacy and overall tolerability disappeared, suggesting that many of the perceived benefits of atypical neuroleptic drugs are really due to excessive doses of the comparator drugs used in trials. Other reviews of atypical neuroleptic drugs have not added anything new (25,26). Both types of neuroleptic drugs have serious shortcomings, particularly their adverse effects on the extrapyramidal and endocrine systems. However, quality of life is said to be superior with atypical neuroleptic drugs, from an analysis of seven controlled trials and eight open trials (27).

An independent cross-sectional survey, not sponsored by the pharmaceutical industry, in schizophrenic outpatients clinically stabilized on a neuroleptic drug for a period of 6 months showed that quality-of-life measures and Global Assessment of Functioning did not differ significantly in patients taking typical neuroleptic drugs ($n = 44$) and novel ones (risperidone, $n = 50$; olanzapine, $n = 48$; quetiapine, $n = 42$; clozapine, $n = 46$) (28).

Adverse effects have been studied in people with mental retardation treated with atypical neuroleptic drugs ($n = 17$), typical neuroleptic drugs ($n = 17$), or no drugs ($n = 17$) (29). The patients taking atypical neuroleptic drugs did not have different overall adverse events from those taking no medications, and both had significantly

© 2006 Elsevier B.V. All rights reserved.

fewer overall adverse effects than those taking typical neuroleptic drugs. However, the study had some important flaws: patients taking typical neuroleptic drugs were on average 7 years older than those taking atypical drugs; they had also taken medication for longer and had more stereotypic movement disorders at baseline. This jeopardizes the conclusions.

Atypical drugs versus haloperidol

In a randomized double-blind trial in 157 inpatients with chronic schizophrenia, clozapine ($n = 40$), olanzapine ($n = 39$), and risperidone ($n = 41$), but not haloperidol ($n = 37$), produced statistically significant improvements in total scores on the Positive and Negative Syndrome Scale after 14 weeks (30). Patients who had failed to respond to any typical neuroleptic drug were eligible, including patients who had previously failed to respond to haloperidol. High doses were used (the mean daily doses achieved during the last period of study were: clozapine 525 mg, olanzapine 30 mg, risperidone 12 mg, and haloperidol 26 mg). There was a significant fall in the Extrapyramidal Symptom Rating Score with the three atypical drugs at the end of the study and no change with haloperidol. One patient developed agranulocytosis, two had hypertensive episodes, and four had seizures while taking clozapine.

The results of 11 studies in 1933 patients with schizophrenia, who were randomly assigned to amisulpride ($n = 1247$), haloperidol ($n = 309$), risperidone ($n = 113$), flupenthixol ($n = 62$), or placebo ($n = 202$) have been reviewed (31). Extrapyramidal signs occurred in 15% of those given amisulpride ($n = 579$), 12% of those given risperidone ($n = 113$), and 31% of those given haloperidol ($n = 214$). In contrast, endocrine disorders were more frequent with amisulpride (4%) and risperidone (6%) than with haloperidol (1%). In a subgroup of patients with predominant negative schizophrenia who had at least one electrocardiogram recorded during treatment, there was a relative prolongation of the QT_c interval of at least 60 ms in three of 296 patients treated with amisulpride compared with no cases with both haloperidol ($n = 80$) and risperidone ($n = 91$); however, there were no ventricular dysrhythmias.

Clozapine versus typical neuroleptic drugs

A meta-analysis of 30 randomized controlled comparisons of clozapine with typical neuroleptic drugs ($n = 2530$) has been published (32). Clozapine was more effective in reducing symptoms in patients with both treatment-resistant and non-resistant schizophrenia. In a subset of 13 trials hematological problems tended to be more frequent in patients taking clozapine (OR = 1.93, CI = 0.96, 3.87); hypersalivation was also more frequent (OR = 5.50, CI = 4.26, 7.10), as were fever (OR = 1.89, CI = 1.38, 2.60) and sedation (OR = 1.94, CI = 1.50, 2.50). Xerostomia (OR = 0.29, CI = 0.20, 0.42) and extrapyramidal symptoms (OR = 0.46, CI = 0.28–0.75) were more frequent in the patients treated with typical neuroleptic drugs. There was no difference between the two groups in weight gain (OR = 1.07, CI = 0.37, 3.10), hypotension or dizziness (OR = 1.66, CI = 0.74, 3.71), or seizures (OR = 1.60, CI = 0.84, 3.04). Although there were fewer deaths in the clozapine group, statistical significance was not reached (OR = 0.50, CI = 0.11, 2.30). One of the flaws of this meta-analysis was that there was no information on dropouts.

Clozapine versus chlorpromazine

In 42 elderly patients (mean age 67 years) with schizophrenia randomly assigned to clozapine, titrated to 300 mg/day ($n = 24$), or chlorpromazine, titrated to a maximum of 600 mg/day ($n = 18$), the two medications were equally effective at 5 weeks (33). In each group there was one patient with a serious and potentially fatal adverse effect: agranulocytosis in the clozapine group and paralytic ileus in the chlorpromazine group; both drugs significantly lowered the white cell count.

Clozapine versus chlorpromazine and haloperidol

Clozapine has been compared with typical neuroleptic drugs in seven studies in patients with chronic refractory schizophrenia (34) ($n = 1124$). Of the 10 comparisons of second-generation versus typical neuroleptic drugs ($n = 1801$), there was a significant difference in six favoring second-generation neuroleptic drugs on measures of treatment efficacy; in the other four there was no significant difference between treatments. ANCOVA with the baseline score as a co-variate was performed to compare the efficacy of clozapine with that of typical neuroleptic drugs in terms of BPRS total score; there was a significant reduction in psychopathology in those who took clozapine, and the reduction was greater among those with higher BPRS scores. When the assessment was performed with other scales (BPRS positive symptom subscale, SANS) there were no significant treatment effects for clozapine over typical neuroleptic drugs. The subjects who took clozapine had significantly fewer extrapyramidal effects; tardive dyskinesia occurred equally in the two groups. Weight gain was reported in patients who took chlorpromazine (1%) and clozapine (7.1%), but in none of those who took haloperidol. Patients taking chlorpromazine (3.4%) or clozapine (2.9%) had difficulty in concentrating, but none of those taking haloperidol did. Other adverse events reported in patients taking clozapine included neutropenia (2.0%), enuresis (1.0%), and seizures (0.4%); neuroleptic malignant syndrome developed in 0.5% of the patients who took chlorpromazine. Completion rates were higher for clozapine (70%; $n = 400$) than for the typical neuroleptic drugs (56%; $n = 398$). Despite the superior efficacy of clozapine in the treatment of resistant patients, the extent of this in terms of scope (symptoms improved) and magnitude (effect size) was variable. Using what might be regarded as a non-stringent criterion of a 20–30% reduction in total psychopathology scores, under half of the patients responded in most of the studies.

Clozapine versus haloperidol

Clozapine and haloperidol have been compared in 75 schizophrenic outpatients, who met criteria for residual positive or negative symptoms after being treated for at least 6 weeks with typical neuroleptic drugs, in a 10-week randomized, double-blind, parallel-group comparison (35). There was no evidence of any superior efficacy or

© 2006 Elsevier B.V. All rights reserved.

long-term effect of clozapine ($n = 38$) on primary or secondary negative symptoms compared with haloperidol ($n = 37$). Long-term clozapine was associated with significant improvements in social and occupational functioning, but not in overall quality of life. There were no significant differences between the two groups in adverse effects from previous neuroleptic drug treatment, and dizziness (50 versus 19%), salivation (82 versus 19%), and nausea (37 versus 11%) were significantly more common in patients treated with clozapine. In contrast, dry mouth was significantly more common with haloperidol (62 versus 18%). Patients who completed the double-blind study ($n = 58$) entered a 1-year open clozapine study. Over the course of that year, there was a small reduction in adverse effects, apart from hypersalivation, which increased significantly. Over the first 6 months there was weight gain followed by a plateau.

Clinical predictors of response to clozapine have been examined in 37 partially treatment-refractory outpatients who had been assigned to clozapine in a double-blind, haloperidol-controlled, 29-week study (36). Clozapine responders were rated as less severely ill, had fewer negative symptoms, and had fewer extrapyramidal adverse effects at baseline compared with non-responders.

Olanzapine versus chlorpromazine

In 103 previously treatment-resistant patients with schizophrenia were given a prospective 6-week trial of 10–40 mg/day of haloperidol; 84 failed to respond and were randomly assigned to a double-blind, 8-week, fixed-dose trial of either olanzapine 25 mg/day alone ($n = 42$) or chlorpromazine 1200 mg/day plus benzatropine mesylate 4 mg/day ($n = 39$) (37). There was no significant difference in completion rates. Neither drug produced a substantial change in the level of psychosis from prerandomization baseline, and there were no differences between the groups in efficacy. However, olanzapine had a better adverse effects profile.

Olanzapine versus haloperidol

The global efficacy of olanzapine was not substantially different from that of haloperidol in two of three comparative trials involving 2500 patients, according to a comprehensive review of the safety and efficacy of olanzapine; in addition, the only relevant comparative trial failed to demonstrate superiority of olanzapine over risperidone (38). Olanzapine has fewer adverse neurological effects than haloperidol, but there is no evidence that it differs from other atypical neuroleptic drugs in this respect.

A meta-analysis of four comparisons of olanzapine and haloperidol showed similar efficacy, with fewer extrapyramidal effects with olanzapine (15). Similar conclusions were reached in another meta-analysis of three randomized, double-blind, controlled comparisons of olanzapine and haloperidol (39). Only 15% of olanzapine-treated patients ($n = 1620$, dosage 5–20 mg/day) needed anticholinergic drugs compared with 49% of those treated with haloperidol ($n = 786$, dosage 5–20 mg/day).

Olanzapine has been compared with haloperidol in cannabis-induced psychosis (40), schizoaffective disorder (41), first-episode psychosis (42), and treatment-resistant schizophrenia (43); the two last studies were reanalyses of data from large clinical trials promoted by the manufacturers, Eli Lilly. In all cases olanzapine was better than haloperidol at reducing BPRS scores, but in patients with cannabis-induced psychotic disorders they were similar. Increased appetite was consistently reported more often in olanzapine-treated patients and extrapyramidal signs more often in those treated with haloperidol.

A re-analysis of data from a large double-blind comparison of olanzapine with haloperidol ($n = 1996$) showed that in patients who had an initial response, there was no significant difference between olanzapine and haloperidol when outcome was measured using either 52-week relapse rates or the time to first non-compliance; after 12 months, the estimated mean times to discontinuation were 271 days and 241 days respectively (44). However, while the dose of olanzapine was well within the recommended range, the dose of haloperidol was too high (modal doses 13 and 12 mg/day respectively).

In a double-blind trial, 28 patients with paranoid schizophrenia who had had a partial response to typical neuroleptic drugs were randomized to receive either olanzapine or haloperidol in flexible doses for 14 weeks (45). The two groups showed similar improvement on the Brief Psychiatric Rating Scale positive symptoms subscale, while improvement in the same negative symptoms subscale was significant only with olanzapine. There were no significant differences between the two groups on the Simpson and Angus rating Scale scores, but there was a significant difference in the Barnes Akathisia Rating Scale. No patient taking olanzapine had akathisia, while a few patients taking haloperidol did. Apart from the small sample, patients with a partial response to typical neuroleptic drugs were included, which precludes firm conclusions.

In a double-blind, placebo-controlled, dose-response trial, 270 acutely agitated patients were randomized to receive 1–3 intramuscular injections of olanzapine (2.5, 5, 7.5, or 10 mg), haloperidol (7.5 mg), or placebo within 24 hours (46). Olanzapine had a dose-related effect in reducing agitation; olanzapine was better than placebo but not better than haloperidol; the most frequently reported adverse event was hypotension, which occurred with olanzapine ($n = 7$) but not haloperidol or placebo. Acute dystonias did not occur in patients given olanzapine or placebo but occurred in two patients given haloperidol.

Quality of life is said to be superior with atypical neuroleptic drugs, from an analysis of seven controlled trials and eight open trials (27). However, in a comparison of olanzapine and haloperidol in 335 patients there was no significant change in quality of life (47). Moreover, in all the studies, mean doses of haloperidol were higher than 12 mg/day, and in some studies as high as 28 mg/day. This is in accordance with the results of a double-blind, randomized, comparison of olanzapine (mean dosage 11 mg/day; $n = 159$) and haloperidol (mean dosage 11 mg/day; $n = 150$) in 309 schizophrenic patients (48). There were no significant differences between the groups in positive, negative, or total symptoms of schizophrenia, quality of life, extrapyramidal symptoms, or withdrawals. Olanzapine was associated with less akathisia but there were more reports of weight gain and significantly higher costs.

Olanzapine and risperidone versus haloperidol

A prospective 6-month open study, promoted by Lilly, the market authorization holder of olanzapine, has been conducted, in which olanzapine ($n = 2128$), risperidone ($n = 417$), and haloperidol ($n = 112$) were compared (49). Age, sex, and duration of disease did not differ among the groups. The initial and overall mean daily doses were respectively: olanzapine 12.2 and 13.0 mg; risperidone 5.2 and 5.4 mg; haloperidol 13.9 and 13.6 mg. The improvements were similar in the three groups. A lower proportion of patients taking olanzapine had extrapyramidal symptoms (37%) compared with risperidone (50%) and haloperidol (76%). Weight gain was significantly more common with olanzapine (6.9%) than risperidone (1.9%) or haloperidol (0.9%).

In other studies, outcome variables have been discontinuation, relapse, and compliance (44) or quality of life (27). A re-analysis of data from two large double-blind comparisons of olanzapine with haloperidol ($n = 1996$) and of olanzapine with risperidone ($n = 336$) showed that in patients who had an initial response, there was no significant difference between olanzapine and haloperidol when outcome was measured using either 52-week relapse rates or the time to first non-compliance; after 12 months, the estimated mean times to discontinuation were 271 days and 241 days respectively (44). There were no differences between olanzapine and risperidone. However, while the dose of olanzapine was well within the recommended range, the dose of haloperidol was too high (modal doses, 13 and 12 mg/day respectively).

Olanzapine versus pimozide

The use of olanzapine in patients with Gilles de la Tourette syndrome has been explored in a 52-week, double-blind, crossover comparison of olanzapine (5 and 10 mg/day) and low-dose pimozide (2 and 4 mg/day) in four patients (aged 19–40 years) with a high frequency of tics (2–10/minute), vocalizations, and lack of co-morbidity (50). There was a highly significant reduction in rating scale scores for the syndrome with olanzapine 10 mg versus baseline and versus pimozide 2 mg, and a significant reduction with olanzapine 5 mg versus pimozide 4 mg; only moderate sedation was reported by one patient during olanzapine treatment while three complained of minor motor adverse effects and sedation during pimozide treatment.

Quetiapine versus haloperidol

A 6-week, multicenter, double blind, randomized comparison of quetiapine (mean dose 455 mg/day) and haloperidol (8 mg/day) has been carried out in 448 patients with schizophrenia (51). By day 42, the total score on the Positive and Negative Symptom Scale (PNSS) was equally reduced in the two groups. There were 69 withdrawals among the 221 patients who took quetiapine and 80 among the 227 who took haloperidol. Of the patients who took quetiapine, 154 (70%) had one or more spontaneously reported adverse events, whereas 171 (75%) of the haloperidol-treated patients reported adverse events. Motor and extrapyramidal effects were much more frequent among haloperidol users. In the quetiapine group the most common adverse events were somnolence (20%), insomnia (13%), and dry mouth (10%); in the haloperidol group the most frequent adverse events were akathisia (20%), insomnia (15%), and hypertonia (13%). The overall mean weight gain was 1.9 kg in those who took quetiapine and 0.3 kg in those who took haloperidol. With quetiapine, there was a fall in prolactin concentration from baseline by more than 16 μg/l and with haloperidol a rise of just under 6 μg/l during the same period. There was one death from acute heart failure in the haloperidol group.

Another similarly designed comparison of quetiapine and haloperidol in patients with schizophrenia with a partial response to other neuroleptic drugs gave similar results (52). Patients with a history of partial response to typical neuroleptic drugs and a partial or no response to fluphenazine (20 mg/day) for 1 month were randomly allocated to haloperidol 20 mg/day ($n = 145$) or quetiapine 600 mg/day ($n = 143$). By 8 weeks the total score on the PNSS was reduced to the same extent in the two groups. Similar numbers of patients withdrew during the randomized phase of the trial in the quetiapine ($n = 32$) and haloperidol ($n = 28$) treatment arms. The proportions of patients who were taking anticholinergic drugs at the end of the study were 44% and 60% for quetiapine and haloperidol respectively. The most frequently reported adverse events with quetiapine were somnolence (9.8%), postural hypotension/dizziness (7.7%), dry mouth (5.6%), increased muscle tone (5.6%), and akathisia (5.6%). In contrast, the most common adverse events with haloperidol were related to extrapyramidal signs: tremor (12%), akathisia (9.0%), hypertonia (6.9%), extrapyramidal syndrome (6.3%), and insomnia (6.2%). The mean increase in body weight was 1.4 kg with quetiapine and 0.7 kg with haloperidol.

In a study funded by Astra Zeneca, the marketing authorization holder of quetiapine, 25 patients with schizophrenia were randomly assigned double-blind to quetiapine 300–600 mg/day ($n = 13$) or haloperidol 10–20 mg/day ($n = 12$) for 6 months; 11 completed the study, 8 with quetiapine and 3 with haloperidol (53). After Bonferroni correction for 34 comparisons, only the beneficial effect of quetiapine on the revised Wechsler Adult Intelligence Scale (WAIS-R) was significant. Three patients had weight gain with quetiapine versus one with haloperidol. Two patients had raised hepatic enzymes with quetiapine. One patient taking quetiapine had tiny subcapsular blebs, which were apparent at baseline as small dots and appeared larger after 8 weeks of treatment.

Risperidone versus haloperidol

In 62 patients with co-existing psychotic and depressive symptoms, risperidone (mean dose 6.9 mg/day) was compared with a combination of haloperidol 9 mg/day and amitriptyline 180 mg/day ($n = 61$) in a multicenter, randomized, double-blind study over 6 weeks (54). The results suggested that haloperidol plus amitriptyline was superior to risperidone alone. The incidence of extrapyramidal adverse effects was slightly higher with risperidone (37%) than haloperidol plus amitriptyline (31%); the use of concurrent anticholinergic drugs was significantly higher with risperidone (37%) than haloperidol plus amitriptyline (20%).

© 2006 Elsevier B.V. All rights reserved.

In patients aged 18–73 years with disturbing extrapyramidal symptoms during previous neuroleptic drug treatment ($n = 77$), there was a greater reduction of parkinsonism over 8 weeks with risperidone ($n = 40$; average dose 7.4 mg/day) than with haloperidol ($n = 37$; average dose 9.9 mg/day) (55). With risperidone the most frequently mentioned adverse effects were headache ($n = 4$), oculogyric crisis ($n = 3$), and hypersalivation ($n = 3$); with haloperidol the adverse effects were sleep disorders ($n = 4$), tremor ($n = 4$), and vomiting ($n = 3$).

The effects of risperidone and haloperidol in preventing relapse in 365 patients with schizophrenia have been compared (56). The patients were randomly assigned to receive risperidone ($n = 177$; median duration 364 days; mean dose 4.9 mg/day) or haloperidol ($n = 188$; median duration 238 days; mean dose 11.7 mg/day). Primary analyses were performed on all subjects who underwent randomization and were assessed at least once during drug treatment. The risk ratio for relapse with haloperidol was 1.93 (95% CI = 1.33, 2.80), and early withdrawal for any reason was more frequent among haloperidol-treated patients (RR = 1.52; 95% CI = 1.18, 1.96). Patients who took risperidone had greater reductions in mean severities of both psychotic symptoms and extrapyramidal adverse effects than those who took haloperidol. There were adverse events in 90% of those who took risperidone and 91% of those who took haloperidol. Events that were reported in more than 10% of subjects in at least one group were somnolence (14% with risperidone; 25% with haloperidol), agitation (10% and 18%), and hyperkinesia (5% and 20%). There was a mean weight gain of 2.3 kg in those who took risperidone—similar in magnitude to the weight gain seen in short-term studies—and a mean loss of 0.73 kg in those who took haloperidol.

A qualitative analysis of extrapyramidal effects has been performed using Extrapyramidal Symptom Rating Scale (ESRC) data reported in 11 double-blind risperidone comparisons with haloperidol or placebo (57). Between-group comparisons showed no differences between placebo and risperidone 1–2 mg/day, but parkinsonism, tremor, akathisia, and sialorrhea were more likely to occur with haloperidol 1–6 mg/day than with placebo or risperidone. At risperidone dosages of more than 8 mg/day, the severity of acute extrapyramidal effects lay between those of placebo and haloperidol; the severity of tardive dyskinesia was greater with placebo than with either drug. However, others emphasized that those who received haloperidol in this study took a relatively high mean modal dose (12 mg per day) and 81% of the patients taking haloperidol took a daily dose of 7.5–20 mg (58–60). Many studies have shown that doses of haloperidol over 3.75–7.5 mg/day have no increased clinical efficacy but are associated with a significantly increased risk of extrapyramidal effects.

In a comparison of risperidone and haloperidol in patients with chronic schizophrenia, those taking risperidone had greater reductions in the mean severity of both psychotic symptoms and extrapyramidal adverse effects than those taking haloperidol (56) (SEDA-26, 53). The conclusion was that "the preponderance of the evidence now supports the use of risperidone as a first-line treatment for patients with schizophrenia" (61). Nevertheless, the use of "higher-than-optimal doses of typical drugs" was also mentioned as a caveat of the study.

A meta-analysis has compared risperidone with haloperidol (62). Six of the nine trials met criteria for inclusion, that is they were randomized and double-blind, had a duration of at least 4 weeks, and used risperidone in schizophrenic patients in a dosage range of 4–8 mg/day or in a flexible dose regimen. Risperidone was associated with higher clinical response rates (mean difference 14%; 95% CI = 5.6, 22), less prescribing of anticholinergic drugs (mean difference 18%; CI = 9.4, 26), and fewer treatment dropouts (mean difference 13%; CI = 9.4, 26). It was concluded that risperidone was more efficacious than haloperidol, suggesting both a lower incidence of extrapyramidal symptoms and improved treatment compliance.

Another meta-analysis has further compared risperidone and haloperidol (63). Almost all the randomized controlled clinical trials of risperidone versus haloperidol (number of studies = 18; number of patients = 3591) used a 20% improvement on the BPRS and PNSS to define a clinical response. However, an overall analysis using a 50% improvement showed that risperidone was better than haloperidol (OR = 1.6; 95% CI = 1.4, 1.8). Meta-regression did not show that the dose of the haloperidol comparator had a significant effect on positive or negative symptoms. The authors stated that previous meta-analyses had underestimated the risperidone-comparator difference, because they included the suboptimal 1 mg or 2 mg dose in their comparisons, which were not included in this one. Others have suggested that the apparent advantage of risperidone in some trials may be explained by the use of doses of typical drugs that are less than optimal, leading to poorer tolerability and effectiveness (61).

Risperidone versus pimozide

Risperidone ($n = 26$, mean dosage 3.8 mg/day) has been compared with pimozide ($n = 24$, mean dosage 2.9 mg/day) in a 12-week, multicenter, double-blind, parallel-group study in patients with Tourette's disorder (64). Tics significantly improved in both groups, as measured by the Tourette's Symptom Severity Scale (TSSS) and there was also significant improvement in scales of Global Assessment of Functioning and Clinical Global Impressions, and in symptoms of anxiety and depressive mood; however, obsessive-compulsive behavior was significantly improved only by risperidone. Fewer patients who took risperidone reported extrapyramidal adverse effects ($n = 4$) compared with those who took pimozide ($n = 8$), and depression, fatigue, and somnolence were the most prominent adverse effects in both groups.

Risperidone versus typical drugs

When compared with typical neuroleptic drugs, risperidone may be more acceptable to those with schizophrenia. It may also have marginal benefits in terms of clinical improvement and its adverse effects profile. The superiority of risperidone in these respects may have been overestimated, owing to possible publication bias in favor of risperidone. Any marginal benefit has to be balanced against the greater cost of risperidone and its

© 2006 Elsevier B.V. All rights reserved.

increased tendency to cause other adverse effects, such as weight gain.

Tiapride versus haloperidol

Tiapride has been assessed for the treatment of agitation and aggressiveness in elderly patients with cognitive impairment in a multicenter, double-blind study, in which patients were randomly allocated to tiapride 100 mg/day ($n = 102$), haloperidol 2 mg/day ($n = 101$), or placebo ($n = 103$) (65). The percentage of responders after 21 days, according to the Multidimensional Observation Scale for Elderly Subjects (MOSES) irritability/aggressiveness subscale, was significantly greater in both of the active treatment groups (haloperidol 63%, tiapride 69%) than in the placebo group (49%). There were 10 dropouts in the tiapride group, 21 in the haloperidol group, and 16 in the placebo group. The number of patients with at least one extrapyramidal symptom was significantly smaller with tiapride (16%) than with haloperidol (34%) and identical to that with placebo (17%); there was no significant difference across the groups in the numbers of patients with endocrinological adverse events. Four deaths were reported: one with placebo (stroke), one with tiapride (pneumonia), and two with haloperidol (stroke and heart failure).

Ziprasidone versus haloperidol

Intramuscular ziprasidone has recently been compared with intramuscular haloperidol in the treatment of acute psychosis for a very short period (66). Patients were randomly allocated to intramuscular ziprasidone for up to 3 days of flexible dosing ($n = 90$; last oral daily dose 91 mg) or haloperidol ($n = 42$; last oral daily dose 14 mg) followed by oral treatment to day 7. Mean reductions from baseline in all efficacy variables were significantly greater with ziprasidone than with haloperidol at the end of the study. The percentage of patients who had any adverse event was lower with ziprasidone (46%) than with haloperidol (60%); most of the adverse effects were mild or moderate. Four patients discontinued ziprasidone owing to adverse events compared with one in the haloperidol group.

Both ziprasidone and haloperidol reduced overall psychopathology in 301 schizophrenic outpatients aged 18–64 years who were randomized to flexible-dose oral ziprasidone 80–160 mg/day ($n = 148$) or haloperidol 5–15 mg/day ($n = 153$) for 28 weeks in a double-blind, multicenter study (67). The median duration of treatment was 113 days with ziprasidone and 139 days with haloperidol; the rates of withdrawal due to insufficient clinical response were the same in the two groups (18%), but twice as many patients discontinued haloperidol (16%) as ziprasidone (8%) because of treatment-related adverse effects; the percentage of patients in whom any movement disorder emerged was markedly higher with haloperidol (41%) than with ziprasidone (15%). Mean changes in body weight from baseline to end-point were small and similar with ziprasidone (+0.31 kg) and haloperidol (+0.22 kg). With regard to electrocardiographic changes, the mean baseline and endpoint QT_c intervals were 398 and 404 ms with ziprasidone and 389 and 387 ms with haloperidol; no patient had a QT_c interval over 500 ms at any time. It must be stated that some patients included in the study had already been taking haloperidol, 26% in the ziprasidone group and 25% in the haloperidol group. The study was funded by Pfizer, the marketing authorization holder for ziprasidone.

Ziprasidone 160 mg/day is as effective as haloperidol 15 mg/day, and is less likely to cause extrapyramidal symptoms. Such was the conclusion of a study in which, after a single-blind washout period of 4–7 days, patients were randomly assigned to one of four dosages of ziprasidone—4 mg/day ($n = 19$), 10 mg/day ($n = 17$), 40 mg/day ($n = 17$), or 160 mg/day ($n = 20$)—or haloperidol 15 mg/day ($n = 17$) for 4 weeks (68). There was less use of benzatropine at any time during the study with ziprasidone 160 mg/day (15%) than with haloperidol (53%). One patient taking ziprasidone 4 mg/day had confusion and hyponatremia, and another taking 40 mg/day had seizures.

Zotepine versus typical drugs

The use of zotepine in short-term trials (4–8 weeks) has been reviewed (69). Comparisons have been carried out with haloperidol (three trials; $n = 212$), chlorpromazine (two trials; $n = 328$), perazine (two trials; $n = 81$), and tiotixene (one trial; $n = 94$). In these double-blind trials, zotepine 150–300 mg/day was as effective as typical neuroleptic drugs in controlling the symptoms of schizophrenia. The results suggested that zotepine may be effective in the management of patients with negative symptoms and in those with treatment-resistant schizophrenia. The most common adverse effects of zotepine were constipation, dry mouth, insomnia, sleepiness, weakness, and weight gain. The incidence of extrapyramidal symptoms was 8–29%, significantly less than with haloperidol and chlorpromazine, but there were no differences between zotepine and some other typical neuroleptic drugs in this respect. There was an increase in the risk of generalized seizures with zotepine at dosages over 300 mg/day.

Zotepine versus chlorpromazine

In a trial funded by Knoll Pharmaceuticals, the market authorization holder, zotepine was compared with chlorpromazine and placebo (70). Patients with exacerbation of schizophrenia were randomly allocated to zotepine 150–300 mg/day ($n = 53$), chlorpromazine 300–600 mg/day ($n = 53$), or placebo ($n = 53$) for 8 weeks. Mean BPRS scores improved statistically significantly more with zotepine than chlorpromazine or placebo. During the study, 14 patients reported extrapyramidal symptoms, 5 taking zotepine, 4 taking chlorpromazine, and 5 taking placebo. In all, 99 patients (zotepine 43; chlorpromazine 33; placebo 23) reported a total of 257 adverse events (zotepine 120; chlorpromazine 85; placebo 52) during the study. The mean weight reduction with placebo (1.4 kg) was significantly different from the mean weight gain with zotepine (2.4 kg) and chlorpromazine (1.4 kg). Two patients (one taking zotepine, one taking chlorpromazine) with suspected myocardial infarction required hospitalization, but both subsequently recovered.

Zuclopenthixol versus typical drugs

Case series and reviews have suggested superior effectiveness of zuclopenthixol acetate in the acute management

© 2006 Elsevier B.V. All rights reserved.

of disturbed behavior caused by serious mental illness. However, this seems not to have been supported by the evidence from an analysis of randomized controlled trials (71). A meta-analysis of five randomized comparisons of zuclopenthixol acetate with other neuroleptic drugs in patients with considerable behavioral disturbance showed that in all studies there was some improvement in mental state scores (BPRS; CGI), but none showed statistically significant differences between zuclopenthixol acetate and "standard treatment." In three studies there was more sedation in those who took zuclopenthixol acetate than in those allocated to haloperidol. With regard to adverse effects, the studies were not homogeneous: one study showed that people who took zuclopenthixol acetate were more likely to need antiparkinsonian drugs (OR = 6.4; CI = 1.5, 17); other studies did not show any differences in this particular outcome.

Comparisons of different atypical drugs

There have been systematic reviews from the Cochrane Collaboration (www.cochrane.org.uk) of head-to-head comparisons of atypical neuroleptic drugs in non-treatment-resistant schizophrenia.

The benefits of the atypical neuroleptic drugs in patients with bipolar disorder and the possibility that risperidone, quetiapine, olanzapine, and clozapine cause tardive dyskinesia have been studied (72), and there has been a retrospective comparison of clozapine (5 trials), risperidone (25 trials), and olanzapine (20 trials) using data from consecutive treatment trials in the Massachusetts General Hospital (73). The overall results suggested equivalent efficacy of the novel neuroleptic drugs according to changes in Clinical Global Impressions Scale scores. Extrapyramidal symptoms occurred in about 29% of cases in all groups. There were no prolactin-related adverse effects. Substantial weight gain of more than 4.5 kg was significantly more frequent in patients taking olanzapine.

Amisulpride versus risperidone

Amisulpride has been compared with risperidone in patients aged 18–65 years with an acute exacerbation of schizophrenia who were randomized double-blind to receive amisulpride 800 mg/day ($n = 115$) or risperidone 8 mg/day ($n = 113$) for 8 weeks (74). The two treatments were equally effective. Antiparkinsonian medication was begun in 23% of patients taking risperidone and in 30% of those taking amisulpride. The only notable difference was that patients taking risperidone had significant weight gain (1.4 kg) compared with those taking amisulpride (0.4 kg).

In another comparison of amisulpride and risperidone ($n = 228$) there were no significant differences in efficacy or acceptability, with the exception of agitation, which was more frequent with amisulpride (19).

Clozapine versus olanzapine

Olanzapine and clozapine have been compared in a double-blind study by Lilly Research Laboratories for 18 weeks in 220 patients with schizophrenia; conclusions were based on the one-sided lower 95% confidence limit of the treatment effect observed from the primary efficacy variable (Positive and Negative Syndrome Scale (PANSS) total score) (75). The two drugs were comparably effective in neuroleptic drug-resistant patients. Significantly fewer olanzapine-treated patients (4%) withdrew owing to adverse effects than their clozapine-treated counterparts (14%). Among spontaneously reported adverse effects, increased salivation, constipation, dizziness, and nausea were reported significantly more often by patients taking clozapine, whereas only dry mouth was reported more often by patients taking olanzapine.

The efficacy and safety of olanzapine and clozapine have been studied in an open 12-week study in 18 patients with Parkinson's disease and dopaminergic drug-induced psychosis (76). All the patients who took clozapine (mean dosage 13 mg/day) completed the study, despite reporting a number of adverse effects, including somnolence, falls, orthostatic hypotension, and syncope. In contrast, early withdrawal was required in three of the nine patients who took olanzapine, owing to severe gait deterioration and drowsiness (mean dosage 3.9 mg/day). Psychotic symptoms improved in both groups. However, parkinsonism improved in the clozapine group according to the Cornell University Rating Scale (with a 20% fall in raw score and a 7.9% fall in weighted score), while the six patients who took olanzapine and who finished the study had worse parkinsonian symptoms (with a 26% worsening in raw score and a 25% worsening in weighted score).

Clozapine versus risperidone

After a baseline period of treatment with fluphenazine for a minimum of 2 weeks, 29 patients with chronic schizophrenia participated in a randomized, double-blind, 6-week comparison of clozapine and risperidone (13). Clozapine was superior to risperidone for positive symptoms and parkinsonian adverse effects. In addition, clozapine produced fewer effects on plasma prolactin than risperidone. The mean daily doses during week 6 of the trial were 404 mg of clozapine and 5.9 mg of risperidone.

Clozapine has also been compared with risperidone in 60 treatment-resistant patients with schizophrenia in India (14). There was clinical improvement (a more than 20% reduction from baseline PANSS scale scores) in 80% of the clozapine-treated patients and 67% of the risperidone-treated patients. The predominant adverse effects with clozapine ($n = 30$) were tachycardia (77%), hypersalivation (60%), sedation (60%), weight gain (43%), and constipation (30%); one patient had a seizure. The adverse effects of risperidone ($n = 30$) were constipation (50%), dry mouth (47%), weight gain (43%), akathisia (37%), insomnia (33%), tachycardia (30%), and impotence (27%). The final mean daily doses after 16 weeks of treatment were 343 mg for clozapine and 5.8 mg for risperidone.

Clozapine and risperidone have been compared in 10 patients with psychosis in Parkinson's disease, who were randomized to risperidone or clozapine for 12 weeks (77). The mean improvement in the total BPRS score was 3.0 with clozapine (mean dose 62.5 mg/day) and 6.0 with risperidone (mean dose 1.2 mg/day). The white blood cell count fell below 3.0×10^9/l after 10 weeks in one

© 2006 Elsevier B.V. All rights reserved.

subject taking clozapine and rose to 5.0×10^9/l after withdrawal. One subject taking clozapine had a marked increase in rigidity and incontinence of urine after 4 weeks, and there were similar effects in a patient who took risperidone for 10 weeks. All three adverse events resolved on withdrawal.

Clozapine and risperidone have been compared in a randomized, open study in patients with schizophrenia for 10 weeks; treatment outcomes were assessed blindly and 19 patients entered the randomized phase (78). There were no significant differences between the groups in baseline or end-point positive or negative symptoms, disease severity, or global or social functioning scores, and patients' opinion on the two drugs did not differ. These results have corroborated previous evidence that risperidone may be as effective as clozapine, but it is probable that this study does not have enough power to detect a difference.

The relation between the anticholinergic effects of clozapine and risperidone and their cognitive adverse effects has been studied in 22 patients (79). Anticholinergic potency was indexed by a reduction in the receptor occupancy rates of quinuclidinyl benzylate. Patients who took clozapine ($n = 15$) had significantly higher anticholinergic concentrations than those who took risperidone ($n = 7$). However, they all had essentially equivalent scores on cognitive measures. These data suggest that anticholinergic activity distinguishes clozapine and risperidone in vivo, but that this effect is not associated with differences in global cognitive functioning.

Olanzapine versus risperidone

Olanzapine and risperidone seem to be broadly similar, according to the numbers of patients who respond to treatment (40% reduction in PANSS scores: $n = 339$, RR = 1.14, 95% CI = 0.99, 1.32) (www.cochrane.org.uk). More of those who took risperidone withdrew early ($n = 404$, RR = 1.31, 95% CI = 1.06, 1.60; NNT = 8, 95% CI = 4, 32) and they had more extrapyramidal adverse effects ($n = 339$, RR = 1.67, 95% CI = 1.14, 2.46; NNH = 8, 95% CI = 5, 33), although comparative doses of risperidone were higher than those recommended in practice.

In an open comparison of risperidone and olanzapine (mean daily doses at follow-up 4.5 and 13.8 mg respectively) in 42 schizophrenic patients, there was a greater reduction in psychotic symptoms after 6 months of treatment with risperidone, although akathisia was more frequent (80).

A re-analysis of data from a large double-blind comparison of olanzapine with risperidone ($n = 336$) showed that there were no differences between the two (44).

Olanzapine ($n = 172$) has been compared with risperidone ($n = 167$) in an international, multicenter, double-blind, parallel-group, 28-week prospective study in 339 patients who met DSM-IV criteria for schizophrenia, schizophreniform disorder, or schizoaffective disorder (81). Both olanzapine (starting dosage 15 mg/day) and risperidone (starting dosage 1 mg bd) were effective in the management of psychotic symptoms. However, olanzapine had greater efficacy for negative symptoms and overall response rate. The most common adverse events were somnolence, headache, insomnia, rhinitis, depression, and nausea. Weight gain was reported significantly more often with olanzapine, whereas nausea, amblyopia, extrapyramidal syndrome, increased salivation, attempted suicide, abnormal ejaculation, back pain, increased creatine kinase, and urinary tract infection were reported statistically significantly more often with risperidone. A significantly greater proportion of patients taking olanzapine had raised alanine transaminase activity at any time than those taking risperidone. Similarly, significantly more patients taking olanzapine had low neutrophil counts at any time (olanzapine 4.3%, risperidone 0.6%).

The results of one of the clinical trials in which olanzapine (Eli Lilly) was compared with risperidone (Janssen Pharmaceutica) (SEDA-22, 64) gave rise to a debate between researchers of the two pharmaceuticals companies on some of the possible flaws (82–87). Since the modal dosage over the 28-week trial was 7.2 mg/day, significantly higher than that used in actual clinical practice (average dose 4.6 mg/day), the higher incidence of risperidone-associated adverse effects could have been explained by this dosage difference.

In other studies, outcome variables have been discontinuation, relapse, and compliance (44) or quality of life (27). A re-analysis of data from two large double-blind comparisons of olanzapine with haloperidol ($n = 1996$) and of olanzapine with risperidone ($n = 336$) showed that in patients who had an initial response, there was no significant difference between olanzapine and haloperidol when outcome was measured using either 52-week relapse rates or the time to first non-compliance; after 12 months, the estimated mean times to discontinuation were 271 and 241 days respectively (44). There were no differences between olanzapine and risperidone. However, while the dose of olanzapine was well within the recommended range, the dose of haloperidol was too high (modal doses 13 and 12 mg/day respectively).

The use of neuroleptic drugs in conditions other than schizophrenia

There is enormous interest in the effectiveness of neuroleptic drugs in conditions other than schizophrenia, such as autism (1) and psychosis in patients with dementia (2). Neuroleptic medication for treatment of psychosis and agitation in patients with dementia was generally effective; in double-blind, placebo-controlled trials; mean improvement rates were 61% with neuroleptic drugs and 35% with placebo. However, the number of well-designed studies in this area has been small so far.

Amisulpride

In a randomized, double-blind, multicenter trial for 8 weeks in 278 patients with depression there were no differences in efficacy or tolerability between amisulpride 50 mg and SSRIs (88).

Clozapine

Special subgroups of patients can benefit from clozapine (SEDA 24, 61). Of 10 adolescent inpatients (aged 12–17

© 2006 Elsevier B.V. All rights reserved.

years) with severe acute manic or mixed episodes, who did not improve after treatment with typical drugs and who were given clozapine (mean dose 143 mg/day), all responded positively after 15–28 days and adverse effects (increased appetite, sedation, enuresis, sialorrhea) were frequent but not severe enough to require reduced dosages (89). Mean weight gain after 6 months was 7 kg (11%), and neither reduced white cell counts nor epileptic seizures were reported during follow-up for 12–24 months.

In a case series in which clozapine was used as add-on medication, two patients with bipolar disorder and one with schizoaffective disorder had marked reductions in affective symptoms after clozapine had been added to pretreatment with a mood stabilizer; transient and moderate weight gain and fatigue were the only adverse effects (90).

Olanzapine

The efficacy and safety of olanzapine in disorders other than schizophrenia have been studied (SEDA-24, 67) (SEDA-25, 64) (SEDA-26, 61). In a 3-week, randomized, double-blind clinical trial, the effects of a flexible dose of olanzapine (5–20 mg/day) and divalproex (500–2500 mg/day) for the treatment of patients with acute bipolar manic or mixed episodes have been compared (91). The olanzapine treatment group ($n = 125$) had significantly greater mean improvements in mania rating and a significantly greater proportion of patients achieved protocol-defined remission. With olanzapine there was significantly more weight gain (12 versus 7.9%), dry mouth (34 versus 6.3%), increased appetite (12 versus 2.4%), and somnolence (39 versus 21%), while more cases of nausea (29 versus 10%) were reported with divalproex.

The efficacy of adding olanzapine to either valproate or lithium alone in acute manic or mixed bipolar episodes has been studied in a 6-week, double-blind, randomized, placebo-controlled trial (92). Compared with valproate or lithium alone, the addition of olanzapine provided better efficacy. Olanzapine was associated with somnolence, dry mouth, weight gain, increased appetite, tremor, and slurred speech.

Olanzapine, mean dose 5.4 mg/day, has been given to 21 patients with apathy in the absence of depression after long-term treatment with SSRIs for non-psychotic depression in an open, flexible-dose study (93). The more frequent adverse effects were sedation ($n = 12$), increased appetite ($n = 8$), stiffness ($n = 7$), edema ($n = 6$), and dry mouth ($n = 5$).

The medical records of 10 patients with a DSM-IV diagnostic of cluster B personality disorder (narcissistic personality disorder) who had received olanzapine 2.5–20 mg/day for 8 weeks have been reviewed (94). The mean Social Dysfunction and Aggression Scale score was 29 for the 8 weeks before olanzapine therapy and improved to 14 after 8 weeks of treatment. Five of the ten patients developed severe weight gain.

Risperidone

Risperidone has been used in bipolar disorder, dementia, disruptive behavior disorder with subaverage intelligence, Tourette's syndrome, and autism (SEDA-23, 69) (SEDA-25, 67) (SEDA-26, 64). The efficacy and safety of low doses of risperidone in the treatment of autism and serious behavioral problems have been studied in 101 children aged 5–17 years with autistic disorder accompanied by severe tantrums, aggression, or self-injurious behavior, who were randomly assigned to risperidone for 8 weeks ($n = 49$; dosage 0.5–3.5 mg/day) or placebo ($n = 52$) (SEDA27.6.10) (95). Risperidone produced a 57% reduction in the Irritability Score, compared with a 14% reduction in the placebo group; all other parameters were also significantly improved. Risperidone was associated with an average weight gain of 2.7 kg, compared with 0.8 kg with placebo; increased appetite, fatigue, drowsiness, dizziness, and drooling were more common with risperidone. In two-thirds of the children with a positive response to risperidone at 8 weeks, the benefit was maintained at 6 months.

Organs and Systems

Cardiovascular

Neuroleptic drugs can reduce exercise-induced cardiac output as a result of drug-induced increases in plasma catecholamine concentrations and concurrent alpha-adrenoceptor blockade (96). Cardiomyopathy has been associated with neuroleptic drugs, including clozapine (97–99).

Hypotension

Neuroleptic drugs with alpha-blocking activity can cause hypotension. Those of high and intermediate potency, such as haloperidol and loxitane, have minimal alpha-blocking effects and should be less likely to cause hypotension, although in one report orthostatic changes (a fall of 30 mmHg) were reported with these drugs in 27% and 22% of cases respectively (SED-11, 106) (100). An exception to the relatively safe use of high-potency agents has been noted in the combination of droperidol with the narcotic fentanyl, which can cause marked hypotension (101).

Postural hypotension is particularly hazardous in susceptible patients, such as the elderly and those with depleted intravascular volume or reduced cardiovascular output. The risk of orthostatic hypotension is markedly increased after parenteral administration. The combination of alpha-adrenoceptor blockade and sedative effects may explain the increased risk of falling when taking neuroleptic drugs (SEDA-12, 52).

Significantly more low blood pressures were documented by 24-hour ambulatory blood pressure monitoring compared with typical blood pressure measurement obtained an average of 3.6 times a day in patients treated with psychotropic drugs ($n = 12$), most of which were neuroleptic drugs (102). This finding may be of clinical relevance, in view of the potential hemodynamic consequences of hypotension, especially in older patients taking more than one psychotropic drug.

Cardiac dysrhythmias

Neuroleptic drugs are vagolytic and can increase resting and exercise heart rates. Cardiac dysrhythmias have been reported, and include atrial dysrhythmias,

© 2006 Elsevier B.V. All rights reserved.

ventricular tachycardia, and ventricular fibrillation. Bradycardia is unusual. The risk of cardiac dysrhythmias is dose-related and is increased by pre-existing cardiovascular pathology (SEDA-2, 48), interactions with other cardiovascular or psychotropic drugs (particularly the highly anticholinergic tricyclic antidepressants), increased cardiac sensitivity in the elderly, hypokalemia, and vigorous exercise.

In elderly people it is advisable to avoid low-potency neuroleptic drugs, such as thioridazine, which produce significantly more cardiographic changes than high-potency agents, such as fluphenazine (103). In any patient with pre-existing heart disease, a pretreatment electrocardiogram with routine follow-up is recommended.

QT interval prolongation due to neuroleptic drugs has been reviewed (104). It is not a class effect: among currently available agents, thioridazine and ziprasidone are associated with the greatest prolongation. Dysrhythmias are more likely to occur if drug-induced QT prolongation co-exists with other risk factors, such as individual susceptibility, congenital long QT syndromes, heart failure, bradycardia, electrolyte imbalance, overdose of a QT interval-prolonging drug, female sex, restraint, old age, hepatic or renal impairment, and slow metabolizer status; pharmacokinetic or pharmacodynamic interactions can also increase the risk of dysrhythmias. Prolongation of the QT interval occurs more often in patients taking more than 2000 mg of chlorpromazine equivalents daily (105).

In an open study in 164 patients with schizophrenia of the effect of several neuroleptic drugs on the QT interval, the study drugs were given for 21–29 days and three separate electrocardiograms were obtained after steady state had been achieved and drug concentrations were at their maximum (106). The mean changes in the QT_c interval were:

(a) thioridazine 36 ms (95% CI = 31, 41; $n = 30$);
(b) ziprasidone 20 ms (95% CI = 14, 26; $n = 31$);
(c) quetiapine 15 ms (95% CI = 9.5, 20; $n = 27$);
(d) risperidone 12 ms (95% CI = 7.4, 16; $n = 20$);
(e) olanzapine 6.8 ms (95% CI = 0.8, 13; $n = 24$);
(f) haloperidol 4.7 ms (95% CI = −2, 11; $n = 20$).

Mechanism

Torsade de pointes, first described in 1966 by Dessertenne (107), is a potentially fatal ventricular tachydysrhythmia with a characteristic pattern of polymorphous QRS complexes, which appear to twist around the isoelectric line. It is often associated with ventricular extra beats immediately before the dysrhythmia. Torsade de pointes typically occurs in the setting of a prolonged QT interval, which includes depolarization and repolarization times. Conditions or agents that delay ventricular repolarization, causing long QT interval syndromes, can trigger the dysrhythmia. It has been hypothesized that prolongation of the QT interval is caused by early after-depolarization, which in turn may develop in response to abnormal ventricular repolarization (108–110). Evidence linking QT interval prolongation, potassium channel function, and torsade de pointes to neuroleptic drugs has been reviewed (111).

Among the non-cardiac drugs that can cause QT interval prolongation, torsade de pointes, and sudden death (112) the neuroleptic drugs have particularly been associated with conduction disturbances, torsade de pointes being one of the most worrisome (SED-14, 141) (113,114) (SEDA-20, 36) (SEDA-21, 43) (SEDA-22, 45) (SEDA-23, 49) (115,116). Although the role of neuroleptic drugs in sudden death is controversial (SEDA-18, 47) (SEDA-20, 36), and although there are other non-cardiac causes of this syndrome, including asphyxia, convulsions, or hyperpyrexia, QT interval prolongation and torsade de pointes provide a plausible mechanism of sudden death.

QT_c prolongation has been proposed as a predictor of sudden death, and psychiatrists are encouraged to perform electrocardiograms in patients taking high-dose neuroleptic drugs to detect conduction abnormalities, especially QT_c prolongation. It has been suggested that QT_c prolongation in itself is not necessarily an indicator of the risk of sudden death (117). Instead, QT_c dispersion, the difference between the longest and the shortest QT_c interval on the 12-lead electrocardiogram, is an indication of more extreme variability in ventricular repolarization, which could be regarded as a better predictor of the risk of dysrhythmias.

Epidemiology

Electrocardiographic changes are relatively common during treatment with neuroleptic drugs, but there is a lack of unanimity regarding the clinical significance of these findings. The changes that are generally considered benign and non-specific are reversible after withdrawal. Potentially more serious changes include prolongation of the QT interval, depression of the ST segment, flattened T waves, and the appearance of U waves. Non-specific T wave changes are commonly seen during the mid-afternoon, and may be related to the potassium shift and other changes that result after meals, so that a prebreakfast cardiogram may be more desirable.

The prevalence of QT_c prolongation in psychiatric patients has been estimated, to assess whether it is associated with any particular neuroleptic drug (118). Electrocardiograms were obtained from 101 healthy control individuals and 495 psychiatric patients (aged 18–74 years) in various inpatient and community settings in North-East England. Exclusion criteria were atrial fibrillation, bundle-branch block, and a change in drug therapy within the previous 2 weeks (3 months for depot formulations). The threshold for QT_c prolongation (456 ms) was defined as 2 standard deviations above the mean value in the healthy controls. Values were abnormal in 40 patients. Significant independent predictors of QT_c prolongation in psychiatric patients after adjustment for potential confounding effects were aged over 65 years and the use of tricyclic antidepressants, droperidol (RR = 6.7; CI = 1.8, 25), or thioridazine (RR = 5.3; CI = 2.0, 14). Increasing neuroleptic drug dosage was also associated with an increased risk of QT_c prolongation. Abnormal QT dispersion or T wave abnormalities were not significantly associated with neuroleptic drug treatment. Based on these results, the authors recommended electrocardiographic screening, not only in patients taking high doses of any neuroleptic drug but also in those taking droperidol or

© 2006 Elsevier B.V. All rights reserved.

thioridazine, even at low doses. In other studies, dose and age were similarly found to be predictive factors (105), as was co-administration of carbamazepine (119).

Management

Adverse effects related to QT interval prolongation can be prevented by avoiding higher doses and by avoiding the following patients at risk: those with organic heart disease, particularly congestive heart failure; those with metabolic abnormalities (such as hypokalemia and hypomagnesemia); and those with sinus bradycardia or heart block. Concomitant administration of drugs that inhibit drug metabolism should also be avoided, and the potassium concentration should be controlled. If torsade de pointes is suspected, neuroleptic drugs must be withdrawn.

Magnesium sulfate 2 g (20 ml of a 10% solution intravenously) suppresses torsade de pointes (120). Most patients report flushing during this injection. A case of torsade de pointes related to high dose haloperidol and treated with magnesium has been reported (121).

- A 41-year-old woman, with liver lacerations, rib fractures, and pneumothorax after a motor vehicle accident, was given haloperidol for agitation on day 7. During the first 24 hours she received a cumulative intravenous dose of 15 mg, 70 mg on day 2, 190 mg on day 3, 160 mg on days 4 and 5, and 320 mg on day 6. An hour after the first dose of 80 mg on day 7, she had ventricular extra beats followed by 5-beat and 22-beat runs of ventricular tachycardia. The rhythm strips were consistent with polymorphous ventricular tachycardia or torsade de pointes and the QT_c interval was 610 ms (normally under 450 in women). She received intravenous magnesium sulfate 2 g. Concurrent medications included enoxaparin, famotidine, magnesium hydroxide, ampicillin/sulbactam, nystatin suspension, midazolam, and 0.45% saline with 20 mmol/l of potassium chloride. She had no further dysrhythmias after haloperidol was withdrawn. Eight days after the episode of torsade de pointes she had a QT_c interval of 426 ms.

Cardiomyopathy

The relation between neuroleptic drug therapy and myocarditis and cardiomyopathy has been examined using the international database on adverse drug reactions run by the World Health Organization (122). Myocarditis and cardiomyopathy were reported rarely as suspected adverse drug reactions, and accounted for under 0.1% ($n = 2121$) of almost 2.5 million reports. The association of clozapine with those adverse reactions was statistically significant (231 reports out of 24 730), as was the association with "other antipsychotics" (89 of 60 775).

Venous thromboembolism

Typical neuroleptic drugs have been associated with an increased risk of venous thromboembolism (123). The mechanism may be related to increased platelet aggregation (124).

Respiratory

Gag and cough reflexes can be suppressed by neuroleptic drugs (SED-11, 107). Periodic examination of the gag reflex, particularly in patients with tardive dyskinesia, has been recommended.

Acute respiratory failure, which can be complicated by pneumonia, has been reported in psychiatric patients receiving long-term neuroleptic drugs (SED-11, 107) (125).

Pulmonary embolism without a primary focus was surprisingly frequent in cases of sudden death.

Aspiration asphyxia in patients treated with neuroleptic drugs has been described (SEDA-4, 40) (SEDA-5, 51), and it has been suggested that this could have been due to laryngeal-pharyngeal dystonia (126). Patients with asthma treated with neuroleptic drugs may be at increased risk of serious complications of asthma (127).

Diaphragmatic, laryngeal, and glottal dyskinesias have been described as part of the tardive dyskinesia syndrome and can cause respiratory complications (128,129).

Nervous system

Information on neurological adverse effects in particular groups of patients, such as young patients (130) and those with Alzheimer's disease (131,132), AIDS (133), or Gilles de la Tourette syndrome (134), have been published. The use of neuroleptic drugs in patients with Alzheimer's disease is controversial because of the significant adverse effects profile associated with these drugs. Therefore, other pharmacological and psychological methods should be explored before using neuroleptic drugs in dementia. This was the conclusion of a retrospective study in which 80 patients, 40 with confirmed Alzheimer's disease and 40 with confirmed Lewy body dementia, were assessed for neuroleptic drug use and adverse effects (131). Neuroleptic drugs were used in 15 of the patients with Alzheimer's disease and 21 of those with Lewy body dementia. Only six of the latter (29%) had a definite severe sensitivity reaction to neuroleptic drugs, which included cognitive impairment, parkinsonism, drowsiness, and features of the neuroleptic malignant syndrome. All the reactions occurred within 2 weeks of new neuroleptic drug prescription or a dosage change and were associated with a reduction in survival. Certain motor disturbances, measured before neuroleptic drug treatment was begun, could be used to predict the development and severity of neuroleptic drug-induced parkinsonism in patients with Alzheimer's disease treated with very low-dose neuroleptic drugs (132). Parkinsonism occurred in 67% of the patients with Alzheimer's disease. Pretreatment instrumental, but not clinical, measurement of bradykinesia was a predictor of post-treatment parkinsonism.

Seizures

Neuroleptic drugs cause slowing of alpha rhythm and increased synchronization and amplitude with superimposed sharp fast activity. They also induce discharge patterns in the electroencephalogram similar to those associated with epileptic seizures of the tonic-clonic generalized or focal types (SED-11, 108) (135).

Convulsions associated with typical neuroleptic drugs are relatively rare (probably less than 1%) (SED-9, 81) (136).

Predisposing factors to neuroleptic drug-induced seizures include an abnormal electroencephalogram,

© 2006 Elsevier B.V. All rights reserved.

pre-existing CNS abnormalities, parenteral administration of high doses, and a family history of seizures or febrile convulsions (135).

It has been suggested that the less potent sedative neuroleptic drugs (aliphatic or piperidine phenothiazines) lower the convulsive threshold more than the potent neuroleptic drugs (piperazine phenothiazines) (137). Variable and unpredictable effects on seizure activity related to butyrophenones have been reported (138).

An in vitro technique, claimed to assess the relative risks of neuroleptic drug-induced seizures, was reported to produce striking differences between neuroleptic drugs in spike activity in hippocampal slices. Tentatively, molindone, pimozide, and butaclamol were the safest compounds, based on these in vitro experiments (139).

However, they are more common with clozapine (SEDA-22, 57) and are said to occur in 0.9% of patients taking olanzapine (SEDA-24, 67). Olanzapine has been reported to cause a lowered seizure threshold (140).

- A 30-year-old man with paranoid psychosis for 5 years and seizures for 12 years (two generalized seizures a year) was switched to olanzapine 10 mg/day; he was also taking zuclopenthixol and valproate. He then had more frequent seizures, culminating in a generalized tonic-clonic seizure, which resulted in bilateral humeral head fractures. There were no metabolic or electrolyte disturbances. An electroencephalogram showed multifocal generalized epileptiform discharges similar to those seen with clozapine. They resolved on withdrawal of olanzapine and reintroduction of zuclopenthixol.

Extrapyramidal effects

Neuroleptic drugs cause several different types of extrapyramidal adverse effects:

(a) acute dystonic reactions;
(b) akathisia;
(c) parkinsonism and pseudoparkinsonism;
(d) tardive dyskinesia;
(e) tardive akathisia;
(f) tardive Tourette's syndrome;
(g) tardive dystonia;
(h) rabbit syndrome.

Except for tardive dyskinesia, the extrapyramidal adverse effects are largely reversible by giving anticholinergic drugs and withdrawing or lowering the dosage of the neuroleptic drug. These effects have been reviewed (SED-9, 78) (SEDA-7, 61) (SEDA-16, 40) (SEDA-18, 48) (141).

The dose-response relations for a variety of adverse effects of neuroleptic drugs have been reviewed (142). Although the dose-response relations for extrapyramidal effects are not fully understood, the evidence supports a dose-related effect. The relation is probably not linear and is influenced by several factors, but it is reasonable to conclude that systematic attempts to use the lowest possible clinically effective dosage should be strongly encouraged. It is possible that there are susceptible patients in whom tardive dyskinesia can occur at a relatively low cumulative or average daily dose, while in others increasing doses beyond this range may not lead to a substantially increased risk. Since in most patients high dosages do not lead to better therapeutic effects, but are associated with more frequent and severe adverse effects, the use of the smallest dosage necessary to produce neuroleptic benefit is recommended. When sedation is required, the concurrent use of moderate doses of a neuroleptic drug with a benzodiazepine may be preferable to the use of high dosages of a neuroleptic drug alone.

The CYP2D6 genotype is not a determinant of susceptibility to acute dystonic reactions, but may be a contributory factor in neuroleptic drug-induced movement disorders, including tardive dyskinesia (143).

The hypothesis that extrapyramidal adverse effects result from neurotoxicity due to oxidative damage by neuroleptic drugs has been reviewed (SEDA-20, 39) (144).

Patients with AIDS are sensitive to the extrapyramidal adverse effects of neuroleptic drugs and have evidence of depletion of dopamine in the cerebrospinal fluid (SEDA-22, 52). Of 115 consecutive HIV-infected patients, six developed parkinsonism and three of the cases were precipitated by the use of neuroleptic drugs (133).

Since the gamut of the clinical pharmacology of tics is broad, it is often difficult to differentiate tics from other hyperkinetic movement disorders. Of 373 cases of Gilles de la Tourette syndrome, 18 had both tics and other abnormal movements; 12 were secondary to neuroleptic drug treatment (134). Akathisia was the most common movement disorder.

In 15 schizophrenic inpatients aged 16–55 years, there was a 50% probability that a patient would have a tremor when the plasma concentration of chlorpromazine was 46 ng/ml or more, corresponding to the minimum that has been associated with a good clinical response (145). The use of objective accelerometric recordings was said to improve the accuracy of diagnosis of neuroleptic drug-induced tremor. This conclusion was reached in a study in which repeated accelerometric recordings showed constant and regular waveforms and frequencies (4–7 Hz) in each of 14 patients treated with neuroleptic drugs and diagnosed as having neuroleptic drug-induced tremor (146).

In an Australian psychiatric hospital, a rating of movement disturbances was compared with standardized scales (the Abnormal Involuntary Movement Scale (AIMS), Simpson-Angus, and BARS) and the psychiatrists' clinical assessments of such disturbances in 38 consecutive patients (147). The patients were taking neuroleptic drugs and 47% fulfilled the Simpson-Angus criteria for the presence of parkinsonian symptoms compared with 39% who were rated as having mild, moderate, or severe parkinsonian symptoms by their psychiatrists. When BARS was used, 11% of the patients scored some degree of akathisia versus 17% identified by the psychiatrists. The corresponding figures for dyskinesia when using AIMS were 11 versus 14%. In the light of these results, the authors suggested that standardized measures should be introduced into routine practice.

Several studies have shown a relation between neuroleptic drug dosages, extrapyramidal adverse effects, and the degree of dopamine D_2 receptor occupancy (SEDA-18, 48) (148,149). Atypical neuroleptic drugs, such as olanzapine, quetiapine, risperidone, and sertindole, which have lower affinities for D_2 receptors, cause fewer extrapyramidal effects than typical neuroleptic drugs (150,152,153). However, there are reports of

© 2006 Elsevier B.V. All rights reserved.

extrapyramidal effects associated with these atypical neuroleptic drugs (154–156).

A comprehensive review of neuroleptic drug-induced abnormal movements focused on older patients (157). Since there is no effective treatment for patients with tardive dyskinesia once it develops, attention should be paid to its prevention and close monitoring. It was confirmed that striatal D_2 receptor occupancy is an important mediator of response and adverse effects in neuroleptic drug treatment (158). In a double-blind study, 22 patients with first-episode schizophrenia were randomly assigned to a starting dose of haloperidol 1 or 2.5 mg/day. After 2 weeks, D_2 receptor occupancy was determined with raclopride and positron emission tomography; the clinical response, extrapyramidal adverse effects, and prolactin concentrations were also measured. The patients had a wide range of D_2 receptor occupancy (38–87%). The likelihoods of clinical response, hyperprolactinemia, and extrapyramidal adverse effects and akathisia increased significantly as D_2 receptor occupancy exceeded 65%, 72%, and 78% respectively. Since 65–70% D_2 receptor occupancy was obtained with haloperidol 2.5 mg/day in most of the patients, the authors suggested that a dose of 2–3 mg/day should be the optimal starting dose for first-episode patients, which contrasts with the 10–20 mg/day reported in other studies.

Acute dystonic reactions

Acute dystonic reactions are dramatic, acute-onset muscular spasms that occur within the first 24–48 hours after starting therapy, or in a few cases when the dosage is increased. A circadian pattern of acute dystonic reactions has been described (159). Men are more susceptible than women to this reaction, and the young more so than the elderly (160). Drug-induced dystonia can also be precipitated by emotional arousal (161,162). The muscles of the head and neck are mainly affected: opisthotonos, torticollis, oculogyric crisis, and macroglossia (all of which can occur together) are dramatic effects relieved by the use of intramuscular antiparkinsonian or antihistaminic drugs.

- A man in his late twenties, with a several-year history of intravenous heroin use, developed diplopia after he had received single doses of chlorpromazine 100 mg and ibuprofen 400 mg for anxiety (163). There was no extraocular muscle paresis and neurological examination was unremarkable. The diplopia resolved after 6–8 hours.

Temporomandibular joint dislocation has also been reported (164).

Acute laryngeal dystonia is probably under-reported but it is potentially lethal and can mimic anaphylaxis (165). It can occur within hours to days of starting therapy with neuroleptic drugs and is characterized by sudden onset of difficulty in breathing and swallowing (SEDA-22, 51) (166,167).

- A 26-year-old schizophrenic woman developed throat pain and dyspnea while taking haloperidol.
- A 76-year-old man reported difficulty in starting to swallow after taking haloperidol (6 mg/day), sertraline (200 mg/day), lithium, and temazepam for 6 weeks for recurrent depression.

A prospective study has identified cocaine as a risk factor for neuroleptic drug-induced acute dystonia (168). The study sample consisted of a high-risk group for neuroleptic-induced acute dystonia: 29 men aged 17–45 years who had used high-potency neuroleptic drugs within 24 hour of admission and had not taken neuroleptic drugs in the last month. Nine men developed acute dystonia: six of nine cocaine users and three of twenty non-users, a relative risk of 4.4 (95% CI = 1.4, 14). Cocaine users did not differ significantly in age, mean daily neuroleptic drug dose, or peak dose.

A comprehensive review has strongly advocated immediate intravenous administration of anticholinergic drugs to relieve acute dystonia.

Akathisia

Akathisia is a variant of the restless legs syndrome associated with anxiety and/or dysphoria (SEDA-19, 44) (SEDA-20, 36) (169–171). It can be confused with an exacerbation of the disorder being treated. Suicidal tendencies can occur in psychotic patients who developed neuroleptic-induced akathisia (172). On the other hand, recent evidence suggests that depressive symptoms may not be induced or worsened, and may even be reduced, by prescribing atypical neuroleptic drugs (173–175). Subjects show various degrees of restlessness and an inability to sit or stand still; in severe cases, the presentation can merge with behavioral disorders.

Akathisia has been associated with strong effects of terror, anger, and extreme anxiety, the most serious complication being a feeling of helplessness or being out of control, which might lead to suicidal ideation or attempted suicide. Five reported cases of neuroleptic drug-induced akathisia and suicidal tendencies in psychotic patients have further emphasized these risks (172). Doctors ought to pay attention to these symptoms, as suicidal tendencies disappear when symptoms of akathisia are relieved. Patients should also be told that akathisia is a treatable adverse effect of neuroleptic drugs.

Incidence rates of akathisia are reported to be 25–75%. Most cases occur within the first few days of neuroleptic drug treatment, and dosage increase has been identified as a risk factor (176).

Of 23 patients with bipolar affective disorder taking neuroleptic drugs, 15 developed akathisia and 18 had parkinsonism during their entire inpatient treatment (177). The patients initially received high-potency neuroleptic drugs (maximum 2000 mg/day of chlorpromazine equivalents) and were assessed weekly. Akathisia developed in 44% of the patients with severe headache or nausea who received prochlorperazine 10 mg intravenously ($n = 100$) within 1 hour (178). None of the 40 patients receiving other medications, who served as controls, developed akathisia.

Two cases of acute neuroleptic drug-induced akathisia in patients with traumatic paraplegia have been published (179). The authors emphasized the possibility of drug-induced akathisia when patients with traumatic paraplegia or other physical disabilities develop increasing restlessness and an inability to sit or lie still.

Akathisia observed at any time, whether treated or not, has been associated with a poor outcome.

© 2006 Elsevier B.V. All rights reserved.

Antiparkinsonian agents are sometimes helpful, beta-blockers often more so (SEDA-19, 43) (180–182). Low-dosage mianserin has also been used in the treatment of akathisia (183).

Prevention and treatment

Following the development of akathisia, biperiden 5 mg was given intravenously to 17 patients and intramuscularly to 6 (184). The mean times to onset of effect were 1.6 and 31 minutes, respectively, and the maximum effects occurred at 9.2 and 50 minutes. Adverse effects occurred in six patients after intravenous biperiden (slight or mild confusion, drowsiness, dizziness, palpitation, and dry mouth) and in two after intramuscular biperiden (drowsiness and dry mouth).

In 100 adults who were randomly assigned to receive a 3-minute infusion of diphenhydramine or placebo after receiving intravenous prochlorperazine 10 mg for nausea/vomiting or headache, akathisia developed in 18 of 50 subjects in the control group and in seven of 50 subjects in the diphenhydramine group (185). The only adverse effect of diphenhydramine was sedation. Diphenhydramine may be effective in akathisia by more than just an anticholinergic mechanism, since it crosses the blood–brain barrier and blocks central alpha-adrenoceptors and muscarinic, 5-HT, and H_1 histamine receptors. This is claimed to be the first randomized controlled study of the efficacy of single-dose adjuvant diphenhydramine in preventing intravenous drug-induced akathisia.

Mirtazapine is a tetracyclic antidepressant, similar to mianserin, and is a potent 5-$HT_{2A/2C}$ receptor antagonist. It has been successfully used to treat akathisia. In a double-blind, placebo-controlled study in 26 patients with schizophrenia who were receiving neuroleptic drugs, mirtazapine 15 mg/day for 5 days was associated with less akathisia (186).

- A 28-year-old man with akathisia who was taking haloperidol 10 mg/day for schizophrenia complained of leg restlessness, an inability to sit still, and a constant urge to move (187). Biperiden (4 mg bd for 5 days) with the subsequent addition of diazepam (10 mg/day for 3 days) had no effect. Mirtazapine (15 mg/day for 5 days) produced substantial relief of the subjective component of the akathisia, and the abnormal movements disappeared.

Apart from mianserin, other 5-$HT_{2A/2C}$ receptor antagonists, such as ritanserin and cyproheptadine, have also been used to treat akathisia (186).

In one case, severe akathisia was abolished by passive motion when travelling as a car passenger (188).

- A 48-year-old woman developed akathisia soon after having been treated with chlorpromazine 400 mg/day for a bipolar affective disorder. Although the medication was changed a number of times over the next 4 years, there was no improvement. Fluvoxamine 150 mg/day and fluoxetine 20 mg/day seemed to aggravate the movement disorder; neither orphenadrine 200 mg/day nor procyclidine 15 mg/day affected her akathisia; nor did she experience relief from propranolol up to 320 mg/day. Both the subjective feeling of a need to move and the fidgeting in her legs were abolished within seconds of the car's beginning to move. Other movements (for example rocking in a chair or using an exercise bike) were ineffective, as were relaxation techniques and hypnosis.

Since this case emphasizes the importance of sensory input in akathisia, the authors suggested that the recurrent pacing observed in akathisia may be an attempt to alleviate the condition through sensory stimulation, rather than through motor activity.

Akathisia has been associated with iron deficiency (SEDA-17, 49). However, the rationale for iron supplementation in the treatment of akathisia is poor, and there are potential long-term adverse consequences (SEDA-20, 38). This issue has been addressed in patients with acute psychotic disorders who received neuroleptic drugs; 33 patients who developed akathisia were compared with 23 who did not (189). Serum iron was similar in the two groups but ferritin concentrations were significantly lower in akathisia; nevertheless, iron and ferritin concentrations were within the reference ranges.

Parkinsonism and pseudoparkinsonism

Parkinsonism or pseudoparkinsonism induced by neuroleptic drugs is clinically indistinguishable from post-encephalitic or classical parkinsonism. It begins in the head and neck and causes loss of movement in the muscles, which spreads to the arms, producing varying degrees of akinesia and rigidity. Cases of neuroleptic drug-induced parkinsonism with dysphagia as one of the main features have been reported (SEDA-19, 44) (190–192).

The neuroleptic drugs that elicit parkinsonism are those that bind with higher affinity than dopamine to D_2 receptors, while those that cause little or no parkinsonism (clozapine, melperone, quetiapine) bind with lower affinity (193). Antiparkinsonian drugs are more often required in patients taking typical neuroleptic drugs, but they can cause objective and subjective deficits (194,195).

Parkinsonism has been studied in special groups, such as elderly patients (196), patients with bipolar disorders (177), and patients who have received acute medication (178). The incidence of neuroleptic drug-induced parkinsonism has been examined in 50 older newly medicated psychiatric patients (196). After controlling for spontaneous parkinsonism with two groups of 15 unmedicated patients and 49 healthy elderly individuals, 32% of the patients, who were taking an average of 43 mg/day chlorpromazine equivalents of a typical neuroleptic drug, met strict criteria for neuroleptic drug-induced parkinsonism.

Different strategies for the treatment of neuroleptic drug-induced parkinsonism have been reviewed (SEDA-18, 48) (SEDA-20, 40) (197,198). The WHO has recommended that anticholinergic drugs should not be given routinely to patients who are starting to take neuroleptic drugs.

Olanzapine was effective in extinguishing typical neuroleptic drug-induced tremor (199).

Tardive dyskinesia

DoTS classification (BMJ 2003;327:1222–5)
Dose-relation: collateral effect
Time-course: intermediate or delayed
Susceptibility factors: age; sex

© 2006 Elsevier B.V. All rights reserved.

Originally, tardive dyskinesia was described as comprising spontaneous irregular movements, mainly affecting the mouth and tongue; chewing, licking, and smacking movements of the tongue and lips were involved, including protrusion of the tongue outside the buccal cavity and various abnormal movements of the tongue within the buccal cavity. This condition is now also known to include choreoathetoid movements of the fingers and toes, sometimes associated with rocking movements, and akathisia; truncal muscles and respiratory muscles can be involved. Tardive dyskinesia can affect the neural control of any voluntary muscle (SEDA-22, 50). However, smooth pursuit eye movements were not related to tardive dyskinesia in patients with schizophrenia with ($n = 40$) and without ($n = 25$) the condition (200).

The tongue protrusion test, that is an inability to maintain tongue protrusion, is a measure of severity of tardive dyskinesia, and is present mainly in advanced cases; abnormal movements within the buccal cavity occur over a much wider range of severity, suggesting that abnormal tongue movements may be more helpful in the early detection of tardive dyskinesia (201).

There are insufficient data to support the use of drug holidays in detecting the risk of tardive dyskinesia, but they may help to diagnose the covert type by unmasking dyskinesia (202).

When abnormal involuntary movements occur in a patient taking a neuroleptic drug they are not always an adverse effect of the drug, but may be, at least partly, an inherent part of some psychotic illness. Five of forty-nine neuroleptic-naive patients with a first episode of schizophrenia had spontaneous dyskinesias (203) and they were found in 5.8% of individuals in 18 population studies (SED-11, 109) (204). Even higher rates have been recorded, especially among elderly patients; senile dyskinesias in two studies of drug-free elderly subjects occurred in 9% and 37% of individuals (205,206). There is also evidence that dyskinetic movements can be a feature of severe chronic schizophrenia unmodified by neuroleptic drugs (SED-11, 109) (203,207–211), which could mean that neuroleptic drugs merely trigger already latent dyskinesias in patients with schizophrenia.

Whether certain typical neuroleptic drugs are more likely than others to cause tardive dyskinesia is unknown (202), but virtually all typical neuroleptic drugs have been associated with it (212). Although there is evidence that atypical neuroleptic drugs are associated with a low risk (213,214), this needs to be evaluated in more prospective studies (213,215).

A review of the literature did not support the notion that neuroleptic drugs with central anticholinergic properties are particularly likely to cause tardive dyskinesia. However, anticholinergic antiparkinsonian drugs tend to produce reversible increases in the severity of dyskinetic movements, and the authors suggested that antiparkinsonian agents can be used as pharmacological probes in the evaluation of neuroleptic drug-induced movement disorders (216–218).

Discussion about tardive dyskinesia is necessary in the process of obtaining informed consent to treatment with neuroleptic drugs (SEDA-15, 46) (SEDA-21, 42) (SEDA-21, 45). The effect of education about tardive dyskinesia has been evaluated in 56 patients taking maintenance neuroleptic drugs, who completed a questionnaire assessing their knowledge of the condition (219). Education made patients more knowledgeable at 6 months, but had no effect on the clinical outcome.

In a consensus meeting the risk of tardive dyskinesia with typical and atypical neuroleptic drugs was addressed (220). There is sufficient evidence to conclude that atypical neuroleptic drugs are less likely to cause tardive dyskinesia than typical drugs, and that atypical neuroleptic drugs, apart from clozapine or ziprasidone, should be selected before typical drugs for patients with a first episode of schizophrenia or for patients whose history of response to neuroleptic drugs is not available. However, a meta-analysis has shown that atypical neuroleptic drugs have advantages over typical drugs only in studies in which haloperidol in relatively high doses was used as the comparison drug; when doses of haloperidol were below 12 mg/day, there were no advantages of the newer agents (24). Furthermore, clinical studies have not shown an advantage of haloperidol in dosages over 5 mg/day, which leads to a high occupancy of dopamine D_2 receptors, as demonstrated by positron emission tomography and single-photon emission computed tomography (153).

Incidence

Tardive dyskinesia usually occurs after long-term use of neuroleptic drugs, but some cases of early onset (less than 1 year) have been reported (SEDA-6, 47) (SEDA-7, 61). The incidence among patients with extrapyramidal effects is 2.32 times higher than among those without, and the risk could be even higher during the first 2 years of exposure (221). In a prospective study, the cumulative incidence of tardive dyskinesia was 5% after 1 year, 10% after 2 years, 15% after 3 years, and 19% after 4 years. The authors suggested that prevalence increases with increasing duration of neuroleptic drug exposure and that the increase is linear for at least the first 4–5 years (221). The average incidence rate of tardive dyskinesia has been estimated at 0.053 per year and the 5-year risk was 20% (SEDA-18, 49) (222). In another study, the cumulative incidence in patients over age 45 years was 26, 52, and 60% after 1, 2, and 3 years, respectively (223). Figures vary from center to center. In one study, there was a cumulative incidence of presumptive tardive dyskinesia of 6.3% after 1 year, 12% after 2 years, 14% after 3 years, and 18% after 4 years (224). In patients receiving neuroleptic drugs, the prevalence has been reported as 0.5–65% (225). One reviewer has gone so far as to suggest that the prevalence of tardive dyskinesia among all patients taking neuroleptic drugs is so low as not to justify any alarm (226). No cases of the severe form were found in a 12-year follow-up study of 99 chronically hospitalized patients who had received extensive neuroleptic drug treatment (227). Absence of severe tardive dyskinesia was reported in a group of Hungarian schizophrenic outpatients (216). Prevalences of 8.4–39% were reported in other cross-cultural studies of different ethnic groups (228–231).

A group of 261 neuroleptic drug-naive patients aged 55 years or over (mean 77 years) were identified at the time they were starting to take neuroleptic drugs (232).

© 2006 Elsevier B.V. All rights reserved.

The length of follow-up was 3–393 (mean 115). weeks; 60 developed dyskinesias. The cumulative incidences were 25%, 34%, and 53% after 1, 2, and 3 years respectively of cumulative neuroleptic drug treatment. A greater risk of tardive dyskinesia was associated with a history of electroconvulsive therapy (ECT), higher mean daily and cumulative neuroleptic drug doses, and the presence of extrapyramidal signs early in treatment.

Although there are difficulties in establishing a reference figure for the incidence or prevalence of dyskinesia, Australian psychiatrists seem to underestimate the prevalence of tardive dyskinesia. According to a survey of 139 psychiatrists, 80% estimated the prevalence of "mild reversible" tardive dyskinesia as being 5% of those treated with neuroleptic drugs (233).

These wide variations in incidence are perhaps due to the lack of a precise objective definition of the syndrome. The availability of standardized rating scales (234) and research diagnostic criteria represents a significant advance in resolving these problems (235). A multinational study of tardive dyskinesia in Asians ($n = 982$) found that the overall prevalence of tardive dyskinesia was 17% (range 8.2–22%). There was a significant difference in tardive dyskinesia prevalence from center to center within the same ethnic group. The reasons for such a difference are unclear. Two studies showed that Afro-Americans have a greater incidence of tardive dyskinesia than whites (222,223). However, there is still a lack of convincing evidence that there are true inter-ethnic differences in the prevalence of tardive dyskinesia (236,237).

The risk of tardive dyskinesia with typical and atypical neuroleptic drugs has been addressed in a consensus meeting (220). There is sufficient evidence to conclude that atypical neuroleptic drugs are less likely to cause tardive dyskinesia than typical drugs, and that atypical neuroleptic drugs, apart from clozapine or ziprasidone, should be selected before typical drugs for patients with a first episode of schizophrenia or for patients whose history of response to neuroleptic drugs is not available. However, a meta-analysis has shown that atypical neuroleptic drugs have advantages over typical drugs only in studies in which haloperidol in relatively high doses was used as the comparison drug; when doses of haloperidol were below 12 mg/day, there were no advantages of the newer agents (24). Furthermore, clinical studies have not shown an advantage of haloperidol in dosages over 5 mg/day, which leads to a high occupancy of dopamine D_2 receptors, as demonstrated by positron emission tomography and single-photon emission computed tomography (153).

Susceptibility factors

Considerable information, although not entirely consistent, is available on predisposing factors (SED-11, 108) (202,225,238). The condition is apparently more common in women and the elderly; and elderly women in particular seem susceptible to a relatively severe form of the condition (SED-11, 108) (225,239). It has been suggested that estrogen plays a role (240,241). Here too, however, the epidemiology has been challenged; not all studies have confirmed that women are more vulnerable (242), although the consensus supports this conclusion.

Chronically hospitalized elderly inpatients with schizophrenia ($n = 121$; mean age 74 years) were rated for tardive dyskinesia and cognition (243). Subjects with tardive dyskinesia (60%) were older than those without. In subjects who were taking typical neuroleptic drugs ($n = 119$) there was no difference in dosage between those with and without tardive dyskinesia. Cognitive scores (Mini-Mental Status Examination) were significantly lower in the subjects with tardive dyskinesia affecting the orofacial regions. This raises the question of whether neuroleptic drug-induced brain changes underlie both the dyskinesia and cognitive impairment or whether the cognitive impairment represents a degenerative process that is itself a vulnerability factor for the emergence of tardive dyskinesia.

Conversely, tardive dyskinesia is said to be less common in young than in old patients, and a lower incidence has been observed in a retrospective chart review in 40 adolescents taking neuroleptic drugs (244). After 2 years, the figure was 18%; although comparability of those studies is far from optimal. Average daily dose, non-adherence to therapy, early age of illness, and concomitant use of antiparkinsonian drugs were associated with increased susceptibility.

Of 34 schizophrenic children and adolescents followed after a drug-free period that lasted up to 4 weeks at 2-year intervals, 17 had either withdrawal dyskinesia or tardive dyskinesia at some time. Patients who developed dyskinesia had greater premorbid impairment and a greater severity of positive symptoms at baseline, and there was a trend toward more months of neuroleptic drug exposure.

Negative symptoms of schizophrenia have been associated with the severity of orofacial tardive dyskinesia, and positive symptoms were associated with limb dyskinesia (245).

In a retrospective study in a psychiatric hospital in Curaçao, Netherlands Antilles, 133 Afro-Caribbean inpatients (mean age 52 years), with no organic disorders and a history of current use of neuroleptic drugs for at least 3 months, were assessed for tardive dyskinesia (246). The prevalence was 36%. When the number of interruptions to neuroleptic drug therapy was split into up to two and more than two, the resulting adjusted odds ratio was 3.29 (95% CI = 1.27, 8.49). Thus, the number of interruptions turned out to be the second risk factor after age. Cumulative dosages of neuroleptic or anticholinergic drugs were not risk factors.

Another factor that increases the risk of tardive dyskinesia is prolonged treatment with neuroleptic drugs (242). This has been supported by the preliminary results of a prospective study, but there are conflicting results (202,238); one outpatient study showed that the duration of treatment with neuroleptic drugs did not explain the differences in severity of tardive dyskinesia (239). However, dose may be important; one study showed that while age, sex, diagnosis, and race had no significant effects on presumptive tardive dyskinesia, it was predicted by greater neuroleptic drug exposure: each increase in neuroleptic drug dose of 100 mg

© 2006 Elsevier B.V. All rights reserved.

chlorpromazine equivalents resulted in a 6% increase in the hazard of presumptive tardive dyskinesia (224). Furthermore, a positive correlation between tardive dyskinesia and circulating neuroleptic drug concentrations has been reported (247); however, in one study there was no significant difference in serum concentrations of thioridazine, its metabolites, or radio-receptor activity between patients with and without tardive dyskinesia (248). Histories of more and longer drug-free periods were more common in moderate and severe tardive dyskinesia than in mild forms (249). There was a positive association between neuroleptic drug-free periods and persistent tardive dyskinesia (250).

In one study, previous neuroleptic drug use at study entry was the only significant predictor of tardive dyskinesia (251). Psychiatric outpatients aged over 45 years, who had taken neuroleptic drugs for 0–30 days ($n = 176$), were compared with 131 who had taken neuroleptic drugs for more than 30 days. The cumulative incidences of tardive dyskinesia were 23% and 37% at the end of 12 months. In the patients who had never used neuroleptic drugs before ($n = 87$), the mean cumulative incidence of tardive dyskinesia after the use of typical neuroleptic drugs (median dose 68 mg/day of chlorpromazine equivalents) was 3.4% at baseline and 5.9% at 1 and 3 months.

The relation between handedness and tardive dyskinesia has been studied. The estimated rate ratio, comparing left-handers and mixed-handers with pure right-handers, adjusted for confounders, was 0.25. The handedness effect was stronger for men than for women (252).

There are various other possible risk factors, for example diabetes mellitus (SEDA-16, 47) (253), organicity, affective disorder, and a history of ECT or alcohol abuse (254).

Mechanism

Pharmacogenetic assessments of neuroleptic drug-induced tardive dyskinesia have been reviewed (255). The dopamine D_3 receptor (DRD3) gene has a single nucleotide polymorphism that results in a serine to glycine amino acid substitution (Ser9Gly) in the N terminal and gives rise to allelic differences in dopamine affinity; autosomal inheritance of two polymorphic Ser9Gly alleles (2–2 genotype), but not homozygosity for the wild-type allele (1–1 genotype), was a susceptibility factor (256). The severity of tardive dyskinesia was greater in homozygotes for the glycine variant of DRD3 than in serine/serine homozygotes or serine/glycine heterozygotes.

Another polymorphism has been identified in intron 1 of the CYP1A2 gene; similarly, there is an association between the severity of tardive dyskinesia and one of the corresponding genotypes. It is said that CYP1A2 may be important in neuroleptic drug metabolism after CYP2D6 saturation during long-term treatment.

The hypothesis of oxidative damage to striatal neurons mediated by neuroleptic drug enhancement of glutamatergic neurotransmission has been tested in a case-control study (257). Several markers of excitatory neurotransmission (*N*-acetylaspartylglutamate, *N*-acetylaspartate, aspartate, and glutamate) and of oxidative damage (superoxide dismutase, protein carbonyl content, and lipid hydroperoxides) were measured in the CSF of patients with schizophrenia who had taken neuroleptic drugs chronically, and who had ($n = 11$) or had not ($n = 9$) developed tardive dyskinesia. There was an inverse correlation between CSF concentrations of aspartate and superoxide dismutase activity in tardive dyskinesia, what suggests a causative relation between enhanced excitatory amino acid neurotransmission and the oxidative damage associated with tardive dyskinesia. Another plausible model for the development of tardive dyskinesia is that lower activity of superoxide dismutase renders the striatal neurons more vulnerable to excitatory neurotransmission that is exacerbated by neuroleptic drugs, as shown in a subgroup of patients with schizophrenia.

There are conflicting results on the possible relation between plasma iron concentrations and movement disorders (SEDA-19, 45). A significant correlation between serum ferritin concentrations and the severity of choreoathetoid movements has been observed (258). All 30 subjects had a minimum lifetime cumulative exposure to typical neuroleptic drugs of 3 years. Nevertheless, and as was stated by the authors, it is unclear whether higher body iron stores exacerbate the symptoms of tardive dyskinesia or predispose to its development.

Reversibility

The rate of reversibility of tardive dyskinesia after drug withdrawal is 0–90% (225). Since patients with tardive dyskinesia rarely have subjective complaints (259), periodic assessment of dyskinetic movements is essential in making an early diagnosis and can increase the chance of reversing the disorder. Some reports are relatively encouraging regarding reversibility (260,261); the characteristics of reversible and irreversible forms have been reviewed, but no firm conclusion can be drawn (262). However, the prognosis of tardive dyskinesia was better in patients treated for a shorter duration and in those treated with lower doses (263).

Prevention and treatment

In dealing with the whole problem of dyskinesia, the preeminent role of prevention must be emphasized (254), particularly because treatment is so unrewarding. Various agents have been studied, including agonists and antagonists at various CNS neurotransmitters, and newer dopamine receptor antagonists, which supposedly act only at dopamine D_2 receptors (sites that are not linked to adenyl cyclase). The few supposedly positive results that have been claimed for a number of drugs must be interpreted with great caution (SEDA-18, 49) (264).

Treatment of tardive dyskinesia is often unsatisfactory, especially in severe cases. A large number of treatments have been proposed (SEDA-20, 40), including antiparkinsonian drugs, benzodiazepines, baclofen, hormones, calcium channel blockers, valproate, propranolol, opiates, cyproheptadine, tryptophan, lithium, manganese, niacin, botulinum toxin, ECT, dietary control, and biofeedback training. In an open study, 20 patients (mean age 65 years) with severe unresponsive tardive dyskinesia (mean duration 44 months, mean exposure 52 months) were treated

© 2006 Elsevier B.V. All rights reserved.

with tetrabenazine (mean dose 58 mg/day) (265). The mean score on the AIMS motor subset, determined from videotapes, improved by 54%. Sedation was the only subjective complaint.

Abnormal lipid peroxidation and low lipid-corrected plasma concentrations of vitamin E are associated with tardive dyskinesia (266).Vitamin E has therefore been used for its antioxidant properties (SEDA-21, 47) (267–270). A meta-analysis has summarized eight double-blind, placebo-controlled studies of vitamin E in the treatment of tardive dyskinesia in 221 patients (271). Overall, vitamin E had a better effect than placebo; 28% of those who took vitamin E had a 33% or greater reduction in AIMS scores, compared with only 4.6% in the placebo arm. The number of patients included in any study was very small, never more than 28. The rationale for using vitamin E and for finding a better indicator of vitamin E deficiency has been explored (266). Since much of the vitamin E in plasma is carried in the low-density lipoprotein fraction, relating vitamin E content to the sum of cholesterol and triglycerides in the plasma could produce a high degree of specificity and sensitivity in defining vitamin E deficiency. Patients with tardive dyskinesia had lower concentrations of lipid-corrected vitamin E. However, the authors admitted that the lower concentration of vitamin E could have resulted from, predisposed to, or served as a marker of the susceptibility to tardive dyskinesia. The possible involvement of free radicals and treatment with vitamin E has been extensively reviewed (272). A further study has concluded that the addition of vitamin E to neuroleptic drug medication at the start of treatment can reduce the severity of acute neuroleptic drug-induced parkinsonism (273). This has been observed by comparing two groups of randomly allocated patients treated with neuroleptic drugs ($n = 20$) or with neuroleptic drugs plus vitamin E 600 IU/day ($n = 19$). From days 0–14, there was a mean reduction in SARS scores of 10% in those treated with vitamin E versus an increase of 78% in the comparison group. More recently, vitamin E (alpha-tocopherol), with its antioxidant properties, has been reported to be effective.

A beneficial effect of pyridoxine has been reported (274).

- A 22-year-old man with chronic organic persecutory paranoid ideation and recurrent explosive attacks had received neuroleptic drugs since the age of 7. While taking haloperidol, up to 25 mg/day, and trihexyphenidyl, up to 4 mg/day, he developed involuntary movements that were diagnosed as tardive dyskinesia: blinking, movements of the forehead and eyebrows, tongue-thrusting, licking of the lips, smacking, and chewing. He scored 27 on items 1–7 of the AIMS. He began to take pyridoxine, 200 mg/day, and after 5 days had a drastic reduction in the severity of all his movement disorders.
- A 41-year-old man had dramatic relief from tardive dyskinesia and akathisia with high-dose piracetam (275).

Reserpine has been used with apparent improvement in symptoms, but deterioration followed withdrawal (276), and reserpine has also been reported to cause the condition.

A double-blind study of propranolol showed short-term improvement, and two of four subjects responded to long-term propranolol (277); unfortunately this study has not been replicated.

Tetrahydroisoxazoylpyridinol (THIP), an analogue of gamma-aminobutyric acid (GABA), which is a GABA receptor antagonist, produced no change in tardive dyskinesia, in either a dose-finding study or a 4-week placebo-controlled study, but pre-existing parkinsonism increased significantly and eye-blinking rates fell (278); these are preliminary findings, more than a decade old, and hard to interpret.

Tardive akathisia

Akathisia can occur relatively early, within days or weeks, but sometimes occurs later. A 1986 review (279) considered 24 cases of tardive akathisia seen over a long period; in three of these the condition had appeared after only 1 or 2 months of neuroleptic drug therapy, but the remainder had been treated for at least 1 year, and seven had been treated with neuroleptic drugs for at least 5 years. Whereas tardive dyskinesia most often starts in the bucco-oral region and extends to the fingers and occasionally to the lower limbs and trunk, tardive akathisia most often affects the legs or is described as a generalized sensation throughout the limbs and trunk. Moreover, while a reduction in dosage can induce a temporary worsening of masked tardive dyskinesia and an increased dosage an improvement, the effects of dosage changes on akathisia are less certain.

Tardive Tourette's syndrome

There have been at least seven published cases of Tourette's syndrome ascribed to neuroleptic drugs and emerging either during treatment or after withdrawal. Some authors believe that a tardive Tourette-like syndrome may be a subtype of the more frequent tardive dyskinesia, because it can be masked by an increase in neuroleptic drug dosage and exacerbated by withdrawal. However, the symptoms can readily be confused with exacerbation of the underlying psychosis; misdiagnosis of the condition, at least in some of the published case reports, cannot be completely ruled out.

Tardive dystonia

Tardive dystonia is a rare, late-onset, persistent dystonia associated with neuroleptic drugs, which usually affects young men. It tends to affect the muscles of the neck, shoulder girdle, and trunk, causing opisthotonos. Sometimes, patients can become incapacitated (280,281). The incidence is 1–2% (282). Once developed, it is a very persistent disorder, with a low remission rate of only 14%; withdrawal of neuroleptic drugs increases the chances of remission.

Tardive dystonia has sometimes been thought to be a subtype of tardive dyskinesia (SED-13, 123). However, some features of this condition are clearly different from those of tardive dyskinesia (SEDA-20, 41). The diagnosis of tardive dystonia should meet the following criteria: (a) the presence of chronic dystonia; (b) a history of neuroleptic drug treatment preceding (less than 2 months) or

© 2006 Elsevier B.V. All rights reserved.

concurrent with the onset of dystonia; and (c) exclusion of known causes of secondary dystonia (283).

Tardive dystonia developed at any time between 4 days and 23 years after exposure to a neuroleptic drug in 107 patients who fulfilled these diagnostic criteria (284). Although the majority had a focal onset involving the craniocervical region, tardive dystonia tended to spread over the next 1–2 years and resulted in segmental or generalized dystonia in most cases.

Pleurothotonus (Pisa syndrome) is a special form of tardive dystonia that involves tonic flexion of the trunk to one side accompanied by slight backward rotation, in the absence of other dystonic symptoms. However, it can also occur immediately after the administration of neuroleptic drugs (SED-13, 123). Nine of twenty patients (mean age 40 years) who developed Pisa syndrome while taking neuroleptic drugs (mean duration 12 years) improved within 3 weeks of treatment with trihexyphenidyl 12 mg/day (285). Reduction or withdrawal of the daily dose of the neuroleptic drugs was beneficial to the remaining patients.

Antecollis is a rare form of tardive dystonia, in which there is forward bending of the neck (286). Patients with this disorder are usually quite disabled and distressed, have severe difficulties with vision, speech, swallowing, and inspiratory obstruction, and are unable to lie supine. In three reported cases (286), the patients developed the symptoms after receiving a number of neuroleptic drugs for 4 months to 14 years. Neither withdrawal of neuroleptic drugs nor the administration of anticholinergic agents affected their symptoms.

The differential diagnosis includes idiopathic torsion dystonia, parkinsonism, idiopathic torticollis, Huntington's disease, Wilson's disease, and Meige's syndrome (blepharospasm, oromandibular dystonia). A retrospective evaluation of the records of patients with idiopathic cervical dystonias ($n = 82$) and tardive cervical dystonias ($n = 20$) has been performed, in a search for clinical features that could help separate these closely related disorders (287). Despite the overall similarity, the presence of a dystonic head tremor was strongly suggestive of the idiopathic form, which was present in 42% and did not occur at all in the tardive group. A family history of dystonia (10%) was also exclusive to the idiopathic group.

A thorough and extensive review has addressed the treatment of tardive dystonia (288). For patients taking typical neuroleptic drugs, a switch to clozapine is suggested, or, if clozapine is contraindicated, to risperidone, olanzapine, or sertindole. Other alternatives are anticholinergic drugs, particularly trihexyphenidyl, benzodiazepines, tetrabenazine, reserpine, tocopherol, bromocriptine, and (in children and adolescents) baclofen. Local injection of botulinum toxin, which blocks acetylcholine release at the neuromuscular junction, is effective in the treatment of focal dystonias (SEDA-19, 45) (SEDA-22, 52). The therapeutic effects of botulinum toxin last on average for 2–6 months. In one study, botulinum toxin injections produced symptomatic relief, but benzodiazepines were associated with a poorer outcome, probably because of reverse causality, since non-remitting patients were more likely to use benzodiazepines as a second-line treatment (284). In another study there were no differences in responses to injections of botulinum toxin in patients with tardive oromandibular dystonia ($n = 24$) or idiopathic oromandibular dystonia ($n = 92$) (289). Surgical treatment, such as local denervation myectomy, thalamotomy, and pallidotomy, and deep brain stimulation can be considered only for patients with disabling dystonia and in those in whom medical treatment has failed to provide improvement. The successful treatment of tardive dystonia with low-dose levodopa plus benserazide, 50/12.5 mg tds, has been reported (290).

About 50% of patients with tardive dystonia have retrocollis; if the trunk is involved, most of the patients have back-arching opisthotonos. Five such patients experienced relief with a custom-made mechanical device that delivers constant contact to the occiput and shoulders (291).

Misinterpretation of symptoms has led to ineffective management of dystonia (292).

- A 14-year-old boy with Tourette's syndrome developed withdrawal dystonia while being treated with pimozide 12 mg/day. Increased blinking, facial pain, dystonic movements, and other facial movements at each dose reduction pointed toward withdrawal dystonia rather than toward a worsening of Tourette's syndrome.

Rabbit syndrome

Rabbit syndrome is a late-onset extrapyramidal adverse effect associated with neuroleptic drugs. It is characterized by a rapid tremor of the lips and occasionally the jaw. The movements usually respond well to antiparkinsonian agents and withdrawal of neuroleptic drugs. It has been suggested that the rabbit syndrome is the clinical converse of tardive dyskinesia (293).

Neuroleptic malignant syndrome

DoTS classification (BMJ 2003; 327:1222–5)

Dose-relation:?toxic effect
Time-course: intermediate or delayed
Susceptibility factors: high doses or intravenous administration; psychiatric disorders; dehydration; postpartum

The neuroleptic malignant syndrome (SEDA-11, 47) (SEDA-14, 50) (294,295) is a rare but potentially fatal disorder characterized by muscle rigidity, hyperthermia, altered consciousness, and autonomic dysfunction (296). Severe rigidity may explain the increased body temperature, because of heat generated by the muscles, and it may contribute to a rise in serum creatine kinase activity, reflecting a risk of myoglobinuria and acute renal insufficiency. Hyperthermia can lead to dehydration and electrolyte imbalance, leaving the patient exposed to infections and other consequences. Patients with neuroleptic malignant syndrome are more likely to be agitated or dehydrated before the syndrome develops, they often need restraint or seclusion, and they have often received larger doses of neuroleptic drugs soon after hospitalization. Previous treatment with ECT increases vulnerability (297).

This description applies to most of the cases reported since 1960, but the syndrome is still poorly defined and

© 2006 Elsevier B.V. All rights reserved.

overlaps to some extent with lethal catatonia, neuroleptic drug-induced hyperpyrexia, and sudden death due to cardiac dysrhythmias. Similar symptoms have also been reported in non-schizophrenic patients after exposure to dopamine-depleting drugs (298) and after withdrawal of indirect dopamine receptor agonists (299). There is no consensus about the boundaries, causes, or management of the syndrome (SEDA-18, 50) (300,301). Neuroleptic malignant syndrome without pyrexia has been reported (SEDA-19, 4) (302). The syndrome shares clinical features with malignant hyperthermia, which is genetically acquired, but there does not appear to be a common pathophysiological link between the two (SED-11, 111).

The occurrence of neuroleptic malignant syndrome in a patient with cancer after the use of haloperidol has given rise to some comments: (a) clinical oncologists are not familiar with the neuroleptic malignant syndrome; (b) neuroleptic malignant syndrome is difficult to diagnose, because its presentation resembles that of cancer itself, and sometimes other treatment-related complications (303).

There have been reports of neuroleptic malignant syndrome precipitated by promethazine 100 mg/day to treat neuroleptic drug-induced extrapyramidal symptoms and lorazepam 6 mg/day to treat agitation (304), after the addition of intramuscular haloperidol 23 mg to atypical neuroleptic drugs (305), and in other instances in children and adolescents (306).

Cases of neuroleptic malignant syndrome with different features have been published (307–311).

- A 21-year-old woman had bilateral dislocations after being struck by an automobile (307). Postoperatively, she had signs of delirium and agitated behavior, and was given haloperidol 3–5 mg intravenously or intramuscularly and lorazepam 2 mg intravenously. Her general muscular tone increased during the next several days, leading to spontaneous dislocations/subluxations of multiple joints; there was mild hyperthermia (38.4°C), a raised neutrophil count (12×10^9/l) in the absence of an identifiable source of infection, and a raised creatine kinase activity (361 U/l; reference range 0–150). Neuroleptic malignant syndrome was diagnosed. Haloperidol and droperidol were withdrawn, and she was given dantrolene sodium 1 mg/kg orally every 8 hours for 14 days. Within 24 hours her temperature had fallen and during the next week her spasticity progressively improved.

In two other cases there were features of neuroleptic malignant syndrome within 10 days of autotransplantation, with rapid improvement after withdrawal of the neuroleptic drugs (308). Since neuroleptic drugs are often used during transplantation, it is important to recognize that the use of these drugs in concert with the physiological stress of the operation can result in this drug-related complication. In two other cases of neuroleptic malignant syndrome, computerized tomography showed evidence of cerebral edema, which is claimed not to have been reported before (309).

Acute renal insufficiency has been reported as a severe complication of neuroleptic malignant syndrome (SED-13, 124) (SEDA-21, 49), and a patient who developed severe hyponatremia and progressed to neuroleptic malignant syndrome, myoglobinuria, and acute renal insufficiency deserves attention (310).

- A 42-year-old man with a history of paranoid schizophrenia developed confusion and vomiting. His medications included buspirone and tiotixene. He also had a generalized seizure that resolved spontaneously. His serum sodium concentration was 114 mmol/l, which was thought to be secondary to psychogenic polydipsia and which was corrected. The next day his temperature rose to 40°C and the day after that he became lethargic and non-verbal and developed generalized muscle rigidity. A diagnosis of probable neuroleptic malignant syndrome was made, and he was given dantrolene sodium 1 mg/kg intravenously; neuroleptic drugs were withdrawn. The serum creatine kinase activity was over 234 500 U/l. Urinalysis showed more than 3 g/l of protein, a trace of ketones, and hemoglobin and leukocytes. By the following day, his muscle rigidity and fever had resolved and his mental status had markedly improved.

Two patients developed non-convulsive status epilepticus and neuroleptic malignant syndrome (311). Whether this constitutes one syndrome or merely the co-existence of the two is academic, because it makes no difference to therapy.

The syndrome is reported most often in young men. It can occur suddenly days or weeks after initiating or intensifying drug therapy, and usually lasts 5–10 days after withdrawal. Although it is unusual, the syndrome can occur while neuroleptic drug dosage is being reduced (SEDA-19, 46).

The prevalence has been suggested as being less than 1% (312), but the precise frequency is unknown, and a trend toward fewer reports in recent years suggests that factors such as the use of lower dosages of neuroleptic drugs may be important. In a 1986 review it was argued that the neuroleptic malignant syndrome represents a heterogeneous group of neuroleptic drug-induced extrapyramidal syndromes with concurrent fever, and the existence of neuroleptic malignant syndrome as a discrete syndrome was questioned (313).

There is no consistent evidence that any one neuroleptic drug or class of drugs is more or less likely to produce the syndrome. It has been reported with atypical neuroleptic drugs, such as clozapine (314–320) and risperidone (321–326), although less often than with typical neuroleptic drugs. Neuroleptic malignant syndrome attributed to clozapine (19 cases) and risperidone (13 cases) has been reviewed (327). However, relatively more cases have been associated with high-potency neuroleptic drugs, and the course of the syndrome may be particularly prolonged and difficult to treat when depot forms of these drugs have been used. The authors of one review found insufficient evidence to support the concept of an atypical neuroleptic malignant syndrome with novel neuroleptic drugs (327).

Mechanism

It has been suggested that neurotransmitter abnormalities other than reduced dopaminergic function may be responsible for the neuroleptic malignant syndrome, in the light of three cases in which the syndrome occurred after neuroleptic drug administration during

© 2006 Elsevier B.V. All rights reserved.

benzodiazepine withdrawal (328). Benzodiazepines potentiate GABA transmission and their long-term use is associated with a compensatory reduction in GABA activity; since nigral dopaminergic neurons are modulated through the action of GABAergic projection neurons, reduced GABA could facilitate the occurrence of the syndrome.

Susceptibility factors

Susceptibility factors that have been proposed for the development of neuroleptic malignant syndrome include a history of prior episodes of neuroleptic malignant syndrome, the use of high potency drugs, rapid escalation in dosage or parenteral administration of neuroleptic drugs, dehydration, agitation, catatonia, and certain conditions, including mood disorders, schizophrenia, and mental disorders due to medical conditions (SEDA-22, 52). Acute encephalitis has been suggested to be another susceptibility factor (329). It has been reported in five patients who developed neuroleptic malignant syndrome after being treated with neuroleptic drugs for the psychiatric symptoms associated with encephalitis. HIV encephalitis has in particular been associated with neuroleptic malignant syndrome (SEDA-19, 47).

The postpartum period is said to be a susceptibility factor for neuroleptic malignant syndrome. During 30 months, 11 cases of neuroleptic malignant syndrome were detected in a university general hospital in India (330). Five patients were women and in three the onset was in the postpartum period. One was taking a small dose of oral chlorpromazine (20 mg). In contrast, agitation and ECT, which have been proposed as susceptibility factors (SEDA-22, 52), have been questioned as independent susceptibility factors (331,332). Since catatonia was mentioned without reporting the number of affected patients, the authors suggested that some of the agitated patients would actually correspond to catatonic patients. However, catatonia was present before the onset of neuroleptic malignant syndrome in only one subject from the neuroleptic malignant syndrome group (333). On the other hand, ECT remains, at best, an association that possibly flags the characteristics of the primary psychiatric disorder that prompted the treatment.

Malignant catatonia associated with a low serum iron concentration carries a high risk of evolving into neuroleptic malignant syndrome, going by the results of a retrospective study, in which 39 catatonic episodes in patients with low ($n = 17$) or normal ($n = 22$) serum iron concentrations were compared (334). All had been exposed to neuroleptic drugs. Hypoferremia has previously been related to the neuroleptic malignant syndrome.

Susceptibility factors that have been proposed for the development of neuroleptic malignant syndrome include, among others, a history of prior episodes (SEDA-22, 52). A case report has further illustrated that possibility (335).

- A 19-year-old man with bipolar disorder received intramuscular haloperidol 30 mg/day and chlorpromazine 300 mg/day and developed neuroleptic malignant syndrome; the neuroleptic drugs were withdrawn. One month later he had a recurrence. It transpired that he had discontinued his medication 2 weeks after discharge, but because his manic symptoms recurred his relatives had started to give him haloperidol 10 mg/day again, which led to the recurrence.

Treatment

Early recognition and prompt treatment of the neuroleptic malignant syndrome, in particular immediate recognition of new rigidity, may be the best means of arresting its progress and preventing further complications (300). If there is fever, although other possible causes should be investigated, there should be no delay in instituting appropriate treatment, and in particular anticholinergic treatment of severe rigidity. There is no proven specific treatment, but immediate withdrawal of neuroleptic drugs is essential, followed by supportive therapy and intensive monitoring of respiratory, renal, and cardiac function. Anticholinergic drugs are often used, but when the temperature exceeds 101°F, they can exacerbate fever, and other treatments may be preferred. It should be remembered that the simultaneous withdrawal of neuroleptic and anticholinergic drugs can exacerbate extrapyramidal features and that anticholinergic drugs should if possible be continued for 1 week after the withdrawal of the neuroleptic drug. Carbamazepine (336), amantadine (337), and bromocriptine (338) have been successfully used as empirical treatments in isolated cases. However, dopamine receptor agonists are preferred when the temperature exceeds 101–103°F, and muscle contraction can be further alleviated with dantrolene or benzodiazepines (339). Botulinum toxin was used for preventing muscle contractions in one case (340).

Dantrolene may be effective in reducing muscle rigidity in neuroleptic malignant syndrome (341,342) (SEDA-20, 42), but a reliable regimen has not been established (343).

- A 39-year-old man receiving haloperidol 4 mg and trihexyphenidyl 2 mg for schizophrenia developed a fever of over 40°C and clouding of consciousness 19 days after the start of medication. Neuroleptic malignant syndrome was suspected and dantrolene 40–80 mg/day was given intravenously for 5 days, with no improvement; disseminated intravascular coagulation and acute renal insufficiency developed. Dantrolene 200 mg was given intravenously over 10 minutes. One hour later, his temperature fell to 38.4°C. Continuous intravenous infusion of dantrolene 400 mg/day was started in combination with oral bromocriptine 15 mg/day. Dantrolene was changed to the oral route after 14 days and was withdrawn after 28 days.

Six cases successfully treated with ECT have been reported (344,345).

Five patients had residual catatonia after withdrawal; two recovered gradually with supportive treatment (346). Three patients were treated with ECT; two had an initial positive response, but one died later of intercurrent pneumonia; the third did not respond.

After resolution of symptoms, neuroleptic drugs can be reintroduced safely in most patients (347). In all cases the lowest effective dose of neuroleptic drug should be used, along with anticholinergic therapy or thioridazine, which has anticholinergic effects.

It is said that the risk of recurrence on re-exposure to neuroleptic drugs (about 15–30%) can be minimized by

© 2006 Elsevier B.V. All rights reserved.

delaying rechallenge by 2 weeks or by using a neuroleptic drug of an alternative class.

Meige's syndrome

Meige's syndrome is characterized by blepharospasm and spasm of the lower facial or oromandibular muscles (348).

- A 52-year-old woman developed Meige's syndrome 2 days after the appearance of akathisia. She had taken neuroleptic drugs for years, but her current medication had been changed to bromperidol 18 mg/day and trihexyphenidyl (benzhexol) 6 mg/day; 2 days later she developed akathisia. Oral perphenazine 12 mg and trihexyphenidyl 6 mg dose-dependently reduced the frequency of blepharospasm; the dosages of bromperidol and trihexyphenidyl were gradually reduced to 8 mg/day and 3 mg/day respectively over 3 months, by which time her symptoms had completely disappeared.

Sleep

Oversedation and/or drowsiness is the most common adverse effect of neuroleptic drugs. However, most patients develop tolerance to this effect. Patients with Alzheimer's disease, as well as having impaired cognitive function and a change in personality, have a tendency to develop sleep–wake cycle disturbances that may be aggravated by classical neuroleptic drugs.

- Haloperidol was given to a 54-year-old patient with dementia; 10 days later, the circadian rest–activity cycle began to disintegrate and there was total dysrhythmicity for over 2 months; deterioration was progressive (349). Because of extrapyramidal symptoms, haloperidol 40 mg/day was changed to clozapine 50 mg/day and treatment with donepezil was begun. Two weeks later there was sudden and rapid normalization of the rest-activity cycle, started by an apparent shift of wake-up time to earlier each day, until it attained a new stable timing; orientation and memory also improved.

Other neurological effects

Myasthenia gravis caused by neuroleptic drugs has been reported (SED-11, 110). Such cases may be due to impairment of neuromuscular transmission.

Different degrees of frontal atrophy have been observed in 31 psychotic patients who had taken neuroleptic drugs for 5 years (350). All underwent computed tomography when they were drug-naive and 5 years later. Logistic regression analysis identified neuroleptic drugs as having a significant impact on the development of frontal atrophy, and the estimated risk of atrophy increased by 6.4% for each additional 10 mg of chlorpromazine equivalents.

Sensory systems

Various neuroleptic drugs, particularly low-dose phenothiazines and thioxanthenes, commonly cause blurred vision secondary to their anticholinergic activity. This is primarily a nuisance, except in the rare patient with closed-angle glaucoma.

Of more concern are two distinct types of adverse effects in the eye, which can be produced by various neuroleptic drugs: lenticular and corneal deposits, cataract, and pigmentary retinopathy (141,351,352). Deposits in the lens or cornea probably result from deposition of melanin-drug complexes and are best detected by slit-lamp examination. These deposits are probably dose- and time-related, since they generally occur only after years of treatment. Fortunately, they are in large part benign and reversible, but if undetected they can progress to interfere with vision. They are most often reported with chlorpromazine or thioridazine and can occur in association with pigmentary changes in the skin. Non-phenothiazines appear to have minimal propensity to cause oculocutaneous reactions and may be preferred when these problems have occurred during treatment with a phenothiazine (SED-11, 113), although the patient should still be closely monitored.

- A 46-year-old schizophrenic patient, who had taken chlorpromazine 200 mg/day for 9 years and then 400 mg/day for 7 years, developed ocular pigmentation (353).

The interesting thing about this report was its striking photographs, in which multiple, small, dark pigment deposits in the conjunctiva were seen; in addition, the cornea had multiple, small, discrete, yellowish specks, and both lenses had anterior capsular opacities.

Various rarer ocular effects have been reported, including oculomotor palsies, transient myopia, optic atrophy, blue-green blindness, and night-blindness. For a long time it has been suspected that neuroleptic drugs may increase the risk of cataract (352).

A further case of cataract has been reported (354).

- A 50-year-old woman with schizophrenia had a 1-year history of gradual deterioration of vision in both eyes. For several years she had been taking chlorpromazine 300 mg/day, trifluoperazine 10 mg/day, and trihexyphenidyl 4 mg/day. Slit lamp examination showed fine, discrete, brown refractile deposits on the corneal endothelium in both eyes, and characteristic bilateral stellate cataracts with dense, dust-like brown-yellow granular deposits were noted along the suture lines in the anterior pole of the lens and obscured the visual axis.

Psychological, psychiatric

Although neuroleptic drugs are relatively effective in treating psychiatric symptoms, their mental adverse effects can impair the quality of life of some individuals. The effects of newer neuroleptic drugs on cognitive functioning and the implications for functional outcome have been summarized and methodological and conceptional issues addressed (355).

In 44 stable schizophrenic outpatients, a significant proportion of the variance was explained by a combination of protracted duration of illness and dysphoric subjective responses to neuroleptic drugs (356). In terms of the individual items on the Negative Subjective Response subscale, only the statement "I feel weird, like a zombie on medication" was associated with statistically significant differences in quality of life. Patients who agreed with this statement ($n = 10$) had a significantly poorer quality of life than those who disagreed ($n = 34$). Related to this possible impairment of the quality of life

© 2006 Elsevier B.V. All rights reserved.

is the observation, in 45 patients with chronic schizophrenia, that neuroleptic drugs playing a role in the development of depressive symptoms and negative symptoms (174). Duration of treatment correlated positively with the depressive and the negative symptoms.

Notwithstanding this finding, the differentiation between disease-related and neuroleptic drug-induced negative symptoms, such as flat affect, can be especially difficult in some patients. To investigate the interactions among psychomotor performance, negative symptoms, and neuroleptic drug effects, dopamine D_2 receptor availability (measured by the binding of ^{123}I-iodobenzamide) psychopathology, and psychomotor reaction time have been assessed in eight drug-free and eight neuroleptic drug-treated patients with schizophrenia (357). Negative symptoms increased in the patients taking neuroleptic drugs compared with drug-free patients and correlated positively with neuroleptic blockade of dopamine D_2/D_3 receptors. Furthermore, parkinsonism correlated with a flat affect and psychomotor retardation. There were some limitations to this observational study: the sample size was small; different neuroleptic drugs were used, including risperidone (in seven patients), which may not behave in the same way than others neuroleptic drug owing to its antagonistic effect on 5-HT_2 receptors, although it has been observed that dopamine D_2 receptor occupancy and extrapyramidal adverse effects with risperidone do not differ significantly from those observed with traditional neuroleptic drugs; and the duration of disease was longer in the patients who took neuroleptic drugs.

Psychiatric abnormalities

Neuroleptic drugs can cause a depression-like syndrome. This should be differentiated from neuroleptic-induced akinesia. Long-acting drugs have been particularly implicated (SED-11, 107) (141). However, a double-blind, placebo-controlled, randomized study of long-acting neuroleptic drugs did not support this conclusion (358).

Toxic delirium caused by neuroleptic drugs with potent anticholinergic properties has been widely reported (SED-11, 107), and has been reported with low-dose clozapine (359).

Obsessive-compulsive symptoms have been described with both typical neuroleptic drugs (for example chlorpromazine) and atypical drugs (for example clozapine and risperidone) (SEDA-19, 51) (SEDA-20, 47) (360,361).

Other uncommon effects include psychotic exacerbation, catatonia-like states, and Klüver–Bucy-like syndrome (SED-9, 81) (SEDA-7, 67) (141).

Cognitive effects

The effects of atypical neuroleptic drugs on cognitive functioning and the implications for functional outcome have been summarized and methodological and conceptional issues addressed (355).

Cognitive function is reduced in schizophrenia, and neuroleptic drugs can cause further impairment (362,363). However, the extent to which they do so is disputed. In one study, the more anticholinergic drugs impaired short-term verbal memory (SEDA-18, 48) (364). Another study showed that patients with schizophrenia who took neuroleptic drugs had superior information processing compared with unmedicated patients with schizophrenia; the authors claimed that neuroleptic drugs probably do not cause, and may actually reverse, slow information processing in patients with schizophrenia (365). However, a substantial number of patients with schizophrenia declare that neuroleptic drugs slow their thinking, cause them to forget, and remove interest and motivation. These responses to neuroleptic drugs are claimed to be dysphoric and are often associated with drug-induced extrapyramidal symptoms, particularly akathisia (366). Akinesia can also contribute to feelings of apathy and diminished spontaneity, and can be difficult to distinguish from the negative symptoms of schizophrenia or the psychomotor retardation of post-psychotic depression (367).

Visuomotor testing has been performed in 76 patients with schizophrenia or a schizophreniform disorder receiving haloperidol ($n = 23$; mean dose 10 mg/day), olanzapine ($n = 26$; 10.6 mg/day), or risperidone ($n = 27$; 4.4 mg/day) (363). Cognitive function was better in patients receiving risperidone or olanzapine compared with those receiving haloperidol; patients receiving haloperidol or risperidone had more severe extrapyramidal signs than those receiving olanzapine. The authors concluded that the benefits on cognitive functioning had resulted from a direct effect and were not related to reduced extrapyramidal effects. However, the patients receiving haloperidol were older and had a longer duration of illness than those receiving olanzapine or risperidone; this precludes any firm conclusions.

A comparison between haloperidol ($n = 25$) and atypical neuroleptic drugs (clozapine, $n = 24$; olanzapine, $n = 26$; risperidone, $n = 26$) has been conducted in patients with treatment-resistant schizophrenia in a 14-week, randomized, double-blind trial (368). Global neurocognitive function improved significantly with olanzapine and risperidone, by about 8–9 "IQ-equivalent" points. According to the authors, the finding was not mediated by changes in symptoms, adverse effects, or blood drug concentrations. In the haloperidol group, higher blood concentrations were associated with less improvement in motor function.

In another study, there was a small but significant negative correlation between the dosages of typical neuroleptic drugs and "mental functioning" when the data were controlled for psychopathology; this correlation was also seen for risperidone and clozapine, but there were no significant differences between patients taking low or high dosages of atypical agents. The authors pointed out that the dosage range in patients taking atypical agents was rather narrow and it is possible that higher doses of atypical neuroleptic drugs may give different results (369).

In 207 schizophrenic patients who answered the short form of a questionnaire entitled "Subjective Well-Being under Neuroleptic Treatment" (SWN-S), those taking risperidone ($n = 26$) and olanzapine ($n = 40$) took part in a study with random assignment after a washout period of at least 3 days, whereas patients taking typical neuroleptic drugs ($n = 106$; predominantly haloperidol and flupenthixol) were assessed during treatment (370).

Endocrine

The effects of neuroleptic drugs on menstrual status and the relation between menstrual status and neuroleptic drug efficacy and adverse effects have been explored (371). In contrast to prior reports (SEDA-18, 50), there was not a high prevalence of menstrual irregularities or amenorrhea in 27 premenopausal women with chronic schizophrenia treated with typical neuroleptic drugs.

Prolactin

Neuroendocrine effects of neuroleptic drugs include a rise in growth hormone, inappropriate ADH and prolactin secretion, and disturbances of sex hormones (SEDA-7, 67). Galactorrhea (SEDA-20, 43) and gynecomastia can follow the rise in prolactin.

A correlation between serum concentrations of neuroleptic drugs and prolactin has been claimed (372,373).

However, no further rise in plasma prolactin concentration was observed with higher dosages of haloperidol (over 100 mg/day), which was explained as being related to saturation of the pituitary dopamine receptors by a modest amount of haloperidol (373). A low prolactin concentration during maintenance neuroleptic drug treatment predicted relapse after withdrawal, and it was suggested that serum prolactin concentration may be helpful in monitoring treatment (374). Hirsutism, amenorrhea, and a false-positive pregnancy test associated with neuroleptic treatment have also been reported (SED-11, 111) (371,375).

The effects of haloperidol and quetiapine on serum prolactin concentrations have been compared in 35 patients with schizophrenia after a 2-week washout period in a randomized study (376). There was no significant difference in prolactin concentration between the groups at the start of the study, although prolactin concentrations were significantly lower with quetiapine than haloperidol. After 6 weeks, the mean prolactin concentration was significantly increased in those taking haloperidol but not in those taking quetiapine. Two patients taking haloperidol had galactorrhea related to hyperprolactinemia.

There is concern that neuroleptic drugs may increase the risk of breast cancer because of raised prolactin concentrations. For a long time, findings did not confirm this association (377), but a Danish cohort study of 6152 patients showed a slight increase in the risk of breast cancer among schizophrenic women (378).

In eight patients receiving neuroleptic drugs, serum prolactin concentrations were grossly raised (379). The time-course of the prolactin increase was examined in 17 subjects whose prolactin concentrations rose during the first 6–9 days of treatment with haloperidol (380). The increase was followed by a plateau that persisted, with minor fluctuations, throughout the 18 days of observation. Patients whose prolactin concentrations increased above 77 ng/ml ($n = 2$) had hypothyroidism, and it is known that TRH (thyrotropin) stimulates the release of prolactin (381). It was concluded that all patients should have had TSH determinations at the start of therapy with neuroleptic drugs.

Sex differences in hormone concentrations have been investigated in 47 patients (21 men and 26 women) with schizophrenia or related psychoses who were using different neuroleptic drugs (382). The median daily dose and the median body weight-adjusted daily dose were twice as high in men as in women. However, neuroleptic drug-induced hyperprolactinemia was more frequent and occurred at a lower daily dose in women. The growth hormone concentration was normal in all patients.

Some patients who take clozapine take another neuroleptic drug, and the consequences of this practice in terms of prolactin have been studied in five patients (383). After the addition of haloperidol (4 mg/day) to clozapine the mean prolactin concentration increased from 9.7 ng/ml to 16 ng/ml at week 4 and 19 ng/ml at week 6. Each subject had an increase in the percentage of D_2 receptor occupancy, and the group mean increased from 55% at baseline to 79% at week 4; the increased prolactin concentrations correlated with receptor occupancy.

The effects of haloperidol and quetiapine on serum prolactin concentrations have been compared in 35 schizophrenic patients after a 2-week washout period in a randomized study (376). There was no significant difference in prolactin concentration between the groups at the start of the study, although prolactin concentrations were significantly lower with quetiapine than haloperidol. After 6 weeks, the mean prolactin concentration was significantly increased in those taking haloperidol but not in those taking quetiapine. Two patients taking haloperidol had galactorrhea related to hyperprolactinemia.

Inappropriate ADH secretion

Polyuria and polydipsia have long been associated with schizophrenia, and neuroleptic drugs appear to aggravate these symptoms, sometimes with an accompanying syndrome of inappropriate ADH secretion. However, water retention and edema occur very rarely during treatment with neuroleptic drugs. Water intoxication has been reported during treatment with thioridazine and may be due to its pronounced anticholinergic properties and/or direct stimulation of the hypothalamic thirst center (384).

Metabolism

The charts of 94 long-term inpatients have been reviewed retrospectively to examine the changes in weight, fasting glucose, and fasting lipids in those taking either risperidone ($n = 47$) or olanzapine ($n = 47$) (385). The patients had increased weight, triglycerides, and cholesterol, and the changes were significantly higher with olanzapine; olanzapine but not risperidone considerably increased glucose concentrations. One case of new-onset diabetes mellitus occurred in a patient taking olanzapine.

Lipid concentrations

In a cross-sectional study in 44 men, olanzapine had a worse metabolic risk profile than risperidone (386). The men (mean age 29 years) took olanzapine ($n = 22$; mean duration 18 months; mean dose 13 mg/day) or risperidone ($n = 22$; mean duration 17 months; mean dose 2.8 mg/day). Those who took olanzapine had significantly higher plasma triglyceride concentrations, significantly higher very low density lipoprotein cholesterol concentrations, a trend to a lower HDL cholesterol concentration, and a trend to a higher cholesterol/HDL cholesterol ratio.

© 2006 Elsevier B.V. All rights reserved.

Despite similar mean body weights (olanzapine 84 kg versus risperidone 81 kg), 32% of those who took olanzapine were characterized by the atherogenic metabolic triad (hyperinsulinemia and raised apolipoprotein B and small-density LDL concentrations) compared with only 5% of those who took risperidone.

Diabetes mellitus

Several cases of de novo onset or exacerbation of existing diabetes mellitus in patients treated with neuroleptic drugs have been reported and were not significantly related to weight gain. These included eight patients treated with clozapine (387,388) and two patients treated with olanzapine (388).

Neuroleptic drug treatment of non-diabetic patients with schizophrenia can be associated with adverse effects on glucose regulation, as has been suggested by the results of a study in which modified oral glucose tolerance tests were performed in 48 patients with schizophrenia taking clozapine, olanzapine, risperidone, or typical neuroleptic drugs, and 31 untreated healthy control subjects (389). Newer neuroleptic drugs, such as clozapine and olanzapine, compared with typical agents, were associated with adverse effects on blood glucose regulation, which can vary in severity regardless of adiposity and age.

Weight gain

Shortly after the typical neuroleptic drugs were introduced in the 1950s, marked increases in body weight were observed, and excessive weight gain has been reported in up to 50% of patients receiving long-term neuroleptic drug treatment (390–396).

However, changes in weight during psychosis are also related to the condition; Kraepelin wrote, "The taking of food fluctuates from complete refusal to the greatest voracity... Sometimes, in quite short periods, very considerable differences in the body weight are noticed ..." (397). It was observed early on that food intake and weight often fell as psychosis worsened, but eating and weight returned to normal or increased when an acute psychotic episode abated. However, since the start of the neuroleptic drug era in the 1950s, a new pattern of sustained increased weight has commonly been detected. The question of whether weight gain is associated with efficacy is important; in one study there was no obvious relation between the magnitude of weight gain and therapeutic efficacy (398).

The association between clozapine-related weight gain and increased mean arterial blood pressure has been examined in 61 patients who were randomly assigned to either clozapine or haloperidol in a 10-week parallel group, double-blind study, and in 55 patients who chose to continue to take clozapine in a subsequent 1-year, open, prospective study (399). Clozapine was associated with significant weight gain in both the double-blind trial (mean 4.2 kg) and the open trial (mean 5.8 kg), but haloperidol was not associated with significant weight gain (mean 0.4 kg). There were no significant correlations between change in weight and change in mean arterial blood pressure for clozapine or haloperidol.

Serum leptin, a peripheral hormone secreted by fat, correlates inversely with body weight; in 22 patients taking clozapine who gained weight, those who had the most pronounced 2-week increase in leptin had the least gain in body weight after 6 and 8 months (400).

Epidemiology

Several reviews have addressed the issue of weight gain (401–405). Comparison of different studies of weight gain during treatment with atypical neuroleptic drugs is hampered by problems with study design, recruitment procedures, patient characteristics, measurement of body weight, co-medications, and duration of therapy. These problems have to be considered when assessing this type of information, particularly figures collected in accordance with the last-observation-carried-forward technique, which is one of the most common approaches taken; this type of analysis can produce marked underestimates of the magnitude of weight gain.

There has been one comprehensive meta-analysis including over 80 studies and over 30 000 patients (406). A meta-analysis of trials of neuroleptic drugs showed the following mean weight gains in kg after 10 weeks of treatment: clozapine, 4.5; olanzapine, 4.2; thioridazine, 3.2; sertindole, 2.9; chlorpromazine, 2.6; risperidone, 2.1; haloperidol, 1.1; fluphenazine, 0.43; ziprasidone 0.04; molindone, −0.39; placebo, −0.74 (407,408). In one study, excessive appetite was a more frequent adverse event in patients treated with olanzapine versus haloperidol (24 versus 12%) (152). Loss of weight has been observed after withdrawal of neuroleptic drugs (409).

The percentages of patients who gain more than 7% of their baseline body weight are highest for olanzapine (29%) and lowest for ziprasidone (9.8%). Although these figures are useful for comparing different drugs, they do not illustrate how weight increases over time, nor the total gain. Body weight tends to increase at first but reaches a plateau by about 1 year; with olanzapine 12.5–17.5 mg/day, patients gained, on average, 12 kg (410).

Risperidone and olanzapine, the two most commonly used atypical drugs, have been compared in trials; patients who took olanzapine gained almost twice as much weight (4.1 kg) as those who took risperidone (2.3 kg) (81). In two groups of inpatients, who took either risperidone ($n = 50$) or olanzapine ($n = 50$) for schizophrenia the mean body weight at baseline was 83 kg in the risperidone group and 85 kg in the olanzapine group; after 4 months of treatment, the mean body weights were 83 and 87 kg respectively (411). The increase in body weight with olanzapine was statistically significant.

In a retrospective chart review of 91 patients with schizophrenia (120 treatment episodes; mean age 38 years), there was weight gain with zotepine (4.3 kg), clozapine (3.1 kg), sulpiride (1.9 kg), and risperidone (1.5 kg), but not in patients treated with typical neuroleptic drugs (mean gain 0.0–0.5 kg) (412). The mean duration of treatment was 28–34 days, the maximum weight gain being in the first 3–5 weeks. The mean increases in weight were 4.3% in the patients with normal weight, 3.0% in those with mild obesity, and 1.9% in those with severe obesity (BMI over 30).

In another retrospective study, 65 patients with schizophrenia who gained weight while taking clozapine for 6 months were followed (413). After that they were

© 2006 Elsevier B.V. All rights reserved.

switched to a combination of clozapine with quetiapine for 10 months: clozapine was tapered to 25% of the current dose and quetiapine was added proportionately. During clozapine monotherapy the mean weight gain was 6.5 kg and 13 patients developed diabetes. At the end of the combination period, the mean weight loss was 9.4 kg; patients who developed diabetes showed significant improvement, resulting in a rapid fall in insulin requirements and/or withdrawal of insulin and replacement with an oral hypoglycemic agent. The mechanism of clozapine-associated weight gain is uncertain.

Mechanism

The mechanisms of weight gain are not known. Olanzapine, for example, affects at least 19 different receptor sites, may have reuptake inhibition properties, and may affect hormones such as prolactin. Animal models do not help to elucidate mechanisms, since they have not shown clear results: some studies have shown weight gain with neuroleptic drugs in rats and others have not.

However, a serotonergic mechanism has been proposed (414). Most of the atypical drugs, which most commonly cause weight gain, interact with 5-HT_{2C} receptors; however, ziprasidone also binds to 5-HT_{2C} receptors with high affinity and does not cause weight gain or does so to a lesser extent. In 152 patients treated with clozapine, Cys23Ser polymorphism of the 5-HT_{2C} receptor did not explain the weight gain that occurred (415), nor was there an association between specific alleles of the dopamine D_4 receptor gene (416). In contrast, in 19-year-old monozygotic twins who gained around 40 kg after taking mainly clozapine, weight gain was related to an unspecified genotype (417). An association between weight gain and a 5-HT_{2C} receptor gene polymorphism has been identified in 123 Chinese Han patients with schizophrenia taking chlorpromazine ($n = 69$), risperidone ($n = 46$), clozapine ($n = 4$), fluphenazine ($n = 3$), or sulpiride ($n = 1$) (418). Weight gain was substantially greater in the patients with the wild-type genotype than in those with a variant genotype (–759C/T), at both 6 and 10 weeks; this effect was seen in men and women.

Susceptibility factors

In general, people with schizophrenia have a greater tendency to be overweight and obese than those who do not have schizophrenia (419). The evidence suggests that weight gain will progress most rapidly during the first 3–20 weeks of treatment with second-generation neuroleptic drugs; there is little evidence that dose affects weight gain. There are no sex differences, but there is a positive correlation between weight gain and age. Smokers treated with neuroleptic drugs may gain less weight than non-smokers (412,420). Patients in hospital are more likely to gain weight than those in the community, perhaps because they have an unrestricted diet and limited physical activity; there is some evidence that those with a lower baseline BMI are likely to gain more weight (402).

However, in the USA, data from a large health and nutrition survey ($n = 17\,689$) and from patients with schizophrenia to be enrolled in a clinical trial ($n = 420$) showed no differences; the mean BMIs were high and a substantial proportion of the population was obese (419).

The genetic basis of some reactions associated with neuroleptic drugs is of particular interest. An important association between weight gain and a 5-HT_{2C} receptor gene polymorphism has now been identified in 123 Chinese Han schizophrenic patients taking chlorpromazine ($n = 69$), risperidone ($n = 46$), clozapine ($n = 4$), fluphenazine ($n = 3$), or sulpiride ($n = 1$) (418). Weight gain was substantially greater in the patients with the wild-type genotype than in those with a variant genotype (–759C/T), at both 6 and 10 weeks; this effect was seen in men and women. In addition, a homozygous non-functional genotype, CYP2D6*4, was found in a 17-year-old schizophrenic patient who developed severe akathisia, parkinsonism, and drowsiness after taking risperidone 6 mg/day for 3 months; he had a high plasma concentration of risperidone and an active metabolite (421).

Clinical features

Obesity is associated with increased risks of dyslipidemia, hypertension, type 2 diabetes mellitus, cardiovascular disease, osteoarthritis, sleep apnea, and numerous other disorders; all these conditions have been associated with increased mortality. In the EUFAMI (European Federation of Associations of Families of Mentally Ill People) Patient Survey undertaken in 2001 across four countries and involving 441 patients, treatment-induced adverse effects were a fundamental problem; of the 91% of patients who had adverse effects, 60% had weight gain, and of these more than half (54%) rated weight gain as the most difficult problem to cope with (422). Furthermore, weight gain can adversely affect patients' adherence to medication, undermining the success of drug treatment for schizophrenia.

A report has illustrated how extreme the problem of weight gain associated with neuroleptic drugs can be (423).

- A 32-year-old man with schizophrenia taking neuroleptic drugs was switched to olanzapine 20 mg/day for better control. He weighed 101 kg and his BMI was 31 kg/m^2. After 6 months he had gained 4.5 kg and after 1 year 17 kg. Because of poor control, risperidone 4 mg/day was added and 16 months later he had had a 34.6 kg increase from baseline and had a BMI of 42 kg/m^2 (that is in the range of severe obesity). He had both increased appetite and impaired satiety. His serum triglycerides were 4.0 mmol/l, and his fasting blood glucose was 6.7 mmol/l. He and his physician agreed on a goal of losing 12 kg over 12 months and he was referred to a dietician. Over the next 5 weeks, he lost 2.7 kg and after 2 years his BMI was 38 kg/m^2 and 1 year later 39 kg/m^2. He was given nizatidine 300 mg bd and 1 year later his weight was 95 kg (BMI 29 kg/m^2). His triglycerides and fasting blood glucose concentrations were within the reference ranges.

Comparative studies

The charts of 94 long-term inpatients have been reviewed retrospectively to examine the changes in weight, fasting glucose, and fasting lipids in those taking either risperidone ($n = 47$) or olanzapine ($n = 47$)

© 2006 Elsevier B.V. All rights reserved.

(385). The patients had increased weight, triglycerides, and cholesterol, and the changes were significantly higher with olanzapine; olanzapine but not risperidone considerably increased glucose concentrations. One case of new-onset diabetes mellitus occurred in a patient taking olanzapine. Weight should be monitored in patients taking maintenance atypical neuroleptic drugs, especially dibenzodiazepines.

Management

Behavioral treatment of obesity has given good results in patients taking neuroleptic drugs (424). More dubious is the use of antiobesity drugs, as some of them can cause psychotic reactions.

Good results have been reported with amantadine, which increases dopamine release (425). In 12 patients with a mean weight gain of 7.3 kg during olanzapine treatment, amantadine 100–300 mg/day over 3–6 months produced an average weight loss of 3.5 kg without adverse effects. In contrast, calorie restriction did not lead to weight loss in 39 patients with mental retardation who were taking risperidone, 37 of whom gained weight, the mean gain being 8.3 kg over 26 months (426).

Electrolyte balance

Care should be taken when treating hyponatremic patients with neuroleptic drugs (427).

Mineral balance

In one controlled study, 12 patients who were receiving various neuroleptic drugs had significantly increased urinary calcium and hydroxyproline concentrations and reduced urinary alkaline phosphatase compared with five controls (428). The possibility of a reduction in bone mineralization (429) may contribute to the increased risk of hip fracture associated with neuroleptic drug treatment in the elderly.

Hematologic

Rarely reported hematological reactions to various neuroleptic drugs include agranulocytosis, thrombocytopenic purpura, hemolytic anemia, leukopenia, and eosinophilia. These are thought to represent allergic or hypersensitivity reactions, although this has been questioned in one detailed case report of chlorpromazine-induced agranulocytosis (430).

The reported incidence of agranulocytosis is variable, ranging from 1 in 3000 to 1 in 250 000. Most cases are seen within the first 2 months after the start of treatment, but there have been a few reports in which agranulocytosis occurred only after many years. Frequent white cell counts are of limited value in monitoring, since counts fall rapidly and abruptly. Careful attention should be given to possible early warning signs, such as fever, sore throat, and lymphadenopathy. Treatment requires immediate withdrawal and preventive measures against infection. Granulocyte colony-stimulating factor (GCSF) has been used to treat neuroleptic drug-induced agranulocytosis (431).

In view of the association of agranulocytosis with clozapine and of aplastic anemia with remoxipride, hemopoietic disorders have been studied using information from the UK monitoring system (432). The Committee on Safety of Medicines and the erstwhile Medicines Control Agency in the UK received 999 reports of hemopoietic disorders related to neuroleptic drugs between 1963 and 1996; there were 65 deaths. There were 182 reports of agranulocytosis; chlorpromazine and thioridazine were associated with the highest number of deaths—27 of 56 and 9 of 24 respectively. The much lower mortality with clozapine-induced agranulocytosis—two of 91 (2.2%)—was explained as a function of the stringent monitoring requirements for this drug, which allow early detection and treatment.

There is greater variability in the reference ranges for all white blood cell indices in patients with schizophrenia than in the healthy population (433). This suggests that abnormal hematological findings in patients with schizophrenia should be assessed in the context of a reference range specifically determined in patients with schizophrenia.

Gastrointestinal

The possibility of fatal intestinal dilatation, although very rare, warrants careful evaluation of persistent complaints of constipation, particularly in patients who also have vomiting and abdominal pain, distension, or tenderness (434). Acute intestinal pseudo-obstruction (Ogilvie's syndrome) has been reported in a patient taking haloperidol plus benzatropine (435).

- A 64-year-old woman started to take oral haloperidol 0.5 mg tds, and 3 days later was given intravenous benzatropine 2 mg for dystonia plus a second dose 1 hour later because she had not responded to the first dose. Her dystonia improved, but she started to develop abdominal distension and discomfort, and within the next 3–4 hours her whole abdomen had become significantly distended. Haloperidol and benzatropine were withdrawn and she was treated with hydration, nasogastric suction, a rectal tube, and frequent change of position. With this conservative therapy, her abdominal distension resolved completely in 24 hour.

Liver

When a neuroleptic drug causes jaundice it generally occurs within 2–4 weeks and has many characteristics of an allergic reaction, being accompanied by fever, rashes, and eosinophilia, although a direct toxic mechanism has also been implicated. Symptoms generally subside rapidly after withdrawal, but cholestasis may be prolonged.

Liver damage due to atypical neuroleptic drugs generally occurs within the first weeks of treatment, but the delay is highly variable, being 1–8 weeks for clozapine, 12 days to 5 months for olanzapine, and 1 day to 17 months for risperidone (436).

There is evidence of a significant hepatotoxic effect of the phenothiazines and in persons under age 50, but not over 50 (437).

Hepatotoxicity may be as frequent with piperidine and piperazine phenothiazines as with chlorpromazine, despite previous suggestions that the toxicity of these compounds is less.

© 2006 Elsevier B.V. All rights reserved.

More common are minor dose-related abnormalities in liver function tests with various neuroleptic drugs.

Urinary tract

Urinary retention, incontinence, or dysuria can occasionally occur with neuroleptic drugs that have marked anticholinergic effects.

Skin

Many skin reactions have been reported with neuroleptic drugs, including urticaria, abscesses after intramuscular injection, rashes, photosensitivity or exaggerated sunburn, contact dermatitis, and melanosis or blue-gray skin discoloration. Skin rashes are usually benign. Chlorpromazine is most often implicated (incidence 5–10%).

Non-phenothiazines, such as haloperidol and loxitane, cause fewer urticarial reactions. As with any other class of drug, patients may be allergic to excipients in various tablet or capsule forms, or to preservatives, for example methylparabens in liquid dosage forms (438).

Abnormal skin pigmentation (SEDA-19, 49) is more common in women and generally occurs on the exposed parts of the body. This reaction may be due to deposition of melanin-drug complexes. It was commonly seen in the decade after the introduction of the phenothiazines, but rarely today (438).

- A 45-year-old schizophrenic woman with blue eyes and blond hair who had received a lifetime exposure of at least 1748 g of chlorpromazine had blue discoloration of the skin by age 36 (439). Chlorpromazine was withdrawn and clozapine substituted (up to a maximum of 600 mg/day). The skin pigmentation resolved over 4 years.

Complications at the site of injection of depot neuroleptic drugs, including pain, bleeding or hematoma, leakage of drug from the injection site, acute inflammatory induration, and transient nodules, have been reported (SEDA-20, 43).

Seborrheic dermatitis has been observed in patients receiving long-term neuroleptic drugs (SEDA-17, 57), and this adverse effect appears to be highly associated with drug-induced parkinsonism.

More serious types of skin reactions are rare, but angioedema, non-thrombocytopenic purpura, exfoliative dermatitis, and Stevens–Johnson syndrome have been reported.

Potentially serious skin reactions are best treated by withdrawing the offending agent and switching to a structurally unrelated neuroleptic drug. When the offending agent is a phenothiazine, non-phenothiazines such as haloperidol or molindone may be preferable to the more closely related thioxanthenes.

Musculoskeletal

Rhabdomyolysis has been described in a handicapped child without other symptoms of neuroleptic malignant syndrome (440).

- A 6-year-old boy who was taking clonazepam 2.6 mg/day, diazepam 10 mg/day, and phenobarbital 50 mg/day was given oral haloperidol (0.3 mg/day) plus biperiden (0.3 mg/day) for choreoathetosis. After haloperidol had been introduced, his mother noticed that his urine sometimes became dark brown. He had myoglobinuria (660 ng/ml; reference range below 10 ng/ml) but no renal insufficiency. Haloperidol and biperiden were withdrawn and 2 days later his urine was normal.

A marked increase in creatine kinase activity without neuroleptic malignant syndrome has been previously described (SEDA-21, 48) and, another report has further emphasized this possibility (441).

- A 19-year-old schizophrenic patient taking risperidone 6 mg/day and olanzapine 20 mg/day had a creatine kinase activity of 6940 U/l without clinical manifestations of neuroleptic malignant syndrome; when he switched to clozapine (dose not stated) the creatine kinase fell to about 300 U/l. Because he developed granulocytopenia, he was given quetiapine instead, and the creatine kinase again rose to 3942 U/l but fell after 4 days to 389 U/l without withdrawal of quetiapine.

The authors concluded that the mechanism by which creatine kinase increases is not comparable for olanzapine, quetiapine, and clozapine, and that the increase can be self-limiting.

Sexual function

The frequency and course of sexual disturbances associated with neuroleptic drugs have been studied in a prospective open study of clozapine 261 mg/day (in 75 men and 25 women, mean age 29 years) and haloperidol 16 mg/day (41 men and 12 women, mean age 26 years) (442). There were no statistically significant differences between those taking haloperidol and those taking clozapine. During 1–6 weeks of treatment with clozapine, the most frequent sexual disturbances among women were diminished sexual desire (28%) and amenorrhea (12%), while among men they were diminished sexual desire (57%), erectile dysfunction (24%), orgasmic dysfunction (23%), ejaculatory dysfunction (21%), and increased sexual desire (15%).

Neuroleptic drug-induced sexual dysfunction, including erectile and ejaculatory dysfunction and changes in libido and the quality of orgasm, appear to be reversible on withdrawal.

Male dysfunction

Although the mechanism involved in neuroleptic drug-induced male sexual dysfunction is not entirely understood, it can occur at several levels, including the cortex, hypothalamus, pituitary gland, and the gonads, involving, for example, gonadotrophins and testosterone. Another mechanism involves the sympathetic and parasympathetic nervous systems and may explain why thioridazine and other highly anticholinergic drugs are mainly responsible for male sexual dysfunction, including impotence and retrograde ejaculation (443,444).

The first report of spontaneous ejaculation associated with the therapeutic use of neuroleptic drugs was described in 1983 (445).

© 2006 Elsevier B.V. All rights reserved.

One study showed a reduction in the strength of erection in men with schizophrenia, further accentuated in those who are taking neuroleptic drugs (SEDA-20, 44).

In 12 men with schizophrenia (mean age 36 years) receiving neuroleptic drugs, amantadine 100 mg/day for 6 weeks improved sexual function (446). All 12 patients, who had a sustained relationship with a female partner, had reported sexual dysfunction. Four areas of sexual function were assessed: desire, erection, ejaculation, and satisfaction; there was an improvement in all but ejaculation. Amantadine had no effect on the symptoms of schizophrenia.

Priapism

Neurotropic drug-induced priapism has been reviewed (447). It is said that neuroleptic drugs are most commonly implicated. A prior history of prolonged erections can be identified in as many as 50% of patients presenting with priapism who are using neuroleptic drugs. According to another review, the frequency of priapism with neuroleptic drugs may be increased by the fact that schizophrenia is said to be accompanied by an increase in sexual activity (448).

In one case, priapism followed the use of first risperidone and then ziprasidone (449).

- A 22-year-old African-American with chronic undifferentiated schizophrenia developed priapism after taking risperidone 4 mg bd, clonazepam 0.5 mg bd, vitamin E 400 IU bd, and a multivitamin for over 6 months. He did not respond to subcutaneous terbutaline 0.25 mg. Irrigation of the corpora with phenylephrine 200 μ resulted in detumescence; risperidone was withdrawn. A few months later he took ziprasidone 20 mg bd for 1 week, clonazepam 1 mg bd, and vitamin E 400 IU bd. The ziprasidone dosage was increased to 40 mg bd, but early the next morning he developed a firm erection with some discomfort that lasted about 2 hour and resolved when he urinated; the next morning he had a similar erection that also lasted 2 hour and resolved.

Priapism in twins suggests a hereditary predisposition (450).

- Identical twin brothers, aged 37 years, had both suffered from bipolar disorder since their early twenties and had been treated with chlorpromazine, haloperidol, lithium, and carbamazepine before developing priapism. One of them developed priapism after taking trazodone 400 mg/day, and in the 2 years after the initial episode he suffered recurrent painless erections. Initially they occurred daily and lasted 4–5 hours. During a relapse of mania at age 37, he was given oral zuclopenthixol 40 mg/day. On the tenth day he presented with priapism of 4 days duration, which persisted despite zuclopenthixol withdrawal, needle aspiration, and phenylephrine instillation, but subsided 2 weeks later with conservative management. The other twin presented with priapism of 75 hour duration and hypomania at age 31 years. He had been taking lithium and chlorpromazine for the preceding 2 years.

Priapism necessitates prompt urological consultation and sometimes even surgical intervention (443,451,452).

Female dysfunction

Female orgasm is inhibited by some central depressant and psychotropic drugs, including neuroleptic drugs, antidepressants, and anxiolytic benzodiazepines (165).

Immunologic

Hypogammaglobulinemia in a 22-year-old woman with brief psychotic disorder has been attributed to neuroleptic drug therapy (453). About 4 months after she had started to receive neuroleptic drugs, her serum concentrations of total protein had fallen to 58 g/l, with an IgG concentration of 3.49 g/l, an IgA concentration of 0.54 g/l, and an IgM concentration of 0.34 g/l.

Antiphospholipid syndrome is a disorder of recurrent arterial or venous thrombosis, thrombocytopenia, hemolytic anemia, or a positive Coombs' test, and in women recurrent idiopathic fetal loss, associated with raised concentrations of antiphospholipid antibodies. In systemic lupus erythematosus, the risk of this syndrome is about 40%, compared with a risk of 15% in the absence of antiphospholipid antibodies (454). However, only half of those with antiphospholipid antibodies have systemic lupus erythematosus, and the overall risk of the syndrome is about 30%. In patients who have antiphospholipid antibodies associated with chlorpromazine, there appears to be no increased risk of the syndrome. In contrast, in the primary antiphospholipid syndrome, the only clinical manifestations are the features of this syndrome.

- Symptomatic antiphospholipid syndrome has been described in a 42-year-old woman treated with chlorpromazine 260 mg/day (455). She presented with sudden right-sided weakness, numbness, and headache. Examination confirmed upper motor neuron signs affecting the right arm, leg, and face, with hemiplegia and hemiparesthesia. Autoantibody screening showed positive antinuclear antibodies, with an IgG titer of 50 and an IgM titer of 1600. Anticardiolipin antibody was positive with a raised IgM titer of 24 (normal less than 9). The symptoms and the serological findings resolved after withdrawal of the phenothiazine.

Drug-induced lupus erythematosus has been reviewed (456,457). Neuroleptic drugs, particularly chlorpromazine and chlorprothixene, have often been associated with this autoimmune disorder. It is recommended that several diagnostic criteria for this condition should be met: (1) exposure to a drug suspected to cause lupus erythematosus; (2) no previous history of the condition; (3) detection of positive antinuclear antibodies; and (4) rapid improvement and a gradual fall in the antinuclear antibodies and other serological findings on drug withdrawal. Rare disorders of connective tissue resembling systemic lupus erythematosus have been reported with chlorpromazine, perphenazine, and chlorprothixene (458).

Body temperature

Neuroleptic drugs interfere with the temperature regulatory function of the hypothalamus and peripherally with the sweating mechanism, resulting in poikilothermy. This can result in either hyperthermia or hypothermia, depending on the environmental temperature.

© 2006 Elsevier B.V. All rights reserved.

Hyperthermia

A series of cases has been reported in which heat stroke occurred during hot weather, probably due to impaired heat adaptation in patients taking benzatropine and ethylbenzatropine (459); this can occur with other anticholinergic and neuroleptic drugs as well.

Hypothermia

Reduced body temperature has been observed in a study of 14 drug-free and 7 patients with schizophrenia taking different neuroleptic drugs (460). The temperature fell by about 0.36°C at 24 hours after the drug-free subjects started to take neuroleptic drugs.

Hypothermia, defined as a body temperature lower than 35°C, has been observed in individual cases.

- A 73-year-old woman with diabetes mellitus and schizophrenia was given haloperidol 8 mg/day instead of zuclopenthixol; she also took levomepromazine 75 mg at night; 10 days later she was found unconscious with a rectal temperature of 31.5°C (461). A few weeks later, she had two further episodes, first with olanzapine 10 mg/day (rectal temperature 31.7°C) and then with thioridazine 40 mg/day (rectal temperature 34°C). She was therefore given dixyrazine 150 mg/day and alimemazine 20 mg at night, and had no more episodes of hypothermia.
- An 83-year-old woman developed a rectal temperature of 33.1°C 3 weeks after starting to take olanzapine 5 mg/day (462).
- A 68-year-old schizophrenic woman with type 1 diabetes mellitus developed a body temperature of 33.4°C 1 week after starting to take quetiapine 100 mg bd (462).

In the two last cases, the most common causes of hypothermia, such as hypothyroidism, infection, and cold exposure, were ruled out.

Death

The role of neuroleptic drugs in sudden death is controversial (SEDA-18, 47) (SEDA-20, 26) (SEDA-20, 36). Cardiac dysrhythmias may be involved, but there may also be multiple non-cardiac causes, including asphyxia, convulsions, or hyperpyrexia.

Long-Term Effects

Drug withdrawal

Various somatic complaints have been reported in patients in whom neuroleptic drugs are abruptly withdrawn (SEDA-20, 44). The incidence of these complaints varies widely in different reports, from 0 to 75%. Common complaints include headache, vomiting, nausea, diarrhea, insomnia, abdominal pain, rhinorrhea, and muscle aches. On rare occasions, the symptoms resemble those of benzodiazepine withdrawal (appetite change, dizziness, tremulousness, numbness, nightmares, a bad taste in the mouth, fever, sweating, vertigo, tachycardia, and anxiety), but it is possible that in some of the reported cases there was actually benzodiazepine withdrawal. Some of these symptoms may also have been linked to the simultaneous withdrawal of anticholinergic drugs (SED-11, 113) (463). Parkinsonism, not explained by withdrawal of anticholinergic drugs, has also been reported as an unusual withdrawal effect of neuroleptic drugs (464).

Worsening of psychotic symptoms and/or dyskinetic movements can occur when dosages are lowered or a neuroleptic drug is withdrawn. A functional increase in mesolimbic and striatal dopaminergic sensitivity has been suggested as an explanation (465). Psychotic relapse is rarely seen in the first 2 weeks after withdrawal, but physical withdrawal symptoms generally begin within 48 hours of the last dose (SEDA-14, 54).

Withdrawal emergent syndrome has been described in children (466,467) and consists of nausea, vomiting, ataxia, and choreiform dyskinesia primarily affecting the extremities, trunk, and head after sudden withdrawal of neuroleptic drugs (468). In one study, there were withdrawal symptoms in 51% of children, twice as many being affected by the withdrawal of low-dose, high-potency compounds compared with other drugs. Symptoms usually appear within a few days to 2 weeks after drug withdrawal; spontaneous remission is likely within the next 8–12 weeks.

The Omnibus Budget Reconciliation Act of 1987 (OBRA '87) regulations (www.elderlibrary.org) specify when neuroleptic drugs can and cannot be used to treat behavioral disturbances in nursing home residents in the USA. Accordingly, neuroleptic drugs can legally be used in patients with delirium or dementia only if there are psychotic or agitated features that present a danger to the patient or others. Preventable causes of agitation must be excluded and the nature and frequency of these behaviors must be documented. Non-dangerous agitation, uncooperativeness, wandering, restlessness, insomnia, and impaired memory are insufficient in isolation to justify the use of neuroleptic drugs. With this in mind, the effects of withdrawing haloperidol, thioridazine, and lorazepam have been examined in a double-blind, crossover study in 58 nursing home residents (43 women and 15 men, mean age 86 years), half of whom continued to take the psychotropic drugs that had been prescribed, while the other half were tapered to placebo (469). After 6 weeks, the patients were tapered to the reverse schedule and took it for another 6 weeks. There were no differences between drug and placebo in functioning, adverse effects, and global impression. Cognitive functioning improved during placebo. The authors concluded that gradual dosage reductions of psychoactive medications must be attempted, unless clinically contraindicated, when trying to withdraw these drugs. Similar conclusions have been reached in other studies (SEDA-22, 54).

There has been a randomized controlled study of the factors that affect neuroleptic drug withdrawal or dosage reduction among people with learning disabilities, who were being treated for behavioral problems with typical neuroleptic drugs (470). Of 36 patients, 12 completed full withdrawal and a further 7 achieved and maintained at least a 50% reduction. Drug withdrawal or dosage reduction was not associated with increased maladaptive behavior. This result reinforces concerns that neuroleptic drug treatment for maladaptive behavior reduction is often ineffective and inappropriate.

© 2006 Elsevier B.V. All rights reserved.

Mutagenicity

There was an increase in markers of genotoxicity in patients receiving long-term neuroleptic drugs in combination with other psychotropic drugs ($n = 36$) compared with controls ($n = 36$) (471). In another study there was an association between the frequency of chromosomal aberrations in lymphocytes and the probability of tumor induction (472).

Tumorigenicity

There is concern that neuroleptic drugs may increase the risk of breast cancer because of raised prolactin concentrations. For a long time, findings did not confirm this association (377), but a Danish cohort study of 6152 patients showed a slight increase in the risk of breast cancer among schizophrenic women (378).

Second-Generation Effects

Fertility

The effects of neuroleptic drugs on fertility are not clear; many of the data are controversial, often being based on animal studies, for example reduction in male rat copulation by chlorpromazine. However, oligospermia, polyspermia, necrospermia, and reduced sperm motility have been reported with various phenothiazines and butyrophenones; these are likely to improve after withdrawal (473). Furthermore, fertility may be impaired by neuroleptic drugs, since they increase prolactin concentrations and can cause amenorrhea (4).

Teratogenicity

There have been reviews of neuroleptic drug use during pregnancy (474–478).

All neuroleptic drugs cross the placenta and reach the fetus in potentially significant amounts. However, most large-scale controlled studies have shown that they can be used safely during pregnancy (141). Nevertheless, there have been isolated case reports of malformations (SEDA-7, 68) (479).

Should a neuroleptic drug be required during pregnancy, a drug such as chlorpromazine or trifluoperazine would be preferred, as there is considerably more worldwide experience with these drugs than with newer drugs (141). However, clozapine caused no serious complications or developmental abnormalities during pregnancy in two cases (480).

Although studies have failed to identify an increased rate of malformations with haloperidol, isolated cases have been reported (481) (SEDA-22, 5) (SEDA-23, 57) (477,478).

Phocomelia associated with neuroleptic drugs has been reported (482).

- A 38-year-old woman was admitted to hospital in the third week after conception and acute schizophrenia was diagnosed. She was given oral haloperidol 1.5 mg at 12-hourly intervals. In the fourth week after conception, intramuscular depot fluphenazine 12.5 was added every 15 days. At 8 weeks of gestation, after the pregnancy had been diagnosed, haloperidol and fluphenazine were withdrawn and trifluoperazine 5 mg was started and continued until 8 weeks before the baby was born. The child was born with phocomelia of the left arm, with an extremely short humerus and an absent forearm.

Fetotoxicity

A variety of pharmacological effects can occur in the infant after birth, particularly when the mother has received these agents in the weeks before delivery. These include postnatal depression and acute dystonic reactions (which may interfere with normal delivery). Hypotonia can persist for months (483) and may respond to diphenhydramine 5 mg/kg/day. Severe rhinorrhea and respiratory distress in a neonate exposed to fluphenazine hydrochloride prenatally has been reported (484). Neonatal jaundice, hyperbilirubinemia, and melanin deposits in the eyes have occurred when neuroleptic drugs were given during the last trimester or longer during pregnancy.

Lactation

Neuroleptic drugs appear in breast milk in very low concentrations, related to maternal dosage. Typical regimens of neuroleptic drugs yield low or negligible concentrations (141,485). In one study, breast-fed infants ingested up to 3% of the maternal daily dose, and small amounts of the drugs were detected in their plasma and urine. In addition, three breast-fed infants had a fall in developmental scores from the first to the second assessment at 12–18 months (486). Until these issues are further clarified, it would be best to avoid breast-feeding by mothers who are receiving neuroleptic drugs.

Susceptibility Factors

Age

Children

Neuroleptic drugs have been prescribed for children in the treatment of psychotic disorders, Tourette's syndrome, attention deficit disorder, hyperactivity, behavioral and psychiatric complications of mental retardation, and pervasive developmental disorders, for example infantile autism (487,488).

Untoward effects of neuroleptic drugs in children are said to be similar to those seen in adults (489).

However, adverse effects of neuroleptic drugs in children can be unpredictable and a suggestion that they can cause sudden infant death remains hypothetical (466). Significant weight gain has been reported in almost 100% of neuroleptic drug-treated children, and there seems to be a relatively high incidence of extrapyramidal adverse effects (467). Since there is little information regarding the pharmacokinetics and pharmacodynamics of neuroleptic drugs in children, careful supervision of treatment is vital; the use of high dosages is inadvisable.

Their use in children and adolescents has been extensively reviewed (490–492). Typical neuroleptic drugs have been assessed in three randomized, double-blind, placebo-controlled studies in 122 patients and atypical drugs in five (one clozapine, $n = 21$; two amisulpride,

© 2006 Elsevier B.V. All rights reserved.

$n = 36$; and two tiapride, $n = 59$). The studies were of short durations, 4–10 weeks. Extrapyramidal signs occurred in 25–73% of those treated with the typical neuroleptic drugs.

Elderly people

There is wide individual variation in the extent to which older people tolerate these drugs, and adverse effects, such as postural hypotension and anticholinergic effects, can be more problematic (493). Caution with neuroleptic drug use in old people is further warranted because several of these drugs are metabolized by CYP2D6, which is inhibited by many commonly used drugs (SEDA-20, 44).

Neuroleptic drugs have often been associated with increased rates of falls (SEDA-19, 40) (494).

Older people are supposedly susceptible to delirium caused by centrally acting anticholinergic drugs. This can take the form of anxiety, agitation, or frank hypomania. Such difficulties are more likely if the patient is also taking neuroleptic drugs (most of which also have a weak anticholinergic effect) or anticholinergic antiparkinsonian drugs.

In a study that was claimed to be the first published placebo-controlled dose comparison of neuroleptic drugs used to treat psychoses and disruptive behavior in dementia, haloperidol 2–3 mg/day was compared with 0.50–0.75 mg/day in 71 outpatients with Alzheimer's disease (495). After 12 weeks, there was a favorable therapeutic effect of haloperidol 2–3 mg/day, although 25% of the patients developed moderate to severe extrapyramidal signs. No patient developed tardive dyskinesia, but neuroleptic drug exposure needs to be considerably longer for that to occur.

Drug Administration

Drug formulations

Depot formulations

Guidelines for depot neuroleptic drug treatment in schizophrenia were developed during a consensus conference held in 1995 in Siena in Italy, since when a thorough review devoted to depot neuroleptic drugs has been published (496). The authors reported that depot neuroleptic drugs are associated with significantly fewer relapses and rehospitalizations than oral neuroleptic drugs. The potential disadvantages of depot drugs include patient reluctance to accept injections or a sense of being too subject to control. In addition, clinicians, and sometimes patients, fear that if adverse effects occur they will be more difficult to manage because of an inability to withdraw treatment rapidly. However, these formulations are not associated with a significantly higher incidence of adverse effects than oral drugs. Some patients have pain or discomfort at the injection site. In some cases the injection site becomes edematous and tender or pruritic, with a palpable mass for up to 3 months. The recommendations are to rotate the injection site, to limit the volume of the injection, and to assure deep intramuscular injection.

Drug administration route

Intramuscular injection of neuroleptic drugs in depot formulations is important for compliance in outpatients with schizophrenia, and the benefits and risks have been emphasized (SEDA-23, 73). In a retrospective study in a tertiary center in Riyadh, of 69 patients (mean age 35 years; mean duration of illness 11 years; 38 men) who had been given depot neuroleptic drugs during 1991–2000, only 24 were still receiving their depot injections regularly in that clinic (497). The authors suggested that negative attitudes of families and society toward mental illness and interference with psychiatric treatment by traditional and faith healers could have accounted for this lack of compliance. Although the use of depot neuroleptic drugs is advocated as maintenance treatment for patients with bipolar disorders, no such patients were identified. The authors pointed out that in spite of the fact that patients had been clinically stable, 7% had been receiving their depot neuroleptic drugs for more than 8 years, with no attempts to reduce the dosage or to increase the interval of administration.

Drug overdose

Suicide is the leading cause of premature death among patients with schizophrenia. The lifetime incidence of completed suicide among patients with schizophrenia is about 10% (498) and 18–55% of patients with schizophrenia make suicide attempts (499), sometimes with neuroleptic drugs. In autopsies and toxicological analyses in Vienna from 1991 to 1997, 97 neuroleptic compounds were detected in 85 fatal intoxications (500). Of these, 17 fatal poisonings were attributed to a single compound, 3 were due to two neuroleptic drugs, 57 to a combination of one neuroleptic drug with other drugs, 7 to two neuroleptic drugs with other drugs, and in one case three neuroleptic drugs combined with other drugs. Relating the number of deaths by a drug to the number of Defined Daily Doses, a fatality index was estimated. At the top of the rating were levopromazine, prothipendyl, and chlorprothixene, which had f-values significantly higher than the mean. However, since the estimates were not adjusted for age or condition, these data should be taken with caution.

In another study there were large differences in fatality from overdosage between different neuroleptic drugs (501). Pimozide had the lowest fatality index (the number of deaths divided by the number of prescriptions) and loxapine the highest.

Although mortality is generally low and infrequently associated with residual impairment (SED-13, 129), important exceptions occur when there is co-ingestion with alcohol, tricyclic antidepressants, or antiparkinsonian agents. In acute overdosage of neuroleptic drugs alone, the most serious complications include shock, seizures, and cardiac dysrhythmias. These can be more problematic when the neuroleptic drugs are of low potency, for example thioridazine and chlorpromazine, but taken in high dosages.

Acute extrapyramidal reactions occur more often after ingestion of high-potency drugs, such as haloperidol and fluphenazine; these respond to parenteral benzatropine, but anticholinergic drugs should be used judiciously, so as

© 2006 Elsevier B.V. All rights reserved.

not to worsen peripheral or central autonomic toxicity. Other serious, but less frequent, complications include paralytic ileus and hypothermia. Acute renal insufficiency has been very rarely reported, but is apparently reversible and can occur secondary to severe hypotension or other causes after acute ingestion (502).

Of 524 inquiries received by the National Poisons Information Service concerning new neuroleptic drugs over 9 months, only 45 cases involved overdose with a single agent (olanzapine, $n = 10$; clozapine, $n = 8$; risperidone, $n = 10$; sulpiride, $n = 16$) (503). There were no deaths or cases of convulsions. Cardiac dysrhythmias occurred only with sulpiride. Symptoms were most marked with clozapine: most patients had agitation, dystonia, central nervous system depression, and tachycardia. Most of the patients who had taken risperidone were asymptomatic.

Neuroleptic drug poisoning in 86 children has been retrospectively studied in two pediatric hospitals in the USA (1987–1997), with about 9000 and 11 000 annual admissions (504). Most (70%) occurred in children under 6 years of age; over two-thirds of the cases (78%) were unintentional. The owner of the medication, when identified (85% of cases), was the grandmother (22%), another family member (21%), the patient (13%), or a non-family caregiver (8%); the most common places where ingestion occurred were the patient's home (64%) or a relative's home (22%). There was a depressed level of consciousness in 91% and a dystonic reaction in 51%; there were no deaths.

- A 46-year-old woman took amisulpride (12 g), alprazolam (40 mg), and sertraline (1 g) with suicidal intent, and 3 hours later was still unconscious and was intubated (505). Her body temperature rose from 37.1°C on admission to 38°C soon after. She was discharged on the third day.
- A 50-year-old man who took an overdose of ziprasidone 3120 mg (52 tablets) had no serious effects; he was a little drowsy and his speech was slightly slurred (506). Ziprasidone blood concentrations were not measured.

Fatal intoxication has been reported with melperone (507).

- A 36-year-old woman was found dead in her flat about 2 days after her last contact with one of her relatives. Besides melperone, she was known to take diazepam and carbamazepine. The police found four empty containers of 100 melperone tablets (100 mg per tablet). Post-mortem blood concentration analysis showed melperone, diazepam, nordiazepam, and carbamazepine; the melperone concentration in venous blood was very high (17.1 μg/ml).

Drug–Drug Interactions

Adrenoceptor agonists

Neuroleptic drugs can reduce or block the pressor effects of alpha-adrenoceptor agonists. When using drugs with both alpha- and beta-adrenoceptor activity, neuroleptic drug blockade of alpha-adrenoceptors can lead to unopposed beta predominance, resulting in severe hypotension (508).

A neuroleptic malignant-like syndrome occurred when norephedrine was combined with neuroleptic drugs (338).

Alcohol

Alcohol-induced CNS and respiratory depression is enhanced by neuroleptic drugs (509), but enhancement can be slight if both are used in reasonable amounts (510).

Alpha-adrenoceptor antagonists

Neuroleptic drugs can intensify the effects of alpha-adrenoceptor antagonists, for example phentolamine, causing severe hypotension (467).

Amfebutamone (bupropion)

Bupropion has about the same seizure potential as tricyclic antidepressants (SEDA-8, 30), but the manufacturers noted an increased risk of seizures in patients taking over 600 mg/day in combination with lithium or neuroleptic drugs (SEDA-10, 20).

Antacids

Antacids containing aluminium and magnesium reduce the gastrointestinal absorption of chlorpromazine and other phenothiazines by forming complexes (511). The clinical significance of this is unknown.

Antihistamines

Drugs with a CNS depressant effect (antihistamines, hypnotics, sedatives, narcotic analgesics, alcohol, etc.) will have an increase in effect caused by interaction with neuroleptic drugs.

Benzatropine

Benzatropine and ethylbenzatropine are particularly likely to interact additively with other drugs with both anticholinergic and antihistaminic activity, such as neuroleptic drugs; complications such as hyperpyrexia, coma, and toxic psychosis have been reported several times when such combinations were used (512–514).

Benzodiazepines

Neuroleptic drugs can potentiate the sedative effects of benzodiazepines pharmacodynamically.

In a brief review, emphasis has been placed on pharmacokinetic interactions between neuroleptic drugs and benzodiazepines, as much information on their metabolic pathways is emerging (515). Thus, CYP3A4, which plays a dominant role in the metabolism of benzodiazepines, also contributes to the metabolism of clozapine, haloperidol, and quetiapine, and plasma neuroleptic drug concentrations can rise.

Intramuscular levomepromazine in combination with an intravenous benzodiazepine has been said to increase the risk of airways obstruction, on the basis of five cases of respiratory impairment in patients who received injections of psychotropic drugs (516). The doses of levomepromazine were higher in the five cases that had accompanying airways obstruction than in another 95 patients who did not.

© 2006 Elsevier B.V. All rights reserved.

Beta-adrenoceptor antagonists

The cardiac effects of neuroleptic drugs can be potentiated by propranolol (517).

In general, concurrent use of neuroleptic and antihypertensive drugs merits close patient monitoring (518).

Bromocriptine

The dopamine-blocking activity of neuroleptic drugs can antagonize the effects of dopamine receptor agonists, such as bromocriptine. Conversely, bromocriptine has been reported to cause exacerbation of schizophrenic symptoms (519).

Caffeine

Neuroleptic drugs can precipitate from solution when mixed with coffee or tea (520), but the clinical significance of this physicochemical interaction is unknown (521).

Caffeine can alter blood concentrations of neuroleptic drugs (SEDA-5, 6).

Excess caffeine can stimulate the CNS, which can worsen psychosis and thus interfere with the effects of neuroleptic drugs (522).

Cannabis

In 10 patients, schizophrenia was acutely worsened after cannabis use, despite verified adequate depot treatment with neuroleptic drugs (523).

Carbamazepine

Plasma concentrations of neuroleptic drugs can be lowered by carbamazepine, and patients should be monitored for reduced efficacy (524).

- A 54-year-old man who had been taking neuroleptic drugs for about 30 years developed neuroleptic malignant syndrome within 3 days of taking add-on carbamazepine (400 mg/day) (525).

This syndrome does not appear to have been described with carbamazepine alone, and it was speculated that its pathogenesis could involve rebound cholinergic activity after a reduction in plasma neuroleptic drug concentrations by carbamazepine.

Cocaine

In a retrospective study of 116 patients taking neuroleptic drugs, 42% of cocaine users versus 14% of non-users developed dystonic reactions (526). This suggests that the use of cocaine may be a major risk factor for acute dystonic reactions secondary to the use of neuroleptic drugs.

This has been confirmed in a 2-year study on the island of Curaçao in the Netherlands Antilles, where cocaine and cannabis are often abused (168). The sample consisted of 29 men with neuroleptic-induced acute dystonias aged 17–45 years who had received high potency neuroleptic drugs in the month before admission; 9 were cocaine users and 20 non-users. Cocaine use was a major risk factor for neuroleptic-induced acute dystonia and should be added to the list of well-known risk factors such as male sex, younger age, neuroleptic dose and potency, and a history of neuroleptic-induced acute dystonias. The authors suggested that high-risk cocaine-using psychiatric patients who start to take neuroleptic drugs should be provided with a prophylactic anticholinergic drug to prevent neuroleptic drug-induced acute dystonias.

Corticosteroids

By reducing gastrointestinal motility, neuroleptic drugs enhance the absorption of corticosteroids (509).

Digoxin

By reducing gastrointestinal motility, neuroleptic drugs increase the systemic availability of digoxin and other inotropic drugs and thereby increase the potential for toxicity (510).

Guanethidine

Phenothiazines may inhibit the hypotensive action of guanethidine (510). This antagonism does not occur with molindone (508).

Hypoglycemic drugs

Because phenothiazines affect carbohydrate metabolism, they can interfere with the control of blood glucose in diabetes mellitus (387,509).

Levodopa

Levodopa and neuroleptic drugs can interfere with the effects of each other at dopamine receptors; the patient should be monitored for deterioration in both parkinsonism and mental state. If an antiemetic is required in a patient taking levodopa, one that does not affect central dopamine receptors should be chosen.

Lithium

Neuroleptic drugs are often used in mood stabilizer combinations. However, there have been few controlled studies of the use of such combinations, and interactions are potentially dangerous. The advantages and disadvantages of all currently used mood stabilizer combinations have been extensively reviewed (527). Some effects are well known: neurotoxicity, hypotension, somnambulistic-like events, and cardiac and respiratory arrest associated with the combination of lithium and traditional neuroleptic drugs considered as a first-line treatment for classic euphoric mania with psychotic features.

Several cases of neurotoxicity have been reported when lithium was combined with thioridazine, and patients should be carefully monitored (528–530).

Occasionally, long-term use of lithium is associated with cogwheel rigidity and a parkinsonian tremor. More often than not, concurrent or past treatment with a neuroleptic drug is involved. Neuroleptic malignant syndrome has also been reported in patients taking lithium and a neuroleptic drug, such as amoxapine (531), clozapine (532), haloperidol (533), olanzapine, (534), and risperidone (535). However, a causal interaction has not been established (536), and it should also be remembered that lithium toxicity itself can cause neuroleptic malignant syndrome (537).

© 2006 Elsevier B.V. All rights reserved.

Lysergic acid diethylamide

Phenothiazines and butyrophenones can counteract the psychoactive effects of lysergic acid diethylamide (LSD) (538).

Metrizamide

The role of chlorpromazine in facilitating metrizamide-induced convulsions has been confirmed in animal studies (539); phenothiazines should be withdrawn at least 48 hours before intrathecal use of metrizamide.

Monoamine oxidase inhibitors

There can be additive hypotensive effects when monoamine oxidase inhibitors are combined with neuroleptic drugs.

Four healthy volunteers taking moclobemide (600 mg/day for 9 days) had reduced clearance of dextromethorphan, a marker of hepatic CYP2D6 activity (540). These findings suggest that at the higher end of its therapeutic dosage range, moclobemide may inhibit the metabolism of drugs that are substrates for CYP2D6, for example neuroleptic drugs and tricyclic antidepressants (SEDA-22, 14).

Narcotic analgesics

CNS and respiratory depression due to narcotic analgesics can be enhanced by neuroleptic drugs (509).

Oral contraceptives

Estrogen-containing formulations can further promote neuroleptic drug-induced prolactin stimulation (509).

Neuroleptic malignant syndrome occurred in a woman taking haloperidol and thioridazine 12 hours after she started to take an oral contraceptive. The authors suggested that this could have been a pharmacodynamic interaction involving dopaminergic neurotransmission (541).

Phenytoin

Chlorpromazine, and in some cases other phenothiazines, has been reported to increase plasma phenytoin concentrations (542–545), to reduce plasma phenytoin concentrations (543–547), or to have no effect (544). In one case co-administration of thioridazine caused phenytoin toxicity (548).

Phenytoin induces hepatic microsomal drug-metabolizing enzymes and thus reduces concentrations of haloperidol (549,550), thioridazine (550), and tiotixene (551). In two patients phenytoin reduced plasma clozapine concentrations and worsened psychosis (552).

Piperazine

High doses of piperazine can enhance the adverse effects of chlorpromazine and other phenothiazines (553).

Quinidine

Concurrent administration of quinidine with neuroleptic drugs, particularly thioridazine, can cause myocardial depression (508).

Sedatives and hypnotics

Neuroleptic drugs increase sedative- and hypnotic-induced sleep time and respiratory depression. Lower dosages of barbiturates or other hypnotics should be used, at least initially, in patients receiving neuroleptic drugs (508).

Sevoflurane

- A 19-year-old taking cyamemazine for schizophrenia had severe dystonia during inhalation of sevoflurane (554). One minute after taking four or five maximum breaths in a closed system filled with 8% sevoflurane in a 50% nitrous oxide/oxygen mixture, the patient being unconscious, torticollic posturing began to develop and the stiffness rapidly extended to the left trapezius and scalenus muscles. This was followed by severe rotation of the head, trismus, and opisthotonos. Muscle spasm resolved with an injection of atracurium 30 mg.

An interaction of sevoflurane with cyamemazine was suggested as a possible explanation, without precluding a role of nitrous oxide.

Spiramycin

Acute dystonia occurred during spiramycin therapy in a patient who was being treated with neuroleptic drugs (323).

SSRIs

Paroxetine and fluoxetine are potent inhibitors of CYP2D6, and can therefore interact with neuroleptic drugs that are metabolized by this enzyme.

- Urinary retention and severe constipation occurred in a patient who started to take sertraline when already taking haloperidol and clonazepam (555). After a week, she discontinued sertraline and her symptoms disappeared in a few days.

Three of fourteen adults with Gilles de la Tourette syndrome had acute severe drug-induced parkinsonism when neuroleptic drugs and SSRIs were used together (556). There were no adverse reactions in almost 75 children receiving similar treatment. The authors suggested that age-related changes in dopamine neurotransmitter systems could confer vulnerability. On the other hand, SSRIs themselves can cause parkinsonism and also inhibit P450 enzymes, leading to increases in plasma concentrations of neuroleptic drugs during combined treatment (SEDA-20, 50) (SEDA-21, 51) (SEDA-22, 55). Surprisingly, in a double-blind, randomized, placebo-controlled study, there were no significant differences in plasma haloperidol concentrations when sertraline ($n = 18$) or placebo ($n = 18$) were added at 2, 4, 6, and 8 weeks (557).

Thiazide diuretics

Combined use of neuroleptic drugs and thiazide diuretics has rarely resulted in severe hypotension (508).

© 2006 Elsevier B.V. All rights reserved.

Tricyclic antidepressants

Various neuroleptic drugs inhibit the metabolism of imipramine, nortriptyline, and amitriptyline (SED-11, 114) (558,559).

Valproate

The combination of valproate and traditional neuroleptic drugs, a first-line treatment for mixed or rapid-cycling episodes or dysphoric mania with psychotic features, is associated with altered mental status and electroencephalographic abnormalities (527).

Smoking

Smoking, common in schizophrenics (SEDA-20, 44), has important effects on plasma concentrations of neuroleptic drugs.

Interference with Diagnostic Tests

Pregnancy testing

Phenothiazines can cause a false-positive pregnancy test, but only with the virtually obsolete Ascheim–Zondek animal test method (SED-11, 115).

Urinary ketones

Phenothiazines can cause increased urinary ketones (ferric chloride test) (SED-11, 115).

Urinary steroids

Phenothiazines can interfere with the measurement of urinary steroids (colorimetry) or oxosteroids (Porter–Silber test) (SED-11, 115).

Neuromuscular blocking drugs

See also Individual agents

General Information

There are two broad classes of neuromuscular blocking drugs: non-depolarizing agents, of which the prototype is curare (for example, d-tubocurarine, atracurium, metocurine, mivacurium, pancuronium, rocuronium, vecuronium) and depolarizing blockers, such as suxamethonium. This monograph is largely concerned with the former; suxamethonium is the subject of a separate monograph.

Non-depolarizing neuromuscular blocking agents compete with acetylcholine for receptors at the neuromuscular junction and clinical relaxation begins when 80–85% of the receptors on the motor end-plate are blocked. They do not produce depolarization themselves and, by blocking access to the receptors, prevent the normal acetylcholine-induced depolarization. Flaccid paralysis ensues. Their action terminates when acetylcholine again gains access to the receptors, due to diffusion of the relaxant molecules away from the neuromuscular junction. This may be hastened by greatly increasing the number of acetylcholine molecules at the motor end-plate by giving an anticholinesterase such as neostigmine. In contrast, the depolarizing blockers first depolarize the motor end-plate and then prevent further depolarization.

Combining different non-depolarizing neuromuscular blocking agents can result in additive or synergistic effects. When pancuronium is given together with D-tubocurarine or metocurine, the resulting block is greater than would be expected if the effects were purely additive. This potentiation is not seen with the metocurine D-tubocurarine combination (1). Synergism resulting from such combinations is thought to be a postsynaptic effect (2). When different non-depolarizing agents are given consecutively, the neuromuscular blocking action of the second may be considerably modified by the first; the action of vecuronium, for example, lasts longer than expected if pancuronium has been given first (SEDA-11, 124) (3). Caution should therefore be exercised when giving a small dose of a normally short-acting non-depolarizer near the end of an operation when another long-acting agent has been given earlier. The resulting block can be greater than expected and last much longer than desired. Reversal with anticholinesterases can be difficult at the end of surgery if the block is still greater than 90%.

Specialized accounts of adverse effects and interactions in this field are available (4–7), including a review of the older literature (8).

Organs and Systems

Ear, nose, throat

Endotracheal intubation is less traumatic when it is facilitated by a muscle relaxant. Vocal cord hematoma after intubation occurred in six of 36 patients when only fentanyl plus propofol was used, compared with one of 37 when atracurium was added (9).

Nervous system

Drug accumulation will result in paralysis lasting from hours to days. Occasionally, however, paralysis can persist for weeks or even months because of relaxant-associated myopathy (10). Muscle weakness, causing difficulties in the subsequent weaning of such patients from artificial ventilation, has often been described (11–15). This condition has been observed most often after concomitant administration of muscle relaxants and high-dose glucocorticoids, typically in patients with exacerbated asthma requiring mechanical ventilation (16–21). It is not known how these factors combine to produce myopathy; myopathic changes can also occur after either high-dose glucocorticoid therapy or long-term muscle relaxant administration alone. Serial electrophysiological testing, and eventually muscle biopsy, is necessary to diagnose myopathy accurately and to avoid useless trials of weaning the patient from the ventilator. Within some weeks, muscle weakness will resolve sufficiently to allow successful weaning, but extensive rehabilitative measures are required for several months until the patient is independent. In view of the multitude of potential mechanisms of muscle weakness in critically ill patients, it is advisable always to monitor neuromuscular function and to avoid complete paralysis for any length of time in intensive care patients who are treated with muscle relaxants.

Musculoskeletal

Several authors have described heterotopic ossification or myositis ossificans after long-term administration of neuromuscular blocking agents to ICU patients (22–25). However, the causative role of muscle relaxants in the development of this phenomenon has been questioned (26), because of the observation that heterotopic ossification also occurred in critically ill patients not treated with such agents (27). It was suggested that prolonged immobilization is an important factor in the pathogenesis of heterotopic ossification, and that both deep sedation and neuromuscular blockade, by producing complete immobilization, might contribute to the pathophysiology of this severe complication in critical illness, which may require prolonged rehabilitation and surgical removal of ectopic

bone to allow the patient to be ambulatory and self-sufficient.

Residual paralysis

Residual paralysis after the use of long-acting muscle relaxants, such as pancuronium, is not uncommon and can result in significant pulmonary complications (28). Many anesthetists have assumed that this was less of a problem with agents of intermediate duration. However, a surprisingly high incidence of residual neuromuscular impairment has been reported after a single intubating dose of muscle relaxants of intermediate duration as well (29). Two hours after either rocuronium, vecuronium, or atracurium, the train-of-four ratio was still below 0.7 in 10% of patients and below 0.9 in 37%, which was not reliably detected by clinical evaluation (head lift, tongue depressor test) or qualitative measurements (repetitive nerve stimulation with tactile evaluation of fade). Similar results have been reported by others (30–33). Pharyngeal dysfunction with a risk of aspiration has been observed in partially paralysed awake volunteers at train-of-four ratios below 0.9 (34–35). Therefore, patients with a train-of-four ratio below 0.9 at the end of the operation should receive a cholinesterase inhibitor, such as neostigmine, in order to reduce the impact of residual paralysis. This obviously implies that quantitative monitoring of neuromuscular transmission should be used routinely. Only if this is not possible should a cholinesterase inhibitor be given blindly. This represents a change in our opinion: we had previously stated that anticholinesterase drugs should be used to reverse residual neuromuscular block detected by monitoring of neuromuscular transmission or producing clinical symptoms (SEDA-24, 157). Now we acknowledge that a reversal agent is justified, even in asymptomatic patients, because residual dysfunction of certain muscle groups may still be present. For the time being, there is nothing to support the routine use of an anticholinesterase drug if spontaneous recovery with a train-of-four ratio of 0.9 or above can be demonstrated. We should like to stress that attempts to reverse intense neuromuscular blockade must be avoided. Therefore, some evidence of recovery of neuromuscular transmission (for example spontaneous ventilation, voluntary movements, twitch response to nerve stimulation) should be observed before any anticholinesterase is given. In addition, it should be mentioned that large doses of cholinesterase inhibitors can cause deterioration rather than improvement of neuromuscular function (36,37). It is unnecessary to use more than 2.5 mg of neostigmine or equivalent (38). Neostigmine 1.25 mg or equivalent can be as effective (39) and is associated with a reduced incidence of postoperative nausea and vomiting (40).

Immunologic

Hypersensitivity reactions can occur with all neuromuscular blocking agents, including the newer agents (41–43). Allergic reactions during anesthesia have been reviewed (44).

Frequency

The incidence of life-threatening anaphylactic or anaphylactoid reactions occurring during anesthesia is variably reported as being between one in 1000 and one in 10 000 anesthetics (45,46), and in one survey was one in 6500 (47). The frequency quoted depends on the criteria used. An epidemiological study (48) has suggested that the incidence is somewhat greater than one in 5000 anesthetics. The mortality from such serious reactions is reported to be in the range of 3.4–6% (46–48). Minor systemic reactions attributable to histamine release probably occur in more than 1% of anesthesia (49). Neuromuscular blocking drugs are the triggering agents in 50% or more of these reactions (50–52), and of them D-tubocurarine is the most potent histamine liberator. During the last two decades, however, several large series of patients have been investigated, and the data suggest that suxamethonium is the relaxant most likely to produce life-threatening reactions, if allowances are made for the frequency of usage of the different agents (SEDA-17, 12) (48,50,52–56). Pancuronium has repeatedly been shown to be the relaxant least often associated with anaphylactoid reactions major or minor.

The incidence of allergic reactions to several muscle relaxants has been assessed in relation to the number of vials sold in France (57). In line with a previous publication (58), the proportion of reported reactions to rocuronium was higher than its corresponding market share. Based on that, the authors suggested classifying the risk of allergic reactions to neuromuscular blocking agents as high (suxamethonium, rocuronium), intermediate (pancuronium, vecuronium, mivacurium), and low (atracurium, cisatracurium). This classification is based on the assumption that the ratio of used/sold vials is similar for each agent, which may or may not be true. The authors themselves insisted that they did not recommend one muscle relaxant over another on the basis of their allergic potential (59). As highlighted before (SEDA-26, 150), there are significant methodological and statistical problems when such rare events are compared. What we need is an international network of clinics specialized in investigating patients after suspected intraoperative allergic reactions, and the French GERAP centers are an excellent example of this.

Mechanisms

Much controversy still surrounds the issue of the possible mechanisms by which a neuromuscular blocking agent produces the clinical picture of an anaphylactoid reaction, but new insight into the matter has been gathered (60). In most cases (that is the mechanism is a Type I hypersensitivity reaction) (50,52,56,61,62), even though the frequent lack of previous exposure to relaxants seems to exclude this. Direct histamine release and several other mechanisms have also been postulated (63,64). Non-specific histamine release probably is dose dependent (60). Drug-specific IgE antibodies to suxamethonium and other neuromuscular blocking agents have been demonstrated (52,65,66). It has been hypothesized that such antibodies are directed against quaternary and tertiary ammonium ion determinants (65,66). This would help to explain the phenomenon of cross-reactivity with different relaxants and also suggests that prior sensitization could occur via other quaternary or tertiary ammonium-ion-containing compounds in drugs, cosmetics, disinfectants, and the

© 2006 Elsevier B.V. All rights reserved.

like (50,61). Two quaternary ammonium groups may be necessary for histamine release by neuromuscular blocking agents (62,63).

Diagnosis

Anaphylactoid reactions are easily misdiagnosed during anesthesia (67), since circulatory collapse accompanied by sinus tachycardia may be the only signs (49). These are the presenting features in 70–90% of cases. Mucocutaneous manifestations (erythema, urticaria, angioedema) are reported in 60–80% of reactions, but are often only noticed much later when the acute phase is over. Bronchospasm is present in about 40% of cases. Reactions are more common in women (up to 80%), in atopic patients, and in those who have a history of asthma (who are particularly prone to develop bronchospasm) or allergy, and in patients who have had a previous reaction to anesthetic drugs (50,53); they also seem to be more common in patients under 40 years of age (54).

The diagnosis of an allergic reaction to a muscle relaxant is based on clinical features, measurement of histamine and tryptase concentrations in the plasma during the reaction, and subsequent skin testing a few weeks later. However, during general anesthesia isolated symptoms can occur, most often hypotension or bronchospasm. Therefore, the clinical features of anaphylaxis may not be recognized as such.

The investigation of a reaction during anesthesia requires serial blood samples during the first 24–72 hours and further laboratory tests, such as basophil histamine release, and intradermal skin testing 4–8 weeks later (45,52,53,64,68). Plasma tryptase concentration, measured 30 and 120 minutes after the shock, is a sensitive and relatively specific marker of anaphylaxis (60,69). The possibilities of postmortem diagnosis have now been extended to the use of blood samples taken up to 3 hours after a patient's death and subjected to radioimmunoassay for mast cell tryptase activity and drug-specific IgEantibodies (70). However, histamine and tryptase concentrations may be ambiguous.

Radioallergosorbent tests (RAST) which detect IgE antibodies to specific muscle relaxants have been developed (65,66) and are commercially available for some anesthetic drugs (64,71). However, the sensitivity of IgE testing is variable and reached 90–97% in selected specialized centers only (72).

Skin testing has been used to confirm the diagnosis and to identify the causative agent (73). The sensitivity of skin testing for reactions to muscle relaxants is thought to be greater than 95% (73), although significantly lower for opioids, barbiturates, and synthetic colloids (44). However, opinions differ as to the value and the reliability of intradermal skin testing. The proponents of skin testing emphasize that strict criteria must be used in performing and interpreting the tests (74).

Additional biological tests have been suggested to improve the accuracy further. The leukocyte histamine release test has been found helpful (75) but it is expensive and time-consuming. Several surface molecules have been studied as markers, for example CD63. IgE-mediated degranulation of basophils after incubation of the patient's serum with a neuromuscular blocking agent can be detected by flow cytometry if a relevant proportion of basophils express the surface marker CD63 (76–77). An assay for CD63 and CCR3 was reported to have a sensitivity of 54% compared with 63% for the detection of specific IgE (78). Combined, these tests had a sensitivity of 80% and a specificity of 100%. The authors regarded this as a promising approach to the diagnosis of muscle relaxant allergy in cases where discrepancies between the clinical presentation and the laboratory result.

Morphine, which has a single substituted quaternary ammonium ion group, binds to antibodies that react with neuromuscular blocking drugs. Morphine radioimmunoassay was more sensitive in detecting IgE antibodies to neuromuscular blocking agents than assays specific for the various agents (79). Consequently, morphine radioimmunoassay was suggested as a diagnostic tool in cases of suspected anaphylaxis to neuromuscular blocking agents. In addition, IgE-mediated degranulation of basophils after incubation of the patient's serum with a neuromuscular blocking agent may be detected by flow cytometry if a relevant proportion of basophils express the surface marker CD63 (76,77).

Prevention and treatment

Measures for the prevention and treatment of hypersensitivity reactions have been reviewed (53,54,80,82).

The possibility of cross-reactivity with different relaxants (80,83,84) should also be investigated and the patient issued with an appropriate warning-card. After an anaphylactic reaction during anesthesia, the drug responsible is usually determined by skin testing. Most often in such cases, a neuromuscular blocking drug is found to be the triggering substance, and since cross-sensitivity between neuromuscular blocking agents can occur, a variety of these drugs should be tested. Neuromuscular blocking agents that produce negative skin results are considered safe for future anesthesia. However, there have been descriptions of several patients with previous anaphylactic reactions to neuromuscular blocking agents who had a second severe anaphylactic reaction when skin-test negative agents were used (85,86). The authors assumed that the skin tests had been falsely negative in these patients, but they conceded that newly acquired sensitivity might also have been an explanation. They concluded that all neuromuscular blocking agents should be avoided in patients with previous anaphylaxis to one of these drugs. If that is not possible the patient should be given antiallergic pretreatment and the anesthetic team should be prepared for resuscitation. In addition to standard pretreatment with both H1 and H2 histamine receptor antagonists, monovalent haptens might prove effective in blocking anaphylaxis to neuromuscular blocking agents (80).

Second-Generation Effects

Pregnancy

The pharmacokinetics of neuromuscular blocking agents in pregnancy and the impact on anesthesia for cesarean section have been reviewed (87). Key statements are:

(1) The umbilical/maternal vein concentration ratio of non-depolarizing neuromuscular relaxants varies

© 2006 Elsevier B.V. All rights reserved.

from 7 to 26%. Clinical doses of these drugs can induce partial curarization in neonates.
(2) Despite reduced plasma cholinesterase activity, the duration of effect of suxamethonium 1 mg/kg is usually not significantly increased in pregnant women.
(3) At clinical doses, transplacental passage of suxamethonium is insufficient to produce paralysis of the neonate.

However, inadequate muscular activity requiring ventilatory support has been reported in babies born to mothers with atypical plasma cholinesterase.

Susceptibility Factors

Age

Children

Neonates are said to be more sensitive to non-depolarizing neuromuscular blocking drugs. Neonates have a lower muscle mass per kilogram body weight, maturation of neuromuscular transmission occurs in the 2 months after full-term birth (88,89), and the "margin of safety" for neuromuscular transmission (that is the fraction of receptors that must be occupied before neuromuscular block can be detected) is reduced in infants under 12 weeks of age (90). Thus, smaller doses should be used in the very young. The greater body water content of neonates, however, tends to mitigate the increased sensitivity, so that several authors recommend similar doses to adults (calculated on a body weight basis). Owing to longer elimination half-lives, recovery is slower in neonates and maintenance doses are needed at longer intervals (91), certainly where most of the older, long-acting relaxants are concerned. There are conflicting data about whether the actions of vecuronium and atracurium (and even pancuronium) are prolonged or not (92).

Most investigators concur that neonates and infants require a larger dose per kilogram of suxamethonium (2–4 mg/kg) to achieve an equivalent effect to that seen in adults. In young children the plasma clearance of non-depolarizing relaxants is quicker and their duration of action shorter (93,94), so that doses may have to be given more often.

Interindividual variation in dose requirements is even more marked in neonates and infants than in adults, so that monitoring of neuromuscular function is essential. Small dysmature babies, especially with temperatures below 36°C, are notoriously unpredictable in their response to relaxants.

Elderly people

In elderly people there is much slower recovery from non-depolarizing relaxants (about 60% in patients over 75 years of age given pancuronium), associated with a decreased rate of elimination (probably through reduced glomerular clearance and, to a lesser extent, reduced hepatic blood flow). The potency of relaxants is not altered. While the initial dose required to produce full relaxation is the same as in young adults, smaller maintenance doses are required at much longer intervals (95,96). The duration of action of atracurium is not increased, since termination of its action does not depend on renal or hepatic function.

Other features of the patient

Acid–base and electrolyte changes

It has long been accepted that respiratory acidosis tends to potentiate the blockade produced by non-depolarizing relaxants and respiratory alkalosis produces resistance to their action. This is true for the monoquaternary agents D-tubocurarine, vecuronium, and rocuronium (possibly by increased conversion to the bisquaternary forms at lower pH), but it may not hold for the bisquaternary relaxants metocurine, pancuronium, and alcuronium (97–99).

Protein binding of muscle relaxants is maximal between pH 8 and 9 and this may account for increased dose requirements in alkalosis.

Alkalosis is often associated with hypokalemia, in which the actions of non-depolarizing agents may be increased and those of depolarizing agents reduced. Hyperkalemia has the opposite effects, probably by lowering muscle transmembrane potential.

Variations in serum sodium affect neuromuscular blocking agents in a similar manner to potassium changes. However, serum concentrations of electrolytes do not always reflect intracellular concentrations or, perhaps more important, the intra/extracellular concentration ratios; in addition, changes in pH and the concentrations of potassium, sodium and other electrolytes are linked and have opposing influences at several sites in the processes of neuromuscular function, so that the expected effect of a change, taken in isolation, may not be found. Nevertheless, it is of practical importance that respiratory acidosis may enhance non-depolarizing block and makes its reversal by neostigmine more difficult. Such a vicious circle in the recovery room is best broken by ventilating the patient until the cause of the respiratory depression is removed or corrected.

Hypermagnesemia enhances the actions of both depolarizing and non-depolarizing neuromuscular blocking agents. Lithium may also do this. Hypercalcemia may be associated with prolongation of suxamethonium blockade and reduced potency of non-depolarizing agents.

Body temperature

In hypothermia, a reduction in blood flow to muscle increases the time to onset of neuromuscular blockade. The actions (depth of block and duration) of depolarizing relaxants are increased. The potency of non-depolarizing neuromuscular blocking agents is reduced according to some investigators, while others maintain that potency is increased and the duration of action prolonged (100–102). Hypothermia produces different changes in the twitch (103) and electromyographic (104) responses to nerve stimulation in the absence of relaxants. The excretion and the metabolism of relaxants are reduced by hypothermia.

Hemodilution

Hemodilution (for example the replacement of 1 liter of blood by dextran-40) increased the potencies and prolonged the actions of suxamethonium, pancuronium, D-tubocurarine, and vecuronium (SEDA-17, 151) (105). To avoid this, blood collection should be carried out before the administration of anesthetic drugs.

Muscle diseases

The neuromuscular blocking effects of muscle relaxants in patients with neuromuscular disorders can differ significantly from those in healthy individuals. This can result in overdose and residual curarization on the one hand or in inadequate muscle relaxation on the other. Patients with Duchenne muscular dystrophy often require surgery for contractures and kyphoscoliosis. The neuromuscular blocking effects of vecuronium in eight children with Duchenne muscular dystrophy (11–15 years old) have been compared with those in eight children (8–18 years old) without this disease (106). After vecuronium 50 microgram/kg, the median train-of-four ratio was 0.14 in the patients versus 0.86 in the controls. The median time for recovery of the train-of-four ratio from 0.1 to 0.25 was 36 minutes in the patients versus 6 minutes in the controls. The authors concluded that patients with Duchenne muscular dystrophy need smaller initial doses of vecuronium. Because of the increased recovery time, patients should be closely observed for signs of residual curarization. Monitoring of neuromuscular transmission is strongly recommended in all patients with neuromuscular disorders who are given neuromuscular blocking agents.

Organ failure

Long-term administration of non-depolarizing muscle relaxants can result in prolonged paralysis, owing to accumulation of the drug itself or of pharmacologically active metabolites (107,108). Patients with renal or hepatic insufficiency are prone to this complication, but prolonged paralysis also has been noted in patients without these risk factors. The incidence of prolonged paralysis can probably be reduced if neuromuscular transmission monitoring is used to guide relaxant administration (109,110). In addition, agents with non-organ-dependent metabolic pathways may be of advantage (111). Residual curarization is only one of the potential reasons for prolonged paralysis after long-term neuromuscular blockade in severely ill patients. The interaction of different agents with other neuromuscular abnormalities, such as relaxant-associated myopathy, critical illness polyneuropathy, or other myopathic changes in the critically ill, still have to be evaluated.

Use in the intensive care unit

In the intensive care unit muscle relaxants are used to facilitate airway management and mechanical ventilation. The duration of administration can range from a single dose to continuous infusions for up to several weeks. Patients in ICU are more likely to have abnormalities of acid–base balance, electrolyte balance, body temperature, and liver and kidney function, predisposing them to the adverse effects of neuromuscular blocking drugs.

The most dangerous adverse effect of muscle relaxants in the ICU is suxamethonium-induced hyperkalemic cardiac arrest (112–117). Prolonged immobilization is believed to result in a spread of immature acetylcholine receptors on the muscle surface, which may mediate massive long-lasting potassium release if suxamethonium is given (118). By this mechanism, cardiac arrest can occur within minutes after suxamethonium administration. Standard resuscitative techniques have often failed, and several patients have died of this complication. Suxamethonium should therefore not be used in patients who are immobilized in the ICU for more than a few days. The shortest period of immobilization reported to be associated with fatal hyperkalemic cardiac arrest after suxamethonium administration was 4 days in a previously healthy young woman with bacterial meningitis (117).

Drug–Drug Interactions

Antibiotics

In very high doses or in sensitive patients (for example in myasthenia), antibiotics can produce paralysis and act additively or synergistically with neuromuscular blocking drugs.

Aminoglycosides

The aminoglycosides have a magnesium-like effect, acting prejunctionally to reduce transmitter release and postjunctionally to increase transmitter release; they also reduce postjunctional sensitivity to acetylcholine. In most cases their effects can be reversed, partly at least by calcium or 4-aminopyridine. Tobramycin is thought also to have a direct effect on muscle.

Beta-lactam antibiotics

Penicillins G and V (119) have been reported to cause neuromuscular block in animal preparations, but only at exceptionally high doses. Calcium is effective in reversal. The acylaminopenicillins augment vecuronium-induced blockade (120). Possible "re-curarization" with piperacillin was successfully reversed by neostigmine (121).

Lincosamides

The lincosamides have prejunctional and postjunctional effects, the principal action probably being on the muscle. This blockade is difficult to reverse with cholinesterase inhibitors or calcium.

Polymixins

The polymyxins probably produce a predominantly postjunctional effect (via ion channel block) and reduce muscle contractility. The block is difficult to reverse, calcium being only partly successful. Neostigmine has been reported to increase blockade produced by polymyxin B and colistin; in such cases 4-aminopyridine might be helpful.

Tetracyclines

The tetracyclines produce a small effect, partly by calcium chelation, thus reducing transmitter release. Reversal is usually, but inconsistently, obtained with calcium or neostigmine.

Peptide antibiotics

An unusually high dose of vancomycin augmented vecuronium-induced block during recovery, thus delaying the detubation of the patient for about 30 minutes (SEDA-16, 7). In another patient vancomycin prolonged the recovery

© 2006 Elsevier B.V. All rights reserved.

from blockade induced by a suxamethonium infusion for some hours (SEDA-18, 14).

Management

If it is suspected that an antibiotic is contributing to prolonged neuromuscular blockade, the patient should be monitored and the effect of calcium (up to 1 g of calcium chloride slowly) should be observed. If this is unsuccessful, neostigmine (maximum dose 5 mg for an adult) or edrophonium (0.5 mg/kg) can be tried, but these agents may intensify a block due to colistin, lincomycin, or polymyxin B. If the other remedies fail, 4-aminopyridine (maximum dose 0.3 mg/kg) can be successful. Artificial ventilation should be continued until adequate spontaneous efforts are achieved and other possible factors, such as acidosis or electrolyte disturbances, are corrected.

This subject has been reviewed (119,122,123).

General anesthetics

Inhalational anesthetics

The volatile inhalational anesthetic agents and cyclopropane potentiate the actions of neuromuscular blocking drugs. The extent depends on the particular relaxant and inhalational agent used and the concentration of the latter. In comparative studies, isoflurane was the most potent in this respect, enflurane almost as potent, and both were 2–3 times more potent than halothane, which was in turn twice as potent as nitrous oxide, the volatile agents being administered at concentrations of 1.25 MAC (mean alveolar concentration) and the relaxant studied being D-tubocurarine (124). Concerning the older agents, the relaxant dose can be reduced by half with ether anesthesia and by one-fifth or more when cyclopropane is used. The degrees of potentiation by ether and cyclopropane probably lie between those of enflurane and halothane.

The higher the anesthetic concentration, the greater the degree of potentiation and the smaller the dose of relaxant needed (125). The full potentiating effect will only be seen when the tissues are saturated by the inhalational agent. Reducing the concentration of the inhalational agent generally reduces the degree of neuromuscular blockade (126), a desirable feature at the end of an operation. However, this maneuver can take some time to be effective (about half-an-hour for enflurane) and will only diminish the "volatile" contribution to the total block. Nevertheless, there may be occasions, such as in patients with myasthenia or renal or hepatic disease, when the advantages of using higher concentrations of inhalational anesthetic and lower doses of relaxants may outweigh the disadvantages (127).

The potentiation of D-tubocurarine block produced by enflurane slowly continues to increase with time, even after the usual equilibration period has passed (SEDA-5, 132) (128). This does not occur with halothane, and the discrepancy is said to mean that more D-tubocurarine will be required in the first hour of enflurane anesthesia than during equipotent halothane anesthesia, but that thereafter less will be required during enflurane anesthesia. It has been suggested that enflurane, unlike halothane, may produce an effect on muscle that takes time to develop. This may also be part of the mechanism, in addition to the greater potentiating action of enflurane, that explains the report that there is slower spontaneous recovery from pancuronium and a greatly impaired antagonistic effect of neostigmine in patients anesthetized with enflurane 1.3–1.4% compared with halothane 0.55–0.65% (end-tidal, in 70% nitrous oxide) (129). The experimental conditions in this last study, however, were somewhat different from usual clinical practice (130).

It is unfortunately not possible to come to a categorical conclusion on precisely how great the potentiation of a given relaxant will be by a particular inhalational anesthetic, because the effects of inhalational agents are multifactorial and diverse, and the numerous studies done have involved different methods (125,127,131–134). Very approximately, isoflurane and enflurane potentiate the longer-acting relaxants, such as D-tubocurarine and pancuronium, by 50–70% and the shorter-acting agents, vecuronium, atracurium, and mivacurium, by 20–25%. However, the degree of potentiation reported for the shorter-acting relaxants varies greatly (from 0 to 70% for vecuronium), depending on the duration of exposure of the skeletal muscles to the inhalational agent, the mode of nerve stimulation, whether the relaxant is given as a single bolus or by cumulative bolus doses or by infusion (steady-state or not), and the nature of the circulatory changes produced. The potentiation produced by halothane is much less than for isoflurane and enflurane.

Muscle relaxants may also contribute to anesthesia. Pancuronium 0.1 mg/kg has been reported to lower the MAC for halothane by 25% (135). It was conjectured that this could be due to a central effect or peripheral effect, through reduction of afferent input from muscle spindles to the reticular activating system. Recently, however, a similar though not identical study (SEDA-15, 124) (136) failed to confirm that pancuronium, vecuronium, or atracurium lowers the MAC for halothane.

Intravenous anesthetics

Intravenous anesthetic agents have much less influence on the neuromuscular blocking effects of relaxants and most have no clinically significant effect. However, ketamine (SEDA-14, 113) has been reported to significantly potentiate atracurium (137), and also D-tubocurarine but not pancuronium (138) in man. Animal studies suggest that all relaxants will be potentiated by ketamine in a dose-dependent manner (139,140). It has been suggested that had Johnston et al. (138) used a higher dose of ketamine (than 75 mg/m^2), they would have seen potentiation of pancuronium. The main effect of ketamine appears to be a reduction in the sensitivity of the postjunctional membrane to acetylcholine, possibly by ion-channel blockade. Propofol has been reported to potentiate vecuronium-induced and atracurium-induced blocks (141).

Laboratory investigations have shown that some benzodiazepines can produce biphasic effects (142,143), higher doses potentiating neuromuscular blocking agents (142,144); however, several human investigations have failed to show a significant effect (145–147). It has been suggested that agents that are added to commercial formulations of some benzodiazepines to render them more water-soluble may mask the benzodiazepine effect (147).

Nevirapine

See also Non-nucleoside reverse transcriptase inhibitors (NNRTIs)

General Information

Nevirapine is a non-nucleoside reverse transcriptase inhibitor (1). Concerns about the adverse effects of nevirapine have delayed its implementation in preventing perinatal HIV. Decision analysis has been used to compare three strategies: a single dose of nevirapine, a short course of zidovudine, and no intervention (2). The

© 2006 Elsevier B.V. All rights reserved.

authors concluded that nevirapine would prevent more deaths than either zidovudine and no intervention, as long as the rate of nevirapine toxicity did not respectively exceed nine and 42 times that observed in an earlier nevirapine clinical trial (HIVNET). Nevirapine would be economically preferable to zidovudine as long as the rate of toxicity did not exceed 22 times that observed in the clinical trial. They thought that implementation of nevirapine should not be delayed by concerns about its adverse effects.

Observational studies

In 77 HIV-positive subjects randomized to switch from protease inhibitors to nevirapine or efavirenz or to continue taking protease inhibitors, quality of life significantly improved among those who switched (3). Lipid profiles improved in those who took nevirapine but gamma-glutamyltransferase and alanine aminotransferase activities increased significantly and one patient interrupted treatment because of hepatotoxicity.

Organs and Systems

Psychological, psychiatric

Various psychiatric abnormalities (delirium, an affective state, and a psychosis) have been described in three patients who took nevirapine for 10–14 days (4):

- cognitive impairment, clouding of consciousness, and a paranoid episode in a 35-year-old man
- delusions of persecutory and depressive thoughts in a 42-year-old woman
- delusions of persecution and infestation and hallucinations in a 36-year-old woman

All three responded to withdrawal of nevirapine.

Metabolism

Lipodystrophy, well recognized with stavudine, has also been reported in nine of 56 patients taking combined HAART therapy including nevirapine, although there must be some doubt as to which drug or combination was responsible (5).

Hematologic

Two patients developed grade 4 thrombocytopenia (under 25×10^9/l) after 42 and 151 days of treatment with nevirapine (6). In the first patient, zidovudine and intravenous immunoglobulin were added to continued nevirapine, and the thrombocytopenia resolved by day 89. In the second, nevirapine was discontinued and alternative antiretroviral therapy was started, whereupon the platelet count returned to normal within 22 days.

Liver

The most frequent laboratory abnormality during nevirapine treatment is an increase in serum gamma-glutamyl transpeptidase activity, usually without changes in other measures of hepatic function. However, in a randomized, placebo-controlled comparison of zidovudine plus nevirapine, zidovudine plus didanosine, and the triple combination of zidovudine plus didanosine and nevirapine in 151 patients, there were abnormal liver function tests in increased frequency in the patients taking nevirapine (19% and 12% versus 6%) (7). Five of 98 patients taking nevirapine had to stop the drug permanently because of raised alanine aminotransferase activity, after which the laboratory abnormalities resolved completely.

Of 70 HIV-infected patients taking nevirapine 33 developed rises in transaminase activities (8). Higher nevirapine concentrations and hepatitis C virus infection were independent predictors of liver toxicity. In those with chronic hepatitis C, nevirapine concentrations over 6 μg/ml were associated with a 92% risk of liver toxicity. The authors concluded that monitoring nevirapine concentrations, especially in individuals with chronic hepatitis C, may be warranted.

In a prospective study of the incidence of severe hepatotoxicity in 312 patients taking nevirapine, hepatitis C and hepatitis B viruses were detected in 43% (9). There was severe hepatotoxicity in 16%, but only 32% of episodes were detected during the first 12 weeks of therapy. The risk was significantly greater among those with chronic viral hepatitis (69% of cases) and those taking concurrent protease inhibitors (82% of cases). However, 84% of patients with chronic hepatitis C or hepatitis B did not have severe hepatotoxicity.

Severe hepatitis has been attributed to nevirapine (10).

- A 36-year-old woman with HIV and hepatitis C infection developed fever, right upper quadrant pain, headache, confusion, and a generalized skin rash. Her antiretroviral treatment included lamivudine (150 mg bd), stavudine (40 mg bd), and nevirapine (200 mg bd). The dose of nevirapine had been doubled 2 weeks before. Her laboratory results were as follows: white cell count 4.1×10^9/l with 18% eosinophils, aspartate aminotransferase 879 U/l, alanine aminotransferase 1424 U/l, lactate dehydrogenase 3268 U/l, activated prothrombin time 14 seconds, partial thromboplastin time 29 seconds. Abdominal ultrasound was normal. Her antiretroviral medications were stopped. She was given intravenous prednisolone (60 mg 6-hourly) and within 8 hours the signs of sepsis had abated and her liver function began to improve and resolved over the next few days. Several weeks later, she was rechallenged with lamivudine and zidovudine, without recurrence of liver toxicity or rash.

The authors argued that, although the syndrome could not be definitively attributed to nevirapine, several factors suggested that nevirapine was the most likely precipitant, including the fact that hepatic failure coincided with a systemic allergic response, which is commonly associated with nevirapine, especially after dose escalation. The rapid improvement with steroid therapy suggested that the hepatic failure was a manifestation of a systemic hypersensitivity reaction. However, since stavudine has also been associated with hepatitis, a causative role of stavudine cannot be excluded. The fact that lamivudine was given again without recurrence of hepatitis renders it an unlikely culprit.

In another case there was severe hepatic failure, which resolved on withdrawal and in which there was no other obvious cause than the use of nevirapine (11).

© 2006 Elsevier B.V. All rights reserved.

Significant hepatic deterioration, consistent with cholestasis, occurred 5 months into a HAART regimen including nevirapine (12).

- A 49-year-old man with severe factor VIII deficiency and stable chronic hepatitis C infection took stavudine, didanosine, and nevirapine. After 5 months of well-tolerated therapy, during which his viral load fell from 39 550 cpm to under 50 cpm, he developed anorexia, nausea, vomiting, fatigue, agitation, and biochemical evidence of deteriorating liver function. All drugs were withdrawn. There was no evidence of an infective cause and his hepatitis C status had not changed. Transvenous biopsy of the right hepatic lobe showed profound cholestasis and mild sinusoidal fibrosis, consistent with drug-induced cholestasis.

In four men aged 27, 41, 47, and 49 years, nevirapine was associated with a skin rash, malaise, and icteric hepatitis, 4–6 weeks after the start of therapy; resolution occurred after withdrawal of nevirapine (13).

Two health-care workers exposed to HIV developed severe hypersensitivity reactions to nevirapine; one required orthotopic liver transplantation to overcome the complications of acute hepatic failure and coma (14).

Skin

The principal, dose-limiting, adverse effect of nevirapine in adults is a rash, which occurs in 3–20% of patients, and which progresses to Stevens–Johnson syndrome in 0.5–1% of cases (15). Rash appears to be sex-specific; in 95 women and 263 men, women had a seven-fold higher risk of severe rash and were 3.5 times more likely to discontinue nevirapine than men (16).

In a review of the medical records of HIV-positive patients who had taken nevirapine, delavirdine, or both, the frequency of skin reactions was determined, as were the consequences of rechallenge with the same or the alternative agent (17). The overall incidence of rash attributed to the use of one of the non-nucleoside reverse transcriptase inhibitors (NNRTIs) was 37%. While rash due to delavirdine was more common (8/20 versus 25/69), the rash due to nevirapine was more severe and necessitated more frequent hospitalization. Rash recurred in six of eight patients who were rechallenged with the same agent and in seven of 10 who were switched to the alternative agent. The conclusion was drawn that there is little value in attempting to re-treat patients who have had skin reactions to NNRTIs, except possibly those with limited treatment options.

In a multiple dose study, 21 children aged 3 months to 15 years were treated with nevirapine in dosages of 7.5–400 mg/m^2/day for up to 168 days (18). When it was intended to use dosages over 240 mg/m^2/day they were pretreated with a lower dosage (120 mg/m^2/day) for 28 days to reduce the risk of rash. However, a rash developed in one child after 2 weeks of treatment with nevirapine at a dosage of 240 mg/m^2/day, resolved on withdrawal, and recurred on rechallenge with a single dose of 120 mg/m^2.

An unusually high incidence of nevirapine-associated rash has been reported in Chinese HIV-infected patients (19). Of eight Chinese patients, five developed a rash within 4 weeks of treatment, resolving on withdrawal. Since the total number of patients in this report was small, it remains to be shown whether Chinese are indeed at increased risk of hypersensitivity reactions to nevirapine.

Prevention

While skin reactions to nevirapine cannot be prevented by the use of glucocorticoids (6,20), it is possible to induce tolerance to them, enabling treatment to continue (6). All the same, very severe skin reactions, with characteristics of both Stevens–Johnson syndrome and Lyell's syndrome, have occasionally been reported (21).

A 14-day lead-in period reduces the frequency of rash, and other effective interventions include antihistamines and a longer lead-in period (4 weeks) (22). In an attempt to reduce the rate of nevirapine-associated rash, 469 patients were randomly assigned to different schedules of induction therapy (23). Using a standard procedure, 19% developed a rash compared with 11, 8.6, and 7.7% in subjects assigned to a slowly escalating dose, concomitant administration of prednisone, or both. The rate of drug withdrawal was also reduced by a half using the new approaches.

Drug–Drug Interactions

Methadone

When methadone is used in HIV infection (for pain or treatment of opioid dependence) nevirapine given simultaneously can reduce methadone blood concentrations, the effect being sufficient to cause methadone withdrawal symptoms (24,25).

Oral contraceptives

The mutual pharmacokinetic interaction of nevirapine with ethinylestradiol + norethindrone has been studied in 10 women (26). After a single dose of ethinylestradiol + norethindrone, they took oral nevirapine 200 mg/day (days 2–15), followed by 200 mg bd (days 16–29); on day 30 they took another dose of ethinylestradiol + norethindrone. Steady-state nevirapine reduced the AUC of ethinylestradiol by 29% and significantly reduced its mean residence time and half-life. The AUC of norethindrone was significantly reduced by 18%, but there was no change in C_{max}, mean residence time, or half-life. The kinetics of nevirapine were not affected by the oral contraceptive. The authors attributed this interaction to increased clearance of ethinylestradiol and concluded that oral contraceptives should not be the primary method of birth control in women of child-bearing potential who are taking nevirapine.

Protease inhibitors

Nevirapine induces CYP3A4 and therefore interacts with drugs such as protease inhibitors (27).

St John's wort

St John's wort reduced nevirapine concentrations, because of induction of CYP3A4 (28).

© 2006 Elsevier B.V. All rights reserved.

Warfarin

Nevirapine induces the metabolism of warfarin.

- A 38-year-old man with severe primary pulmonary hypertension and AIDS took warfarin 2.5 mg/day while he was taking zidovudine plus didanosine (29). His INR was 2.1–2.4. Later, because of virological failure, he was given a combination of stavudine, lamivudine, and nevirapine, and the INR promptly fell to 1.3. The dosage of warfarin was increased to 5 mg/day and anticoagulant activity was restored. All the antiretroviral drugs were then stopped because of an urticarial eruption, and a few days later stavudine, lamivudine, and saquinavir were given; warfarin 2.5 mg/day produced a stable INR.

Nicardipine

See also Calcium channel blockers

General Information

Nicardipine is a dihydropyridine calcium channel blocker that has been used intravenously for hypertensive crises in adults, although increase in intracranial pressure was observed in a case series (1).

Organs and Systems

Cardiovascular

Severe bradycardia has been attributed to nicardipine (2).

- A 75-year-old man with atrial fibrillation undergoing surgery for esophageal carcinoma developed hypothermia and bradycardia during anesthesia. In an attempt to reduce his blood pressure of over 190/100 mmHg, he was given intravenous nicardipine 1 mg twice, 3 minutes apart. After the second dose, his blood pressure fell and his heart rate fell to 10/minute. He recovered after cardiopulmonary resuscitation.

The authors suggested that direct suppression of the sinoatrial node by nicardipine in the presence of low sympathetic tone might have been the mechanism of this serious adverse reaction.

Liver

Spider nevi, typical of chronic liver disease, have been seen in patients taking long-term nicardipine (3). The lesions disappeared within 2 weeks of drug withdrawal.

Second-Generation Effects

Pregnancy

Nicardipine has been compared with magnesium sulfate in acute therapy of preterm labor in a randomized trial in 122 women (4). The women treated with nicardipine were less likely to have recurrent preterm labor and adverse effects. Neonatal outcomes were similar in the two groups. The most frequent adverse effect was nausea or vomiting with magnesium sulfate (12/65 women).

Susceptibility Factors

Age

Nicardipine has scarcely been used in children. Intravenous nicardipine was effective in controlling blood pressure in three cases of hypertensive emergency secondary to renal disease (5). Children aged 12–14 years received intravenous infusions of 1–3 μg/kg/minute for 3–27 days, which normalized blood pressure without significant adverse reactions.

Intravenous nicardipine reduced systolic (16%) and diastolic (23%) blood pressures in a retrospective uncontrolled series of 29 children aged 2 days to 18 years (6). Tachycardia was recorded in four patients, palpitation in one, and flushing in one.

Nickel

General Information

Nickel is a white, magnetic, metallic element (symbol Ni; atomic no. 28) that is found in various ores, including annabergite (arsenate), chloanthite (arsenide), garnierite (silicate), millerite, pentlandite, and pyrrhotite (sulfides), and zaratite (carbonate).

Nickel is used in alloys in dental medicine (1) and implant materials (2). Various medical, surgical, and dental routines expose the body to metallic nickel. Exposure to nickel is not always readily traced. For example, it may be present in contaminated cosmetics (SEDA-12, 531) and it may be used in dialysis apparatus. Non-medical exposure is a well-recognized health risk in occupational medicine, but it also occurs after body-piercing; although gold needles are generally used in body-piercing, cheap body-rings are often nickel-plated. Gold salts used in the treatment of rheumatoid arthritis may be contaminated by nickel, thus causing adverse effects not attributable to gold. Nickel (for example as nickel alloys) is also used in orthodontic and orthopedic appliances and in some prostheses.

Many antidotes to nickel poisoning have been tried. Chelating agents and other substances can be used to bind nickel or reduce its penetration through the skin, and hence to reduce symptoms in subjects with nickel sensitivity (3). Topical use is mostly described, but in some studies chelating agents have been given systemically. The most effective ligand for nickel so far described is 5-chloro-7-iodoquinolin-8-ol.

The toxicity of nickel has been reviewed (4).

© 2006 Elsevier B.V. All rights reserved.

Nickel in metal implants and prostheses

Complications from the use of metal implants and prostheses can arise because of biochemical and histological reactions to some of the materials used (SEDA-22, 250). These include titanium, stainless steel (10–14% nickel, 17–20% chromium), and cobalt chrome alloys (27–30% chromium, 57–68% cobalt, and up to 2.5% nickel). All of these metals can produce sensitization or elicit toxic reactions when they are solubilized and come into contact with tissues; it can be difficult or even impossible to differentiate between hypersensitivity and toxic reactions.

Nickel plays a major role in sensitization of patients. Even the small amounts present in cobalt chrome alloys often suffice to elicit allergic reactions. Reactions to cobalt are more generally toxic in nature (5). An increased rate of allergy to cobalt and nickel has been found in those patients bearing metallic implants who have developed bone infection in the surroundings of osteosynthesis material.

Metals from prostheses can continue to be released into the system for many years. The development of hypersensitivity takes time, and allergic reactions are usually delayed for weeks, months, or 1–2 years. The symptoms can assume a variety of forms. Local reactions can cause loosening of the device or local pain. Dermatological reactions include eczema, bullous pemphigoid, urticaria and "muscle tumors."

- A 35-year-old non-atopic diver with no previous history of metal allergy slipped on a wet pier and sustained a multiple compound trimalleolar fracture of the right ankle (6). The tibia and fibula were immediately surgically realigned and retained by metal plates and screws, and the ankle was immobilized in plaster for 5 weeks. One month later he developed itching, scaling, vesiculopapular dermatitis on several fingers of both hands, which worsened over the next few months. Patch-testing was positive to nickel sulfate, chromate, and cobalt.

The author concluded that the patient had become sensitized to nickel and chromate in the orthopedic metals. It was also apparent that sensitization to cobalt had occurred, even though no cobalt could be shown on analysis. The hand dermatitis improved after removal of the metal from the ankle, but nevertheless continued to relapse.

There have been attempts to predict metal sensitivity in the individual patient so that the choice of material can be made accordingly. In vitro tests for metal allergies have been developed on the basis of lymphokine (MIF) release from sensitized T lymphocytes exposed to metal-protein complexes (7). About 6% of patients without a previous metal implant had positive reactions to nickel, chromium, or cobalt. However, it is still not clear whether such a positive reaction is a reliable predictor of clinical problems. In practice few patients have either local or systemic reactions; when symptoms occur and other causes are ruled out, the implant should be removed. Some workers recommend removal of an implant whenever there is both a positive MIF test and a positive skin test, even in the current absence of a serious reaction. Allergic dermatitis will clear up as soon as the metal has begun to be cleared from the tissue. The type of metal and the amount released into the tissue will affect the time taken for the disappearance of toxic dermatological phenomena.

Organs and Systems

Respiratory

The lungs of nickel workers can be affected by a toxic pneumosclerosis resulting from extrinsic alveolitis, as observed in persons engaged in hydrometallurgic nickel production (8). The pathogenesis of the condition includes changes in lung surfactant, an imbalance between lipid peroxidation and antioxidant activity, immune disorders, and the formation of circulating immune complexes.

Immunologic

Nickel allergy is an adverse effect of the use of nickel-containing medical appliances, such as orthopedic metal alloys, dental materials, and implants (9), and allergic reactions are common. Nickel allergy and contact dermatitis with nickel-based appliances have been reviewed (10).

- A 13-year-old non-atopic girl with a 1-year history of recurrent itchy eyelid inflammation and conjunctivitis in both eyes had been fitted with a removable orthodontic appliance 14 months before (11). The metal wires of the orthodontic appliance were made of steel containing 10–13% nickel and 16–19% chromium. Patch-testing confirmed allergy to nickel. A low nickel diet improved the dermatitis, but it did not clear. She was advised to stop wearing the orthodontic appliance, and the ocular lesions cleared within 2 weeks.

In 700 Finnish adolescents, of whom 476 had a history of orthodontic treatment with metallic appliances and others a history of ear-piercing, the frequency of nickel sensitization was 19% (12); in other studies of adolescent girls, among whom body-piercing was popular, sensitivity has been as high as 30%. A review of the literature concerning nickel hypersensitivity in relation to orthodontic appliances has shown that the risk is very low for patients who are not nickel hypersensitive at the start of the treatment (13).

Occupational exposure explains most cases of nickel-associated asthma (14) and rhinitis (15).

Contact dermatitis as a reaction to nickel is well known but usually reflects continuing non-medical exposure, for example among hairdressers (16); nickel released from injection needles and from Dermojets can, however, also give rise to cutaneous hypersensitivity reactions.

Exceptionally, nickel contained in food has caused recurrence of an earlier contact dermatitis to the metal (17); sensitivity to nickel in food may be caused by a type IV immunological reaction in the gut. The commonly recommended patch test procedure is not fully reliable for diagnosing nickel allergy. The lymphocyte transformation test has been suggested as a useful additional tool (18); an increased incidence of HLA-B21 was found in patients with cutaneous nickel hypersensitivity (19).

Although sensitization to nickel sulfate is common in patients with anogenital contact dermatitis and in patients with dermatitis in other body sites, the relevance to anogenital complaints of sensitization to nickel sulfate should

© 2006 Elsevier B.V. All rights reserved.

always be doubted (20–22). However, direct transmission of nickel between the hands and the anogenital region has to be taken into account, and food can be a rare source of nickel contact in the anogenital area. In these cases relevance can be proved by oral nickel provocation and a nickel-restricted diet for a limited period may be justified (23).

The therapeutic use of intramuscular chrysotherapy has been limited by the high incidence of skin adverse effects. The pathogenic mechanisms of these are unknown, but could include allergic reactions to gold or to nickel as a contaminant. In order to investigate these mechanisms further, 15 patients who developed skin eruptions after chrysotherapy were assessed using skin biopsy and lymphocyte transformation stimulated by gold and nickel salts in vitro (24). Chrysotherapy caused two main cutaneous eruptions: lichenoid reactions and non-specific dermatitis. Peripheral blood mononuclear cells from patients with lichenoid reactions proliferated in response to gold salts in vitro, while those who developed non-specific dermatitis responded mainly to nickel. Nickel was a significant contaminant of the gold formulation (sodium aurothiomalate, Myocrisin, Rhone-Poulenc Ltd), amounting to a total dose of 650 ng over 6 months. The authors suggested that a significant percentage of skin reactions during chrysotherapy are due to nickel contamination.

- A 79-year-old woman had an abdominal aortic aneurysm repaired with a straight Vanguard R stent, mainly composed of nickel (about 55%) and titanium (about 21%) with a reinforcing thread of platinum (25). Three weeks later she developed severe erythema and eczema on the legs with continuous pruritus and excoriated papules. Patch tests were positive to nickel sulfate and cobalt chloride.

The need for preoperative patch-testing for metals is controversial. Enquiry about metal allergy is recommended before endoluminal surgical procedures.

The mobile-phone culture has spread rapidly and possible effects connected with its use may still be underestimated (26).

- A 36-year-old dermatologist with a history of jewellery intolerance developed dermatitis on the right side of the chin, with red pruritic papules. The dermatitis had worsened after prolonged use of her mobile phone. Patch tests were positive to nickel sulfate. She solved the problem by covering the phone with a plastic case.
- A 32-year-old woman developed dermatitis on her left cheek and suggested that it might have been caused or worsened by her mobile phone. Patch tests showed only positive reaction to nickel sulfate. The dimethylglyoxime test for nickel on the side of her phone was positive. The skin lesion resolved rapidly after she covered the phone with a plastic case.

Long-Term Effects

Tumorigenicity

Carcinogenetic effects of nickel, recognized from occupational medicine, can involve the upper or lower respiratory tract.

Drug Administration

Drug overdose

Nickel poisoning is well defined in occupational medicine and is occasionally experienced as a complication of exposure to nickel (or nickel-plated) medical devices. Use of nickel-plated dialysis equipment gave rise to nickel poisoning in 23 patients in one hemodialysis unit. They developed nausea, vomiting, weakness, headache, and palpitation, all of which remitted 3–13 hours after the end of dialysis (SEDA-6, 225).

Niclofolan

General Information

Niclofolan has been used to treat trematode infections, including clonorchiasis, fascioliasis, and paragonimiasis. Sweating, generalized pains, and transient rises in serum transaminase activities have been reported with niclofolan in the treatment of pulmonary infections due to *Paragonimus uterobilaterali* (SEDA-11, 597) (1).

Reference

1. Nwokolo C, Volkmer KJ. Single dose therapy of paragonimiasis with menichlopholan. Am J Trop Med Hyg 1977;26(4):688–92.

Niclosamide

General Information

Niclosamide, widely used in the treatment of tapeworm infestation, is well tolerated in doses of 2 g taken orally before breakfast and is the drug of choice for mass chemotherapy (1). It is has also been used as a molluscicide and in the control of *Schistosoma japonicum* (2).

Niclosamide is not absorbed and reactions consist of mild gastrointestinal disturbances. When treating *Tenia solium* infections an antiemetic is usually given before niclosamide, and patients are subsequently purged to reduce the theoretical risk of cysticercosis, because the dose of niclosamide active against *T. solium* does not destroy ova contained within the tapeworm. Alcohol is usually restricted during treatment, since niclosamide can interfere with its metabolism.

Nicorandil

See also Antianginal drugs

General Information

Nicorandil is a potassium channel activator. The potassium channel activators include cromakalim and its levorotatory isomer lemakalim, bimakalim, nicorandil, and pinacidil (1). Older drugs with this property include minoxidil and diazoxide. Nicorandil, a nicotinamide derivative, is the only drug in the group to be specifically designed as one of this fourth class of agents in the management of angina pectoris after organic nitrates, beta-blockers, and calcium antagonists. Apart from being an arterial/coronary vasodilator, through modulation of ATP-sensitive potassium channels, nicorandil also contains a nitrate moiety, giving it properties similar to organic nitrates but lacking the disadvantages of drug tolerance. Thus, nicorandil has two major hemodynamic actions. It causes venodilatation, reducing preload, by its nitrate-like effect, and systemic arterial vasodilatation, reducing systemic vascular resistance and afterload, by its potassium channel opening effect. In the heart it has a selective effect on coronary vasculature compared with myocardial muscle (2), and it does not appear to affect the sinus node or atrioventricular conduction in animals (3). It also has a vasospasmolytic action (4), and in animals is cardioprotective in induced myocardial ischemia (5).

Nicorandil is effective in controlling 69–80% of cases of chronic stable angina when used as monotherapy (6,7). However, clinical experience with nicorandil is still limited, although it has been in general use in Japan for over 8 years. A review of toxicity data has been published (8).

General adverse effects

The arterial and venous vasodilatory properties of nicorandil precipitate postural hypotension, leading to dizziness, syncope, palpitation, and headache, through a mechanism similar to that of organic nitrates. Other minor gastrointestinal symptoms, such as nausea, vomiting, abdominal pain, and diarrhea have been reported, as has flushing

© 2006 Elsevier B.V. All rights reserved.

due to cutaneous vasodilatation. There have been no reports of hypersensitivity reactions. Tumor-inducing effects have not been reported in animals or man.

Organs and Systems

Cardiovascular

The systemic hemodynamic actions of nicorandil are occasionally associated with a transient increase in heart rate of up to 18% (9,10). Larger doses are associated with cardiac depression, a dose-dependent fall in sinus rate and atrioventricular conduction velocity (11), and shortening of the cardiac action potential duration (12). However, no prodysrhythmic effects have been observed in man (13,14). Single oral doses over 40 mg have been associated with severe postural hypotension, dizziness, and syncope (10,15).

Respiratory

Experimental asthma caused by IgE antibodies in animals is inhibited by nicorandil (16). The relevance of this to man is not known.

Nervous system

Headache occurs in up to one-third of cases in dosages of 10–20 mg bd (17,18), but it is usually mild to moderate, necessitating withdrawal in about 5% of cases. Headache is more common at the start of therapy and is dose-dependent; it gets better with continued therapy or progressive dose titration (8,19).

Endocrine

Nicorandil suppresses the release of insulin from isolated animal pancreatic cells (20). However, this effect is four times weaker than that of diazoxide, and its effect in man is not known.

Hematologic

Nicorandil has an inhibitory effect on platelet aggregation by increasing intracellular platelet cyclic GMP concentrations (21). Whether this effect will potentiate bleeding or protect against myocardial infarction in patients with coronary heart disease is not known

Gastrointestinal

Nausea, vomiting, gastralgia, diarrhea, and abdominal pains have been reported in some studies (6,10).

Skin

Nicorandil, like minoxidil, appears to enhance the incorporation of cysteine into hair shafts (22). However, hypertrichosis has not been reported.

Anal eczema, which resolved after the withdrawal of nicorandil, has been reported (19).

Sexual function

Nicorandil's potassium channel opening action and its ability to release nitric oxide promotes tumescence in isolated human penile corpus cavernosum (23). This effect has been exploited to provide treatment for erectile dysfunction by local injection. Whether oral nicorandil is associated with enhanced erectile function has not been assessed.

Death

Nicorandil was not associated with an excess of sudden deaths complicating acute myocardial infarction in a Japanese series of 1000 sudden deaths between 1983 and 1987 (24).

Long-Term Effects

Drug withdrawal

Adverse effects have not been observed with the withdrawal of nicorandil after long-term therapy. Unlike organic nitrates, there is no drug tolerance with prolonged use of nicorandil (25), and there does not appear to be any cross-tolerance (26). The effects of organic nitrates depend solely on the activation of cyclic GMP in smooth muscle, but this is not the case with nicorandil. In a comparison of intravenous nicorandil and glyceryl trinitrate it took twice as long for blood concentrations of cyclic GMP to return to baseline after the latter, but the hemodynamic effects of the former continued for longer (27). This may be because of the additional non-nitrate potassium channel opening effect of nicorandil when further formation of cyclic GMP ceases.

Susceptibility Factors

Renal disease

The use of nicorandil in elderly patients with chronic renal insufficiency and in patients with stable hepatic cirrhosis is not associated with any significant alteration in its pharmacokinetics. In addition, its metabolism is not affected by drugs that interfere with drug-metabolizing liver enzymes (28).

Hepatic disease

Nicorandil is denitrated in the liver. Its half-life was slightly prolonged in eight patients with cirrhotic liver impairment given a single intravenous bolus of nicorandil (0.1 mg/kg for 5 minutes, half-life 1.7 versus 1.1 hours in controls) (29). This is unlikely to have any significance in adjusting dosages in patients with stable liver disease.

Other features of the patient

There is a theoretical contraindication to nicorandil in patients with cardiogenic shock, acute left ventricular failure with low filling pressure, and hypotension. A sublingual dose of 20 mg in patients with coronary artery disease and normal left ventricular function was associated with a 12% fall in left ventricular end-systolic pressure, a 3% fall in left ventricular end-diastolic pressure, accentuated diastolic filling, a 13% reduction in mean aortic pressure, and a reduced cardiac output at rest (9,30). However, cardiac output may be augmented by up to 60% in patients with congestive cardiac failure or

© 2006 Elsevier B.V. All rights reserved.

with a previous history of myocardial infarction, principally by reduced preload, reduced afterload, and improved myocardial oxygen supply (31–33).

Drug–Drug Interactions

Beta-blockers

The combination of nicorandil and beta-blockers (atenolol/propranolol) potentiates hypotension, with attenuation of reflex tachycardia (6).

Dipyridamole

The coronary vasodilator response of nicorandil is potentiated by dipyridamole (34).

Food–Drug Interactions

Food reduces the rate but not the extent of absorption of nicorandil after an oral dose (35). Its systemic availability is good and is generally greater than 75% in healthy volunteers, suggesting limited first-pass hepatic metabolism, unlike the organic nitrates (36).

Smoking

Cigarette exposure in animals suppresses and delays the absorption of nicorandil from the gastrointestinal tract (37), but this has yet to be investigated in man.

Nicotine replacement therapy

General Information

The introduction of nicotine replacement systems and agents is a significant advance in the treatment of nicotine addiction. Nicotine replacement reduces the severity of nicotine withdrawal symptoms during smoking abstinence and improves smoking cessation rates. During cigarette smoking, nicotine is rapidly absorbed, producing peak blood concentrations of about 15 ng/ml within the first few minutes, while a 21-mg transdermal nicotine patch produces peak blood concentrations of about 18 ng/ml 5–6 hours after application. Thus, nicotine concentrations are markedly increased when the patch and smoking are combined especially within the early minutes of smoking.

Comparative studies

In a meta-analysis of 42 nicotine chewing gum studies and nine patch studies, comprising 17 000 subjects, the odds ratios of long-term success were 1.61 for gum and 2.07 for patch compared with placebo (1). However, effective use of nicotine gum requires careful instructions. Transdermal uptake of nicotine from patches is about 1 mg/hour (2). Large multicenter studies using 16-hour and 24-hour nicotine patches in primary care have shown double the success rate of placebo (3).

The main objectives of the Collaborative European Anti-Smoking Evaluation (CEASE) were to examine whether long-term success rates (that is complete abstinence sustained for 1 year) could be increased by using higher than standard doses of transdermal nicotine, and/or by prolonging the patch treatment period (4). There were four cases of myocardial infarction during the study period, which comprised 950 treatment years and 1700 study years. One 59-year-old man had a myocardial infarct during treatment with the 25 mg nicotine patch, and one 48-year-old man and one 50-year-old man had myocardial infarcts after discontinuing treatment with 15 mg; one 66-year-old man who took placebo had a myocardial infarct. This compared with the 10.2 cases expected during the study period, based on calculations using data from the Framingham study (5). The overall incidence of adverse events was low, and they were generally transient. In order to examine possible dose-related adverse events, the occurrence of events during the first 8 weeks of treatment in each of the three groups (25 mg, 15 mg, and placebo) was analysed, and nausea and vomiting were the only reported symptoms, with a higher frequency in the 25 mg group (7.3%) than the 15 mg group (5.4%).

General adverse effects

The pharmacokinetics of nicotine transdermal systems have been documented in several studies. In one study, a number of users had headache and transient itching at the site of application (6). In another study in 37 subjects, three reported itching and headache, and one had allergic reactions to the patch, which disappeared after changing the site of application (7). The subjects in a third study had headache (4%), nausea (4%), and vertigo (4%) slightly more often than the placebo group (8). Skin reactions such as mild itching under the patch, lasting for 15–30 minutes, and erythema and acute eczema, persisting for several days after removal, also occurred. Skin reactions necessitating withdrawal of the patches occurred in 10% in another study (9). In the same report sleep disturbances of varying severity was a commonly reported adverse effect.

The effect of transdermal nicotine on concomitant medications has been reported in an open non-comparative study of 80 smokers (42 men and 38 women) who used 24-hour nicotine patches (10). Adverse effects included itching and local erythema, insomnia, and abnormal taste sensations. Two subjects withdrew because of adverse effects. At 12 weeks, 17 were non-smokers. At 26 weeks, 19 were non-smokers and a further 14 had reduced their use of cigarettes significantly.

Nicotine gum used for smoking cessation in 114 smokers caused sore mouth, hiccups, and abdominal pain and vomiting (11). One subject withdrew from the study because of vomiting. Hot flushes have also been reported (12).

Nicotine (15–25 mg/day) has also been used to treat active ulcerative colitis. The most common adverse effects were nausea, light-headedness, headache, sleep disturbance, dizziness, and skin irritation (13,14).

© 2006 Elsevier B.V. All rights reserved.

Organs and Systems

Cardiovascular

Nicotine can aggravate cardiovascular disease through the hemodynamic consequences of sympathetic neural stimulation, or systemic release of catecholamines, or both (15). Although several cardiovascular events have been ascribed to nicotine patches, including cerebral arterial narrowing with severe headaches and transient neurological deficits (16), relatively few adverse effects have been reported (15). Suicide attempts by means of overdosage using nicotine patches, presumably with the intention of precipitating myocardial infarction, have failed (17), and it would seem that the risk of nicotine replacement therapy is likely to be much less than that of cigarette smoking, even in patients with coronary heart disease (15).

Nicotine can provoke angina in patients with coronary artery disease and can also trigger myocardial infarction. It has been hypothesized that activities associated with increased catecholamine concentrations can both trigger plaque rupture and promote an occlusive thrombus formation that can result in myocardial infarction or sudden cardiac death. By evoking the release of catecholamines (stimulating platelet aggregation and increasing platelet/vessel wall interactions), nicotine could therefore be a potent trigger of myocardial infarction. However, a randomized, double-blind, placebo-controlled trial in 584 patients with at least one diagnosis of cardiovascular disease clearly showed that transdermal nicotine does not cause a significant increase in cardiovascular events in high-risk patients with cardiovascular disease. On the other hand, the efficacy of transdermal nicotine as an aid to smoking cessation in such patients has proved to be very limited and may not be sustained over time (18). In another study (19) from the Pharmacovigilance Division of the Federal Ministry for Health and Consumer Products of Austria, 41 cases of myocardial infarction were associated with the use of nicotine patches.

Atrial fibrillation was described in association with normal or large doses (20,21), suggesting that accumulation can occur when nicotine gum is taken daily.

Respiratory

In one study, 27% of the participants reported coughing, and 15% had irritation of the mouth or throat after 3–5 days (22). At 3 weeks 7% reported coughing and 10% mouth and throat irritation. In another study, 18 healthy subjects inhaled nicotine for 20 minutes (80 inhalations) every hour for 10 hours at three different environmental temperatures (20, 30, and 40°C) (23). Adverse events were twice as frequent at 40°C as at 20°C. Most often reported were coughing, a lump in the throat, and a sore or irritated throat. Belching, hiccups, pressure over the chest, headache, and heartburn were reported occasionally. About one-fifth of the subjects experienced coughing after the first 5–10 inhalations.

Nervous system

In 53 subjects, two- and three-dimensional analyses of nicotine-induced eye movements were performed to evaluate whether they were primarily of vestibular or oculomotor origin (24). Nicotine-induced nystagmus was detected in 27 subjects (51%). These findings suggest that nicotine causes an imbalance in the vestibulo-ocular reflex.

Psychiatric

A woman developed hallucinations and cerebral arterial narrowing after using nicotine patches (16). In another case delusions and hallucinations occurred when a woman who had been using nicotine to try to stop smoking took a cigarette (25).

Gastrointestinal

Smoking is negatively associated with ulcerative colitis and positively associated with Crohn's disease; it is the most striking and firmly established epidemiological factor associated with the two conditions. The first association of nonsmoking with ulcerative colitis was made over 20 years ago (26), and was followed within 2 years by the observation that patients with Crohn's disease were more often smokers (27). Smoking also has opposite effects on the clinical course of the two conditions, with possible benefit in ulcerative colitis (28) and a detrimental effect in Crohn's disease (29). Nicotine is probably the principal active ingredient in smoking responsible for these associations.

In a pilot study of oral nicotine in the treatment of primary sclerosing cholangitis in eight patients, only five completed 1 year of treatment; two had no adverse effects, but three had to temporarily reduce the dose of nicotine because of nausea, dizziness, insomnia, or light-headedness, but later resumed the full dose (30). One patient completed only 4 months of treatment because of dizziness and bouts of palpitation, even at the lowest dose, requiring permanent discontinuation of nicotine. One patient with ulcerative colitis, who was completely asymptomatic at the time of entry, had insomnia and watery diarrhea shortly after starting oral nicotine; however, his ulcerative colitis later responded to transdermal nicotine. One patient had moderately active Crohn's colitis and bloody diarrhea treated with corticosteroid enemas and mesalazine; his bloody diarrhea increased shortly after starting oral nicotine, requiring drug withdrawal and an increased frequency of corticosteroid enemas; nicotine was not restarted.

Skin

Local skin reactions to transdermal nicotine patches have been reported (31). Other local adverse effects, including erythema with edema, erosions, and systemic skin reactions have also been described (32).

Skin tolerability in patients with a history of eczema, psoriasis, or other skin disorders has been studied in 1481 participants (33). The adverse effects reported were erythema, rash, pruritus, irritation, edema at the site of application, musculoskeletal pain related to the application site, dreaming, and other sleep disturbances.

Musculoskeletal

The acetylcholine receptors involved in myasthenia gravis are nicotinergic, and in myasthenia gravis they are reduced in number at the neuromuscular junction, which can lead to functional overdosage after the use of nicotine, similar to a cholinergic crisis. This is comparable to

© 2006 Elsevier B.V. All rights reserved.

the myasthenic syndromes that were described during the Second World War in tobacco chewers without any muscle impairment.

- Myasthenia gravis was worsened by a nicotine transdermal system in a man who used to smoke 40 cigarettes a day without an effect on his myasthenia (34). Two hours after applying a nicotine transdermal system he developed increased bilateral ptosis, total ophthalmoplegia, difficulty in chewing, and generalized weakness. The symptoms improved after the patch was removed.

Immunologic

Leukocytoclastic vasculitis has been ascribed to nicotine patches in two patients (35). Two other patients developed vasculitis in association with the use of nicotine patches (36). The authors concluded that it was likely that the reactions in the two patients were related to the nicotine therapy. However, the possibility of a reaction to the vehicle (coconut oil and polymers) could not be excluded.

Susceptibility Factors

Anecdotal reports of paroxysmal atrial fibrillation, myocardial infarction (37,38), dysrhythmias (39), and stroke in patients taking nicotine have made physicians wary of prescribing nicotine gum or transdermal patches for patients with cardiac disease.

Occlusive dressings covering transdermal patches can increase the risk of adverse effects (40).

- A 40-year-old man with renal carcinoma and extensive lung metastases who had smoked three packs per day for 25 years, had two 21 mg transdermal nicotine patches placed on a clean hairless area of his body. Before he took a shower the next afternoon, the nursing staff covered the patches with a polyvinylidrine chloride occlusive dressing (Saranwrap). During the hot shower he felt nauseated, light-headed, and tremorous, and nearly lost consciousness. Removal of the patches and occlusive dressing alleviated the adverse effects.

The adverse effects experienced by this patient could have been due to the use of an occlusive dressing and exposure to a high temperature, in combination with a high dose of nicotine. Absorption of nicotine through the skin is greater at high temperatures, because of increased blood flow to the skin. A high ambient temperature (77–84°C) significantly increases dermal absorption and plasma concentrations of nicotine in the first hour of heat exposure, starting 5 hours after application of nicotine patches (41).

Drug Administration

Drug administration route

Nicotine has also been administered in a nasal spray. In one study, sneezing, irritation in the throat, and headache were reported after application of nasal spray (42). However, in a larger study (255 subjects, half of whom had been assigned to nicotine nasal spray and the other half to placebo), there were nine cases of sinusitis (five nicotine and four placebo) and two of nose bleeding and occasional spots of blood from the nostrils (one in each group) (43). Two other studies reported irritated throat, hiccups, heartburn, bad taste sensation, dry mouth, and dizziness, nasal irritation, runny nose, watery eyes, sneezing, and coughing as the most frequently reported adverse effects (44,45).

Drug–Drug Interactions

General

The therapeutic effects of many drugs are less predictable in cigarette smokers, since smoking can potentially alter the pharmacokinetics of a drug by reducing its absorption, increasing its plasma clearance, or inducing cytochrome P450 isozymes. Enzyme induction in smokers is probably due to polycyclic aromatic hydrocarbons, as they are potent inducers of cytochrome P450 (46).

Antimalarial drugs

Although rigorous data on the metabolism of antimalarial drugs are lacking, it appears from in vitro and in vivo studies that chloroquine is metabolized by cytochrome P450 (47). It is therefore conceivable that cigarette smoking alters the hepatic metabolism of antimalarial drugs.

Antimalarial drugs (chloroquine, hydroxychloroquine, or quinacrine) were given to 36 patients with cutaneous lupus, 17 smokers and 19 non-smokers (48). The median number of cigarettes smoked was one pack/day, with a median duration of 12.5 years. There was a reduction in the efficacy of antimalarial therapy in the smokers. Patients with cutaneous lupus should therefore be encouraged to stop smoking and consideration may be given to increasing the doses of antimalarial drugs in smokers with refractory cutaneous lupus before starting a cytotoxic agent.

Nicotinic acid and derivatives

See also Vitamins

General Information

Nicotinic acid is an antilipidemic agent that effectively reduces serum concentrations of total cholesterol, low-density lipoprotein (LDL) cholesterol, very low density lipoprotein (VLDL) cholesterol, and triglycerides, and increases concentrations of high-density lipoprotein (HDL) cholesterol. It has been suggested that the marked lowering of serum cholesterol seen during treatment of dyslipidemia with nicotinic acid results from hepatotoxicity (1).

Nicotinic acid is also a potent vasodilator, probably by a direct action on smooth muscle cells. It produces cutaneous vasodilatation, itching of the skin, facial flushing, a sensation of feeling hot, pounding in the head, gastric irritation, diarrhea, raised transaminases, hyperglycemia, and hyperuricemia. These unpleasant adverse effects limit its acceptability for many patients. Nicotinic acid as such is not used in the treatment of vascular disorders, but some of its derivatives are, albeit with poor evidence of clinical efficacy.

Modified-release formulations of nicotinic acid do not appear to be better tolerated than regular formulations, flushing and itching being the most common adverse effects (SEDA-19, 206). There have also been several reports of hepatotoxicity with this form of the drug (SEDA-16, 438). Other adverse effects are hepatotoxicity (apparently a dose-related direct toxic effect), hyperglycemia, and hyperuricemia. It has been questioned whether the modified-release formulation, which is available over the counter in some countries, ought to continue to be available for self-medication in view of its serious adverse effects (2,3).

Given its many adverse reactions, the safety of using nicotinic acid continues to be discussed. Some are of the opinion that it should only be given to patients with marked dyslipidemia and under close monitoring, and that the initial expectations of fewer adverse reactions with the modified-release form of the drug do not seem to have been borne out in practice (4,5). Others recommend its continued use (6,7). A general warning against indiscriminate use of nicotinic acid as a vitamin supplement has been given (8).

In two studies of accelerated radiotherapy with carbogen and nicotinamide in patients with cancer the adverse effects of nicotinamide have been documented (9,10). In the first study, 62 patients with stage III–IV laryngeal carcinoma were treated with accelerated radiotherapy (total radiation 64 Gy) combined with carbogen breathing in 11 patients and with both carbogen and nicotinamide (Arcon) in 51 patients. Adverse effects attributed to nicotinamide in the 51 patients were nausea in 35 patients, vomiting in 20, flushing, dizziness, epigastric pain, and headache in 2 patients each, and gastrointestinal bleeding, sweating, fatigue, and emotional disturbances in 1 patient each.

In the second study nicotinamide (Nicobion) 6 g was given in tablet form to 15 patients with advanced head and neck and non-small cell lung carcinomas 90 minutes before radiotherapy. Toxicity (nausea and vomiting) did not correlate with any of the pharmacokinetic parameters, such as t_{max}, C_{max}, half-life, or AUC. Gastrointestinal toxicity reached grade 1 (nausea not requiring antiemetics) in four patients, grade 2 (nausea and/or vomiting requiring antiemetics) in four patients, and grade 3 (nausea and/or vomiting requiring nasogastric intubation or parenteral support) in two patients.

It has been hypothesized that long-term survival after recovery from myocardial infarction could be improved with only 1 g of nicotinic acid daily (11).

Nicotinic acid derivatives

Nicotinic acid derivatives include acipimox, aluminium nicotinate, nicotinyl alcohol, and xanthinol nicotinate.

The adverse effects of these compounds appear to be identical to those of nicotinic acid.

Acipimox (*S*-methylpyrazine-2-carboxylic acid 4-oxide) is structurally related to nicotinic acid. Flushing and gastrointestinal disturbances, but there were no effects on blood glucose or uric acid in 7137 patients, of whom 15% stopped taking the drug because of adverse effects (12). In another open study blood glucose was on average slightly lowered in 3009 patients with type 2 diabetes given acipimox for at least 2 months (13).

Acipimox had to be withdrawn in 10 of 32 patients with hypertriglyceridemia, excessive hypertriglyceridemia, and combined hyperlipidemia because of adverse effects or absence of clinical response (14). The other 22 completed 6 months of treatment with no adverse effects. The authors claimed that acipimox is much better tolerated than nicotinic acid, that it has fewer adverse effects, and can therefore be used as a second-line drug.

Aluminium nicotinate perhaps causes slightly less gastrointestinal distress than nicotinic acid, but the same can be achieved by buffering the acid, and neither approach in fact solves the problem, which is probably not primarily one of acidity.

Severe toxicoderma has been reported with xanthinol nicotinate and confirmed by a provocation test (SEDA-1, 333). Flushing is claimed to be less frequent with xanthinol nicotinate than with nicotinic acid, but has nevertheless been repeatedly observed, and its other adverse effects are likely to be the same as those of nicotinic acid.

Organs and Systems

Cardiovascular

Symptoms observed after high doses of nicotinic acid (such as giddiness, faintness, and vasovagal attacks) result from dilatation of the small arteries and arterioles, resulting in reduced peripheral resistance and blood pressure (6). Flushing occurs transiently in all patients and persists in 10–15% of cases. When starting with a high dose, hypotension can occur (15). The flushing of the skin with pruritus is transitory.

Coronary steal with worsening of myocardial ischemia related to vasodilatation has been reported in a patient taking nicotinic acid (16), which should therefore perhaps be withheld in patients with unstable angina.

© 2006 Elsevier B.V. All rights reserved.

Nervous system

Electroencephalographic abnormalities associated with vitamin B therapy have been reported (SEDA-15, 412) (17). Tingling of the fingertips, faintness, and dizziness have been observed. Peripheral neuropathy has been reported (18). Tingling in the orofacial region has been attributed to a neuropathic effect, but this could have been due to vasodilatation.

Sensory systems

Ocular adverse effects of nicotinic acid include sicca syndrome, blurred vision, and eyelid edema.

A few cases of advanced cystoid macular edema have been reported in the older literature; these took months to resolve once nicotinic acid was withdrawn (SEDA-14, 331) (SEDA-20, 191) (15,19). Four new cases have been added in patients who took nicotinic acid 2–4.5 g/day (20,21). The first symptoms of blurred vision appeared 1–18 months after the start of therapy. Withdrawal of nicotinic acid resulted in improvement of visual acuity and resolution of the cystoid macular edema within 1–2 months. A particular feature that distinguishes this form of maculopathy is the absence of leakage on fluorescein angiography. Retinal edema, when it occurs, will abate on withdrawal of nicotinic acid (15).

Three cases of impaired vision occurred after the administration of high-dose nicotinic acid (22).

- A 51-year-old man increased his dose of nicotinic acid from 1 to 4.5 g/day. Within 4 weeks, he noted blurred vision in both eyes. Nicotinic acid was discontinued and his vision improved within a month.
- A 53-year-old man increased his dose of nicotinic acid from 1 to 3 g/day over a year. After he had been taking 3 g/day for 6 months, he noticed a gradual darkening of vision. His symptoms improved within 3 days of withdrawal.
- A 51-year-old man took nicotinic acid 2 g bd. After 18 months he noted visual symptoms, which resolved within 2 months of withdrawal.

Endocrine

Prolonged administration of nicotinic acid can have a diabetogenic effect and decompensation of previously stable diabetes can occur. Severe hyperglycemia has been precipitated by nicotinic acid treatment of hyperlipidemia (23).

Metabolism

During long-term treatment with nicotinic acid, uric acid concentrations tend to rise slightly, but the change is clinically insignificant (24).

Nicotinic acid has a hyperglycemic action (SEDA-13, 1330), and is therefore not recommended as a first-line hypolipidemic drug in patients with type 2 diabetes mellitus (25).

Lactic acidosis has been observed in patients taking nicotinic acid (SEDA-13, 1330).

Hematologic

- A 55-year-old man with localized prostate cancer was given pravastatin (10 mg/day) and aspirin (325 mg/day) (26). He also took food supplements containing about 30 different ingredients, most notably nicotinic acid 2250 g/day. During preparation for prostate surgery it was discovered that his prothrombin time was slightly prolonged (17 seconds, normal 11.4–14.4 seconds). All prescribed medications were withheld, but his prothrombin time continued to be abnormal (24 seconds).

The authors thought that the high dose of nicotinic acid had caused this abnormality.

Intravenous administration of nicotinic acid or nicotinyl alcohol tartrate can cause short-lived fibrinolytic activity (27).

Mouth and teeth

Two patients complained of dental and gingival pain, not previously reported adverse effects of nicotinic acid (28). The pain abated on withdrawal and in one case recurred on rechallenge.

Gastrointestinal

General gastrointestinal symptoms include heartburn, vomiting, persistent nausea (29), abdominal pain, and hunger pains.

In patients with squamous cell carcinomas of the head and neck, accelerated radiotherapy with carbogen and nicotinamide (ARCON) 6 g/day was carried out to determine the feasibility and the adverse effects of this therapeutic approach (30). Accelerated fractionation was combined with carbogen ($n = 11$), daily nicotinamide ($n = 10$), or both ($n = 17$). There were no significant differences in local adverse effects in the three groups. Systemic adverse effects took the form of nausea or vomiting. The authors concluded that in future ARCON trials a lower dose of nicotinamide will be needed to reduce severe upper gastrointestinal toxicity.

Of 61 patients with ischemic heart disease and dyslipidemia treated with nicotinic acid 1.5 and 3.0 g/day, 32 patients were withdrawn, 18 because of adverse effects and 14 for reasons not related to nicotinic acid (31). Of the 29 patients who finished the study, adverse effects included dryness of the skin (14%), acanthosis nigricans (10%), fatigue (6.9%), nausea (6.9%), abdominal pain (3.4%), diarrhea (3.4%), and anorexia (3.4%); the figures in parentheses were the incidences at 33 weeks. Flushing occurred more often at 18 weeks than at 33 weeks (24 versus 6.9%), as did pruritus (35 versus 28%), suggesting tolerance to these effects.

Liver

Nicotinic acid is hepatotoxic, and it is suspected that the modified-release formulation increases the risk (32) (SEDA-13, 1330).

Late adverse effects include hepatic dysfunction, with altered liver function tests and hyperbilirubinemia. After prolonged use of nicotinic acid and nicotinyl alcohol, histological changes, for example parenchymal cell injury, portal fibrosis, cholangitis, cholestasis, biliary casts, and

© 2006 Elsevier B.V. All rights reserved.

lymphocytic infiltrations around the bile ducts, have occasionally been seen.

Rechallenge with crystalline formulations in people in whom liver damage has occurred with the modified-release formulation has been tolerated (33). However, three cases of hepatic dysfunction in patients taking crystalline nicotinic acid 1.5–3.0 g/day have been reported (1). They were all associated with a reduced ratio of esterified cholesterol to free cholesterol in LDL, a reduction in lecithin cholesteryl acyl transferase activity (LCAT), and other evidence of liver dysfunction, including prolonged prothrombin time. Transaminases were in the reference ranges. On reduction of the dosage or withdrawal of nicotinic acid all the abnormalities resolved within 4 weeks. Others have pointed out that some observations suggest that lipid lowering with nicotinic acid is part of a generalized hepatotoxic effect (1).

A "starry sky liver" has been reported in a patient with nicotinic acid-induced hepatitis (34).

- A 50-year-old man developed recurrent sharp lower abdominal pain and nausea, having taken modified-release nicotinic acid 500–2000 mg/day for 8 weeks for hypercholesterolemia. He had a low-grade fever, tachycardia, and hypotension. Abdominal ultrasonography showed a markedly hypoechoic liver of normal size, with relatively echogenic conspicuous portal triads. Aspartate transaminase activity and prothrombin time were raised. Nicotinic acid was withdrawn and the signs and symptoms resolved within several days.

Nicotinic acid can cause hepatic steatosis and clinical hepatic abnormalities that together can simulate the presentation of hepatobiliary neoplasia (35).

- A 52-year-old man with long-standing tetraplegia, who had been taking oral nicotinic acid 2 g/day for several months, developed nausea, vomiting, and fever, raised liver enzymes and total and indirect bilirubin. Ultrasonography showed several hyperechoic intrahepatic lesions and CT scan showed several hypoattenuating lesions, some of which were associated with interrupted vessels and had convex borders, suggestive of a tumor. Other lesions had CT features typical of fatty infiltration of the liver. Niacin was withdrawn. The liver function tests normalized within 4 days and the nausea and vomiting abated. The hepatic lesions on CT scan improved within 1 month and resolved after 9 months.

Skin

Nicotinic acid disturbs the normal cornification of the skin, occasionally leading to reversible ichthyosis and acanthosis nigricans (SEDA-19, 206). Two mechanisms are advanced to explain this effect: insulin resistance induced by nicotinic acid, with compensatory hyperinsulinemia (which in turn leads to increased insulin binding to insulin-like growth factor receptors and stimulation of keratinocytes), or a disturbance of epidermal lipid homeostasis.

Skin problems can be persistent in a proportion of patients, variously estimated at 10–59%, and this can severely limit adherence to therapy. The skin reaction can be ameliorated by concomitant use of non-steroidal anti-inflammatory drugs such as aspirin and indometacin (SEDA-15, 412). Transient exanthems, pruritus, and sometimes wheals are seen, as well as a uniform dryness and scaling of the epidermis, brown pigmentation, and even on occasion an acanthosis nigricans-like dermatosis (15). Persistent rashes can also occur. Doses in excess of 5 g/day are routinely associated with skin manifestations and can on occasion cause liver damage, gout, and ulcer formation. These reactions can be associated with nicotinic acid rather than nicotinamide, which is sometimes recommended as an alternative (36). Increased hair loss has been described.

Musculoskeletal

Nicotinic acid has been associated with the development of myopathy with nocturnal leg aching and cramps, symptoms that can be exacerbated by simultaneous use of other lipid-lowering drugs associated with similar adverse effects, or alcohol, which also has myopathic effects (SEDA-15, 413) (37).

Immunologic

Anaphylactic shock can occur with nicotinic acid (6).

A pseudoallergic reaction has been reported in a patient who took several nicotinic acid-containing formulations (38).

- A previously healthy 40-year-old woman developed a generalized macular erythematous rash associated with palpitation and light-headedness, recurring every few days. The rash started behind the neck and arms, with a sensation of tingling, progressing to a general feeling of heat. She felt ill and had to lie down until the episode subsided after 45–90 minutes, with residual fatigue for several hours. Laboratory findings were all in the reference ranges. She was taking two multivitamin tablets a day, each containing nicotinic acid 20 mg, one B complex tablet containing nicotinic acid 50 mg, and 1–3 tablets of an antiemetic containing nicotinic acid 50 mg. Thus, she had unknowingly taken nicotinic acid up to 240 mg/day. Graded oral challenge with nicotinic acid 20–200 mg reproduced her symptoms.

Drug Administration

Drug formulations

Since nicotinic acid can cause unpleasant flushing and other symptoms of vasodilatation, attempts have been made to develop modified-release formulations. Modified-released nicotinic acid formulations may be better tolerated than the immediate-release formulation, because they reduce the vasodilatory effects of the drug. However, the low frequency of flushing produced by modified-release formulations may be offset by an increased risk of hepatotoxicity. Some reports have suggested a higher frequency of hepatic dysfunction with traditional modified-release nicotinic acid formulations compared with immediate-release products (2,39).

In a double-blind, placebo-controlled study of a modified-release formulation in 128 patients, pruritus was reported in 10 patients taking nicotinic acid and

© 2006 Elsevier B.V. All rights reserved.

rash in 9 patients; there were no similar effects in those taking placebo (40).

In 517 patients taking a modified-release formulation the most commonly reported adverse events were headache in 92 patients, pain in any part of the body except the abdomen in 46, abdominal pain in 54, diarrhea in 97, dyspepsia in 46, nausea in 72, vomiting in 38, rhinitis in 30, pruritus in 56, and rash in 51 (24).

In a study of the efficacy and tolerability of a modified-release formulation in 269 adults and 230 additional adults for whom short-term safety data were available, 13 of 269 patients (4.8%) withdrew because of flushing (41). During the first 4 weeks about half had flushing. The mean intensity was about 4.0 on a visual analogue scale (representing "none" to "intolerable"). Patients were encouraged to use aspirin prophylactically to minimize flushing. Other nicotinic acid-related adverse effects leading to withdrawal included nausea (3.3%) sometimes with vomiting, other gastrointestinal symptoms (1.5%), and pruritus (2.6%). Once case each of gout, acanthosis nigricans, headache, palpitation, raised glucose concentrations, and shoulder pain led to patient withdrawal. Certain adverse events thought to be associated with nicotinic acid were uncommon in the study group. There was one case of peptic ulcer, amblyopia occurred in three patients, and leg aches and myalgias in one patient taking nicotinic acid with simvastatin, with a normal creatine kinase activity.

The efficacy and adverse effects of a modified-release formulation have been studied in 32 patients with type 2 diabetes (42). Of 22 patients who completed 6 months of therapy, 17 took 1000 mg/day, 3 1500 mg/day, and 2 2000 mg/day. Seven of 32 patients discontinued therapy. Of these, three withdrew after 2, 5, and 6 months because of flushing and itching. Three other patients withdrew within 2 months because of nausea, diarrhea, and dyspepsia. One patient withdrew after 7 days because of increased blood glucose concentrations. There were no significant increases in mean transaminase activities, which remained within the reference ranges in all patients.

The safety and efficacy of escalating doses of modified-release tablets of nicotinic acid (Niaspan) have been evaluated in a multicenter, placebo-controlled study in 131 patients with primary hyperlipidemia (43). The dose of nicotinic acid was initially 375 mg/day, then 500 mg/day, and then increasing in 500 mg increments at 4-week intervals to a maximum of 3000 mg/day. Changes in biochemical measurements in patients taking nicotinic acid were significant only for uric acid and phosphorus. Fasting blood glucose, bilirubin, transaminases, alkaline phosphatase, lactate dehydrogenase, and amylase were not altered. Of the 131 patients, 80 completed the study. Of the patients who withdrew, 31 did so for medical reasons (3% taking nicotinic acid and 11% placebo). Eight of the 26 patients who stopped taking nicotinic acid withdrew because of flushing (all before the 2000 mg/day dose) and 5 because of a rash. These reasons accounted for half of the dropouts with nicotinic acid. The number of patients who had episodes of flushing fell with each dose increment of nicotinic acid, suggesting tolerance. Of other adverse events, only nausea (18 and 9%), vomiting (10 and 2%), pruritus (11 and 0%), and rash (10 and 0%) were more common with nicotinic acid.

Drug–Drug Interactions

Ethanol

An apparent interaction between nicotinic acid and alcohol caused toxic delirium and lactic acidosis (44).

Nicotine

An interaction between nicotinic acid and nicotine transdermal patches has also been observed, causing flushing and dizziness (45).

Statins

Nicotinic acid increased the risk of rhabdomyolysis associated with HMG-CoA reductase inhibitors (SEDA-19, 206) (46).

Nifedipine

See also Calcium channel blockers

General Information

Nifedipine is a dihydropyridine calcium channel blocker.

A significant fall in pulmonary vascular resistance with high doses of oral calcium channel blockers seems to be associated with an improved prognosis, and potential clinical efficacy in primary pulmonary hypertension. However, significant adverse effects have been reported during acute testing with calcium channel blockers. Therefore, to identify patients who may benefit from long-term calcium channel blockers, there is a need for a safe, potent, short-acting vasodilator. Two studies have been conducted to assess the use of inhaled nitric oxide, a selective pulmonary vasodilator, for predicting the safety of high-dose oral calcium channel blockers and acute hemodynamic responses to them in primary pulmonary hypertension. In one study, 17 patients with primary

© 2006 Elsevier B.V. All rights reserved.

pulmonary hypertension undergoing a trial of nifedipine (20 mg hourly for 8 hours) were assessed for the hemodynamic response to inhaled nitric oxide, 80 parts per million for 5 minutes (1). All nitric oxide responders also responded to nifedipine, and nine of the ten nitric oxide non-responders were nifedipine non-responders. All nitric oxide responders tolerated a full trial of nifedipine without hypotension. There was a highly significant correlation between the effects of nitric oxide and nifedipine on pulmonary vascular resistance. In conclusion, the pulmonary vascular response to inhaled nitric oxide accurately predicted the acute hemodynamic response to nifedipine in primary pulmonary hypertension, and a positive response to nitric oxide was associated with a safe nifedipine trial. In patients comparable to those evaluated, a trial of nifedipine in nitric oxide non-responders appears unwarranted and potentially dangerous.

In another study the acute response to inhaled nitric oxide and high doses of oral nifedipine or verapamil was assessed in 33 consecutive patients with primary pulmonary hypertension (2). Ten patients responded acutely to nitric oxide, nine of whom responded acutely to calcium channel blockers, without any complications. The other 23 patients failed to respond to nitric oxide and calcium channel blockers. In these non-responders there were nine serious adverse effects with calcium channel blockers. There was no clinical or baseline hemodynamic feature that predicted the acute vasodilator response. Long-term oral treatment with calcium channel blockers was restricted to the nine acute responders, and there was a sustained clinical and hemodynamic improvement in only six patients. It was concluded that nitric oxide may be used as a screening agent for safely identifying patients with primary pulmonary hypertension who may benefit from long-term treatment with calcium channel blockers.

Organs and Systems

Cardiovascular

The long-term safety of dihydropyridine calcium channel blockers has been extensively debated since 1995, with reports of conflicting results from observational and randomized clinical studies about possible increases in cardiovascular mortality, myocardial infarction, and neoplastic diseases (SEDA-22, 214). Two studies have contributed to this controversy.

In the INSIGHT (Intervention as a Goal in Hypertension Treatment) study, a prospective, multicenter, double-blind study in 6321 hypertensive patients aged 55–80 years, long-acting nifedipine 30 mg was compared with co-amilozide (hydrochlorothiazide 25 mg plus amiloride 2.5 mg) (3). There were no differences between the two treatments in the primary end-points of cardiovascular death, myocardial infarction, heart failure, or stroke during follow-up for 4 years.

In the Canadian Study of Health and Aging, a population-based prospective study of people aged 65 years or more, 5-year follow-up of 837 subjects who reportedly used at least one antihypertensive or diuretic agent showed that the risk of all-cause and cardiac mortality was significantly higher among nifedipine users than beta-blocker users (4). Compared with beta-blockers, the hazard ratios (95% CI) were:

- loop diuretics 1.84 (1.21, 2.82);
- nifedipine 1.82 (1.09, 3.04);
- ACE inhibitors 0.98 (0.54, 1.78);
- diltiazem/verapamil 0.96 (0.58, 1.60).

Among nifedipine users, the risk of death increased with the average daily dose and with recent initiation of therapy and remained significant for long-acting formulations.

Myocardial ischemia

Ischemic chest pain is an infrequent but well-documented adverse effect of initiating therapy with nifedipine (5). Its mechanism is unclear, but it may arise from reduced overall coronary blood flow or coronary steal (6).

Ischemic electrocardiographic changes without pain have also been reported (7).

There has been a meta-analysis of 60 published, randomized clinical trials that enrolled at least 10 patients with stable angina and that compared any nifedipine formulation, either as monotherapy or combination therapy, with a non-dihydropyridine active drug or a placebo control for at least 1 week (8). There were 3096 subjects and 5571 treatment exposures. There was an increased risk of cardiovascular events in patients allocated to nifedipine. The unadjusted odds ratios for nifedipine versus controls were 1.40 (CI = 0.56, 3.49) for major events (death, non-fatal myocardial infarction, stroke, revascularization procedures) and 1.75 (CI = 0.83, 3.67) for increased angina. Episodes of increased angina were more frequent with immediate-release nifedipine (OR = 4.19; CI = 1.41, 12.49) and with nifedipine monotherapy (OR = 2.61; CI = 1.30, 5.26). The odds ratio for immediate-release nifedipine was significantly higher than that for modified-release nifedipine, and the odds ratio for nifedipine monotherapy was significantly higher than that for nifedipine combination therapy. This meta-analysis suggests that the adverse effects of nifedipine on cardiovascular events in patients with stable angina are primarily due to more frequent episodes of angina when monotherapy with immediate-release formulations is used. Modified-release formulations and concurrent beta-blockade do not appear to be associated with an increased risk.

Hypotension

Sublingual nifedipine, given for hypertensive crises in elderly patients, can cause adverse effects associated with a precipitous fall in blood pressure, even at low doses. In 93 consecutive hypertensive patients without coronary heart disease, aged 65 years or over, nifedipine reduced blood pressure significantly, increased heart rate, and relieved symptoms associated with raised blood pressure (9). However, there were electrocardiographic changes consistent with myocardial ischemia in six of 55 patients with left ventricular hypertrophy and in one patient without left ventricular hypertrophy.

Cardiac dysrhythmias

A reported causal relation between torsade de pointes and nifedipine (10) has been questioned (11).

© 2006 Elsevier B.V. All rights reserved.

Nervous system

Rapid lowering of the blood pressure with nifedipine, particularly sublingually, can precipitate cerebral ischemia, with confusion, loss of consciousness, and stroke. Cases of cortical blindness with macular sparing secondary to occipital lobe infarction have been reported (SEDA-17, 238).

Transient cerebral ischemia, with aphasia and hemiparesis in one patient and cerebellar dysfunction and loss of consciousness in another, has been observed with nifedipine (12). In addition, rapidly progressive hemiparesis, aphasia, and confusion, accompanied by a substantial fall in blood pressure, occurred in a patient whose hypertension (230/136 mmHg) was treated with sublingual nifedipine (13). Transient retinal ischemia, which may be recurrent, has also been attributed to nifedipine (14,15). Hypotension or cerebral steal are the likely mechanisms.

Cerebral vasodilatation from nifedipine might have contributed to a subarachnoid hemorrhage in a 32-year-old woman with a berry aneurysm (16).

Paresthesia of the hands and feet has been reported with nifedipine (SEDA-17, 237).

Electrolyte balance

Nifedipine can increase urinary potassium loss in patients treated with thiazide diuretics (17), but it has no effect on adrenaline-induced hypokalemia (18). In the Treatment of Mild Hypertension Study, 4 years of monotherapy with amlodipine maleate caused no change compared with placebo in the serum potassium, uric acid, aspartate transaminase, or creatinine of 114 hypertensive patients (19).

- A 56-year-old man developed hypokalemia associated with muscle weakness after taking nifedipine for 2 weeks for angina; the potassium concentration rose on withdrawal, but fell rapidly again on rechallenge (20).

Hematologic

In a case-control surveillance of agranulocytosis and aplastic anemia conducted in the metropolitan area of Barcelona, where 178 cases of aplastic anemia were identified, nifedipine was associated with a significant relative risk of aplastic anemia, which translates into an absolute risk of 1.2 per patient-year. Among the 178 patients, 147 were interviewed and compared with 1295 controls. Six cases (4.1%) and 11 controls (0.8%) had been exposed to nifedipine during the window period, as all of them had taken nifedipine for at least 7 months. The multivariate odds ratio was 4.6 (95% CI = 1.5, 15). All six died within 5 months of diagnosis. The authors concluded that the risk of aplastic anemia associated with nifedipine is of a similar magnitude to that associated with chloramphenicol (1.7 per 100 000 patients) and that associated with phenylbutazone (2.2 per 100 000 patients) (21).

Mouth and teeth

Nifedipine and ciclosporin can cause gingival hyperplasia, which is associated with gingival inflammation and can be mitigated by careful oral hygiene, although this has not been clearly shown. In gingival biopsies from nine nifedipine-treated cardiac outpatients, 13 immunosuppressant-treated renal transplant recipients, nine of whom were also taking nifedipine, and 30 healthy individuals, there were significant differences in macrophage and lymphocyte subpopulations in gingival connective tissue from patients with nifedipine-associated gingival lesions compared with healthy individuals (22). For example, the proportion of CD8-labelled cells was significantly higher and the CD4/CD8 ratio was significantly lower in connective tissue beneath the sulcus epithelium in those taking nifedipine. The authors suggested that immune responsiveness may be altered in drug-induced gingival overgrowth.

In another study, gingival samples were collected from 19 healthy individuals, 12 nifedipine-treated cardiac patients, and 22 immunosuppressant-treated organ transplant recipients, 11 of whom were also taking nifedipine (23). Mitotic activity was measured in the basal cell layer, and the results suggested that the increased epithelial thickness observed in nifedipine- and ciclosporin-induced gingival overgrowth is associated with increased mitotic activity.

The true prevalence of gingival overgrowth induced by chronic treatment with calcium channel blockers is still uncertain, since most studies have been small. In a cross-sectional study in 65 patients taking nifedipine and 147 controls in a primary-care center in Barcelona there was a higher prevalence of gingival overgrowth in patients taking nifedipine (34 versus 4.1%) (24).

Gastrointestinal

Acute abdominal pain due to mesenteric ischemia has been described with nifedipine (25).

Two patients developed severe gastric mucosal damage probably due to nifedipine (26).

- A 62-year-old man with gastric hemorrhage had a deep fundal ulcer in which a tablet of nifedipine was firmly embedded. The tablet was removed endoscopically and he was given cimetidine and recovered.
- A 67-year-old man with diabetes and hypertension, taking glibenclamide and nifedipine, developed dysphagia. Gastroscopy showed severe damage to the mid-esophagus. He did not respond to omeprazole and sucralfate, but gradually improved after nifedipine withdrawal, and the lesion disappeared.

Modified-release formulations of nifedipine have been associated in case reports with the formation of bezoars, concretions of undigested material within the gastrointestinal tract, mostly in the stomach. An unusual case of tablet impaction in the duodenum, with gastric outlet obstruction, was discovered 1 year after the patient stopped taking a modified-release formulation of nifedipine (27).

- A 77-year-old woman developed constipation and weight loss. Esophagogastroduodenoscopy showed a deformed pylorus and an elongated duodenal bulb, with numerous impacted tablets and ulceration in the outlet. Since only a few tablets could be recovered by endoscopy, she underwent partial duodenal resection to remove the contents: 25 intact tablets that were confirmed to be modified-release nifedipine.

© 2006 Elsevier B.V. All rights reserved.

Liver

Hepatic steatosis with Mallory inclusion bodies has been reported with nifedipine (28). In patients with liver cirrhosis, nifedipine increases portal pressure due to splanchnic vasodilatation (29); whether this increases the risk of variceal bleeding is unknown.

Urinary tract

Several reports have linked renal dysfunction with nifedipine. In a study of hypertensive diabetics with renal insufficiency, nifedipine increased proteinuria and worsened renal function (SEDA-16, 196). Others have reported mild reversible renal impairment in patients with chronic renal insufficiency taking nifedipine for angina or hypertension; a biopsy in one of the patients, who had heavy proteinuria, showed focal and segmental glomerulosclerosis (30). Immune-complex nephritis was reported in a patient taking nifedipine, but the proteinuria persisted (and indeed worsened) on changing to verapamil (31).

Nifedipine was associated with an apparent diuresis within a short time of the first dose in 14 of 24 patients (32) and with nocturia, which ceased or improved markedly on withdrawal of therapy in nine patients (33). The nocturia was considered to reflect an effect of calcium channel blockade on detrusor function.

Skin

Bullous eruptions secondary to nifedipine include bullous fixed drug eruptions, phototoxic bullous eruptions, erythema multiforme, and pemphigus foliaceus.

Two cases of pemphigus vulgaris, one aggravated and one induced by nifedipine, have been described (34).

- A 54-year-old woman with an 8-year history of pemphigus vulgaris had a flare-up of her disease, refractory to oral glucocorticoids, after taking nifedipine for 2 years for hypertension. The nifedipine was withdrawn and she was given high-dose immunosuppressant treatment with prednisone and azathioprine. The lesions subsided promptly and cleared totally within several weeks.
- A 68-year-old woman had a bullous eruption of pemphigus vulgaris after antihypertensive treatment with nifedipine. She was given high-dose systemic glucocorticoids. However, she was unresponsive and nifedipine was finally withdrawn. Although new lesions did not appear, she died a few days later with uncontrollable sepsis.

Probable nifedipine-induced pemphigoid has also been reported (35).

- A 70-year-old man with hypertension took nifedipine 10 mg bd and 3 months later developed a pruritic eruption on his back, which spread to cover his trunk, limbs, face, and scalp, with involvement of the mouth. His skin deteriorated after the dosage of nifedipine was increased to 20 mg bd 1 year later. Antibodies to the 230 kDa pemphigoid antigen were detected in his serum. His skin improved considerably after withdrawal of nifedipine and the use of topical steroids and oral minocycline.

The findings supported a diagnosis of pemphigoid.

Photosensitivity (36) and a generalized bullous eruption (37) have been attributed to nifedipine, as have telangiectasia and spider nevi (38).

Musculoskeletal

Severe muscle cramps in the legs and hands can occur during nifedipine treatment (39).

Immunologic

Anaphylaxis has been attributed to sublingual nifedipine (40).

- A 71-year-old man with prostatic adenocarcinoma and a pathological vertebral fracture received sublingual nifedipine for hypertension and 15 minutes later became stuporose and complained of pruritus, generalized erythema, dizziness, and nausea. His blood pressure had fallen to 60/40 mmHg, his pulse rate was 120/minute, and his respiratory rate was 30/minute. He had cyanosis and severe bronchospasm with no focal neurological abnormalities. After treatment with subcutaneous adrenaline, intravenous fluids, hydrocortisone, and aminophylline, his blood pressure increased to 125/70 mmHg. During the following days his neurological and pulmonary status rapidly improved.

Second-Generation Effects

Pregnancy

Tocolytic therapy with nifedipine has been reported in several studies to be at least effective as ritodrine, terbutaline, or magnesium sulfate, with fewer maternal adverse effects (SEDA-18, 216) (SEDA-20, 187) (SEDA-22, 217) (SEDA-23, 211). These observations have been confirmed in two trials in 102 and 54 pregnant women of under 34 weeks gestation, randomized to nifedipine or ritodrine. There were no differences in the time of delivery, but significantly fewer maternal adverse effects in those given nifedipine (41,42).

The possibility that calcium channel blockers can cause cardiovascular adverse effects in pregnancy has been widely debated (SED-14, 598) (SEDA-20, 185) (SEDA-21, 208) (SEDA-22, 214). An uncomplicated non-Q wave myocardial infarction has been reported during nifedipine therapy for preterm labor (43).

- A 29-year-old woman was admitted because of preterm rupture of membranes and uterine contractions at 29 weeks. She was given ritodrine and 30 hours later reported chest pain. The electrocardiogram was normal. Ritodrine was withdrawn. Oral nifedipine was started and 4 hours later she reported chest pain. Her blood pressure was 70/50 mmHg and her heart rate 124/minute. The electrocardiogram showed T wave inversion in lead III and the serum creatine kinase activity was raised.

The authors concluded that even if $beta_2$-adrenoceptor agonists can cause myocardial ischemia in pregnant women by further increasing oxygen consumption, acute myocardial necrosis is rare; however, in this case

© 2006 Elsevier B.V. All rights reserved.

nifedipine could have posed an extra risk by causing hypotension and reflex tachycardia.

In a review of almost 800 patients randomized to beta-adrenoceptor agonists or nifedipine, the latter was associated with more frequent prolongation of pregnancy, a lower incidence of respiratory distress syndrome, and lower incidences of maternal and fetal adverse effects (44).

Fetotoxicity

The use of nifedipine during pregnancy and labor has been widely debated, although its effects on child development have not been well evaluated. In one study nifedipine did not affect the development and health of 190 children, aged 18 months, born to women with mild to moderate hypertension who had been randomized to nifedipine, given for 12–34 gestational weeks before delivery, or expectant management (45).

Susceptibility Factors

Treatment of hypertensive emergencies has been the object of a randomized comparison of isosorbide dinitrate aerosol and nifedipine in 60 adults (46). Two patients taking nifedipine had myocardial ischemia early after administration and four patients had rebound hypertension during the follow-up period. Authors who reviewed the role of nifedipine in hypertensive emergencies reached the conclusion that the use of short-acting sublingual or oral nifedipine is no longer recommended for the treatment of these urgencies because it can precipitate serious adverse reactions (47).

There has been a report of cardiovascular collapse after uncomplicated coronary artery bypass surgery in patients taking nifedipine preoperatively (48); the condition responded to intravenous calcium chloride in three patients and adrenaline in four. Nifedipine may facilitate cardiac arrest during induction of anesthesia by sensitizing the carotid sinus (49).

Drug Administration

Drug overdose

Unlike verapamil and diltiazem, overdose with nifedipine is not usually fatal. Multiple case series of pediatric nifedipine ingestion have been published, and none has reported any deaths. However, two fatal cases of ingestion of long-acting nifedipine in children have been reported: a 24-month-old girl who took 20 tablets of nifedipine 10 mg and a 14-month-old girl who took a single tablet of nifedipine 10 mg; neither responded to aggressive supportive care (50).

Drug–Drug Interactions

Alcohol

There is a substantial increase in the systemic availability of nifedipine when alcohol is taken at the same time (51).

Atenolol

The combination of nifedipine with atenolol in patients with intermittent claudication resulted in a reduction in walking distance and skin temperature, whereas either drug alone produced benefits (52).

Ciclosporin

Ciclosporin significantly inhibits the metabolism of nifedipine, leading to increased effects (53).

Fluconazole

A pharmacokinetic interaction between fluconazole and nifedipine has been reported (54).

- A 16-year-old man with neurofibromatosis type 1, a malignant pheochromocytoma with lung and bone metastases, and candidiasis of the gastrointestinal tract with fungemia was taking nifedipine for arterial hypertension. The fungal infection responded to fluconazole, but three attempts to withdraw the fluconazole resulted in recurrence of headache, palpitation, and increased blood pressure.

After careful pharmacokinetic assessment of the effects of fluconazole withdrawal on 24-hour ambulatory blood pressure and nifedipine plasma concentration, the authors concluded that fluconazole can enhance the blood-pressure lowering effects of nifedipine by increasing its plasma concentrations, most likely by inhibiting CYP3A4.

Lithium

Lithium clearance is reduced by about 30% by nifedipine (55).

Melatonin

Melatonin has a hypotensive effect in both normotensive and hypertensive subjects. In a double-blind, randomized, crossover study designed to evaluate whether evening ingestion of melatonin potentiates the antihypertensive effect of nifedipine monotherapy in 50 patients with well-controlled mild to moderate hypertension aged 38–65 years (28 men, 22 women), there was a surprising significant increase in blood pressure and heart rate throughout 24 hours (56). The authors suggested that there was competition between melatonin and nifedipine, with impairment of the antihypertensive efficacy of the calcium channel blocker.

Phenytoin

Increased serum phenytoin concentrations have been reported after the introduction of nifedipine (57,58).

Quinidine

Nifedipine may enhance the elimination of quinidine (59) and cause hypotension and a loss of antidysrhythmic effect (60).

Tacrolimus

Nifedipine can increase the blood concentration of the macrolide immunosuppressant tacrolimus (SEDA-21, 392).

Food–Drug Interactions

The effect of food on the systemic availability of two modified-release dosage forms of nifedipine for once-daily administration (Adalat OROS, a tablet with an osmotic push–pull system, and Slofedipine XL, a tablet with an acid-resistant coating) has been investigated in 24 healthy men in an open, randomized, crossover study (61). After fasted administration the systemic availability was slightly lower for Slofedipine XL than Adalat OROS, with a point estimate of 82%, mainly resulting from differences in nifedipine concentrations during the first 15 hours after administration. Maximum plasma concentrations were lower after Slofedipine XL compared with Adalat OROS (point estimate 84%). After a high-fat breakfast the differences in availability between the two products were greater than while fasting, with point estimates of 70% for AUC and 81% for C_{max}. Most striking was the lag time after food for Slofedipine XL which was more than 15 hours in 15 of 24 subjects. The availability of nifedipine from Slofedipine XL compared with Adalat OROS was only 28% over the intended dosing interval of 24 hours. The delay in nifedipine absorption when Slofedipine XL is administered may be explained by properties of the formulation, since the acid-resistant coating probably confers delayed absorption, due to prolongation of the gastric residence time, while the osmotic push–pull system is not sensitive to food. The same authors conducted a similar study in 24 healthy subjects, in which they compared Adalat OROS with Nifedicron, a product that consists of a capsule containing several mini-tablets (62). There was a higher rate of availability for Nifedicron in the fasted state, and after a high-fat breakfast the differences between the products became even more pronounced. The most important effect of concomitant food was reflected by a pronounced increase in *C*max after Nifedicron, which resulted in a more than three-fold higher mean concentration than Adalat OROS. This phenomenon may result in safety and tolerability problems.

Niflumic acid

See also Non-steroidal anti-inflammatory drugs

General Information

The three atoms of fluoride in the niflumic acid molecule may be critically implicated in its adverse effects. However, as niflumic acid has been on the market in many countries for more than a decade, fluoride-induced adverse effects are probably very rare, and they are clinically relevant only if therapy is very prolonged. There are no adequate prospective studies of the comparative advantages and disadvantages of niflumic acid.

Organs and Systems

Nervous system

Headache is a common adverse effect of niflumic acid (SED-8, 223).

© 2006 Elsevier B.V. All rights reserved.

Hematologic

A patient with agranulocytosis and a positive lymphocytic stimulation test recovered after withdrawal (1).

Gastrointestinal

Niflumic acid has the same gastrointestinal adverse effects profile as other anthranilic acids (SED-8, 223).

Liver

Hepatic damage has rarely been reported (SEDA-1, 90). Fatal icteric hepatitis occurred in a patient taking niflumic acid and paracetamol (SEDA-13, 83).

Urinary tract

Nephrotoxic effects have often been reported with niflumic acid, although whether this really indicates a relatively high potential for renal toxicity is an open question. Water retention with edema, oliguria, proteinuria, and increases in urea and creatinine concentrations have been described (SED-8, 223) (2).

Seven children taking niflumic acid for ear, nose, and throat disorders for 1-5 days developed acute renal insufficiency due to immune interstitial nephritis; oedema, oliguria, or anuria occurred at 3–6 days (2). There were signs of hypersensitivity (fever, skin rash, eosinophilia, and/or increased IgE) in all cases, leukocyturia in five, and hematuria in six. Renal biopsy showed interstitial lesions with infiltrates of lymphocytes, eosinophils, and plasma cells, but no tubular cell necrosis. In two patients renal insufficiency was irreversible despite the use of methylprednisolone.

Musculoskeletal

Niflumic acid can provoke rhabdomyolysis (SEDA-14, 95).

There are several accounts of skeletal fluorosis attributable solely to chronic intoxication with fluoride as a result of long-term use of the drug (up to 11 years) (SEDA-6, 99). As each capsule of niflumic acid contains 50.5 mg of fluoride, daily intake could be up to 0.30 g. The skeletal fluorosis was asymptomatic and was discovered only by routine radiology. Homogeneous osteosclerosis was in all cases greatest in the axial skeleton. Urinary fluoride concentrations were high and associated with hypocalcemia, hypocalciuria, and increased serum alkaline phosphatase activity. Bone biopsies showed increased trabecular bone volume, suggesting bone fluorosis. Persistent fluoride ingestion leads to a high bone fluoride content, since fluoride is trapped at the site in the apatite mineral lattice that is normally occupied by the hydroxyl group (3). Exactly how fluoride causes changes in bone structure and why osteocondensation is unevenly distributed is not known. It is not clear whether osteoid stimulation increases bone fragility (4). In view of the dangers of fluoride accumulation in renal insufficiency, niflumic acid should not be given in this condition (5).

Nifurtimox

General Information

There are still few drugs available for the treatment of late-stage sleeping sickness due to *Trypanosoma gambiense*. Melarsoprol and eflornithine are equally efficacious, but both are toxic, and eflornithine is expensive. High-dose nifurtimox (30 mg/kg/day) has been used in Zaire for the treatment of arsenic-resistant trypanosomiasis; this dose was more effective and also more toxic. Of the 30 patients, one died after a period of confusion and coma and eight developed neurological effects, namely confusion, tremor, vertigo, and convulsions. One developed a rash and 12 had marked weight loss (SEDA-17, 333).

Acute polymyositis and toxic erythema purpura have been described in a young woman treated with nifurtimox for Chagas' disease; she died with respiratory and renal failure (SEDA-11, 598) (1).

Nifurtimox is the only drug approved for use in the USA (for Chagas' disease), but it is available exclusively on request from the Drug Service of the CDC. For treatment of the acute phase of Chagas' disease and in congenital cases the recommended dosage is 8–10 mg/kg/day, divided into two or three daily doses, for 30–60 consecutive days. In acute Chagas' disease, nifurtimox reduces both the duration of symptoms and parasitemia and mortality, but with limited efficacy in the eradication of parasites. The more frequent adverse effects are anorexia, loss of weight, psychic alterations, excitability or sleepiness, and digestive manifestations, such as nausea, vomiting, and occasionally intestinal colic and diarrhea (2). Other common adverse effects include neurological adverse effects (such as paresthesia, polyneuropathy, and convulsions), hematological adverse effects (such as thrombocytopenia and granulocytopenia), and allergic skin reactions (SEDA-13, 836) (3).

Long-Term Effects

Mutagenicity

Chromosomal aberrations were significantly increased in cultures of peripheral lymphocytes from a small group of children with Chagas' disease treated with nifurtimox. G-binding analysis of chromosomal aberration sites

© 2006 Elsevier B.V. All rights reserved.

showed that treated patients presented coincidence in the chromosome regions affected (SEDA-15, 298).

Nikethamide

General Information

Nikethamide has actions similar to doxapram hydrochloride and was formerly given intravenously, intramuscularly, subcutaneously, or orally for the treatment of overdose due to nervous system depressants. However, it can be dangerous and should not be used.

In addition to generalized restlessness, the adverse effects of nikethamide are itching, flushing, sweating, coughing, nausea, vomiting, muscle twitching, especially of the face, and convulsions (1–3). These are actually toxic effects, the margin between the clinically effective dose and the toxic dose being very narrow.

Nimesulide

See also Non-steroidal anti-inflammatory drugs

General Information

Nimesulide is a selective COX-2 inhibitor. Data from a postmarketing survey on short-term nimesulide treatment of osteoarthritis in 22 938 outpatients confirmed that its adverse effects profile is similar to the profiles of other NSAIDs (SEDA-16, 114). Evidence that nimesulide is well tolerated in aspirin-sensitive asthmatic patients requires confirmation in more extensive well-conducted studies (SEDA-18, 107).

Organs and Systems

Nervous system

Nervous system adverse effects (nervousness, vertigo) have been reported with nimesulide (1).

Hematologic

Thrombocytopenia in an HIV-positive patient treated with nimesulide regressed rapidly when the drug was withdrawn (SEDA-14, 96).

Mouth and teeth

A fixed drug eruption occurred in the mouth of a young woman who had taken nimesulide (SEDA-17, 114).

Gastrointestinal

Gastrointestinal symptoms (pyrosis, pain, nausea) can occur (1), but in a short-term endoscopic study nimesulide caused less gastric damage than indometacin (SEDA-15, 104).

Liver

Many cases of liver toxicity have been reported with nimesulide.

Of five patients, two died as a result of fulminant hepatic failure while taking nimesulide (2).

Six cases of acute hepatitis occurred in four patients during the first 10 weeks of treatment, and in two after 15 weeks of therapy (3). They were represented by jaundice ($n = 5$), itching ($n = 2$), weakness ($n = 3$), and anorexia, nausea, and vomiting ($n = 2$). Increases in liver enzymes varied from 1.5 to over 30 times the upper limit of the reference range. Liver biopsy showed centrilobular or panlobular bridging necrosis in the four women and intrahepatic cholestasis in the two men. Complete recovery of normal liver function tests ensued at follow-up after interruption of nimesulide therapy.

- Fulminant hepatic failure due to massive hepatic necrosis occurred in a 58-year-old woman who took nimesulide for a few weeks for osteoarthritis (4). In the months before, she had received a first short course of the drug, apparently without problems. When she resumed nimesulide therapy she complained of non-specific symptoms, including nausea, and appeared jaundiced. The drug was withdrawn and liver transplantation was performed, but she died of multiorgan failure.

The previous exposure may have sensitized the patient with accelerated liver injury on re-exposure.

Several other reports of the potential hepatotoxicity of nimesulide have appeared (SEDA-25, 135) (5–7). A wide range of types of liver damage have been documented (8). Some patients have required liver transplantation (9) and deaths have occurred (10). The pathogenic mechanism of these unpredictable, sometimes severe, reactions is uncertain (11,12). In some countries nimesulide has been withdrawn from the market or its use has been restricted.

In some cases the hepatitis is severe (SEDA-23, 121). In one case fatal hepatitis occurred after 8 months of treatment (13) and in another treatment for 5 days precipitated fulminant hepatitis (14).

© 2006 Elsevier B.V. All rights reserved.

The Portuguese Pharmacy and Medicines Institute suspended the pediatric formulation of nimesulide in March 1999 (15). This decision was made because of reports of serious adverse drug reactions, including liver damage, in children taking the drug. Nimesulide should be withdrawn immediately if abnormal liver function tests develop, and rechallenge must be avoided. However, it is not yet clear if the potential for hepatotoxicity of this drug is similar or greater to that found with other NSAIDs (16).

Urinary tract

Acute oliguric renal insufficiency caused by interstitial nephritis was attributed to nimesulide in a 68-year-old woman with diffuse arteriosclerosis but normal renal function (SEDA-22, 119).

A series of 11 spontaneously reported cases in which renal impairment was associated with the use of nimesulide has been described (17). The adverse events were represented by acute renal insufficiency ($n = 2$), acute deterioration of chronic renal insufficiency ($n = 3$), fluid retention ($n = 4$), and oliguria and macrohematuria ($n = 1$ each). The patients had a median age of 57 (range 17–81) years and six had some predisposing condition (chronic renal insufficiency, heart failure, diabetes, use of diuretics) to NSAID-induced functional renal impairment. Apart from one patient, nimesulide was taken for a very short time (less than 8 days). A favorable outcome ensued after withdrawal of therapy in all patients. The acute deterioration of renal function described in these patients pointed to hemodynamically mediated renal impairment in all cases, with the exception of one man in whom interstitial nephritis was suspected.

Skin

Reported cutaneous effects of nimesulide include rash and itching (1) and toxic epidermal necrolysis (SEDA-22, 119).

Second-Generation Effects

Fetotoxicity

Various types of nephrotoxicity have been described with nimesulide (SEDA-22, 119) (SEDA-23, 121). Two reports have illustrated the potential danger of using it as a tocolytic (18) or during late pregnancy (19). In both cases, maternal ingestion of nimesulide was accompanied by irreversible neonatal renal insufficiency. In the second case, renal biopsy showed abnormal tubular differentiation and signs of tubulointerstitial nephritis. The mechanism of this adverse reaction is not known, but it is probably related to fetal COX-2 inhibition. COX-2 is fundamental for nephrogenesis, and is upregulated in fetal membranes and myometrium at parturition.

A report has confirmed the potential danger of using nimesulide as a tocolytic agent (SEDA 24, 123). Nimesulide (100 mg bd) was prescribed for postoperative preterm labor prophylaxis, and severe oligohydramnios was identified 3 weeks later (20). After withdrawal the amniotic fluid volume returned to normal over 2 weeks. There were no adverse neonatal renal effects.

Nimodipine

See also Calcium channel blockers

General Information

Nimodipine is a dihydropyridine calcium channel blocker.

In the absence of effective neuroprotective treatment for ischemic stroke, a double-blind, randomized, placebo-controlled trial has been performed in 454 patients in primary care (1). Nimodipine 30 mg/day or placebo was started within 6 hours after the onset of the stroke and continued for 10 days. Nimodipine had no effect on all-cause mortality or dependency in daily life. In patients with ischemic stroke documented by CT scan, nimodipine had a borderline significant adverse effect on outcome. Nimodipine was tolerated as well as placebo (7 versus 8 treatment withdrawals respectively), but the lack of benefit does not support the use of any voltage-sensitive calcium channel blocker in ischemic stroke.

It has been suggested that calcium channel blockers can be used to treat cocaine dependence, and some studies have shown reductions in cocaine-induced subjective and cardiovascular responses with nifedipine and diltiazem. The cardiovascular and subjective responses to cocaine have been evaluated in a double-blind, placebo-controlled, crossover study in five subjects pretreated with two dosages of nimodipine (2). Nimodipine 60 mg attenuated the systolic, but not the diastolic, blood pressure rise after cocaine. In three subjects, nimodipine 90 mg produced greater attenuation than 60 mg. The subjective effects of cocaine were not altered by either dosage of nimodipine.

Organs and Systems

Cardiovascular

When nimodipine was given intravenously to 87 patients with proven subarachnoid hemorrhage in a maintenance dosage of 2 mg/hour, it caused significant hypotension in one-third of cases (3). With maintenance oral administration, the incidence of hypotension was much lower. It is therefore recommended that if nimodipine is prescribed, the oral route is preferable, even in intubated patients who should receive it via a nasogastric tube.

Nervous system

Nimodipine has been routinely used to reduce cerebral vasospasm in patients with subarachnoid hemorrhage. A randomized, double-blind, placebo-controlled trial was stopped early because of excess mortality (8/75 versus 1/74 deaths with nimodipine and placebo respectively), which was attributed to an increased incidence of surgical bleeding (4). In addition, its use for cerebral protection in a cardiac valve replacement trial involving cardiopulmonary bypass was also terminated prematurely because of increased cerebrovascular complications and excessive blood loss in a small subgroup of patients (5). In traumatic subarachnoid hemorrhage, a trial in 123 patients showed a significant reduction in unfavorable outcomes (death, vegetative survival, or severe disability) at 6 months with nimodipine (25 versus 46% for placebo) (6).

Niridazole

See also Benzimidazoles

General Information

Niridazole is used in the treatment of schistosomiasis and of guinea-worm (*Dracunculus medinensis*) infections; it is given in divided daily doses of 25 mg/kg for 5–10 days, depending on the infecting species. Niridazole is well tolerated in *Schistosoma hematobium* infections. It is metabolized in the liver, and its metabolites color the urine dark brown. In the treatment of schistosomiasis it has been largely superseded by newer drugs.

General adverse effects

In the treatment of schistosomiasis adverse effects were seen in 80% of inpatients and 33% of outpatients. Gastrointestinal effects were the most common, with vomiting in 50% of cases. Neurotoxic and psychiatric effects, convulsions, and cardiac effects are less common, except in patients with liver disease. Insomnia, somnolence, vertigo, nightmares, headache, weakness, jaundice, and muscle pains have all been reported (SEDA-12, 244). Toxic reactions are seen more often in *Schistosoma mansoni* infections, especially in patients with poor liver function or portocaval shunts, when neuropsychiatric complications can be expected. Some toxicity is directly related to parasite destruction and liberation of antigen rather than to the drug itself. Allergic reactions related to parasite destruction include urticaria, allergic conjunctivitis, and fever with peripheral eosinophilia. Niridazole is a potent carcinogen in mice, and tumorigenic in hamsters. It

© 2006 Elsevier B.V. All rights reserved.

is not clear what the risks are in man, but it is of course usually given for only a brief period.

Organs and Systems

Cardiovascular

Minor electrocardiographic abnormalities, especially T wave changes, are common but are probably of no functional significance of patients (1). Dysrhythmias with prolongation of the QT interval occur in a small minority of patients (2).

Respiratory

Cough, fever, and dyspnea with pulmonary infiltration have been reported in two cases (3).

Nervous system

Headache, drowsiness, and dizziness are common with niridazole (2,4,5). More severe neuropsychiatric symptoms are more frequent in patients with liver disease, especially those with portosystemic shunts, in whom the drug bypasses the liver (6). Symptoms in these cases include insomnia, anxiety, depression, confusion, hallucinations, and convulsions; the reactions may prove fatal. The electroencephalogram can show slowed alpha rhythms, beta waves, and theta waves, as well as sharp wave and spike forms with niridazole (7). A single case of acute cortical necrosis was recorded in the much older literature, but was probably coincidental (SED-8, 691) (8). Agitation can occur in patients with abnormal liver function.

Hematologic

A peripheral eosinophilia is usual (2). Hemolysis has been reported once in glucose-6-phosphate dehydrogenase (G6PD) deficiency (SED-8, 691) (9).

Gastrointestinal

Bad taste, anorexia, nausea, vomiting, diarrhea, and abdominal pain are common with niridazole (1,2,5). Gastrointestinal bleeding has been seen (10).

Liver

Prolongation of the prothrombin time can occur (11). Niridazole is contraindicated in liver disease.

Urinary tract

Metabolites of niridazole color the urine dark brown (12,13).

Musculoskeletal

Muscle pain, joint pain, and bone pain are commonly reported but may be related to parasite destruction rather than to direct toxicity (5).

Long-Term Effects

Mutagenicity

Niridazole should not be used in pregnancy; mutagenic effects have been seen in bacteria (14).

Second-Generation Effects

Fertility

Transient reduction in spermatogenesis, apparently reversible, can occur (15).

Susceptibility Factors

Genetic factors

Caution is required when using niridazole in individuals with G6PD deficiency (16).

Hepatic disease

Niridazole should not be used in the presence of hepatic disease (17).

Nitazoxanide

General Information

Nitazoxanide is a thiazolide derivative first described in 1975 and originally developed as a veterinary antihelminthic drug. In vitro it has a documented efficacy against protozoa such as *Giardia lamblia*, *Trichomonas vaginalis*, and *Entamoeba histolytica*, and in vivo in particular against *Cryptosporidium parvum* in patients with AIDS, as well as against nematodes such as *Syphacia obvelata*, *Uncinaria stenocephala*, and *Trichuris vulpis*, and cestodes such as *Dipylidium canimum*, *Tenia pisiformis*, and *Hymenolepis nana* (1,2). Since it is also effective against *Fasciola hepatica* in vitro it has been tried in the treatment of fasciola infections in man.

Pharmacokinetics

Nitazoxanide was given to many patients, before its tolerability and pharmacokinetics were adequately assessed (1,2). In men randomly assigned to one of four treatment groups, in each of which two took a placebo and six took a single oral dose of nitazoxanide 1, 2, 3, or 4 g, first fasted and a week later with a standardized breakfast, there were no significant changes in electrocardiograms, vital signs, or laboratory tests (1). Plasma concentrations increased linearly with dose, although there was a trend to increased systemic availability at a dose of 4 g. Food approximately doubled the concentrations of the metabolites of nitazoxanide, deacetylnitazoxanide (or tizoxanide), and tizoxanide glucuronide, irrespective of dose. Tizoxanide glucuronide was eliminated more slowly than tizoxanide. Tolerability was good up to the maximum dose of 4 g. There were 89 adverse events; all were mild and none required treatment. Minor adverse events were dizziness, fatigue, discolored urine, malaise, and postural hypotension. However, the most frequent adverse events were gastrointestinal—diarrhea ($n = 13$), abdominal pain ($n = 8$), flatulence and nausea ($n = 5$), and vomiting ($n = 3$). Their frequency increased significantly with dose under fed conditions but not fasted.

Observational studies

In a village close to Alexandria in Egypt 137 patients were given nitazoxanide 500 mg bd for 6 days (3). On the 30th day 113 patients (82%) were presumed cured, with stools free of fasciola eggs. Nitazoxanide was extremely well tolerated. Only three patients reported adverse effects: abdominal pain in two and vomiting in one. The symptoms were mild and disappeared without medication or withdrawal of treatment. Together with triclabendazole, nitazoxanide can be considered for the treatment of *Fasciola hepatica* infections in man.

Placebo-controlled studies

Nitazoxanide 0.5 g bd and 1 g bd was given to 16 healthy volunteers for 7 days with food to study its pharmacokinetics and tolerability (2). The pharmacokinetics of both tizoxanide and tizoxanide glucuronide were only slightly influenced by repeated administration of nitazoxanide 0.5 g bd; the treatment group had no more adverse events than the placebo group and there was no accumulation. In contrast, repeated administration of nitazoxanide 1 g bd resulted in a significant increase in adverse events: diarrhea ($n = 9$), abdominal pain ($n = 9$), flatulence ($n = 5$), nausea ($n = 4$), and dyspepsia ($n = 1$). All reported discolored urine. Four subjects in the high-dose group reported headaches. Vital signs, electrocardiograms, and laboratory tests were normal. There was accumulation of nitazoxanide metabolites, because of solubility-limited or transport-limited elimination at the higher dose of nitazoxanide.

Nitrates, organic

See also Antianginal drugs

General Information

Organic nitrates have been in use for over 135 years, and their adverse effects are therefore well documented. The first compound of this class to be used was amyl nitrite, synthesized in 1844 by Ballard and used to treat angina pectoris by Brunton in 1869. Glyceryl trinitrate was first synthesized by Ascagne Sobrero in 1847 and was used by William Murrell to treat angina pectoris in 1879.

Nitrates have been produced in many chemical forms, but the current choice lies between the rapid-onset, short-acting glyceryl trinitrate (nitroglycerin) and the longer-acting isosorbide mononitrate and isosorbide dinitrate.

Mechanism of action

The nitrates act by releasing nitric oxide, which relaxes vascular smooth muscle. The discovery that endothelium-derived relaxing factor (EDRF) is nitric oxide (1) stimulated new interest in these drugs, as nitric oxide not only controls local vessel wall tension in response to shear stress, but also plays a role in regulating the interaction of platelets with blood vessel walls. The release of nitric oxide from the walls of atheromatous arteries is reduced, because of malfunctioning or absent endothelium. Atheromatous arteries behave differently from healthy arteries, in that these vessels vasoconstrict rather than vasodilate when stimulated by acetylcholine. This impairment of the acetylcholine vasomotor response appears to be related to serum cholesterol concentration (2).

Uses

Traditionally, nitrates have been first-line therapy in angina. They can be given to treat acute attacks, taken prophylactically before exertion or other stimuli known to provoke an attack, or used as continuous prophylaxis over 24 hours. Since angina is an episodic symptom, the first two methods are attractive, as continuous prophylaxis requires treatment over long periods when there are no symptoms. Tempering this argument is the realization that there may be silent myocardial ischemia, especially overnight, and morning angina on waking can be troublesome. In practice, a combination of continuous prophylaxis and as-required therapy is often used.

Nitrates are the drugs of choice in patients with left ventricular impairment, in whom they are of benefit when used in combination with hydralazine (3), and they should be used in preference to the calcium antagonists, which cause deterioration in myocardial function by an as yet unknown mechanism (4). In black patients with congestive heart failure taking ACE inhibitors and beta-blockers, a combination of isosorbide dinitrate plus hydralazine significantly reduced total mortality (5).

The potentially life-threatening hypotension caused by an interaction with sildenafil citrate (Viagra), a treatment for male erectile dysfunction, should be highlighted, especially in patients with coronary heart disease needing regular nitrates (6).

Observational studies

Glyceryl trinitrate can be used to treat anal fissure, as an alternative to surgery. Although glyceryl trinitrate causes resolution of symptoms in some cases, its local use as ointment is associated with frequent adverse reactions, mostly headache and anal burning (7,8). The difficulty in adjusting the dose and time of application, the high frequency of adverse reactions (up to 75% of patients), and the high rate of recurrence make the use of glyceryl trinitrate in non-surgical treatment of anal fissures questionable (9). In one case, a patient reported itching, dyspnea, and hypotension after applying glyceryl trinitrate. This unexplained systemic reaction to topical glyceryl trinitrate was reported as "anaphylactic," without a clear demonstration that it was an allergic reaction (10).

Besides its usual indications, topical glyceryl trinitrate has been used to prevent intravenous infusion failure because of phlebitis and extravasation, which occur in 30–60% of patients and can cause discomfort and harm, such as pulmonary embolism, septicemia, and increased mortality. Local application of glyceryl trinitrate patches was efficacious in several studies (11); the mechanism is probably vasodilatation and increased capillary flow. Glyceryl trinitrate is safe, since it causes only skin rashes and transient headache.

Transdermal glyceryl trinitrate is effective as an analgesic co-adjuvant for cancer pain. In combination with opiates it is well tolerated and reduces the daily consumption of morphine (12). Transdermal glyceryl trinitrate was safe in potentiating the analgesic effect of spinal sufentanil analgesia after knee surgery (13). The effects of glyceryl trinitrate include headache, a feeling of pressure in the head, nausea, vomiting, dizziness, tiredness, blackouts, and possibly penile erection and ageusia (14,15).

Placebo-controlled studies

In a multicenter, randomized, placebo-controlled, double-blind study of 0.2% glyceryl trinitrate ointment in 132 patients with anal fissures over at least 4 weeks, healing rates were similar with glyceryl trinitrate and placebo, but adverse events were more frequent in those who used glyceryl trinitrate: 34% complained of headache and 5.9% had orthostatic hypotension (16).

High-dose transdermal glyceryl trinitrate 50–100 mg given over a period of 12 hours each day for 3 months improved exercise tolerance and left ventricular systolic function in 29 patients with congestive heart failure taking a long-term ACE inhibitor (17). The most frequent adverse effects were skin irritation at the site of patch application and headache, which caused premature glyceryl trinitrate withdrawal in three patients.

Intravenous glyceryl trinitrate (starting rate 50 micrograms/minute uptitrated with blood pressure monitoring) for an average of 63 hours was very effective in preventing adverse ischemic events in 200 patients with unstable angina secondary to restenosis after coronary artery angioplasty, while heparin had no effect (18). In this acute setting, complications and adverse effects were not frequent, even if there was an excess of cases with headache or hypotension with glyceryl trinitrate, never leading to premature discontinuation. This study has shown that glyceryl trinitrate is safe and effective in

© 2006 Elsevier B.V. All rights reserved.

reducing the need for urgent invasive procedures in these patients.

Comparative studies

Glyceryl trinitrate has been used as a tocolytic to prolong gestation, reducing the incidence of preterm labor. When compared with a widely used tocolytic, the beta$_2$-adrenoceptor agonist ritodrine, in a randomized, multicenter trial, transdermal patches of glyceryl trinitrate 10–20 mg had similar efficacy in 245 women with preterm labor. The main adverse effect of glyceryl trinitrate was headache, while with ritodrine palpitation and tachycardia were significantly more frequent. Headache with glyceryl trinitrate could usually be managed with paracetamol. Therefore, glyceryl trinitrate appears to be an alternative to ritodrine and is devoid of dangerous cardiac adverse effects (19).

In 90 patients randomly assigned to surgery (internal sphincterectomy) or topical glyceryl trinitrate, surgery led to a higher rate of healing than glyceryl trinitrate, with fewer adverse events: 29% of surgical patients versus 84% of the patients given glyceryl trinitrate (20). In conclusion, glyceryl trinitrate should not be used to treat anal fissure.

Variceal bleeding is a frequent and serious event in cirrhosis, and carries an increased risk of death (SEDA-22, 218). Therapy to prevent bleeding is therefore essential in these patients. Propranolol alone has been compared with propranolol plus isosorbide-5-mononitrate in a randomized, double-blind study in 95 patients (21). The combined treatment reduced the incidence of variceal bleeding compared with propranolol alone, but without any improvement in survival. Isosorbide-5-mononitrate added to propranolol appeared to be less well tolerated than propranolol alone, since seven patients had to be withdrawn from treatment because of adverse effects (four with feelings of faintness, two with headache, one with angina-like chest pain), compared with one with atrioventricular block taking propranolol alone.

Isosorbide-5-mononitrate has been tested with and without propranolol in a placebo-controlled study in 30 patients with liver cirrhosis and esophageal varices (22). The aim of the study was to assess the severity of previously reported adverse effects (that is renal dysfunction and hepatic encephalopathy) when vasoactive drugs are used to prevent variceal bleeding. Neither isosorbide-5-mononitrate nor propranolol alone or together had any adverse effect on subclinical hepatic encephalopathy or renal function in patients with well-compensated cirrhosis. Severe headache in those taking isosorbide caused three patients to withdraw.

Routes of administration

Nitrates can be administered by various routes. For example, glyceryl trinitrate is used not only as traditional sublingual tablets but also in the form of modified-release tablets, buccal tablets, aerosolized oral spray, intravenous injection, and topical ointment or skin patches for percutaneous absorption (23). These different formulations have been developed largely as a means of controlling the onset and duration of action of glyceryl trinitrate, since in conventional oral form its action is limited by marked hepatic first-pass metabolism.

General adverse effects

The adverse effects of the nitrates are unaffected by the chemical form or by the route of administration. The spectrum and frequency of adverse effects for the individual drugs, such as glyceryl trinitrate, isosorbide dinitrate, and isosorbide-5-mononitrate, appear to be similar.

Generalized vasodilatation predictably produces some common mild adverse effects. These include headache, flushing, and palpitation, which are most often experienced during the early treatment period and to which a degree of tolerance invariably occurs. More severe adverse effects, including syncope, transient cerebral ischemic attacks, and peripheral edema, are less common. Sublingual glyceryl trinitrate tablets produce a characteristic local burning or tingling sensation. Adverse cardiac effects can follow abrupt withdrawal of treatment after long-term exposure or high-dose therapy. Contact irritation and allergic contact dermatitis can occur with cutaneous glyceryl trinitrate in ointment or skin patches, and may be attributed to the drug itself or an inactive excipient, such as an adhesive agent. There was no excess risk of cancer in a historical cohort study in 2023 male fertilizer workers exposed to industrial nitrates at work in Norway during 1945–79 (24).

Amyl nitrite

Amyl nitrite, despite its name, is also used as a nitrate. It is a yellowish liquid taken by inhalation of its vapor for angina pectoris. It has also been used to treat cyanide poisoning, but is nowadays used exclusively as a substance of abuse. Although it is a prescription-only medicine in the UK, it is sold over the counter in glass ampoules to be used as a "room deodorizer" or "incense." It is known under numerous different nicknames and brand names, including snappers, poppers, Rush, Kix, Liquid gold, Locker room, Hardware, Ram, Thrust, and Rock Hard.

Amyl nitrate can cause headache, flushing, hypotension, tachycardia, dizziness, and relaxation of the anal sphincter. Less commonly it causes fainting, stupor, vertigo, incontinence, dyspnea, glaucoma, and methemoglobinemia.

Organs and Systems

Cardiovascular

Hypotension is a frequent adverse effect of nitrates (24), resulting from dilatation of arteries and veins. It can be associated with reflex tachycardia and palpitation, and even syncope on assuming an upright posture. Hypotension occurs particularly in old people, especially those with recurrent falls (SEDA-16, 196), and more commonly with glyceryl trinitrate oral spray than with sublingual tablets, because of its faster onset of action (24). It tends to occur more commonly in those who take nitrates infrequently.

Alternatively, bradycardia can accompany hypotension or syncope (25–27), presumably due to a vagal effect (it is responsive to atropine); complete heart block has also been reported (28). Occasionally, similar events occur in patients without ischemic heart disease (29), suggesting a mechanism similar to vasovagal syncope or coronary artery spasm (30,31) rather than coronary steal.

© 2006 Elsevier B.V. All rights reserved.

Nitrates can precipitate myocardial infarction in susceptible patients (32), and occasionally worsen myocardial infarction, producing asystole (33) or ventricular fibrillation (34,35), possibly due to coronary steal or reperfusion of ischemic myocardium.

Throbbing headache as a result of dilatation of cerebral vessels (36,37) is common, although it often abates as tolerance develops. The once-a-day modified-release formulations of oral isosorbide mononitrate are particularly likely to cause headache on first exposure and have accounted for premature withdrawal in about 1% of cases in some trials (38,39).

Respiratory

Transient hypoxemia can complicate the use of glyceryl trinitrate and has been described after sublingual (40) and intravenous administration (41). In patients with ischemic heart disease this can result in a paradoxical response, with further angina pectoris and ST segment depression on the electrocardiogram (40). A possible explanation is vasodilatation of pulmonary arteries, leading to relative hypoventilation in some areas of the lungs, and it may be especially common and troublesome when glyceryl trinitrate is being tried for pulmonary hypertensive disease (42,43).

Nervous system

Glyceryl trinitrate can reduce cerebral blood flow, and this may explain occasional reports of impaired cognitive function and neurological disturbances in patients with coronary heart disease. Continuous intravenous infusion of glyceryl trinitrate in 12 healthy volunteers reduced blood flow velocity in the middle cerebral artery and increased slow-wave power during electroencephalography (44). Patients with cognitive disturbances receiving glyceryl trinitrate should be carefully monitored.

Transient cerebral ischemic attacks, unrelated to blood pressure changes, occurred with isosorbide dinitrate and glyceryl trinitrate ointment in a patient with previous cerebrovascular disease, and resolved on withdrawal (45). Such changes may be more frequent than is realized and, added to the risk of hypotension, suggest that nitrates should be used with great caution in patients with cerebrovascular disease.

Isosorbide mononitrate precipitated pituitary apoplexy in a patient with an unsuspected pituitary macroadenoma (46). Intracranial hypertension associated with glyceryl trinitrate has been reported and attributed to cerebral vasodilatation (47). However, it may occasionally be a consequence of hyperosmolality, hemolysis, and lactic acidosis caused by the excipient ethylene glycol used with intravenous isosorbide dinitrate. The risk of this may be greatest in patients with renal impairment (48).

Psychological, psychiatric

In an elderly woman, isosorbide dinitrate caused visual hallucinations and subsequent suicidal ideation, thought to be due to hypotension and cerebral ischemia (49).

Sensory systems

Eyes

On the basis of animal experiments it has been suggested that nitrates could increase intraocular pressure and should therefore not be used in the presence of glaucoma (50). However, both intravenous glyceryl trinitrate and oral isosorbide dinitrate actually lower the intraocular pressure, both in healthy individuals and in patients with open-angle and closed-angle glaucoma (51).

Taste

Glyceryl trinitrate in sublingual tablets causes a burning sensation under the tongue, an indication of the activity of the formulation. Altered and later absent taste sensation developed in a patient taking long-term transdermal glyceryl trinitrate patches (15).

Fluid balance

Peripheral edema occurred in patients treated for left ventricular failure with isosorbide dinitrate (52). This disappeared on withdrawal. The mechanism is unclear, in common with fluid retention reported with other vasodilators.

Hematologic

Methemoglobinemia has been reported after overdosage of sublingual glyceryl trinitrate (53) but does not occur with usual doses; prolonged intravenous infusion (up to 128 micrograms/minute) was not associated with pathological concentrations of methemoglobin (54). Higher mean infusion rates (290 micrograms/minute) (55), or occasionally lower rates in a patient with reduced drug clearance (56), can cause the formation of methemoglobin and could conceivably cause a clinical problem; however, recovery is rapid after injection of methylene blue (57).

In contrast, amyl nitrite can cause methemoglobinemia when abused, since it has a 2000 times higher affinity for hemoglobin (58). In vitro both amyl nitrite and glyceryl trinitrate reacted immediately with oxyhemoglobin to effect oxidation to methemoglobin, while for sodium nitrite there was a lag phase before the reaction occurred. The affinity rate constants were:

- 11 400 M^{-1} $minute^{-1}$ for sodium nitrite;
- 74 500 M^{-1} $minute^{-1}$ for amyl nitrite;
- 35 M^{-1} $minute^{-1}$ for glyceryl trinitrate.

Organic nitrates inhibit platelet aggregation in response to a wide variety of stimuli and prolong bleeding time.

Mouth and teeth

An increased frequency of dental caries with the use of buccal glyceryl trinitrate formulations has been reported in Sweden (SEDA-17, 237).

Skin

In a multicenter comparison of two transdermal nitrate delivery systems, there were skin problems at the application site in 20–39% of patients (59).

© 2006 Elsevier B.V. All rights reserved.

Allergic contact dermatitis has been reported with the use of an ointment containing glyceryl trinitrate (60), and its development should be suspected if persistent erythema, vesicles, papules, hyperpigmentation, or edema follow the use of such formulations. Allergy may be due to the drug itself or to an excipient in the ointment base. However, erythema and pruritus produced by glyceryl trinitrate ointment can also result from the pharmacological action of the drug. The use of transdermal nitrate patches has also resulted in allergic contact dermatitis which was attributed both to the active drug (61) and to an inactive component of the delivery system or adhesive (62).

A causal relation between rosacea and the facial flushing seen with vasodilators such as glyceryl trinitrate seems likely (63).

Long-Term Effects

Drug tolerance

There is progressive attenuation of the effects of nitrates within the first 24 hours of continuous exposure. In a review of a transdermal nitrate system, the short duration of action of the formulation was ascribed to tolerance (64).

At first it was thought that tolerance was due to depletion of intracellular endothelial sulfhydryl groups (65), which are necessary for the biotransformation of organic nitrates to nitric oxide. It seems likely that tolerance occurs through several mechanisms, and the precise mechanisms are still uncertain (66). However, one possible mechanism of tolerance has been elucidated (67). Organic nitrates are converted to *S*-nitrosothiols when combined with sulfhydryl moieties in smooth muscles. These compounds activate guanylate cyclase, leading to an increase in the intracellular concentration of cyclic GMP, with resultant vascular relaxation and vasodilatation. As the supply of sulfhydryl within the smooth muscles is limited, prolonged exposure to organic nitrates results in its depletion and hence tolerance (68). Other mechanisms of nitrate tolerance that have been proposed include neurohumoral adaptation and a plasma volume-dependent mechanism (69). A unifying hypothesis, involving the excess production of superoxide anions, has been proposed (70).

In an assessment of how nitrate tolerance might be avoided, the efficacy of thrice-daily buccal glyceryl trinitrate and that of four times a day oral isosorbide dinitrate were compared (71); over 2 weeks, prolonged antianginal efficacy was maintained only with thrice-daily buccal administration. Nevertheless, in another study, transdermal glyceryl trinitrate seemed to offer a prolonged effect, sufficient to wean patients with unstable angina from intravenous nitrate therapy (71).

It has been convincingly shown that a nitrate-free period reduces nitrate tolerance (72). The modern strategy is to have a nitrate-free period when the patient is asleep, although this results in reduced protection from ischemia in the early morning, the time when many episodes of silent ischemia and myocardial infarction occur. Reports that ACE inhibitors (73) or carvedilol (74) reduce nitrate tolerance are as yet unconfirmed (75).

Three published controlled trials of the use of vitamin C in treating nitrate tolerance in 77 subjects overall have been reviewed (76). Vitamin C (3–6 g/day orally or by intravenous infusion) reduced nitrate tolerance for up to 3 days, without causing adverse reactions. However, before making definitive recommendations, studies of longer duration should be done in a larger number of patients.

Drug withdrawal

Adverse reactions to industrial exposure to glyceryl trinitrate were first reported in 1914 (77), and there have been several subsequent reports of symptoms during the weekend resulting from withdrawal of the sustained vasodilator response of nitrates. Exposure to organic nitrates, for example in workers in the explosives industry, can cause profound vascular changes after departure from the environment (78). Vasoconstriction ensues and can cause non-exertional angina pectoris, or myocardial infarction (79), and peripheral ischemia, with Raynaud's phenomenon and gangrene of the extremities (80). The development of tolerance to the vasodilatory effects of glyceryl trinitrate, with arterial spasm when exposure ceases, has been postulated as the mechanism (81).

- A 41-year-old man employed in a munitions factory was admitted with crushing chest pain on a Sunday morning. There was evidence of an acute inferior myocardial infarction, and cardiac catheterization showed 80% narrowing of the proximal right coronary artery, which was reduced to 10% by intracoronary administration of glyceryl trinitrate. The electrocardiogram became normal.

Despite continuing reports of adverse reactions to withdrawal from chronic occupational exposure to nitrates, there is no clear evidence of similar events in patients taking chronic nitrate therapy. However, since this risk cannot be excluded, patients taking chronic nitrates should be carefully advised and monitored.

Tolerance can also occur in patients who are given long-term continuous treatment with nitrates in high dosages for angina pectoris. Harmful withdrawal symptoms can be avoided by gradual dosage reduction, but high doses should be avoided where possible (82). Likewise, abrupt withdrawal of intravenous glyceryl trinitrate in patients with unstable angina precipitates further angina (SEDA-16, 196).

Tumorigenicity

In view of the hypothesis that nitric oxide can have mutagenic or carcinogenic effects, chromosomal alterations have been sought in blood lymphocytes from patients taking chronic nitrates and after in vitro exposure to a nitric oxide donor (83). No structural alterations were found in vivo or in vitro, only an increased frequency of micronucleus formation, a nuclear morphological change that has been suggested to be associated with a risk of cancer. However, this first report of a genotoxic effect of nitrates probably has no clinical relevance.

Second-Generation Effects

Pregnancy

Glyceryl trinitrate has been used for its relaxing action on smooth muscle during cesarean delivery, with the aim of facilitating fetal extraction. After the publication of reports, a randomized, placebo-controlled trial was performed in 97 patients undergoing elective cesarean delivery after the 34th week of gestation (84). The patients were randomized to receive an intravenous bolus of glyceryl trinitrate (0.25 or 0.5 mg) or placebo. Glyceryl trinitrate did not improve fetal extraction. There were no adverse reactions attributable to glyceryl trinitrate in the neonate or mother.

The safety of glyceryl trinitrate in emergency or elective cesarean delivery has also been documented in a prospective series of 23 women, who received 400–800 micrograms of glyceryl trinitrate spray (85). However, no conclusions about the efficacy of glyceryl trinitrate were possible, owing to the lack of a control group.

Transdermal glyceryl trinitrate 5 mg for 16 hours each day has been compared with placebo in 25 mothers bearing intrauterine growth-retarded fetuses (86). It was applied from week 27 to week 35 of gestation until delivery. Three mothers were excluded from the analysis because they did not use the glyceryl trinitrate correctly. Placental flow, measured by Doppler, was improved by glyceryl trinitrate, and there was a better short-term neonatal outcome. Moreover, a biochemical marker of brain distress, the protein S100B, was normalized after glyceryl trinitrate, without an excess of adverse events in either the neonates or the mothers.

An authoritative overview of the published evidence on the use of glyceryl trinitrate to induce uterine relaxation in obstetric emergencies has shown that it is safe for fetus and mother (87).

Susceptibility Factors

The problems that can complicate the use of nitrates in patients with acute myocardial infarction, severe coronary atherosclerosis, and prior cerebrovascular disease have already been stressed. Hypotension, reflex tachycardia, or bradycardia can all be hazardous in individual patients.

Myocardial infarction

Although meta-analysis of studies in acute myocardial infarction suggested that nitrates protect against death and reinfarction (88), the ISIS-4 study found no such protection for 1 month after infarction (89). However, this study did show that nitrates are relatively safe in suspected myocardial infarction, even though 14% of patients who received nitrates had heart failure. Compared with placebo-treated patients there was an excess of hypotension considered severe enough to withdraw the drug in 15 per 1000 patients; in about half the cases it occurred soon after the start of treatment. The excess risk for headache was 18.7 per 1000 and of dizziness 1.6 per 1000, 0.8 per 1000 being associated with profound hypotension.

Congestive heart failure

The combination of isosorbide dinitrate with hydralazine is safe in systolic heart failure. Only headache and palpitation necessitated drug withdrawal and were more common than with enalapril (90). Headache and dizziness were more common with isosorbide dinitrate plus hydralazine than with placebo in patients taking ACE inhibitors and beta-blockers (5).

Pulmonary hypertension

A paradoxical increase in pulmonary vascular resistance has been reported after intravenous infusion of glyceryl trinitrate, and care is needed when giving potent vasodilators to patients with idiopathic pulmonary hypertension (91).

Hypertrophic obstructive cardiomyopathy

Organic nitrates should be used with caution in patients with hypertrophic obstructive cardiomyopathy, as they reduce afterload and venous return, which can exacerbate intraventricular obstruction and reduce left ventricular filling (SEDA-16, 196).

Exercise

A dramatic rise in plasma glyceryl trinitrate concentrations occurred after exercise in healthy subjects following transdermal administration (92). This altered systemic availability could cause adverse effects.

Drug Administration

Drug administration route

Transdermal

In one case a small explosion occurred when a patient was defibrillated with the paddle placed over a glyceryl trinitrate patch (93). The authors felt that this was probably due to arcing of the electrical current from the aluminium backing of the patch, but they advised that patches and gel should be removed before defibrillation.

An unusual skin burn resulted from the application of a glyceryl trinitrate transdermal patch in a patient who was subsequently exposed to radiation that leaked from a damaged microwave oven. The patient sustained a second-degree burn of the size and shape of his skin patch, probably due to a reaction with a metallic element in the adhesive strip (94).

Anal

Topical nitrates are used as an alternative to surgical treatment of chronic anal fissures. Their often limiting adverse effect is headache, due to vasodilatation, which is why glyceryl trinitrate ointment has been compared with diltiazem cream in a double-blind study in 60 patients with chronic anal fissures (95). After 8 weeks of treatment, 25 of 29 patients who received glyceryl trinitrate and 24 of 31 who received diltiazem had healed or improved; adverse effects were more common with glyceryl trinitrate (21/29) than diltiazem (13/31), the most frequent being headache. The authors suggested that diltiazem might be used as an alternative to glyceryl

© 2006 Elsevier B.V. All rights reserved.

trinitrate in the treatment of chronic anal fissures, since it has similar efficacy with fewer adverse effects.

Drug–Drug Interactions

Aspirin

A retrospective case-control study of 736 consecutive patients admitted with upper gastrointestinal bleeding showed that the combination of aspirin with nitrates may be protective against aspirin-induced gastrointestinal bleeding (96).

Clonidine

The combination of isosorbide dinitrate with clonidine predisposes to postural hypotension (97).

Disopyramide

Disopyramide, by producing xerostomia, can prevent the dissolution of sublingual isosorbide tablets (98).

Ethanol

Alcohol potentiates the hypotensive effects of sublingual glyceryl trinitrate (99).

The presence of high concentrations of ethanol and glycerol in intravenous glyceryl trinitrate formulations has led to alcohol intoxication after high-dose therapy (100–102).

- A 74-year-old man developed Wernicke's encephalopathy, which required treatment with intravenous thiamine after discontinuation of the glyceryl trinitrate infusion.

Thus, high-dose intravenous therapy should be given with caution to patients with prior vitamin deficiency or a history of alcohol abuse (103).

Ethanol has also been implicated as the cause of acute gout in four patients with unstable angina who received intravenous infusions of glyceryl trinitrate (104).

Heparin

There have been reports of heparin resistance associated with glyceryl trinitrate (105) (SEDA-16, 196), but subsequent review of this interaction showed no clinical relevance, provided that heparin anticoagulation is monitored closely (106,107).

Hydralazine

Severe postural hypotension has been observed in patients given both isosorbide dinitrate and hydralazine for chronic heart failure (26), although this has not been a problem in large studies (90).

Lidocaine

Complete atrioventricular block has been reported after the use of sublingual nitrates in patients receiving lidocaine by infusion (108,109) and can result in asystole.

Metoprolol

Dizziness or faintness has been reported to follow the use of sublingual nitrate in patients taking the beta-adrenoceptor antagonist metoprolol (110).

Nifedipine

- A case of laryngeal edema has been reported with the use of isosorbide dinitrate spray followed shortly by sublingual nifedipine in an attempt to reduced high blood pressure (230/130 mmHg) in a 65-year-old woman who presented with coma secondary to a large intracerebral hemorrhage; the same complication recurred when she was rechallenged with the same sequence of drugs (111).

Sildenafil

The combination of organic nitrates and sildenafil citrate (Viagra) can precipitate life-threatening hypotension in patients with angina (112). Sildenafil is a selective inhibitor of cyclic GMP-specific phosphodiesterase type 5, which causes smooth muscle relaxation and vasodilatation, and is an effective treatment for male erectile dysfunction. More than 3.6 million prescriptions have been issued as of August 1998, and so far there have been 69 deaths, 12 of which were attributable to the interaction with nitrates, as reported to the FDA.

The pressure-lowering effect of a step-wise intravenous infusion of glyceryl trinitrate was significantly increased in 12 healthy volunteers treated for 4 days with sildenafil (Viagra) 25 mg tds; episodes of symptomatic hypotension were also more frequent with sildenafil (113). When sublingual glyceryl trinitrate was used, the reduction in systolic blood pressure was four-fold greater in association with sildenafil.

An elderly man with anginal pain died after treatment with glyceryl trinitrate (114). The family physician discovered that the man had also taken sildenafil, and he suggested suicidal intent, since he claimed that the patient was aware of the adverse cardiac events of the association of these two drugs.

Nitrazepam

See also Benzodiazepines

General Information

Nitrazepam is a long-acting benzodiazepine used primarily for insomnia. However, it has a long half-life (about 24 hours) and poses a substantial risk of residual daytime effects, including sedation, psychomotor and cognitive impairment, and accidental injury (1).

Organs and Systems

Death

Between January 1983 and March 1994, 302 patients with intractable epilepsy were entered into a nitrazepam compassionate plea protocol (2). Nitrazepam increased the risk of death, especially in young patients with intractable epilepsy. The authors suggested that nitrazepam should be used with caution in young children with intractable epilepsy, especially if they have difficulties in swallowing, aspiration, pneumonia, gastroesophageal reflux, or a combination of these.

Nitrendipine

See also Calcium channel blockers

General Information

Nitrendipine is a dihydropyridine calcium channel blocker.

Drug–Drug Interactions

Ciclosporin

Nitrendipine had a small but significant nephroprotective effect independent of its antihypertensive action in patients treated for 2 years with ciclosporin and no adverse effect on renal allografts (1). Nitrendipine did not affect blood concentrations of ciclosporin. Thus, nitrendipine, in contrast to most other calcium channel blockers, does not affect ciclosporin blood concentrations and can be safely added in transplant recipients.

Nitric oxide

General Information

Gaseous nitric oxide is a short-lived molecule that has been used in the treatment of patients with primary pulmonary hypertension and is used in subgroups of severely ill and hypoxic children with persistent pulmonary hypertension of the newborn, in preterm infants of less than 34 weeks gestation, and in adults with acute lung injury and adult respiratory distress syndrome. There are some reports of its use for intestinal ischemia, reperfusion injury, thrombotic disorders, and sickle cell crises.

The adverse effects and toxicity of inhaled nitric oxide have been reviewed (1).

Therapeutic studies

The role of nitric oxide therapy in infants with severe acute hypoxemic respiratory failure has been reviewed (2). Inhaled nitric oxide was extremely well tolerated. Inhalation of 80 ppm rapidly improved oxygenation in patients with persistent pulmonary hypertension of the newborn (3). In three randomized, multicenter clinical trials there was a reduction in requirement for extracorporeal membrane oxygenation, with no significant adverse effects. There was no methemoglobinemia, high nitrogen dioxide, or increased rates of intracranial hemorrhage. In the NINOS trial in 235 term neonates (4), the study gas was not withdrawn in any patient because of toxicity. In another study of 58 term neonates receiving inhaled nitric oxide 80 ppm, a reduction in the use of extracorporeal membrane oxygenation (from 71% to 40%) was achieved without significant adverse effects (5).

Organs and Systems

Cardiovascular

There have been several case reports that high doses of nitric oxide (40–80 ppm) reduce pulmonary vascular resistance and increase pulmonary capillary wedge pressure in some patients with left ventricular dysfunction. The acute increase in left ventricular filling pressure that ensues can cause or exacerbate pulmonary edema. The author concluded that in patients with severe left ventricular dysfunction (pulmonary capillary wedge pressure over 25 mmHg) it would be prudent to avoid the use of inhaled nitric oxide.

Systemic hypotension has been reported after the introduction of inhaled nitric oxide (6).

- A 72-year-old woman, who underwent emergency resection of a giant left atrial myxoma, had pulmonary hypertension (pulmonary artery pressure 40 mmHg) and a low cardiac output (2.2 l/minute). Inhaled nitric oxide, 40 ppm, before cardiopulmonary bypass resulted in pulmonary vasodilatation and a fall in pulmonary artery pressure from 39 to 31 mmHg. This was accompanied by a fall in cardiac output from 2.4 to 1.5 l/minute and a fall in mixed venous oxygen saturation. After bypass, inhaled nitric oxide improved pulmonary and systemic hemodynamics and resulted in a rise in cardiac output from 3.0 to 3.5 l/minute.

The authors concluded that inhaled nitric oxide had reduced pulmonary hypertension and pulmonary vascular resistance, but that obstruction by the atrial myxoma had caused the low cardiac output, due to a net reduction in transpulmonary pressure.

Respiratory

In animal and in vitro studies, inhaled nitric oxide has led to surfactant inactivation and promotion of oxidative and nitrosylative lung injury (2). These effects have not been reported during clinical use of inhaled nitric oxide at concentrations less than 80 ppm. In a review of two articles it was noted that nitric oxide does not increase the risk of chronic lung disease of the newborn, despite speculation that it may increase chronic lung disease of prematurity due to the formation of nitrogen dioxide and peroxynitrite, in addition to membrane lipid peroxidation and increased unbound plasma iron in preterm infants (7).

In a randomized, double-blind, placebo-controlled, crossover study of the use of nitric oxide in chronic obstructive pulmonary disease (COPD) 11 patients with documented severe COPD received 25 ppm of nitric oxide combined with supplementary oxygen at a flow rate of 2 l/minute via nasal cannulae (8). Four of the patients reported an increase in cough and a feeling of retrosternal rawness after breathing nitric oxide for 24 hours; two had an increase in dyspnea, and one developed

© 2006 Elsevier B.V. All rights reserved.

wheezing and was unable to perform exercise on a treadmill. There were no significant changes in lung spirometry. The authors noted that one patient had underlying reversible airways obstruction, but did not say if it was this individual who developed the wheezing. Nitric oxide is an irritant and causes inflammatory changes in the airways, so it is possible that nitric oxide could cause bronchoconstriction and aggravate asthmatic inflammation. There was a small but significant beneficial fall in pulmonary vascular resistance (183–137 dyne.s/cm^3) with nitric oxide. This is the first study of the prolonged use of nitric oxide (for 24 hours) in non-anesthetized, non-ventilated patients with COPD.

The role of nitric oxide as salvage therapy to improve pulmonary gas exchange has been studied in children with life-threatening asthma, unresponsive to other therapies (9). Four consecutive patients with hypercapnia or hypoxemia, despite mechanical ventilation, treatment with beta-adrenoceptor agonists, ipratropium bromide, intravenous corticosteroids, magnesium sulfate, and a trial of helium/oxygen mixtures, were treated with incremental concentrations of inhaled nitric oxide up to 80 ppm, after a successful trial in an index case. Four of the five had improvements in gas exchange, with a fall in arterial carbon dioxide tension. Gas exchange was also improved by inhaled nitric oxide 20 ppm, from a baseline PaO_2/FiO_2 ratio of 209 (range 175–276) to 430 (range 139–463). However at the higher dose of inhaled nitric oxide of 40 ppm there was a deterioration in oxygenation, with PaO_2/FiO_2 ratios falling to 163 (range 139–463). One patient did not respond to treatment and had a rise in $PaCO_2$ on treatment with inhaled nitric oxide 40 ppm, so treatment was withdrawn. This study has provided some supplementary evidence that nitric oxide can impair pulmonary gas exchange by causing irritation and further bronchoconstriction in susceptible patients, as noted in the COPD study mentioned above (8). Unfortunately, airways resistance was not measured in this study, but caution should be exercised and close monitoring undertaken when using inhaled nitric oxide in patients with bronchoconstriction.

Nervous system

Of major concern in the treatment of preterm infants is that nitric oxide might increase the incidence or severity of intraventricular hemorrhage. Nitric oxide impairs platelet aggregation and agglutination in vitro by activating guanylate cyclase and so increasing cGMP concentration. In a meta-analysis of randomized, controlled trials of inhaled nitric oxide for the treatment of preterm infants, only three studies were identified (10). In all, 300 infants were included in the analysis and the incidence of intraventricular hemorrhage was comparable between treatment and non-treatment groups, 35 of 111 receiving inhaled nitric oxide compared with 25 of 99 controls (OR = 1.37; 95% CI = 0.69, 2.74). There were no changes in mortality with treatment and no differences in neurological outcomes between nitric oxide and placebo during follow-up. These findings have been supported by a second meta-analysis of the use of nitric oxide in near-term infants with hypoxic respiratory failure, which showed no difference in the rate of neurodevelopmental abnormalities in neonates treated with nitric oxide (11).

In a randomized trial in 248 neonates older than 34 weeks of gestation, 126 of whom received nitric oxide, treatment with nitric oxide afforded no protection against neurodevelopmental abnormalities (12). The only benefits conferred by inhaled nitric oxide treatment in 42 preterm neonates was a reduction in the incidence of chronic lung disease along with improvement in oxygenation (13) and significant reductions in oxygenation index, duration of ventilation, and stay in neonatal ICU (14).

During long-term follow-up of the Neonatal Inhaled Nitric Oxide Study (NINOS), the neurodevelopmental safety of nitric oxide in infants over 34 weeks gestation with hypoxemic respiratory failure was assessed at 18–24 months of age, at which time there was a non-significant increase in disability in infants treated with inhaled nitric oxide (15). Of the 199 surviving infants in the study, 173 were assessed. Sensorineural hearing loss (15 and 13%, controls versus treatment), blindness in one or both eyes (2.2 versus 2.4%), the presence of cerebral palsy (10 versus 12%), and the presence of one or more neurodevelopmental abnormalities (30 versus 35%) were all statistically equivalent between the groups. The only significant difference was a greater rate of seizures after discharge in the control patients (15 versus 4.7% in those given inhaled nitric oxide).

Hematologic

Platelet aggregation

Nitric oxide activates guanylate cyclase and increases cGMP concentrations, thus inhibiting platelet aggregation and agglutination in vitro (1,16). The apparently high rate (63%) of intracranial hemorrhage in preterm neonates given inhaled nitric oxide (17) has not been confirmed in subsequent larger trials or in comparisons with matched controls from a large database (2). In addition, the frequency of bleeding complications in adults and children treated with inhaled nitric oxide has not been significantly increased in comparison with matched controls (16,17). Impaired platelet function and an increased risk of intracranial hemorrhage in preterm infants have not been substantiated in larger trials.

Methemoglobinemia

Nitric oxide oxidizes hemoglobin to methemoglobin, two-thirds of which is reduced by nicotinamide adenine dinucleotide (NAD) methemoglobin reductase (1). Several ethnic groups, such as native Americans, have NAD methemoglobin reductase deficiency. There have been reports of methemoglobinemia after accidental overdosage of inhaled nitric oxide in native Americans and others (1).

- A native American woman developed a rise in methemoglobin from 0.9 to 9.4% over 6 hours of inhaled nitric oxide therapy, 80 ppm; with reduction of the dose to 40 ppm, methemoglobin returned to baseline concentration. A patient who received inhaled nitric oxide through an imprecise delivery device had a methemoglobin concentration of 67%. Another patient who received a dose of 110 ppm had a methemoglobin concentration of 19%.

© 2006 Elsevier B.V. All rights reserved.

In a phase II trial of 177 patients with adult respiratory distress syndrome, four developed a methemoglobin concentration over 5% but none had a concentration over 7%; one received placebo, one received inhaled nitric oxide 40 ppm, and two received 80 ppm.

There may also be partial deficiency of methemoglobin reductase in neonates (1). In the Neonatal Inhaled Nitric Oxide Study the dose of inhaled nitric oxide had to be reduced in 11 of 114 patients (9.6%) because of raised methemoglobin. At doses of 1.25–80 ppm, methemoglobinemia is uncommon; in one study only three of 471 (0.6%) patients discontinued therapy for this reason (17).

The incidence of methemoglobinemia is reduced by the use of low-dose nitric oxide. In a study in which inhaled nitric oxide was used in a dose of 20 ppm for 24 hours, followed by 5 ppm for up to 96 hours, only two infants of 126 randomized to nitric oxide developed methemoglobinemia (12). In 11 children aged 2.6–48 months undergoing surgery for congenital heart defects with associated pulmonary hypertension no infant receiving inhaled nitric oxide up to 80 ppm developed a methemoglobin concentration over 5% (18). Nitrogen dioxide concentrations rose to over 5% in some patients, with resolution once the dose was reduced. There were no adverse effects.

Vitamin B_{12} deficiency

One of the biochemical adverse effects of nitric oxide is inactivation of vitamin B_{12}, with subsequent potentiation of folate deficiency (19). This effect is mediated by irreversible oxidation of the cobalt residue in vitamin B_{12} to its Co^{++} and Co^{+++} forms. This leads to a reduction in methionine synthetase activity, with downstream effects on DNA synthesis. Previous studies have identified five patients with unsuspected vitamin B_{12} deficiency who developed subacute combined degeneration of the spinal cord following inhalation anesthesia with nitrous oxide (20). Nitric oxide has a similar effect on vitamin B_{12}, and its prolonged use could theoretically produce similar disorders in vitamin B_{12} metabolism (19).

Urinary tract

The effect of inhaled nitric oxide 2, 10, or 40 ppm on the frequency of reversal of acute lung injury in nitric oxide responders has been examined in an open-label randomized trial in 268 patients, of whom 180 were responders (PaO_2 increased by more than 20% within 10 minutes) (21). The patients were randomized into equal groups to receive conventional treatment with or without inhaled nitric oxide. Nitric oxide was given in the lowest effective dose until an end point (reversal of acute lung injury or severe respiratory failure) was reached or for 30 days. There was a significantly higher rate of renal insufficiency requiring renal replacement therapy in those given inhaled nitric oxide (25 versus 12%). The reasons for this were unclear. Although the groups were heterogeneous, both groups were similarly matched for risk of renal insufficiency at the start of the trial. The difference could have been due to a true adverse effect or to investigator bias in an open-label study. Owing to the absence of preclinical data suggesting renal toxicity and the absence of a known physiological route that could result in renal impairment, it is reasonable to conclude that the effect may have been due to chance (22).

Long-Term Effects

Drug withdrawal

Acute rebound of pulmonary hypertension and cardiovascular collapse can occur after abrupt withdrawal of nitric oxide. The risk factors for this adverse effect, or its incidence, have not been fully characterized. The incidence, risk factors, and nature of cardiopulmonary deterioration when patients' nitric oxide supply is abruptly withdrawn have been investigated in 56 intubated and mechanically ventilated patients with acute hypoxemic respiratory failure, of whom 39 had improved gas exchange (PaO_2 increased by more than 20 mmHg) during treatment with inhaled nitric oxide (23). After at least 10 hours of treatment (range 10–30 hours), inhaled nitric oxide was abruptly withdrawn and the patients were monitored for the rebound phenomenon and the need for continuing administration of inhaled nitric oxide. The mean dose of inhaled nitric oxide at the time of withdrawal was 22.8 (range 3–80) ppm. There was significant deterioration in gas exchange (decrease in SaO_2 more than 5%) and/or a drop in cardiac output of more than 10% in 23 patients (74%) and 15 (48%) had arterial desaturation within 30 minutes, which responded to reintroduction of inhaled nitric oxide. Eight patients had a rapid fall in cardiac output and/or blood pressure of over 20%, with prompt return to baseline measurements with reintroduction of therapy. Independent predictors of hemodynamic collapse were multiple system organ failure, older age, and an increased initial blood pressure in response to institution of inhaled nitric oxide. Hemodynamic measurements suggested that the acute collapse was primarily due to right ventricular overload. The authors also postulated that nitric oxide therapy causes down-regulation of nitric oxide synthase, and that removal of exogenous nitric oxide leaves the pulmonary vasculature with insufficient vasodilatory influences, allowing vasoconstriction to predominate. This down-regulation has been demonstrated in a rat model, but not in humans (24).

Of 88 patients with adult respiratory distress syndrome treated with inhaled nitric oxide, five developed rebound hypertension and arterial desaturation when inhaled nitric oxide was weaned (25). In an open-label, phase II pilot study of 16 infants over 4 weeks of age with severe bronchopulmonary dysplasia, inhaled nitric oxide, 20 ppm, led to a significant reduction (over 15%) in the concentration of inspired oxygen required to maintain satisfactory arterial oxygen saturation in 11 infants (26). There were no significant adverse effects at doses of 20 ppm. Of the 11 responders, seven developed episodes of desaturation within 10 minutes of withdrawal of inhaled nitric oxide after being weaned to under 8 ppm. Typically, a transient (30 minute) desaturation from 95% to 81% occurred after withdrawal of inhaled nitric oxide. On reinstituting therapy the desaturation rapidly reversed. The authors postulated that this effect may have been due to down-regulation of endogenous nitric oxide synthase.

© 2006 Elsevier B.V. All rights reserved.

In a retrospective case-control study, 12 children with severe pulmonary hypertension were treated with inhaled nitric oxide followed by prostacyclin 10 ng/kg/minute for 24 hours before gradual withdrawal of nitric oxide; the 12 matched controls did not receive prostacyclin (27). Only one of the patients developed rebound hypertension, indicated by arterial desaturation (a 5% or greater fall in SaO_2 within 4 hours of withdrawal), while eight of 12 controls developed the rebound effect.

Severe systemic arterial hypotension has been reported after inadvertent withdrawal of nitric oxide (28).

- A 37-year-old woman with acute respiratory failure due to *Pneumocystis carinii* pneumonia 6 months after allogeneic bone marrow transplantation developed adult respiratory distress syndrome. Because of deteriorating gas exchange, mechanical ventilation and inhaled nitric oxide 10 ppm were given, with improvement in gas exchange and a reduction in mean pulmonary artery pressure from 46 to 36 mmHg. At times of brief withdrawal of nitric oxide rebound pulmonary hypertension occurred, with rapid reversal after reinstitution of therapy. After 6 days of treatment there was a sudden fall in systemic arterial pressure and pulmonary arterial pressure during interruption of nitric oxide delivery and subsequent measurements showed a fall in cardiac index from 3.3 to 2.1 l/minute/m^2.

The authors concluded that after sudden withdrawal of inhaled nitric oxide rebound pulmonary hypertension had contributed to acute right ventricular failure and loss of left ventricular pre-load, with a fall in cardiac output leading to reduced coronary performance and near cardiac arrest.

Nitrofurantoin

General Information

Nitrofurantoin is a synthetic nitrofuran that belongs to a group of organic substances characterized by a heterocyclic ring consisting of four carbon atoms and one oxygen atom (1). Its mechanism of action is not understood. Nitrofurans enter bacterial cells and interact with several enzymes; thereby inhibiting bacterial growth. Nitrofurantoin is active against many Gram-positive and Gram-negative bacteria. It is particularly useful in treating urinary pathogens, including *Escherichia coli*, *Klebsiella* species, and *Proteus* species. However, *Pseudomonas aeruginosa* is almost always resistant.

After almost complete absorption from the gastrointestinal tract, nitrofurantoin produces high urinary concentrations. Blood and tissue concentrations are low. Nitrofurantoin has been used almost exclusively in the treatment and prophylaxis of urinary tract infections (1). Because of the severity of its adverse effects it should not be used as first choice.

General adverse effects

Harmless gastrointestinal adverse effects are most frequent with nitrofurantoin. Polyneuropathy occurs mainly in patients with renal insufficiency, in whom nitrofurantoin is contraindicated. Rarely, hemolytic anemia and hepatitis occur. Adverse events that are believed to be due to hypersensitivity include rashes, generalized urticaria, and acute pulmonary reactions. Although there are some in vitro data suggesting that nitrofurantoin may be a mutagen, a carcinogenic effect has not been proven in vivo. Teratogenic effects of nitrofurantoin have not been reported. High-dose oral nitrofurantoin may influence spermatogenesis and sperm motility.

Frequency

Drug-related adverse events are rare with nitrofurantoin and occur in fewer patients than with co-trimoxazole or trimethoprim, for example (1–3). The frequency of certain adverse reactions varies in different geographical areas (4,5). Lung reactions are more prevalent in Scandinavia and South Africa than in the UK, whereas polyneuropathies or gastrointestinal reactions are more frequent in the UK than in Sweden. These discrepancies are unexplained.

Organs and Systems

Cardiovascular

Except for cardiovascular collapse in anaphylactic shock, adverse cardiovascular events seem to be extremely rare with nitrofurantoin (4,5). In experimental animals, cardiotoxic effects have been described (6).

Respiratory

Acute respiratory reactions to nitrofurantoin include dyspnea, cough, interstitial pneumonitis, and pleural effusion, while interstitial pneumonitis and fibrosis are common chronic reactions (7). Nitrofurantoin causes acute lung injury more often than any other drug. Since the first well-documented case of an acute lung reaction in 1962 (8), several hundred further observations have been published (5,9). The frequency of acute severe pulmonary disease has been estimated to be one in every 5000 first administrations (10). Women aged 40–50 years are mainly affected. The acute lung reactions are not dose-related, and sensitization occurs at the earliest 1–2 weeks after the onset of exposure during the first course of therapy. Symptoms develop 2–10 hours after administration and consist of severe dyspnea, tachypnea, non-productive cough, high fever (usually with chills), cyanosis, and chest pain. Occasionally, arthralgia, backache or headache, vomiting, rash, collapse, and anaphylactic shock accompany the pulmonary symptoms (9). Lung findings include dense crackles or moist râles, predominantly at the lung bases. X-ray examination may be normal, but more often shows bilateral interstitial lower lobe infiltrates, often with pleural effusion. In one case, transient reverse ventilation-perfusion mismatch was documented by scintigraphy (11). Initially the leukocyte count is normal or raised, with neutrophilia and lymphopenia. Later, eosinophilia is common. When nitrofurantoin is withdrawn, clinical symptoms subside rapidly, usually within 1–3 days (5). However, minor X-ray changes can still be found 2 months later. Re-exposure to nitrofurantoin 50 mg re-induces the syndrome. Single cases of death due to heart failure have been reported in debilitated patients.

Acute lung reactions to nitrofurantoin are extremely rare in children (12). Lung tissue findings in acute reactions have shown minor vasculitis, granulomatous vasculitis (hypersensitivity angiitis), proliferation of endothelial cells, and empty alveoli (13). Rapidly progressing bronchiolitis obliterans with organizing pneumonia (BOOP) has been reported (14).

Chronic lung reactions are 10–20 times less frequent than acute reactions and mainly involve older patients. Reactions serious enough to require hospitalization occur in one out of 750 long-term users (15). Acute reactions do not seem to predispose to the later occurrence of chronic reactions. During long-term treatment, dyspnea and usually a non-productive cough without fever develop (15). Restrictive respiratory impairment is common. X-rays show interstitial infiltrations, often in the middle and basal lung regions. Fibrotic changes, alveolar exudates, and pleural effusions are rare. Histologically, chronic interstitial pneumonitis with varying degrees of fibrosis

© 2006 Elsevier B.V. All rights reserved.

most often is found, and in some instances desquamative alveolitis (15–19).

Several mechanisms for the adverse lung effects of nitrofurantoin have been proposed (20–24). The pathogenesis of the acute lung reactions may be allergic (type III reactions) (18). However, there is also evidence that a cytotoxic immune mechanism (type II reactions), cell-mediated immunity (type IV reactions) (2), or direct toxic injury to lung tissue through the production of oxygen radicals (3,4) may be involved (20,21,24,25). In chronic lung reactions, the causative role of nitrofurantoin is less evident. It is supported by analogy and by the clinical course. Sometimes the skin test is positive, even in chronic lung reactions. Lymphocyte transformation tests give variable results. A polyclonal hypergammaglobulinemia is always present, with IgG predominating. Precipitating serum antibodies have not been found. Recent data have supported a toxic pathogenesis similar to that of the herbicide paraquat.

After nitrofurantoin withdrawal, the clinical symptoms regress rapidly. However, in most cases X-ray findings abate slowly and resolution is incomplete in at least 50% of patients. Occasional deaths due to cardiopulmonary failure have also been reported. The therapeutic benefit of corticosteroids is controversial, but the bulk of experience and anecdotal reports suggest that they are useful.

Atypical courses have been rarely described (5). A mixed type of reaction can occur: after an initial short fever peak, the patient becomes either afebrile or subfebrile, despite continuing to take nitrofurantoin and unabated activity of the lung process, or a typical chronic reaction converts to a typical acute reaction on re-exposure to nitrofurantoin after withdrawal. Acute reactions can occur without clinical symptoms, and can be recognized only on X-ray. Single cases of pulmonary hemorrhage, eosinophilic pneumonia, and interstitial giant cell pneumonia have also been reported (26,27).

In nitrofurantoin-induced pulmonary toxicity, in which high-resolution computed tomography initially showed a widespread reticular pattern and associated distortion of the lung parenchyma, thought to represent established and irreversible fibrosis, follow-up scans after drug withdrawal nevertheless showed resolution of pulmonary changes (28). These findings have been corroborated by a report of two middle-aged women who developed respiratory symptoms after prolonged treatment with nitrofurantoin (29). Both had impaired lung function and abnormal CT scans, and lung biopsies showed features compatible with bronchiolitis obliterans organizing pneumonia. Their condition improved when nitrofurantoin was withdrawn and glucocorticoid treatment was given.

In a patient with nitrofurantoin-induced pulmonary toxicity, in whom high resolution CT scans initially showed a widespread reticular pattern and associated distortion of the lung parenchyma, thought to represent established and irreversible fibrosis, follow-up CT scans after withdrawal of the drug showed resolution of the pulmonary changes.

- An 82-year-old woman developed a productive cough after having taken nitrofurantoin 50 mg/day for 4 years (30). She had impaired lung function and abnormal CT scans, and lung biopsies showed features compatible with bronchiolitis obliterans organizing pneumonia. The condition improved when nitrofurantoin was withdrawn and she was given a glucocorticoid.
- In a 58-year-old woman who took nitrofurantoin 100 mg/day for 11 months, pulmonary toxicity occurred, with bilateral interstitial infiltrates in the lower zones of the chest X-ray and loss of lung volume (31). High resolution CT scans showed ground-glass opacification in the mid-thoracic region, with patchy fibrosis and traction bronchiectasis. After withdrawal of nitrofurantoin and administration of prednisone, a chest X-ray 3 months later showed resolution of the pulmonary changes.

Nervous system

More than 140 cases of toxic polyneuropathy have been reported. The frequency depends on dose, tissue concentration, and renal function: in up to 90% of cases polyneuropathy occurred in patients with renal insufficiency (32). Symptoms usually start 9–45 days (at the earliest 3 days) after beginning nitrofurantoin. The neuropathy starts peripherally, predominantly affects the limbs, and remains more severe distally. Initially, there is sensory loss with paresthesia. Later, motor loss develops, often with severe muscle atrophy. As a rule, no further deterioration occurs after withdrawal of nitrofurantoin, and there may be total regression (34% of cases) or partial regression (45% of cases) (32). In some severe cases there is residual disability. The motor loss resolves more slowly and less completely than the sensory impairment. Single cases of retrobulbar optic neuritis, lateral rectus muscle palsy, and facial nerve palsy have been reported (33).

The lesions comprise degeneration of the myelin sheath of the nerves and nerve roots, with degeneration of the corresponding anterior horn cells and muscle fibers. The pathogenesis is unclear. Impairment of glutathione reductase has been considered. Even in healthy people, nitrofurantoin 400 mg/day for 2 weeks causes a significant increase in motor nerve conduction time. If strict attention is paid to the contraindication of renal insufficiency, the risk of polyneuropathy can be reduced. Careful controls for the initial symptoms of paresthesia can prevent the development of severe disablement.

While taking nitrofurantoin after urinary tract surgery, a 10-year-old girl developed diplopia and ptosis (34). A sleep test confirmed ocular myasthenia. Her signs and symptoms resolved after drug withdrawal.

Single cases of benign intracranial hypertension (pseudotumor cerebri), with and without ocular palsy, have been reported (35,36). Uncharacteristic general symptoms, with dizziness, cephalalgia, or drowsiness, are more frequent.

Trigeminal neuralgia (37) and cerebellar symptoms (38) have been attributed to nitrofurantoin.

Sensory systems

One case of crystalline retinopathy has been associated with long-term nitrofurantoin (39).

© 2006 Elsevier B.V. All rights reserved.

Psychological, psychiatric

Rarely, concomitant dysphoric, euphoric, or even psychotic reactions have been reported in patients taking nitrofurantoin (1).

Metabolism

One case of hyperlactatemic metabolic acidosis together with hemolytic anemia due to glucose-6-phosphate dehydrogenase deficiency has been reported (40).

Hematologic

Some cases of hemolytic anemia associated with glucose 6-phosphate dehydrogenase deficiency have been described in patients taking nitrofurantoin (41).

Single cases of nitrofurantoin-induced (or enhanced) hemolytic anemia have occurred in patients with deficiencies of other erythrocyte enzymes (enolase or glutathione peroxidase), as have isolated cases of methemoglobinemia (42).

Nitrofurantoin produces oxidant stress and cellular damage by different mechanisms (43). It can disturb folate metabolism, leading to a megaloblastic component in pre-existing (mostly hemolytic) anemia, which responds to folic acid treatment.

There have been single cases of thrombocytopenia and a severe hemorrhagic diathesis with deficiency of coagulation factors due to a nitrofurantoin-induced hepatic disorder (44). Furthermore, nitrofurantoin experimentally inhibits ADP-induced platelet aggregation (45).

Allergic agranulocytosis or neutropenia have been proven in only a few cases (46,47). Pancytopenia is also rarely seen (5).

Mouth and teeth

Some cases of parotitis, rarely proven by rechallenge, have been associated with nitrofurantoin (48). The symptoms disappear after withdrawal.

Gastrointestinal

Gastrointestinal symptoms are the most common adverse effects of nitrofurantoin. Nausea and anorexia have been most often reported (49,50), whereas abdominal pain and diarrhea are rare. These effects are dose-related and usually harmless. The manifestations occur mostly after absorption of the drug and are mediated by the central nervous system. Measures that delay absorption, such as sugar coating or the use of a macrocrystalline form of the drug, reduce these adverse effects (51).

Liver

Hepatic reactions to nitrofurantoin are rare, and different forms can be distinguished (52–54). They can be associated with fatal liver necrosis (55,56).

Data from The Netherlands suggest that acute reactions are more common than chronic ones. Acute hepatic reactions may be hepatocellular or cholestatic. In the vast majority of subjects, symptoms appear within the first 6 weeks of nitrofurantoin treatment, and in half of the patients they occur within the first week of treatment. Jaundice is most common, followed by abdominal pain, malaise, and nausea. Hepatomegaly has been reported in nearly 50% of cases, fever in 30–65%, eosinophilia in 15–50%, and a rash in 12–60%. An immunological pathogenesis has been proposed (57), but experimental data point to a toxic mechanism involving the formation of glutathione-protein mixed disulfides and/or protein alkylation (58). The prognosis after withdrawal of the drug is good, but fatal courses have been reported when the drug is continued or, rarely, even after it has been discontinued.

Chronic active hepatitis, icteric or anicteric, has been described, almost always in women taking long-term nitrofurantoin. Most patients develop symptoms after a period of about 6 months of nitrofurantoin use. Fever (0–24%), rash (0–3%), and eosinophilia (9–23%) occur rarely compared with acute cases. There is hepatomegaly in 30–60% of chronic cases (54). Sometimes a broad spectrum of autoimmune reactions, a lupus-like syndrome, or mild cholestasis can be present (59,60). Some of these cases have occurred in combination with lung reactions of the protracted acute or chronic type, or in patients with ascites and liver cirrhosis. The clinical symptoms usually improve after withdrawal, but a few cases with extensive hepatocellular necrosis have necessitated liver transplantation or ended fatally (61–64). The histological changes can persist. Re-exposure to nitrofurantoin has reproduced the pathological liver tests.

Granulomatous hepatitis, with a rash or isolated increases in serum transaminase activities, can occur in patients with lung reactions (65). In the protracted acute and in chronic lung reactions liver injury (such as chronic active hepatitis) is more frequent than in acute reactions. Such cases usually show a broad spectrum of serological autoimmune reactions (lupus-like syndrome) (66).

Pancreas

A few cases of nitrofurantoin-induced acute pancreatitis, confirmed by rechallenge, have been reported (67).

Urinary tract

Nitrofurantoin-induced crystalluria, leading to obstruction of indwelling catheters, has been described in a few patients (68).

In rare cases, interstitial nephritis has been observed (69,70).

Skin

Allergic skin reactions occur in 1–2% of patients who take nitrofurantoin and comprise about 21% of all adverse reactions to nitrofurantoin (5,71). They often occur with other reactions, such as drug fever, lung, or liver reactions. The lesions can present as pruritus, as macular, maculopapular, or vesicular rashes, urticaria, angioedema, or erythema multiforme (72). The frequency of serious cutaneous reactions (erythema multiforme, Stevens–Johnson syndrome, or toxic epidermal necrolysis) after nitrofurantoin has been estimated to be 7 cases per 100 000 exposed individuals (71).

Sweet's syndrome has been observed in association with a 7-day course of nitrofurantoin (73).

Transitory alopecia that has been reported in a few cases is dose-related (74).

© 2006 Elsevier B.V. All rights reserved.

Immunologic

About 20 cases of a lupus-like syndrome have been described, mostly in the Scandinavian literature. The clinical picture consisted of arthralgia or, rarely, exacerbation of a pre-existing rheumatoid arthritis and generalized lymphadenopathy, mostly associated with chronic lung and/or liver reactions, such as chronic active hepatitis (19,75,76). In patients with the lupus-like syndrome at least two immunological tests (antinuclear factor, rheumatoid factor, Coombs' test, and antibodies against smooth muscle, thyroglobulin, thyroid cell cytoplasm, or glomeruli) were positive. The lymphocyte transformation test was always positive. However, the LE cell phenomenon was always negative. As in other allergic reactions to nitrofurantoin, circulating albumin IgG complexes were found by immunoelectrophoresis, with tailing of the albumin line (77). The syndrome regresses after withdrawal.

Long-Term Effects

Drug tolerance

Nitrofurantoin is effective against Enterobacteriaceae; the rates of resistance were below 2% in a single-center study (78) and 3.5% in a multicenter study (79).

Mutagenicity

In vitro, nitrofurantoin acts as a mutagen by inhibiting DNA synthetase. In human fibroblast cultures it damages DNA (80). Treatment with nitrofurantoin for 12 months caused a significant increase in chromosome aberrations and sister chromatid exchanges in the lymphocytes of 69 children (81).

Tumorigenicity

Some studies have shown similar metabolism of nitrofurantoin and other (carcinogenic) nitrofurans. Formation of carcinogenic nitrofurantoin metabolites is therefore possible (82). However, a carcinogenic effect has not been proven for nitrofurantoin (83).

Second-Generation Effects

Fertility

High-dose oral nitrofurantoin (10 mg/kg/day) transiently reduces the sperm count in 30% of patients (84). This is due to arrest of maturation. Depression of sperm motility or ejaculate volume can also occur at lower doses (85).

Teratogenicity

Only very small amounts of nitrofurantoin cross the placenta, and teratogenic effects are not known (86). Even when it is used in the first trimester, there have been no associated fetal malformations (87). No teratogenic effects have been associated with nitrofurantoin in Denmark, Finland, Norway, and Sweden (88), or in a Hungarian case-control survey (89).

Fetotoxicity

Hemolytic anemia occurred during the first hours of life in a full-term neonate whose mother had taken nitrofurantoin during the last month of pregnancy (90). It may therefore be wise not to prescribe nitrofurantoin at the end of pregnancy.

Lactation

Nitrofurantoin is actively transported into human milk, achieving concentrations greatly exceeding those in serum. Concern is warranted for suckling infants under 1 month old or for infants with a high frequency of glucose-6-phosphate dehydrogenase deficiency or sensitivity to nitrofurantoin (91).

Susceptibility Factors

Genetic factors

Glucose-6-phosphate dehydrogenase deficiency is decisive for the development of hemolytic anemia in patients taking nitrofurantoin.

Age

Nitrofurantoin is contraindicated during the last trimester of pregnancy and in neonates, because hemolytic anemia can result from immature enzyme systems (90).

Renal disease

The main risk factor for toxic reactions to nitrofurantoin, especially polyneuropathy and gastrointestinal symptoms, is impaired renal function (32).

Drug–Drug Interactions

Estrogens

Nitrofurantoin reduces the enterohepatic circulation of estrogens (92).

Nalidixic acid

Antagonism in antibacterial efficacy between nitrofurantoin and nalidixic acid has been observed (93).

Pyridoxine

Pyridoxine accelerates the renal elimination of nitrofurantoin (94).

Interference with Diagnostic Tests

Glucose measurements

Nitrofurantoin can produce spurious positive urine glucose concentrations or raised blood glucose concentrations if reducing reagents are used (95).

Nitrosourea cytostatic drugs

See also Cytostatic and immunosuppressant drugs

General Information

The nitrosourea cytostatic drugs are alkylating agents that include carmustine, lomustine, nimustine, and streptozocin (all rINNs).

Carmustine (BCNU) is used to treat myeloma, lymphomas, breast cancer, and brain tumors, Topical carmustine has been used to treat mycosis fungoides (1).

Lomustine (CCNU) is used to treat lymphomas and some solid tumors, particularly brain tumors, often in combination with procarbazine and vincristine (2). In contrast to other nitrosoureas, lomustine can be given orally.

Nimustine (ACNU) is used to treat malignant glioma (3).

Streptozocin (streptozotocin) is produced by *Streptomyces achromogenes*. It is used to treat metastatic islet cell carcinoma of the pancreas, but because of its high nephrotoxic and emetogenic potential it should be reserved for patients with symptomatic or progressive disease.

Organs and Systems

Respiratory

Carmustine pulmonary toxicity is well documented. Eight patients developed interstitial pulmonary fibrosis 12–17 years after exposure to carmustine in a total dose of carmustine of 770–1410 mg/m^2 (4).

Lung fibrosis has been described in a long-term follow up 13–17 years after treatment of 31 children given carmustine for brain tumors; six died, and of eight still available for study, six had upper zone fibrotic changes of their lungs on X-ray (5).

Lomustine can cause pulmonary infiltrates and fibrosis (6–8), and fatal pulmonary toxicity has occasionally occurred (9).

Sensory systems

A 2.7% ocular complication rate in 112 patients treated with a cumulative dose of carmustine 370 mg/m^2 for intracranial tumors has been recorded (10).

Eye pain and blindness due to retinal and optic nerve damage are recognized hazards of intracarotid carmustine therapy reference. They are thought to be due, at least in part, to the ethanol content of the diluent. Nimustine (ACNU) is water-soluble and ethanol-free. In a study of 30 patients with malignant gliomas, 123 infusions of nimustine and 53 of carmustine were administered (11). Eye pain was experienced during all carmustine infusions but not with nimustine, and one patient developed unilateral blindness after carmustine. In another study, carmustine was administered in solution with 5% dextrose in water (12). All the patients experienced ipsilateral orbital pain and scleral erythema, suggesting that carmustine itself contributes to the toxicity. Seven additional patients were treated wearing an ocular compression device to decrease blood flow and had not experienced any ocular complications.

Hematologic

Delayed myelosuppression is an important adverse effect of the nitrosoureas (13). It usually occurs 4–6 weeks after administration and can last for about 1–2 weeks. Thrombocytopenia occurs after about 4 weeks and leukopenia after 5–6 weeks.

Of 91 patients treated with topical carmustine, three developed reversible bone marrow suppression (14).

Urinary tract

Nephrotoxicity can rarely occur with lomustine, and all cases have been associated with cumulative doses greater than 1500 mg/m^2 (15).

Streptozocin is highly nephrotoxic, and renal function must be monitored carefully in all patients who are receiving it. Its effects include uremia, proteinuria, anuria, and proximal renal tubular acidosis (16). Uric acid nephropathy has also been reported (17). Adequate hydration has been recommended to reduce the risk of nephrotoxicity (18).

Skin

Local adverse effects of topical carmustine include tender erythema, superficial denudation or bullae, contact allergy, pigment alterations, and patchy telangiectasia (1).

Immunologic

Topical carmustine can cause hypersensitivity reactions, and three previous cases have been supplemented by a fourth (19).

- A 67-year-old woman used topical carmustine for a stage I cutaneous T cell lymphoma. A second course was started after 6 months and resulted in severe erosive inflammation at the site of treatment. Patch tests with carmustine 0.1, 0.5, and 1% in water all gave positive results; 22 controls were tested with 0.1% carmustine and lomustine and were all negative.

The most common adverse effect of chlormethine is an allergic contact dermatitis (20). Neither reducing the concentration of drug applied nor shortening the time of contact appreciably reduces the frequency of this adverse effect, which occurs in 30–80% of patients, although in

© 2006 Elsevier B.V. All rights reserved.

one study of 203 patients with mycosis fungoides, the use of chlormethine ointment was associated with contact hypersensitivity in under 10% of cases. In an open, prospective study in 39 patients with cutaneous T cell lymphomas or parapsoriasis, chlormethine was applied topically and then washed off after 1 hour (21). There was cutaneous intolerance in 19 patients, six of whom had an allergic contact dermatitis after a mean period of 9.3 weeks, while the other 13 developed irritant contact dermatitis after a longer period. Cutaneous intolerance did not differ significantly according to the number of applications per week or the extent of body area treated. Comparison with published studies showed no significant difference in the number of cases of cutaneous intolerance after short-term application, although their occurrence was delayed. Therapeutic response was decreased appreciably by short-term application as compared with results in the literature.

Second-Generation Effects

Fertility

In 21 boys treated with carmustine or lomustine alone or in combination with procarbazine and vincristine for brain tumors, there were 20 cases of persistent testicular damage (22). From assessment of testicular size it was thought that most of those affected would remain infertile. This supports the idea that germinal epithelium is more susceptible than Leydig cells to cytostatic-induced damage.

Drug–Drug Interactions

Cimetidine

Bone marrow suppression by carmustine may be enhanced by cimetidine (23,24).

Nitrous oxide

See also General anesthetics

General Information

Nitrous oxide is a relatively potent analgesic but a weak anesthetic, in use since 1842. At body temperature, its blood/gas partition ratio is only 0.47. It is excreted unchanged via the lungs. Because of the large mass of gas delivered to the patient, important physicochemical problems arise. Its ability to diffuse into and expand any air-filled cavity continues to produce new reports. Nitrous oxide is occasionally abused (1).

The continued use of nitrous oxide in anesthetic practice has been questioned on the basis of its serious adverse effects and the availability of potentially safer short-acting potent analgesic drugs, such as xenon and remifentanil (2).

Organs and Systems

Cardiovascular

Although myocardial depression has been described in healthy volunteers after the use of 40 or 50% nitrous oxide in oxygen, it is usually mild. It is likely that nitrous oxide can worsen myocardial ischemia in patients with critical coronary stenosis, although this may not be of clinical significance (3,4).

Homocysteine concentrations

Nitrous oxide inhibits methionine synthase, thereby preventing the conversion of homocysteine to methionine. A high homocysteine concentration has also been identified as an independent risk factor for coronary artery and cerebrovascular disease.

The effect of nitrous oxide on homocysteine concentrations and perioperative myocardial ischemia/infarction has been extensively reviewed (5). Nitrous oxide causes acute rises in postoperative homocysteine concentrations temporally associated with postoperative myocardial ischemia. Preoperative oral folate and vitamins B_6 and B_{12} blunt nitrous oxide-induced postoperative increases in plasma homocysteine (6).

The effect of nitrous oxide on homocysteine concentrations and myocardial ischemia has been studied in a randomized controlled study in 90 patients, ASA grades 1–3, who received a standardized anesthetic consisting of propofol induction, an opioid, and either inhalational isoflurane or isoflurane + 50% nitrous oxide (7). They underwent carotid endarterectomy (average operation duration 3.3 hours). Electrocardiographic monitoring consisted of a three-channel Holter monitor (leads II, V2, and V5), which was later examined for periods of ischemia by a physician blinded to treatment group. Myocardial enzyme activities were not measured. Baseline homocysteine concentrations (12.7 μmol/l) were significantly increased in the recovery room and at 48 hours to 15.5 and 18.8 μmol/l respectively. The concentrations did not increase in those given nitrous oxide. Periods of preoperative and intraoperative ischemia did not differ. Postoperatively the nitrous oxide group had more patients with ischemia (19 versus 11), longer ischemic events in the first 24 hours (54 minutes versus 17 minutes), and more episodes of ischemia lasting more than 30 minutes (23 versus 14). The authors concluded that nitrous oxide is associated with increased myocardial ischemia. However, they conceded that they had not shown causality. Previous studies have not shown this outcome, but were less sensitive, using only two-channel or once-daily 12-lead electrocardiography, or not monitoring patients postoperatively. The subject warrants a major study before a firm conclusion can be drawn.

Respiratory

Although airway conductance may be reduced by nitrous oxide, respiratory depression is unlikely after short-term exposure (8). The respiratory safety of nitrous oxide inhalation in children has been confirmed (9).

The effects of intraoperative air or nitrous oxide on postoperative oxygen saturation (S_aO_2) in blood have been compared in 40 patients of ASA classes 1 and 2 undergoing elective open cholecystectomy. The incidence of hypoxemia was significantly higher in those treated with nitrous oxide than in those given air 48 hours postoperatively (10). Hypoxemia may also have some mechanical origins. Nitrous oxide diffuses into the endotracheal tube cuff, overexpanding it, and can thus provoke upper airway obstruction, hypoxemia, and trauma in intubated patients during general anesthesia (11).

The poor solubility of nitrous oxide may be dangerous for patients with pneumothorax, pneumoperitoneum, ileus, or air embolism.

Nervous system

Nitrous oxide inactivates the enzyme methionine synthetase, and caution is urged in giving nitrous oxide to patients who may be deficient in vitamin B_{12}. Low serum vitamin B_{12} concentrations have previously been reported in patients with sickle cell disease, but the reason for this is uncertain. Three cases of peripheral neuropathy have been reported in patients with sickle cell disease who received nitrous oxide (12–14). All three had a history of frequent painful sickle crises, for which they received nitrous oxide for prolonged periods. Serum vitamin B_{12} concentrations were slightly reduced in two patients and very low in the third. The patients all presented with difficulty in walking and paresthesia. Peripheral sensorimotor neuropathy was confirmed by nerve conduction studies. The patients all responded well to vitamin B_{12} injections and avoiding further exposure to nitrous oxide. Caution is therefore recommended when using nitrous oxide in patients with sickle cell disease or who are suspected of vitamin B_{12} deficiency. Two cases of polyneuropathy have also been reported after the use of nitrous oxide for 80 minutes and 3 hours in patients who were subsequently found to have pernicious anemia. They both responded well to hydroxocobalamin.

Nitrous oxide has a potential for abuse (15), one of the major complications of which is myeloneuropathy. Altered vitamin B_{12} metabolism has been suggested as a mechanism (16), and in some cases the patients concerned have been found to have pre-existing subclinical B_{12} deficiency (17). Nitrous oxide interferes with vitamin B_{12} formation by causing irreversible oxidation of cobalt in

© 2006 Elsevier B.V. All rights reserved.

an essential co-enzyme. Three cases of myeloneuropathy after nitrous oxide anesthesia have been reported in patients with subclinical vitamin B_{12} deficiency (18,19). In 12 patients who were heavily exposed to nitrous oxide either deliberately or professionally for periods ranging from 3 months to several years, numbness in the hands or legs developed initially, followed by Lhermitte's sign, gait ataxia, impotence, and sphincter disturbances (20). Several similar cases have been reported by others (SEDA-11, 110). Numbness and/or muscle weakness were found four times more often among exposed than non-exposed dental personnel (21).

Since nitrous oxide has some effects on the nervous system, it is not entirely surprising to note a further report that under experimental conditions it can affect memory. That memory changes can occur has been known for a long time, but the pattern of the effects now appears to be distinctly odd.

Myelopathy associated with nitrous oxide abuse has been reported (22).

- A 23-year-old man presented with a 5-day history of gait disturbance and incoordination. He had severe loss of proprioception in his legs and could not walk. He was hypomanic. Severe posterior column myelopathy was diagnosed using MRI scanning. His nitrous oxide use had consisted of 40–60 whipped cream bulbs per day for 6 months. He also admitted to intermittent diamorphine abuse, but not for the 3 weeks before admission. He was treated with hydroxocobalamin and methionine, but still had minor abnormalities 3 months later.

The authors noted that although the evidence is scant, treatment should consist of both vitamin B_{12} and methionine.

Two cases of polyneuropathy and myelopathy associated with chronic nitrous oxide abuse have been reported (23,24).

Inhalation of 50 or 70% nitrous oxide in oxygen for 15 minutes impaired driving skill (25). Patients who receive nitrous oxide should be informed that its after-effects can alter their functioning without their being conscious of the fact (26).

Nitrous oxide can diffuse into any cavity that has air inserted or left in situ. Intraoperative subdural tension pneumocephalus arising during neurosurgery has been described (27). Air injected into the epidural space can cause symptomatic pressure effects if nitrous oxide diffuses into the air pocket.

Sensory systems

Eyes

Nitrous oxide is 34 times more soluble than nitrogen in enclosed body cavity gas spaces and it enters such spaces rapidly, causing expansion and a rise in pressure. Vitreoretinal surgery often uses intraocular gases to replace vitreous humor, in order to internally tamponade the neuroretina to the retinal pigment epithelium. Various long-acting inert gases, such as sulfur hexafluoride or perfluoropropane, can be used as intraocular tamponading agents. Several cases of blindness and severe visual loss associated with nitrous oxide in people with intraocular gas bubbles have been reported (28–30). It has been suggested that all such patients should have warning bracelets detailing the presence of intraocular gas and that nitrous oxide be avoided until it has been shown that the gas bubble has been absorbed.

Ears

- Rupture of the tympanic membrane was attributed to nitrous oxide in a 28-year-old woman with a history of tonsillectomy and a recent respiratory tract infection who underwent dilatation and curettage during laparoscopy (31).

Hematologic

The effect of nitrous oxide on vitamin B_{12} and folate metabolism can cause megaloblastic bone marrow changes, the period required depending on the patient's nutritional status (32).

Dyshemopoiesis after exposure to nitrous oxide may be mediated through a direct inhibitory effect (33). Although clinical sequelae have not been reported, the use of nitrous oxide in bone marrow transplantation needs to be evaluated further and cannot currently be recommended (34).

Gastrointestinal

Nausea and vomiting seldom occur. Nitrous oxide had no effect on recovery from laparoscopic cholecystectomy (35).

Liver

Jaundice after general anesthesia in which nitrous oxide was the only anesthetic has been described (36). However, contamination with halothane was not definitely ruled out.

Urinary tract

Renal blood flow is moderately reduced by nitrous oxide (37). Disturbances of kidney function have been described (38).

Body temperature

Malignant hyperthermia is very rare; the possible role of nitrous oxide as a triggering agent has not been confirmed in pigs (39).

Second-Generation Effects

Pregnancy

Nitrous oxide has been widely used in pregnancy and is generally regarded as being safe (40).

Teratogenicity

Some experimental data have suggested a possible teratogenic potential of nitrous oxide, the clinical relevance of which is unclear (41). The interaction with vitamin B_{12} causes changes in DNA synthesis that could be important in the first trimester of pregnancy. Nitrous oxide is the only inhalational anesthetic that has definitely been

© 2006 Elsevier B.V. All rights reserved.

shown to be teratogenic in experimental animals, but epidemiological studies have suggested that it is not teratogenic in human (42).

Drug–Drug Interactions

Halothane

The addition of nitrous oxide to halothane in coronary patients produced hypotension, with a subsequent risk of myocardial damage (43).

Other inhalation agents

The uptake of any other inhalation agent, given at the same time as nitrous oxide, is accelerated by the rate of uptake of nitrous oxide. This is termed the "second gas effect" (44). Direct pharmacodynamic interactions do not occur.

Interference with Diagnostic Tests

Oxygen dissociation

Nitrous oxide inhalation can give false PO_2 measurement results and shift the oxyhemoglobin curve to the left (45).

Nizatidine

See also Histamine H_2-receptor antagonists

General Information

Nizatidine is a histamine H_2 receptor antagonist. Experience with it is still too limited to make valid comparisons with its earlier congeners. Data sheet warnings of possible adverse effects refer to skin rash, urticaria, somnolence, and thrombocytopenia. Nizatidine is said not to give problems with drug interactions or to affect androgen status.

The efficacy and safety of nizatidine 75 mg/day have been studied in a placebo-controlled trial in 994 individuals with heartburn (1). Nizatidine relieved heartburn significantly faster and/or more consistently than placebo. Nizatidine was well tolerated and the frequencies of adverse events were similar in the two groups.

Drug–Drug Interactions

Dapsone

In a randomized, crossover, open study in 16 healthy volunteers a rise in gastric pH to above 6 by nizatidine did not result in clinically important changes in the rate or extent of absorption of oral dapsone (2).

Nomifensine

General Information

Nomifensine was first introduced in 1977 and eventually became available in over 70 countries. There has been increasing evidence of problems with adverse effects since 1981 (SEDA-5, 19), when cases of "drug fever" were recorded (SEDA-10, 22); this vague term covers a multitude of sins, the origins of which were finally elucidated at almost the exact moment when nomifensine was approved for release in the USA. Finally, in January 1986, the manufacturers withdrew nomifensine worldwide, citing grave concern elicited particularly by cases of rapid acute hemolytic anemia with intravascular hemolysis (SEDA-10, 22) (1).

Non-nucleoside reverse transcriptase inhibitors (NNRTIs)

See also Individual agents

General Information

The non-nucleoside analogue reverse transcriptase inhibitors (NNRTIs) include delavirdine, efavirenz, and nevirapine (all rINNs). The pharmaceutical chemistry and uses of the first- and second-generation NNRTIs have been reviewed (1).

In a non-randomized study of 694 patients taking two NRTIs, who were also given either nevirapine or efavirenz the reasons for discontinuation were as shown in Table 1 (2). In passing, it should be noted that although

© 2006 Elsevier B.V. All rights reserved.

Table 1 Numbers (%) of patients who discontinued therapy in a follow-up study of two NRTIs plus either nevirapine or efavirenz

this paper contains details of adverse events, there is no way of knowing that from a perusal of the title or abstract. Thus, anyone searching online for data for a systematic review of the adverse effects of these drugs might miss this information. When adverse events data are included in accounts of trials, the fact should be mentioned in the title and/or abstract.

Observational studies

Combinations of NRTIs and NNRTIs

The efficacy and safety of abacavir (NRTI) and efavirenz (NNRTI) plus background therapy have been retrospectively evaluated in 50 patients, who had previously been treated with HAART (3). There was some immunological benefit, albeit limited, in most of the patients. Adverse effects were not mentioned in detail, but the dropout rate during the first 4 weeks of treatment was high, owing to skin rashes and hypersensitivity reactions.

Of 80 injecting drug users who took two NRTIs + nevirapine (NNRTI), 20 discontinued treatment and 20 had treatment failures (4). Adverse events led to withdrawal of therapy in 10 patients: eight had a rash (in one case Stevens–Johnson syndrome), one had liver failure thought to be unrelated to the drugs; and one had "general intolerance." Two patients taking methadone had opioid withdrawal symptoms, presumably due to induction of methadone metabolism by nevirapine.

Combinations of NRTIs, NNRTIs, and protease inhibitors

In an open, 48-week, single-arm, multicenter phase II study in 99 patients abacavir 300 mg bd, amprenavir 1200 mg bd, and efavirenz 600 mg/day were associated with rashes in 50 patients, possibly because of abacavir hypersensitivity; 17 permanently discontinued one or more drugs as a result (5). Other adverse effects included nausea ($n = 41$), diarrhea ($n = 27$), sleep disorders ($n = 27$), dizziness ($n = 25$), fatigue ($n = 23$), hypertriglyceridemia ($n = 18$), neutropenia ($n = 8$), hyperamylasemia ($n = 4$), leukopenia ($n = 3$), hypercholesterolemia ($n = 2$), raised alkaline phosphatase ($n = 1$), and raised aspartate transaminase ($n = 1$).

In infants and children assigned to different combinations of one or two NRTIs plus an NNRTI and/or a protease inhibitor, the numbers of patients with moderate or severe adverse events were as shown in Table 2 (6). In cases of rash, the rash was worse in those who were taking nevirapine-containing regimens.

Organs and Systems

Liver

In 13 patients, studied retrospectively, who were given a combination of two NNRTIs, nevirapine + efavirenz, the most common adverse event was a change in liver function tests, to almost three times the upper end of the reference range in three cases; however, it was directly attributable to the antiretroviral drugs in only one case (7).

The incidence of NNRTI-induced hepatotoxicity in HIV-infected patients and the effect of co-infection with hepatitis B or hepatitis C virus have been studied in 272 patients (8). The NNRTIs used were delavirdine ($n = 40$), efavirenz ($n = 91$), and nevirapine ($n = 141$).

Table 2 Numbers (%) of infants and children with moderate or severe adverse events in a study of one or two NRTIs plus an NNRTI and/or a protease inhibitor

System affected by the adverse event	Regimen			
	Stavudine + nevirapine + ritonavir ($n = 41$)	Stavudine + nevirapine + nelfinavir ($n = 44$)	Stavudine + lamivudine + nevirapine + nelfinavir ($n = 44$)	Stavudine + lamivudine + nelfinavir ($n = 52$)
Respiratory	12 (29)	18 (41)	23 (52)	50 (96)

*Significantly different from the other groups.

© 2006 Elsevier B.V. All rights reserved.

There were mild to moderate rises in serum aspartate transaminase or alanine transaminase in 81 patients and large rises in three patients, one of whom was taking efavirenz and two nevirapine. Hepatitis B or hepatitis C virus infection did not significantly increase the risk of hepatotoxicity. The authors concluded that NNRTIs cause little hepatotoxicity, despite the presence of co-infection with hepatitis B or hepatitis C viruses.

More than 100 NSAIDs are marketed or at an advanced stage of development worldwide. Their use is constantly expanding and the search for more efficacious and better-tolerated compounds is still being pursued, and has received renewed impulse with studies on selective inhibitors of cyclo-oxygenase type 2 (COX-2), nitric oxide-releasing NSAIDs, peroxidase inhibitors, enantiomers of already known NSAIDs, NSAIDs associated with zwitterionic phospholipids, and cytokine-modulating antirheumatic drugs.

Predominantly used in the management of rheumatological conditions, NSAIDs are drugs of choice in the treatment of inflammatory arthropathies. However, their use has also been extended to many non-rheumatological problems (for example dysmenorrhea, pain of different origin, neoplastic fever, migraine, thromboembolic disease, and patent ductus arteriosus; they are also used for tocolysis and in some neoplastic diseases) (1). Several clinical, epidemiological, and animal studies have suggested that NSAIDs can reduce the occurrence or progression of colorectal cancer, polyps, and perhaps other gastrointestinal tumors (2–4). Reports and epidemiological studies have shown that NSAIDs can protect against the risk of Alzheimer's disease (5,6). NSAIDs are used locally in the eye to prevent and treat postoperative cystoid macular edema, to control postoperative ocular inflammation and pain, for example after radial keratotomy or photorefractive keratectomy, and for non-surgically induced inflammatory disorders, such as allergic conjunctivitis.

The range and incidence of these conditions clearly justifies extensive use of suitable drugs, and explains the pharmaceutical industry's interest in exploiting the potential revenues of such a large market.

The effort to find new compounds is medically justified by the unsatisfactory benefit-to-harm balance of the NSAIDs that are currently available.

The adverse reactions profiles of many NSAIDs have proved to be unacceptable. Over the last 20 years, 18 NSAIDs have been withdrawn from the market or their clinical studies have been terminated because of unexpected toxicity (7). Selection of an NSAID can be difficult, since reliable information about their relative efficacy and adverse reactions is usually meager.

Although the physicochemical features, pharmacokinetics, and pharmacodynamics of individual NSAIDs differ, it is not known to what extent these differences are significant in the benefit-to-harm balance in the individual patient (8). Certainly they influence the adverse reactions and the general pattern of action of a particular subgroup of NSAIDs or a specific compound within a class, but this still provides no reliable prediction of what the individual patient will experience.

The acidic nature and lipid solubility of these compounds are important. The lipid solubility of an NSAID determines its penetration into the central nervous system and hence the incidence of nervous system-related adverse effects and perhaps adverse skin reactions (9,10). The weak acid nature affects tissue distribution, which explains why NSAIDs have actions at certain sites (for example synovial tissue of inflamed joints) and also contribute to triggering particular adverse reactions at others (for example the stomach and renal medulla) (11).

Pharmacokinetic aspects can play a critical role in the onset of certain adverse effects in some patients (12). NSAIDs are almost entirely absorbed from the gastrointestinal tract (13). The rate and the site of absorption from the gastrointestinal tract can be important; formulations designed to spare the stomach from NSAID toxicity can instead damage the intestinal wall, which seems to have been the case with Osmosin (SEDA-8, 103). There have been a few studies of the chronopharmacology of NSAIDs (SEDA-20, 90). NSAID absorption is probably better in the morning, but there are more adverse effects than when the drug is taken in the evening.

NSAIDs bind avidly to plasma proteins. High protein binding can theoretically predispose patients to drug interactions, which occur most frequently with certain NSAIDs (for example the butazones) in patients who are concomitantly taking drugs such as hypoglycemic agents or oral anticoagulants. The unbound fraction responsible for the pharmacological action of NSAIDs varies with the plasma albumin concentrations, which can be influenced by active rheumatoid arthritis, genetic factors, sex, age, pregnancy, other drugs, and diseases, particularly when the kidney and liver are involved. A correlation between anti-inflammatory action and dose or plasma concentration has been documented for only a few NSAIDs, and there is no direct evidence that an increase in unbound drug concentration is associated with greater toxicity. However, there is convincing evidence that the dose contributes to certain adverse effects (for example gastrointestinal and renal). A record-linkage study has shown an association between NSAID dosage and upper gastrointestinal bleeding (14).

NSAIDs can be roughly divided into those with short and long half-lives. Although the difference in clinical

© 2006 Elsevier B.V. All rights reserved.

effects between these two categories is poorly understood, half-lives have served as a rough guide for NSAID dosage regimens, compounds with long half-lives being administered only once a day. These NSAIDs also have a greater potential to cause adverse effects, at least in some patients. As the half-lives of this type of NSAID vary widely in different patients, drug accumulation can occur in some individuals. When using an NSAID with a long half-life, loading doses can be given to achieve high drug concentrations quickly, but can be associated with increased adverse effects, particularly gastrointestinal intolerance.

NSAIDs are mainly cleared by the liver, and their clearances would be expected to fall with age (13). Their metabolites are generally inactive and excreted in the urine, which as a rule contains very little unchanged drug. Conversely, several NSAIDs that are themselves inactive can be used as prodrugs, since they have active metabolites; some of these compounds, such as sulindac, undergo enterohepatic recycling. Claims that these prodrugs are less toxic than other compounds are not supported by any firm evidence. Some NSAIDs, including carprofen, fenoprofen, indometacin, ketoprofen, and naproxen are metabolized to acylglucuronides; the metabolites are retained and hydrolysed to re-form the parent compound. This is probably one of the mechanisms of toxicity in patients with renal insufficiency.

Pharmacodynamic mechanisms can also be crucial. The main mechanism of action is inhibition of cyclo-oxygenase (COX) activity and consequently of prostaglandin synthesis (15–17). Two forms of COX have been identified: COX-1, which is constitutively expressed in many cells and tissues, and COX-2, which is selectively induced by proinflammatory cytokines at the site of inflammation. The discovery of a second COX enzyme has led to the hypothesis that the toxicity associated with the clinically useful NSAIDs is caused by inhibition of COX-1, whereas the anti-inflammatory properties are caused by the inhibition of COX-2 (18). A selective COX-2 inhibitor may therefore have better anti-inflammatory activity with greater safety than existing NSAIDs. The in vitro potency of NSAIDs as inhibitors of prostaglandin synthesis, which tends to match their anti-inflammatory potency in vivo, varies from one anti-inflammatory agent to the next (19,20). Other mechanisms that are poorly understood may be implicated in determining both a drug's activity and its adverse effects.

These data provide a basis for the practical use of NSAIDs. There can be no doubt that some NSAIDs are more toxic than others, notably those that have the greatest inhibitory effect on cyclo-oxygenase. NSAIDs that inhibit both cyclo-oxygenase and lipoxygenase are particularly toxic. The fact that some NSAIDs are more toxic to single organs than others seems to depend on the physicochemical and metabolic characteristics of single drugs or groups of similar drugs. Despite numerous studies, reliable comparisons of the adverse effects of the different drugs are scanty. However, some data have been produced from the data bank centers of the Arthritis Rheumatism and Aging Medical Information System (ARAMIS) and have been reviewed (SEDA-17, 102). If selective COX-2 inhibitors are confirmed to have less gastrointestinal toxicity than the old NSAIDs, we should have new drugs with fewer risks. However, doubts are emerging about whether COX-1 inhibition makes a contribution to the anti-inflammatory activity of NSAIDs and whether COX-2 activity is implicated in mucosal healing and protective processes (SEDA-22, 109).

The categories of patients who are at higher risk of adverse reactions when treated with NSAIDs are well known and can largely be deduced from what has been said above. They include the elderly (especially women), pregnant women (and their fetuses), neonates, patients with liver, kidney, or cardiac disorders, and those with hypertension, multiple myeloma, peptic disorders, or active rheumatoid arthritis. Greater awareness of these risk factors among medical practitioners, limiting the use of NSAIDs to cases in which there is a precise indication, informing patients, developing systems for monitoring unwanted adverse effects, and carrying out adequate well-designed experimental studies would do much to ensure better use of these drugs. Many of the adverse effects of NSAIDs are, with negligible differences, common to all of them.

Organs and Systems

Cardiovascular

Hypertension

NSAIDs can cause or aggravate hypertension and interact negatively with the effects of antihypertensive drugs, including diuretics, although contrasting data from experimental and clinical studies have been published (21).

The mechanisms by which NSAIDs affect cardiovascular function are complex and controversial. They may include reduced blood flow, a reduction in the filtered load of sodium, an increase in tubular reabsorption of sodium, and a reduction in the synthesis of PGE-1, which may be associated with raised blood viscosity and increased peripheral vascular resistance. This is perhaps the primary mechanism, which is due to increased renal synthesis of endothelin-1.

Meta-analyses

In a meta-analysis of the hypertensive effects of NSAIDs or aspirin (1.5 g/day or greater) in short-term intervention studies; 54 studies and 123 NSAID treatment arms were included (22). Of the 1324 participating subjects, 92% were hypertensive; they had a mean age of 46 years and none was over 65 years. The major outcome studied was the change in mean arterial pressure. The effects of NSAIDs on blood pressure were found solely in hypertensive subjects; among these, the increase in mean arterial pressure, after adjusting for possible confounders (for example dietary salt intake) was different among different NSAIDs. The increase in mean arterial pressure was 3.59 mmHg for indometacin (57 treatment arms), 3.74 mmHg for naproxen (4 arms), and 0.45 mmHg for piroxicam (4 arms). However, mean arterial pressure fell by 2.59 mmHg with placebo (10 arms), by 0.83 mmHg with ibuprofen (6 arms), 1.76 mmHg with aspirin (4 arms), and 0.16 mmHg with sulindac (23 arms).

Overall, only the effects of indometacin on mean arterial pressure were statistically significantly different from those found with placebo, showing that in this population

© 2006 Elsevier B.V. All rights reserved.

the effects of NSAIDs on blood pressure were modest and varied considerably among different drugs. However, one must take into account the important limitations of the analysis: the patients were mostly young, the studies included in the meta-analysis were small and short-term, and information on possible confounders was incomplete. The significance of the results of this study is therefore doubtful.

Another meta-analysis provided more complete and useful results (23). Its primary aim was to produce an estimate of the overall effect of NSAIDs on blood pressure, and its secondary aims were to evaluate the mechanisms by which NSAIDs alter blood pressure and to determine susceptibility factors. Moreover, as NSAIDs have been associated with raised blood pressure in normotensive individuals and in both treated and untreated hypertensive subjects, the authors tried to discover different effects in these subgroups. Finally, they studied whether different NSAIDs alter blood pressure to the same degree.

In all, 50 randomized placebo-controlled trials and 16 randomized comparisons of two or more NSAIDs met the selection criteria. These studies included 771 young volunteers or patients aged 47 years or younger. The studies were small (the mean sample size per trial was 16); many different NSAIDs and antihypertensive drugs were used, but indometacin was used in more than half of all the trials; the duration of therapy with NSAIDs or antihypertensive drugs was 1 week or longer, but in most studies it was less than 3 months. NSAIDs raised supine mean blood pressure by 5.0 mmHg (95% CI = 1.2, 8.7), but had no significant effect on variables measured to assess possible mechanisms (such as body weight, daily urinary sodium output, creatinine clearance, or urinary prostaglandin excretion). Overall, the data suggested that NSAIDs do not appear to increase blood pressure primarily by increasing salt and water retention, because weight and urinary sodium were not altered by NSAIDs and inhibition of blood pressure control was not more marked in patients taking diuretics compared with other antihypertensive drugs. In addition NSAIDs did not significantly alter plasma renin activity or 24-hour urinary excretion of prostaglandin E_2 and 6-ketoprostaglandin $F_{1\alpha}$. Other factors may therefore contribute to the increase in blood pressure caused by NSAIDs. In particular, a potential effect of NSAIDs on peripheral vascular resistance should be considered (24,25). There is good evidence to suggest an important role for prostaglandins in the modulation of two major determinants of blood pressure, vasoconstriction of arteriolar smooth muscle and control of extracellular volume.

NSAIDs inhibited the effects of all antihypertensive drug categories. However, in patients taking beta-blockers and vasodilators, NSAIDs produced a greater increase in supine mean blood pressure than in patients taking diuretics, but only the pooled inhibitory effect of NSAIDs on the effects of beta-blockers achieved statistical significance. When the data were analysed by type of NSAID the meta-analysis showed that all NSAIDs increased supine blood pressure, and that piroxicam, indometacin, and ibuprofen produced the most marked increases. However, only piroxicam had a statistically significant effect with respect to placebo. Aspirin, sulindac, and flurbiprofen caused the smallest increases in blood pressure.

In conclusion this meta-analysis has provided more clear evidence that, as a group, NSAIDs significantly increase arterial pressure and can antagonize the blood pressure-lowering effect of some antihypertensive drugs, by mechanisms that are still unclear. Although the hypertensive effect of NSAIDs was more marked in hypertensive subjects taking antihypertensive drugs than in normotensive subjects not taking antihypertensive drugs, the difference was not statistically significant and its clinical relevance is unclear. It is worth noting that the effects of NSAIDs on blood pressure were similar in patients taking antihypertensive drugs for months or only a few days.

This study also had two main limitations: first, most of the trials were small, which precluded definitive conclusions about the effects of individual NSAIDs or individual antihypertensive drug classes; secondly, in most studies, therapy was short term and the patients were relatively young, making generalization of the results difficult, as NSAIDs are most often prescribed long term and for elderly people.

Prospective studies

A case-control study of the effects of NSAID therapy on arterial pressure has been performed in subjects aged 65 years and over, drawn from a large database (the State of New England Medicaid Program) to determine whether NSAIDs affect blood pressure (26). The investigators calculated the odds ratio (OR) for the initiation of antihypertensive therapy in patients taking NSAIDs relative to non-users after adjusting for possible confounding factors. The 9411 patients had started taking antihypertensive drugs between 1981 and 1990, and a similar number of controls were randomly selected. The date of the first prescription for an antihypertensive drug was defined as the index date. Of those who took antihypertensive drugs, 41% had taken an NSAID during the year before the index date, compared with 26% of the control subjects. This risk increased with the recency of NSAID therapy, and was greatest among recent users (those with a supply of NSAIDs ending more than 60 days before the index date) (OR = 2.10; 95% CI = 1.95, 2.26). For former users (those with a supply of NSAIDs ending more than 60 days before the index date) the adjusted OR compared with non-users was 1.66 (CI = 1.54, 1.80). There was a dose-response relation, with adjusted ORs of 1.55 (CI = 1.38, 1.74), 1.64 (CI = 1.44, 1.87), and 1.82 (CI = 1.62, 2.05) for low, medium, and high daily doses of NSAIDs respectively. The unadjusted ORs for ibuprofen, piroxicam, meclofenamate, and indometacin, were separately calculable, and for each of these drugs the OR increased with increasing dose. The relation between cumulative duration of NSAID use and the initiation of antihypertensive therapy was also examined in recent users. The risk was greatest in those who had used an NSAID for 30–90 days and was less for those who had used an NSAID for less than 30 days or for more than 90 days.

The results of this study suggest that the effects of NSAIDs on blood pressure in older patients taking NSAIDs may be clinically important. Given that 15% of

© 2006 Elsevier B.V. All rights reserved.

the control group were recent users of NSAIDs, and assuming that the adjusted OR of 1.66 represents a causal association of these drugs with the initiation of antihypertensive therapy, the proportion of cases attributable to the use of these drugs in this sample of elderly population was nearly one in ten.

Despite the high prevalence of the use of minor analgesics (aspirin and paracetamol) there is little information available on the association between the use of these analgesics and the risk of hypertension. A prospective cohort study in 80 020 women aged 31–50 years has provided some useful information (27). The women had participated in the Nurses' Health Study II and had no previous history of hypertension. The frequency of use of paracetamol, aspirin, and NSAIDs was collected by mailed questionnaires and cases of physician-diagnosed hypertension were identified by self-report. During 164 000 person-years of follow-up, 1650 incident cases of hypertension were identified. Overall 73% of the cohort had used paracetamol at least 1–4 days/month, 51% had used aspirin, and 77% had used an NSAID. Compared with non-users of paracetamol the age-adjusted relative risk (RR) of hypertension was significantly increased even in women who had used paracetamol for only 1–4 days/month (RR = 1.22; CI = 1.07, 1.39). There seemed to be a dose-response relation, as the RR of hypertension compared with non-users was 2.00 (CI = 1.52, 2.62) in women who had taken paracetamol for 29 days/month or more. For women using aspirin or NSAIDs at a frequency of 1–4 days/month the RRs were 1.18 (CI = 1.02, 1.35) and 1.17 (CI = 1.02, 1.36) respectively. However, after adjusting for age and other potential risk factors, only paracetamol and NSAIDs, but not aspirin, remained significantly associated with a risk of hypertension. In summary, the data from this study support the view that paracetamol and NSAIDs are strongly associated with an increased risk of hypertension in women, the risk increasing with increasing frequency of use. Aspirin did not seem to be associated with an increased risk. This conclusion contrasts with the results of some short-term studies that have shown no effect of paracetamol on blood pressure (28,29).

However, the results from this study must be interpreted with caution, as there were some limitations: the assessments of analgesic use and hypertension were made using a self-reported questionnaire; relative risk can be influenced by many potentially confounding variables; the results are relevant only for young women and cannot be extrapolated to the general population.

The impact of NSAIDs on blood pressure in elderly people has been evaluated in three epidemiological studies, with similar findings (SEDA-19, 92). The use of NSAIDs was significantly associated with hypertension or the use of antihypertensive drugs. Reliable data are available for hypertension in the elderly. Recent users of NSAIDs have a 1.7-fold increase in the risk of initiating antihypertensive therapy compared with non-users, and the use of NSAIDs significantly predicts the presence of hypertension (OR = 1.4; 95% CI = 1.1, 1.7) (21).

Conclusions

The overall results of these studies have provided convincing evidence that NSAIDs and paracetamol can raise arterial blood pressure in a dose-related fashion, interfere with the actions of antihypertensive drugs, and prompt the need for new antihypertensive therapy.

Even if the increase in mean blood pressure is probably modest (less than 5.0 mmHg) the clinical relevance of such an increase can be large, especially in elderly people. In fact, an overview of randomized clinical trials of antihypertensive treatment has shown that a 5–6 mmHg increase in diastolic blood pressure over a few years can be associated with a 67% increase in the incidence of strokes and a 15% increase in coronary heart disease (30). These effects are apparent in both normotensive and hypertensive patients.

Whether these results apply with certainty to patients taking NSAIDs is not known, because these studies included patients not taking NSAIDs, but it is wise to consider this probability. The type and dose of NSAID may be important, but more studies are needed to document this. Hypertensive and elderly patients seem to be particularly at risk. In patients taking long-term NSAIDs, or even paracetamol, periodic monitoring of blood pressure appears to be warranted.

Congestive heart failure

Much less is known about the risk of congestive heart failure with NSAIDs. The rate of hospitalization for congestive heart failure in more than 10 000 patients over 55 years of age during exposure to both diuretics and NSAIDs was compared with the rate in those exposed to diuretics alone (31). At mean follow up of 4.7 years, there was an increased risk of hospitalization when diuretics and NSAIDs were used concomitantly (RR = 1.8; 95% CI = 1.4, 2.4).

In 600 elderly patients with documented congestive cardiac failure there was a possible or probable link between NSAIDs and heart failure in 27 cases (32). In some, the mechanism was apparently a reduction in the effect of furosemide. In others the NSAID may have caused an imbalance in circulatory homeostasis. Pre-existing renal impairment was not observed in any of the 27 cases. This study suggests that in elderly people congestive heart failure may be a complication of NSAIDs.

In a matched case-control study the relation between the recent use of NSAIDs and hospitalization with congestive heart failure in elderly patients has been analysed (33). Cases (n = 365) were patients admitted to hospital with a primary diagnosis of congestive heart failure; controls (n = 658) were patients without congestive heart failure. Structured interviews were used to obtain information on several possible risk factors, such as a history of heart disease and the type and dosage of NSAIDs used. The use of NSAIDs (other than low-dose aspirin) in the previous week was associated with a doubling of the chance of a hospital admission with congestive heart failure (adjusted OR = 2.5, CI = 1.2, 3.3). The risk was even higher in patients with a history of heart disease, in whom the use of NSAIDs was associated with an increased risk of a first admission with congestive heart failure (OR = 11; CI = 0.7, 45), but not in those without a history of heart disease (OR = 1.6; CI = 0.7, 3.7). In contrast to the results of a previous study (31), the risk of admission to hospital with congestive heart failure was positively related to the

© 2006 Elsevier B.V. All rights reserved.

dose of NSAID consumed in the previous week and was higher with long half-life NSAIDs than with short half-life NSAIDs. The authors estimated that, assuming that these relations were causal, NSAIDs might be responsible for about 19% of hospital admissions with congestive heart failure. If confirmed, this burden of illness resulting from NSAID-related congestive heart failure may rival that resulting from damage to the gastrointestinal tract and would represent an under-recognized public health problem. In any case, this study reinforces the timely suggestion that NSAIDs should be used with great caution in patients with a history of cardiovascular disease. This recommendation must also include the use of the selective COX-2 inhibitors, until more information is available.

Respiratory

As 2–20% of adult asthmatics have aspirin hypersensitivity (34), they must be considered at risk from NSAIDs. The mechanism is related to a deficiency in bronchodilator prostaglandins; prostaglandin inhibition may make arachidonic acid produce more leukotrienes with bronchoconstrictor activity. Oral challenge in asthmatic patients is an effective but potentially dangerous method for establishing the presence of aspirin hypersensitivity (35). Occasionally, bronchospasm may be part of an anaphylactoid reaction to NSAIDs; zomepirac was withdrawn for this reason. Intriguingly bee-keepers may be at increased risk for severe reactions from bee stings if they are taking NSAIDs, and it has been suggested that NSAIDs should be prescribed with particular caution for them (36).

Nervous system

NSAIDs cause headaches and confusion in a relatively small number of patients. Headache and dizziness are common with indometacin, and it has been suggested that its chemical similarity to serotonin, which can cause severe headaches, may be responsible (37). Headache due to long-term use of ibuprofen has been reported in children (38,39).

The Australian Drug Reaction Advisory Committee has reported paresthesia as a class effect of NSAIDs, although it is rare and reversible (40).

Studies on the link between falls in elderly people and NSAIDs have yielded conflicting and inconsistent data (41,42), and an increased risk of falls with NSAIDs is difficult to explain.

Some rarer adverse effects, such as aseptic meningitis, have been reported with ibuprofen, sulindac, and tolmetin (37) in patients with systemic lupus erythematosus. A case-control study showed no increased risk of intracerebral hemorrhage in patients using aspirin or other NSAIDs in low dosages as prophylaxis against thrombosis (43).

Sensory systems

Eye disorders, such as blurred vision, ocular discomfort, irritation, and more severe problems, such as optic or retrobulbar neuritis and papilledema, have been described (SEDA-19, 96).

Psychological, psychiatric

Behavioral changes have been reported with indometacin (44).

- A 92-year-old man with a history of senile dementia of the Alzheimer type, glaucoma, and constipation took indometacin 25 mg for pseudogout. After six doses he became very agitated and confused and was physically and verbally aggressive. Indometacin was withdrawn and he recovered over 10 days with the help of haloperidol 0.5 mg/day (45).

NSAIDs should probably be included as one of the many groups of drugs that can cause confusion in the elderly.

Cognitive function in elderly out-patients was assessed in a large retrospective study by a questionnaire; there were no significant differences in the total scores of users and non-users of NSAIDs (SEDA-17, 106). Another study showed that performance in sensorimotor coordination and short-term memory tests can improve in healthy elderly volunteers who take indometacin (46). NSAIDs have also been associated with a reduced risk of Alzheimer's disease (47).

Electrolyte balance

NSAIDs can interfere with fluid and electrolyte homeostasis, thereby causing edema, hyponatremia, hyperkalemia, and blunting of the natriuretic effects of diuretics (48,49).

Hematologic

NSAIDs have been reported to cause potentially severe hematological disorders: thrombocytopenia, agranulocytosis, aplastic anemia, and hemolytic anemia (50). Thrombocytopenia is generally mild and reversible and has a low case-fatality rate, but deaths from bleeding have been reported, particularly with indometacin, oxyphenbutazone, and phenylbutazone (50).

Pyrazolone derivatives and butazones are most frequently blamed for causing agranulocytosis and aplastic anemia (SEDA-9, 85) (SEDA-11, 89). Unfortunately, no reasonably accurate estimate of the overall incidence of either disease or of the risk associated with the use of any particular NSAID is available. The results of the International Agranulocytosis and Aplastic Anemia study (51) have been reviewed in detail (SEDA-11, 89) (SED-11, 171). This epidemiological study was organized by the manufacturer (Hoechst) of the widely incriminated drug dipyrone. The overall annual community agranulocytosis incidence was 4.4 per million (6.2 including hospital cases), with a fatality rate of 10% and an annual mortality rate of 0.4 per million. Analgesics significantly associated with agranulocytosis were dipyrone, indometacin, and two butazones (oxyphenbutazone and phenylbutazone). Other pyrazolones, such as amidopyrine (which is an acknowledged cause of agranulocytosis), or other NSAIDs could not be evaluated because of the small number of cases.

A population-based, case-control study in patients hospitalized with neutropenia has confirmed both the association between NSAIDs and neutropenia and the differences between different classes of NSAID (52). The data on aplastic anemia are also of interest, since

© 2006 Elsevier B.V. All rights reserved.

this was the first study to provide excess risk estimates of this adverse effect in NSAID users. The overall annual incidence was 2.2 per million, with a 2-year fatality rate of 40%. A significantly increased risk for aplastic anemia was associated with any exposure to three drugs: indometacin (multivariate rate ratio 13), butazones (8.7), and, unexpectedly, diclofenac (8.8). Whatever the interpretations by different manufacturers, the study confirmed that dipyrone can cause agranulocytosis and that indometacin can cause aplastic anemia (53). The high relative risk of diclofenac for aplastic anemia is unexpected and requires confirmation.

Hemolytic anemia has occasionally been associated with NSAIDs; many reports involved mefenamic acid, ibuprofen and sulindac (54). No evidence has been found that any NSAID, except aspirin, constitutes a particular risk for subjects with glucose-6-phosphate dehydrogenase deficiency.

A prospective study on bleeding complications in 23 patients undergoing dermatological surgery has shown that NSAIDs and aspirin need not be withdrawn routinely preoperatively, unless the bleeding time is prolonged (55). Relatively few patients developed a prolonged bleeding time while taking aspirin or other NSAIDs and only few had significant intraoperative blood loss. There is variation in the response of patients for unknown reasons and so the recommendation that NSAIDs should be withdrawn before elective surgery awaits confirmation (SEDA-19, 96).

Gastrointestinal

Peptic ulceration

Prostaglandins have a protective effect on the gastrointestinal mucosa. All NSAIDs that non-selectively inhibit prostaglandin synthesis cause gastrointestinal mucosal damage. Direct NSAID-mediated acid damage has been identified as a mechanism of gastrointestinal toxicity (56). Several in vitro and animal studies have provided evidence of early vascular changes and have highlighted the role of leukocyte adhesion to the endothelium in NSAID-induced gastropathy. The pathogenesis of NSAID-associated gastrointestinal damage has been reviewed (SEDA-17, 104).

Clinical presentation

Features of upper gastrointestinal toxicity during NSAID therapy range from relatively mild symptoms (such as heartburn, dyspepsia, and stomach discomfort) to more severe and potentially life-threatening states (for example gastrointestinal erosion or ulceration, bleeding, or perforation). Although dyspepsia is one of the major factors that limit the use of NSAIDs in patients with rheumatic diseases, it does not necessarily predict mucosal damage. There is no close correlation between objective gastroscopy findings and subjective intolerance of medications, or between acute or chronic damage and complications. Epigastric pain was the most common symptom in patients admitted to hospital with hematemesis and/or melena, whether treated or not with NSAIDs in the 14 days before admission (SEDA-17, 103).

"NSAID gastropathy" is the term proposed by Roth and Bennett to describe upper gastrointestinal lesions associated with NSAID therapy. It has its own specific features (primarily antral and prepyloric localization, especially in elderly women), which differentiate it from classic peptic ulcer disease (57). Damage to the upper gastrointestinal tract can also involve the duodenum and, albeit infrequently, the esophagus.

Frequency

Gastrointestinal damage by NSAIDs is a major health problem. Estimates of the absolute risk vary from about two cases of serious upper gastrointestinal adverse effects per 10 000 person-months (58) to a seven-fold increase in the risk of hospitalization in patients with rheumatoid arthritis (59). Estimates of hospitalization for ulcer complications and the excess of gastrointestinal deaths in the UK have shown that 20–30% of all cases of ulcer complications in subjects aged over 60 which result in hospitalization are directly attributable to the use of NSAIDs, and that some 10% culminate in death (60). For the UK, this means that at least 2000 cases of bleeding are caused every year with about 200 deaths (61), in association with about 11 million prescriptions. The relative risk reported in different studies has generally been in the range of 3:1 to 5:1 (62).

In 2747 patients with rheumatoid arthritis, those taking NSAIDs were five times more likely (hazard ratio of 5.2) to be hospitalized for an upper gastrointestinal event (63). The risk of hospitalization for a gastrointestinal event was 15.8 per 1000 person-years in individuals taking NSAIDs, compared with 3.2 per 1000 person-years for controls. Such figures mean that on average one to two out of every 100 patients taking NSAIDs for 1 year are hospitalized for a gastrointestinal event (most commonly an ulcer).

The conclusion of a meta-analysis of 16 studies was that NSAID users have an approximately three-fold greater relative risk of developing serious adverse gastrointestinal events than non-users (64). This has been confirmed by a review (65).

Several authors have suggested that the upper gastrointestinal toxicity shortly after exposure does not persist (SEDA-22, 108), either because there is adaptation to NSAID-induced mucosal damage or because in these studies susceptible patients were selected. However, a population-based, cohort study has provided evidence that upper gastrointestinal toxicity is constant during exposure to NSAIDs and continues for some time after treatment stops (66).

Susceptibility factors

Case-control and surveillance studies have confirmed that the susceptibility factors for peptic ulcer disease are age, a history of ulcers and/or gastric bleeding, combination with corticosteroids, combination with other NSAIDs, and possibly smoking (SEDA-14, 84). The combination of NSAIDs, smoking, and alcohol increased the risk of gastrointestinal perforation nearly 11 times (OR = 10.7; CI = 3.8, 30) (SEDA-21, 97). Data on patients with rheumatoid arthritis taking NSAIDs show that the predisposition to gastrointestinal events is related to the severity of the disease (63). Other potential risk factors are sex (female), the musculoskeletal diseases for which NSAIDs are used, the NSAID taken, and dosage. The

© 2006 Elsevier B.V. All rights reserved.

presence of gastric mucosal erosions at endoscopy was associated with an increased risk of a gastric ulcer, irrespective of prophylactic treatment (misoprostol versus sucralfate) in chronic NSAID users with osteoarthritis evaluated in a large randomized controlled trial (67). This was confirmed in other studies (SEDA-20, 86) (68,69), suggesting that the presence or absence of erosions is a better predictor of the risk of ulceration than the number of erosions.

The role of *Helicobacter pylori* *Helicobacter pylori* and non-steroidal anti-inflammatory drugs (NSAIDs) account for nearly all gastroduodenal ulcers and serious ulcer complications, but the interaction between infection with *H. pylori* and the use of NSAIDs in the pathogenesis of NSAID-induced gastropathy is controversial. In fact, studies that have examined these two susceptibility factors have yielded conflicting results about whether *H. pylori* infection increases the risk of toxicity in NSAID users, has no effect, or may even be protective (70–72).

Since we reviewed this topic 10 years ago (SEDA-16, 103) (SEDA-17, 105) a large amount of information has accumulated and merits further attention.

The pathophysiological mechanisms Among possible common pathophysiological mechanisms of importance are those that compromise the effectiveness of the gastroduodenal mucus–bicarbonate barrier, those that cause recruitment and activation of neutrophils, and those that can interfere with the process of mucosal adaptation (70). Both NSAIDs and aspirin can reduce the effectiveness of mucosal defences, by inhibiting gastroduodenal prostaglandin synthesis and by reducing mucosal blood flow (73). On the other hand *H. pylori* infection can damage the mucus–bicarbonate barrier, by increasing gastric acid secretion and reducing the viscosity of gastric mucus (74). Contrasting data have been reported on the effect of *H. pylori* on mucosal blood flow (75,76) and on mucosal prostaglandin production. However, although *H. pylori* increases mucosal prostaglandin synthesis, the combination of *H. pylori* with NSAIDs or aspirin causes a marked fall in mucosal prostaglandin synthesis, showing that the stimulatory effect of prostaglandin production by *H. pylori* is insignificant in the presence of NSAIDs or aspirin (76,77).

Gastric ulceration induced by NSAIDs is a neutrophil-dependent process (78) and the association of *H. pylori* infection with neutrophil infiltration has also been well documented. Gastric injury by NSAIDs is minimal in neutropenic animals, and the cumulative incidence of peptic ulcers in long-term NSAID users is increased in the presence of neutrophil infiltration in the mucosa of patients who are *H. pylori*-positive, suggesting a possible link between NSAIDs and *H. pylori* in the pathogenesis of peptic ulcers (79,80).

The ability of the gastroduodenal mucosa to adapt to repeated exposure to NSAIDs and aspirin is well documented, and some reports have shown the possible involvement of *H. pylori* in this process (76,81). In one endoscopic study in volunteers, mucosal adaptation to naproxen after 4 weeks of treatment occurred in 53% of *H. pylori*-positive subjects and in 81% in *H. pylori*-negative subjects (82). Similar results were found in another study in volunteers who took aspirin for 2 weeks; mucosal adaptation to the injury caused by aspirin was clearly impaired in the presence of *H. pylori* and was restored after *H. pylori* eradication (83).

In summary, NSAIDs and *H. pylori* can cause adverse effects on gastroduodenal mucosal protective mechanisms in different ways, and so the interaction between these two susceptibility factors might allow damage to occur more readily when NSAIDs are taken in the presence of *H. pylori* infection. However, despite this experimental evidence, the interaction between *H. pylori* infection and use of NSAIDs in the pathogenesis of peptic ulcers and their complications is still unclear from clinical studies.

Clinical studies Most of the early studies of the interaction between *H. pylori* infection and the use of NSAIDs were based on observational studies in long-term NSAID users and gave conflicting results (79, 84–91). In some studies there were significantly more ulcers in NSAID users who were *H. pylori*-positive then in users who were not infected (79,84,85). However, these findings were not confirmed by other investigators (86–89), and they probably reflect a complex relation between *H. pylori* infection and NSAID-associated gastropathy, as well as heterogeneity of methods across studies. For example, differences in population studied (for example the type of NSAID exposure, the age of the patient) and even in the definition of ulcer at endoscopy make direct comparison of results difficult. Most of the few published prospective trials did not show that *H. pylori* is a susceptibility factor for NSAID-induced gastroduodenal damage (77,92–94), and two long-term longitudinal studies (69,95) gave conflicting results, although the data have mostly been derived from studies in small numbers of young healthy volunteers at very low risk of gastropathy, and the results must therefore be treated with great caution. Thus, despite numerous studies we do not have convincing evidence for or against a link between *H. pylori* and NSAIDs in the development of peptic ulcers.

A meta-analysis has helped to clarify this issue (96). The aim was to assess the presence and magnitude of any possible interaction in peptic ulcer disease between these two susceptibility factors, with particular attention to bleeding peptic ulcer disease, the sites of ulceration, and the effect of *H. pylori* eradication. In all, 61 relevant studies were identified, 36 of which were excluded for various reasons. Thus, 25 studies were left for analysis, of which 16 observational studies (eight cross-sectional studies, seven case-control studies, and one cohort study) provided data on the prevalence of peptic ulcer disease in 1633 NSAID users, with data on *H. pylori* status for 1625 patients. The pooled frequency of peptic ulcer disease in NSAID users was 42% in those who were *H. pylori*-positive and 25% in those who were *H. pylori*-negative (OR = 2.12; 95% CI = 1.68, 2.67).

The frequencies of uncomplicated peptic ulcer disease in NSAID users and non-users were compared in eight case-control studies; however, the NSAID users and controls were not matched by age in three studies and so, because *H. pylori* infection is age-dependent, the prevalence of infection was analysed in only five studies.

© 2006 Elsevier B.V. All rights reserved.

Overall, *H. pylori* infection was diagnosed in 47% of the NSAID users and 46% of the controls, but peptic ulcer disease was significantly more common in the NSAID users (36% versus 8.3%; OR = 5.14; CI = 1.35, 20). Compared with patients who were *H. pylori*-negative and were not taking NSAIDs, the risk of ulcer in *H. pylori*-infected NSAID users was very high (OR = 61; CI = 10, 373). *H. pylori* infection increased the risk of peptic ulcer disease in NSAID users 3.53 times in addition to the risk associated with NSAID use (OR = 19). Similarly, in the presence of a risk of peptic ulcer disease associated with *H. pylori* infection (OR = 18) the use of NSAIDs increased the risk of peptic ulcer disease 3.55 times. *H. pylori* infection and NSAID use, respectively, increased the risk of ulcer bleeding 1.79 times and 4.85 times; the risk of ulcer bleeding increased to 6.13 when both factors were present.

From these data we can conclude that both *H. pylori* infection and NSAID use independently and significantly increase the risk of peptic ulcer and ulcer bleeding and that there is synergism in the development of peptic ulcer and ulcer bleeding between *H. pylori* infection and NSAID use.

The meta-analysis also showed that one-third of patients taking long-term NSAIDs have gastric or duodenal ulcers, irrespective of *H. pylori* status and study design. However, peptic ulcer disease was significantly more common in *H. pylori*-infected NSAID users than in non-infected users, suggesting a possible interaction between NSAID use and *H. pylori* infection for the development of peptic ulcers.

Moreover, the meta-analysis clarified another uncertainty: whether in NSAID takers *H. pylori* infection is as important a risk factor for gastric ulcer as it is for duodenal ulcer. A pooled analysis of four studies (75,97–99) showed that *H. pylori* infection is less closely associated with gastric ulcer than with duodenal ulcer in both NSAID users and non-users, and that while NSAID use has a major role in the development of gastric ulcer, duodenal ulcer is more closely related to *H. pylori* infection.

Further convincing evidence for the existence of a possible interaction between *H. pylori* and NSAIDs in the pathogenesis of ulcer has been obtained by investigating the effects of *H. pylori* eradication on the occurrence of NSAID-related ulcers and their complications (for example bleeding), although some divergent findings have been reported from these studies (100,101).

In a prospective, randomized trial of the effect of eradication of *H. pylori* before the start of NSAID therapy on the subsequent risk of ulcer occurrence, patients who required new NSAID treatment and who had *H. pylori* infection but no pre-existing ulcers on baseline endoscopy were recruited (100). Of these patients, 100 were randomly allocated to naproxen for 8 weeks, either alone or preceded by a 1-week course of *H. pylori* eradication. Endoscopy was repeated after 8 weeks or if naproxen was withdrawn early because of adverse effects. The primary end-point of the study was the cumulative rate of gastric and duodenal endoscopic ulcers. At 8 weeks *H. pylori* was eradicated in 40 patients (89%) who took eradication therapy and in none of those who had no pretreatment. Twelve (26%) of those who had no eradication therapy developed ulcers compared with three (7%) who had eradication therapy, two of whom had failure of eradication. Thus, only one patient with successful eradication developed ulcers with naproxen. These data suggest that NSAID-induced ulceration can be reduced by eradication of *H. pylori* before naproxen administration and suggest that *H. pylori* infection is a susceptibility factor for NSAID-induced ulcer disease. Some therefore believe that determination of *H. pylori* infection and eradication in infected patients should be recommended before starting NSAID therapy.

However, the data from this study contrasted with those from another randomized, controlled trial, the HELP study, in which the effect of *H. pylori* eradication was investigated in a different population of 285 patients who had used long-term NSAID therapy, those with current or previous peptic ulcers, or dyspepsia, or both (101). The patients were randomly assigned to omeprazole plus 1 week of eradication therapy ($n = 142$) or to omeprazole plus placebo for 1 week ($n = 143$). They took omeprazole until their ulcer healed or dyspepsia resolved, after which they continued taking the NSAID, with follow-up assessment of ulcer and dyspepsia at 1, 3, and 6 months. The estimated probabilities of being ulcer-free at 6 months were similar in the two groups: 0.56% (95% CI = 0.47, 0.65) with eradication treatment and 0.53 (0.44, 0.62) with control treatment. Moreover, fewer gastric ulcers healed in those who had taken eradication therapy than in the controls (7% versus 100% at 8 weeks). These data suggest that *H. pylori* eradication therapy not only did not reduce the rate of development of peptic ulcer or dyspepsia at 6 months, but actually led to impaired healing of gastric ulcers. On the basis of these results *H. pylori* eradication seems not to be justified.

These conflicting results can probably be explained by important differences in the characteristics of the patients and the study methods. The inclusion criteria in the two studies were mutually exclusive: patients with long-term NSAID use and a history of ulceration were excluded in the first study and included in the second. Furthermore, there were differences in the definition of endoscopic ulcers, the eradication regimen, the definition of *H. pylori* infection, and the length of follow-up.

Data from a later eradication study helped to clarify these uncertainties. The aim of the study was to determine whether among NSAID-naive patients positive for *H. pylori* who have dyspepsia or a history of ulcer and who are about to start long-term NSAID treatment, eradication of *H. pylori* infection reduces the risk of ulcers (102). Bismuth was replaced by omeprazole in the eradication regimen, the observation period was increased to 6 months, and the frequencies of both complicated and symptomless ulcers were assessed. Patients were randomly assigned to omeprazole triple therapy (eradication group, $n = 51$) or omeprazole with placebo antibiotics (control group, $n = 51$) for 1 week. All took diclofenac 100 mg/day for 6 months. The 6-month probability of having ulcers was 12% (95% CI = 3.1, 21) in the eradication group and 34% (21, 48) in the placebo group. The 6-month probability of complicated ulcers was 4.2% (1.3, 9.7) in the eradication group and 27% (15, 40) in the placebo group. These statistically significant differences suggested that screening and treatment for *H. pylori*

© 2006 Elsevier B.V. All rights reserved.

infection significantly reduces the risk of ulceration and bleeding in patients who take long-term NSAIDs.

However, these conclusions may not be valid for patients who take low-dose aspirin for prevention of cardiovascular events, as there are data that suggest that *H. pylori* increases (103), has no effect (104,105), or even reduces (106) the risk of bleeding among users of low-dose aspirin as well as other NSAIDs. This question has been addressed in 400 patients with a history of upper gastrointestinal bleeding who were infected with *H. pylori* and who were taking low-dose aspirin ($n = 250$) or other NSAIDs ($n = 150$) (107). Their ulcers were healed with omeprazole 20 mg/day for 8 weeks. Those who had been taking aspirin were given aspirin 80 mg/day, and those who had been taking other NSAIDs were given naproxen 500 mg bd for 6 months. The patients in each group were then randomly assigned separately to receive omeprazole 20 mg/day for 6 months or 1 week of eradication therapy followed by placebo for 6 months.

Among patients taking aspirin the probability of recurrent bleeding during the 6 months was 1.9% for patients who had taken eradication therapy and 0.9% for patients who had taken omeprazole, a non-statistically significant difference of 1% (95% CI = –1.9, 3.9). Among users of naproxen the probability of recurrent bleeding was significantly greater among patients who had taken eradication therapy (19%) than among those who had taken omeprazole (4.4%). Unfortunately, the absolute reduction in the risk of recurrent bleeding attributable to eradication of *H. pylori* could not be determined, because a placebo group was not included.

This study has therefore shown that in patients infected with *H. pylori* who take low-dose aspirin, eradication of *H. pylori* is as effective as prophylactic therapy with omeprazole in preventing recurrent upper gastrointestinal bleeding. Therefore, patients taking aspirin for cardiovascular prophylaxis could be tested for *H. pylori* infection and treated for it if infection is confirmed. In contrast, omeprazole is superior to eradication of *H. pylori* for the secondary prevention of upper gastrointestinal bleeding in *H. pylori*-infected users of naproxen and presumably other non-aspirin NSAIDs.

Conclusions Whether the eradication of *H. pylori* can reduce the risk of ulcers appears to vary according to the characteristics of the patient. For people who have never taken a non-aspirin NSAID, eradication of *H. pylori* before NSAID treatment is begun reduces the risk of ulcers (100). However, for long-term users of non-aspirin NSAIDs, eradication of *H. pylori* has not been shown to prevent gastroduodenal injury. Moreover, eradication alone is not sufficient to prevent recurrent bleeding in susceptible long-term users.

The divergent outcomes in patients taking aspirin or other NSAIDs suggest that *H. pylori* may have a more important role in ulcer bleeding associated with low-dose aspirin than in bleeding associated with other NSAIDs. A possible explanation is that infection with *H. pylori* impairs gastric adaptation to aspirin (76); eradication restores this capability and increases the mucosal resistance to aspirin.

There are several conclusions from these results.

First, eradication of *H. pylori* is a useful strategy in preventing upper gastrointestinal damage caused by NSAIDs or aspirin in some patients.

Secondly, there are doubts about the correct interpretation and generalizability of the results of some relevant studies on the efficacy of omeprazole and misoprostol in the prevention of gastroduodenal ulcer in chronic NSAID users. In fact in these studies, OMNIUM (108), ASTRONAUT (109), and MUCOSA (110), the patients' *H. pylori* status was not considered and may have modified their outcomes (ulcer recurrence and ulcer healing). Some evidence supporting this hypothesis comes from a reanalysis of the data, taking into account the presence or absence of *H. pylori* (111). The superiority of omeprazole over ranitidine or misoprostol claimed in OMNIUM and ASTRONAUT in preventing NSAID-induced ulcers was markedly affected by *H. pylori* status. In a dosage of 40 mg/day, omeprazole was not superior to the full dose of misoprostol in healing unequivocal NSAID-induced gastric ulcers in chronic NSAID users, but it was superior in those whose NSAID use was complicated by *H. pylori* infection. Duodenal ulcers were markedly overrepresented as a cause of ulcer recurrence in the *H. pylori*-infected patients and most of the effect of omeprazole occurred in this population. Therefore, the therapeutic advantages of using omeprazole to prevent recurrent ulcers or their complications in chronic NSAID users may be different in those with and without *H. pylori* infection.

We have no data on the possible interaction between *H. pylori* status and the ability of COX-2-selective inhibitors to cause gastrointestinal toxicity. However, one would expect that when patients use COX-2 inhibitors *H. pylori* infection would remain a source of continuing ulcer risk, requiring eradication. Although there are no trials, this approach is supported by data from the VIGOR study, in which the residual risk of ulcers in patients taking rofecoxib was approximately doubled in *H. pylori*-infected compared with non-infected patients (112).

Comparative studies of different NSAIDs

Although some reports suggest that some NSAIDs are more gastrotoxic than others, data on individual drugs have been at best fragmentary (SEDA-14, 85). Two well-conducted studies have provided convincing data for clarifying whether some compounds are more likely to cause serious adverse gastrointestinal events (113,114) than others. Ibuprofen was associated with the lowest risk of gastrointestinal toxicity; diclofenac, naproxen, and possibly indometacin were intermediate, while piroxicam and in particular azapropazone had much higher risks. The differences appeared to be due to the fairly low dosage of ibuprofen; there were also dose–response relations for naproxen and indometacin. These results have practical implications. When NSAID treatment is needed the least toxic compound should be selected, on the basis of the data provided by these studies and, because of the substantial increase in risk from low-dose to high-dose NSAID therapy, it is wise to start treatment with low dosages.

The search for less toxic drugs or formulations has been discouraging. Several new formulations may be less

© 2006 Elsevier B.V. All rights reserved.

gastrotoxic than standard formulations in short-term studies, but their long-term merit has not yet been proven. Equally, prodrugs have not protected users against gastric complications (14). Parenteral and rectal administration of NSAIDs does not spare the stomach.

Prevention

Ways of preventing NSAID-induced gastrointestinal damage include the use of histamine H_2 receptor antagonists, the prostaglandin analogue misoprostol, and proton pump inhibitors.

Ulcer-preventing drugs The limited data available indicate that H_2 receptor antagonists do not prevent NSAID-induced gastric ulceration. Two studies on ranitidine, reporting that it reduces the incidence of duodenal ulcers, conflict with others that did not find that it offers protection against gastroduodenal mucosal lesions (SEDA-14, 86). Only high-dose famotidine significantly reduced the cumulative incidence of both gastric and duodenal ulcers in patients taking long-term NSAIDs (68). Other trials gave contrasting results (115,116). A large prospective observational cohort study showed that patients taking antacids and H_2 receptor antagonists in combination with NSAIDs did not have a lower risk of significant gastrointestinal events, and asymptomatic patients who started taking these antiulcer drugs prophylactically had a higher risk of a serious gastrointestinal complication than those who did not (OR = 2.69; 95% CI = 1.36, 5.81) (117). The risk might have been increased because these drugs suppress gastrointestinal symptoms and so encourage the use of higher doses of NSAIDs for longer periods, which finally results in more severe gastrointestinal complications.

Co-administration of misoprostol and NSAIDs significantly reduced the frequency of NSAID-induced gastric ulcer in patients with osteoarthritis (118) and misoprostol reduced serious upper gastrointestinal complications (perforation, gastric outlet obstruction, and perhaps bleeding) by 40% compared with placebo in older patients with rheumatoid arthritis treated with NSAIDs (110,119).

Two studies on the proton pump inhibitor omeprazole (120,121) have provided evidence of effective prophylaxis in patients at low and high risks of developing NSAID-associated ulcers, erosions, or dyspeptic symptoms. Two other trials have shown that in patients with ulcers or multiple erosions in the stomach or duodenum who require continuous NSAID treatment, omeprazole gives greater benefit than ranitidine but not misoprostol (108,109). However, misoprostol may be less effective in healing duodenal ulcers and it is not as well tolerated as omeprazole. A daily dose of omeprazole over 20 mg does not confer any clinical advantage. As far as maintenance therapy is concerned, in patients taking NSAIDs, omeprazole 20 mg od prevents gastroduodenal damage more effectively than ranitidine or misoprostol.

Taking into account the limitations of these studies (SEDA-22, 110), these results should not lead to uncritical prescription of proton pump inhibitors for primary prophylaxis in patients taking NSAIDs. Prophylactic therapy may be justified only in high-risk patients, such as the elderly, patients with a history of peptic ulcer, gastrointestinal bleeding, or concomitant cardiovascular disease, or patients who are concurrently taking warfarin or high-dosage glucocorticoids. Whether patients who start taking NSAIDs should routinely have prophylaxis with antiulcer drugs is not at all clear. The costs of therapy are obviously high (appropriate pharmacoeconomic evaluations on the prophylactic use of omeprazole are lacking), the adverse effects of prophylactic drugs must be taken into consideration, and it would seem logical to limit it to high-risk cases (see below).

Eradication of Helicobacter pylori

See the section on Susceptibility factors under Gastrointestinal in this monograph.

Patient education

The relevance of patient information to the prevention of adverse effects of NSAIDs has been well illustrated in a study of 50 consecutive patients who were admitted to hospital with acute gastrointestinal bleeding and who had taken NSAIDs 3 days before admission, compared with 100 matched control patients who had not bled (122). Despite the limitations of the study (123), it looks as if ignorance of adverse effects can lead to inappropriate compliance and failure to recognize warning symptoms. In fact, if the patients who bled had reduced their intake of NSAIDs in response to epigastric pain to the same extent as the apparently better informed control patients, some episodes of acute gastrointestinal bleeding might have been avoided. Consequently we should consider patient education as one of the main strategies for preventing NSAID-related toxicity.

Esophageal damage

Esophageal damage by NSAIDs, usually considered a rare adverse reaction, has been underestimated, perhaps because the symptoms of esophagitis can be misinterpreted as being of gastric origin. The clinical pattern is characterized by inflammatory changes (erosive and/or ulcerative esophagitis), ulceration with or without bleeding, and/or perforation and strictures. Data suggest that the frequency of erosive/ulcerative esophagitis in patients taking NSAIDs is not as low as was previously thought (SEDA-15, 100). Erosive or ulcerative esophagitis was present in 12 of 60 arthritic patients taking long-term NSAIDs (124). There were esophageal symptoms in 83% of the patients with esophagitis.

Long-term NSAID users have fewer esophageal histological abnormalities than controls (125). However, more epidemiological and experimental prospective studies are needed to define the role of NSAIDs in causing esophageal injury. Data on esophageal function suggest that naproxen does not cause reflux and has no significant effect on motility in healthy subjects (126).

Small bowel damage

The capacity of NSAIDs to cause intestinal damage has been demonstrated in a case-control study (127) as well as by experience with a special formulation of indometacin (Osmosin) (SEDA-15, 93). Severe intestinal damage perforation and bleeding is a very rare complication of

© 2006 Elsevier B.V. All rights reserved.

therapy with conventionally formulated NSAIDs. The expected incidences of lower bowel perforations and bleeding are about ten and seven per 100 000 patients, respectively (127). Uncomplicated intestinal mucosal lesions are more frequent, particularly when NSAIDs are given in the long term (128). Small intestine enteropathy is characterized by inflammation and/or malfunction, with an increase in intestinal permeability. Most patients are asymptomatic, although a few taking long-term treatment have symptoms that mimic the features of Crohn's disease. As NSAIDs can exacerbate Crohn's disease (SEDA-10, 76), the differential diagnosis is difficult in symptomatic patients.

Adverse effects on the small intestine may be more frequent than previously thought and range from asymptomatic enteropathy to severe complications, such as ulceration, bleeding, perforation, and stricture (129). A prospective autopsy study in 713 patients provided an estimate of the prevalence of such lesions (130). Non-specific ulcers in the small intestine were more frequent in the NSAID group than in the control group (8.6 versus 0.6%) and the percentage was slightly higher in long-term users. Most lesions were subclinical, but perforation leading to peritonitis and death was documented in three patients taking long-term NSAIDs. The pathogenesis of NSAID-induced enteropathy is still unknown (SEDA-17, 106).

Whether the "diaphragm disease" (131–133) that is found in a few patients is a distinct NSAID-related disease or only a variant form of congenital intestinal diaphragm remains to be clarified.

Large bowel damage

"Diaphragm disease" has been reported in the ascending colon; these lesions are identical to those in the small bowel and are found only in patients who have taken modified-release NSAIDs for more than a year, because they are probably delivered unabsorbed to the large intestine (SEDA-20, 88) (134).

The causal connection between NSAIDs and large bowel inflammation needs to be confirmed by appropriate epidemiological studies. Many publications have associated NSAID and colonic inflammation (SEDA-10, 77) (SEDA-15, 95), but the differential diagnosis between colonic inflammation arising de novo and exacerbation of underlying inflammatory bowel disease can be difficult, and the role of NSAIDs in aggravating ulcerative colitis or Crohn's disease or other inflammatory bowel disease is controversial (SEDA-10, 76) (SEDA-15, 95). A case-control study showed no association between appendicectomy for acute appendicitis and the use of NSAIDs (SEDA-22, 111).

The evidence that NSAIDs can cause exacerbation of inflammatory bowel disease is at best scanty (SEDA-10, 76) (SEDA-15, 92) (SEDA-17, 102). In the few studies in which drugs as a cause of relapse of chronic inflammatory bowel disease have been investigated, NSAIDs have not been shown to be major contributors.

However, well-documented published series of patients with quiescent inflammatory bowel disease whose colitis became active shortly after they were given NSAIDs make the causal relation probable, at least in some patients (135–138). Because the pathogenesis of inflammatory bowel disease is unknown, it is difficult to say whether episodes of colitis are exacerbations of the underlying disease or unrelated events caused by NSAIDs in predisposed patients.

Two studies of the possible association between NSAIDs and the onset or exacerbation of inflammatory bowel disease have given contrasting results. In the first study (139) the authors interviewed 60 patients (mean age 42 years) with either Crohn's disease or ulcerative colitis who required admission to hospital owing to symptoms of their disease, and 62 matched controls (mean age 46 years) with irritable bowel syndrome who did not require hospitalization. Patients were asked about their use of NSAIDs and the relation in time and duration to the exacerbation or onset of the inflammatory bowel disease. There was an association with the use of NSAIDs in 31% of the patients with inflammatory bowel disease, but in only 2% of those with irritable bowel syndrome. Compared with patients with irritable bowel syndrome the odds ratio (OR) for an exacerbation or new onset of symptoms of inflammatory bowel disease after recent use of NSAIDs (defined as use within 1 month of symptom exacerbation or onset of disease) was 20 (95% CI = 2.6, 160).

In contrast, the second study (140) showed that the use of NSAIDs was not associated with a higher incidence of active inflammatory bowel disease. The authors retrospectively examined the records of 192 outpatients with inflammatory bowel disease: 112 with Crohn's disease (mean age 53 years) and 80 with ulcerative colitis (mean age 61 years). The use of NSAIDs was more common in patients with inactive inflammatory bowel disease than in those with active disease. Of 40 patients with active Crohn's disease, three were using NSAIDs compared with 14 of 72 with inactive disease. Of 58 patients with active ulcerative colitis, eight were using NSAIDs compared with five of 21 patients with ulcerative colitis in remission.

These contrasting results may have been due to different patient populations studied (inpatients versus outpatients) or to other limitations: in the case-control study, the number of patients enrolled was small and the confidence intervals of the odds ratio were very large; in the observational study, the analysis was retrospective and the possibility that some patients had used over-the-counter NSAIDs could not be excluded.

Despite the clinical importance of the problem, we lack a firm answer to the question of whether patients with inflammatory bowel disease should refrain from using NSAIDs.

When administered long-term, the fenamates cause watery diarrhea in more patients than other NSAIDs. Although colonic ulceration has been reported after oral ingestion of several NSAIDs (SEDA-7, 105) (SEDA-10, 77) (SEDA-15, 95), the evidence is not entirely convincing. On the other hand, there is firm reason to conclude that there is a direct causal relation between rectally administered NSAID and rectal ulceration, which seems to occur more frequently when doses are high or treatment is prolonged.

Liver

Serious liver reactions to NSAIDs are rare and unpredictable (SEDA-17, 107) (141), suggesting that most reactions are due to hypersensitivity. However, the FDA has recognized liver reactions as a class effect of NSAIDs. Severe injury and even deaths have been reported (142).

Because of hepatotoxicity, particularly problematic in the elderly, benoxaprofen was withdrawn from the market in 1982, and ibufenac is not on sale for the same reason. Serious hepatocellular reactions have been well-documented with phenylbutazone and the death rate is high (143). Hepatotoxicity has been reported with all of the structural classes of NSAIDs.

Hepatic reactions are more often reported with the pyrazolone, indole, and propionic acid groups of compounds than with the fenamate and oxicam classes (50). Some national monitoring centers have published their experience on liver toxicity with NSAIDs, and the Swedish and Australian agencies have both drawn attention to an apparently higher frequency of liver reactions with sulindac and diclofenac (144,145). Reactions to sulindac are characterized by cholestasis. Diclofenac is associated with more acute hepatocellular derangement and is recognized as a rare cause of acute hepatocellular damage (146).

Cirrhosis with esophageal or cardiac varices

Aspirin can increase the risk of variceal bleeding in patients with cirrhosis. In fact, according to a case-control study (147), patients with cirrhosis and esophageal or cardiac varices who take NSAIDs are three times more likely to have a first episode of variceal bleeding compared with similar patients who are not taking NSAIDs.

In 125 patients with cirrhosis who were admitted to hospital with a first episode of bleeding related to esophageal or cardiac varices, compared with 75 patients with cirrhosis, but no previous or current history of variceal bleeding, who were admitted to the same hospitals, a questionnaire showed that more patients with a first episode of bleeding had used aspirin, either alone or in combination with other NSAIDs compared with controls (OR = 4.9). This increased risk of bleeding was seen only in patients with grade 2 or grade 3 varices.

The results of this small hospital-based study should be interpreted with caution, but as variceal bleeding is a life-threatening event and in cirrhosis other factors (thrombocytopenia and coagulation defects) can also predispose to bleeding, the possible benefit of therapy with aspirin or other NSAIDs should be carefully weighed against the risks of major gastrointestinal bleeding.

Urinary tract

Many of the NSAIDs are associated with renal disorders arising de novo or by aggravation of existent renal dysfunction. Inhibition of PGE-1 synthesis intrarenally leads to a reduction in the vasodilator activity of this prostaglandin, which normally contributes to maintenance of renal functional balance and protection against the vasoconstrictor effects of noradrenaline and angiotensin-II and the action of antidiuretic hormone.

NSAIDs can produce a spectrum of renal diseases: functional renal insufficiency, nephrotic syndrome with or without interstitial nephritis, renal papillary necrosis and chronic interstitial nephritis, acute tubular necrosis, vasculitis, glomerulonephritis, and obstructive nephropathy.

Incidence

Two studies have suggested that the overall incidence of clinical nephrotoxicity with NSAIDs is small (148,149). However, some patients (see below) are at increased risk of particular effects (SEDA-11, 82), and patients with sickle cell anemia can probably be added to the list (SEDA-15, 97).

Although some compound-related variations do occur, every nephrotoxic effect seems to have been reported with every NSAID at some time and no NSAID is free of nephrotoxic potential. This applies to sulindac as to other NSAIDs, although its renal function-sparing effect is disputed (SEDA-15, 99) (150,151). One study suggested that renal effects were more likely to occur with ibuprofen than with piroxicam or sulindac (152), but it was criticized for flawed experimental design (153). There is other evidence that sulindac is relatively safer: short-term sulindac 400 mg/day had no effect on glomerular filtration rate, renal plasma flow, or renal prostaglandin excretion in ten patients with arthritis and impaired renal function, while naproxen 750 mg/day reduced all three (154). Such short-term evidence clearly does not eliminate the problems of long-term use, which constitute the real challenge.

A study of the risk of chronic renal disease associated with the regular use of NSAIDs showed that it was twice as high in men over 65 years and tended to be even higher in patients with heart disease or other disorders that might compromise renal circulation (155). The results of a second investigation, a case control study of 340 patients with end-stage renal disease on a hemodialysis maintenance program and 678 hospitalized controls, confirmed the trend (SEDA-16, 105), but more reliable epidemiological data are needed to show that regular consumption of NSAIDs increases the risk of chronic renal disease. NSAID-associate analgesic nephropathy has been reviewed (SEDA-18, 100).

The actual risk of NSAID-associated acute renal dysfunction also continues to be the subject of controversy. There is adequate evidence that underlying renal insufficiency, congestive heart failure, or hepatic cirrhosis are conditions that carry a high risk of NSAID-related renal functional impairment. It is still not known whether old age is a risk factor, whether the risk of renal impairment varies with different NSAIDs, or whether renal function continues to deteriorate, stabilize, or even improve in affected patients with continued use of NSAIDs. Three cases of renal insufficiency caused by topical NSAIDs have been described (SEDA-18, 100).

Types of complication

Of all the potentially serious adverse effects of NSAIDs, functional renal insufficiency, which is probably the most common, results from the hemodynamic changes secondary to inhibition of prostaglandin synthesis. Renal insufficiency and interference with fluid and electrolyte homeostasis occur in disease states in which prostaglandins are significant determinants of renal function, such as those characterized by hypovolemic states due to salt

© 2006 Elsevier B.V. All rights reserved.

depletion or hypoalbuminemia and those in which there is pre-existing renal impairment due to age, atherosclerosis, hypertensive renal disease, or other intrinsic renal disease. Although the functional renal insufficiency is usually mild and reversible within a few days of withdrawing NSAIDs, it can also be severe and irreversible, so early recognition is essential. All NSAIDs can cause this complication.

A case-control study on recent use of NSAIDs and functional renal impairment at the time of hospitalization showed that there was a weak association between the use of NSAIDs and renal dysfunction. Patients at higher risk had a history of renal disease or of gout and hyperuricemia. While NSAID dosages were only weakly related to renal impairment, there was a statistically significant difference between compounds with half-lives under or over 4 hours: the OR increased from 1.2 (95% CI = 0.6, 2.4) to 4.8 (CI = 1.5, 16) for compounds with half-lives over 12 hours (156). Therefore, long half-life drugs should be avoided in subjects at risk of renal impairment.

A case-control study provided convincing epidemiological evidence that the use of NSAIDs was associated with the risk of hospitalization for acute renal insufficiency (relative risk about 2.0) (SEDA-19, 95) (157).

Acute interstitial nephritis, which is distinct from the methicillin-like form, is the most important type of organic renal damage caused by NSAIDs. Distinguished by a nephrotic syndrome, often with renal insufficiency, the histological picture is an acute interstitial nephritis combined plus a glomerular lesion with fusion of the epithelial foot process. Patients had usually been taking NSAIDs over a long period of time. Acute interstitial nephritis has been reported relatively often in patients taking fenoprofen.

The acute flank pain syndrome associated with reversible renal insufficiency is very rare. It has usually been reported with suprofen (SEDA-12, 89), but flurbiprofen and ibuprofen have also been implicated (SEDA-18, 100).

Membranous nephropathy is rare and causes the nephrotic syndrome, usually with minimal-change glomerulopathy, with or without interstitial nephritis (SEDA-11, 85). A retrospective study provided more data on the frequency and clinical characteristics of membranous nephropathy associated with NSAIDs (158). It confirmed that it is rare (13 of 125 patients diagnosed during the last 20 years met the strict criteria for NSAID-associated membranous nephropathy), and the nephrotic syndrome is reversible after prompt withdrawal. The pathogenesis is unknown but seems to be immune-mediated, given the characteristic deposition of IgG and C3.

Renal papillary necrosis has been reported after long-term intake or abuse of aspirin and other NSAIDs (SEDA-11, 85) (SEDA-12, 79).

Chronic renal disease

The relation between long-term heavy exposure to analgesics and the risk of chronic renal disease has been the object of intensive toxicological and epidemiological research for many years (SEDA-24, 120) (159). Most of the earlier reports suggested that phenacetin-containing analgesics probably cause renal papillary necrosis and interstitial nephritis. In contrast, there is no convincing epidemiological evidence that non-phenacetin-containing analgesics (including paracetamol, aspirin, mixtures of the two, and NSAIDs) cause chronic renal disease. Moreover, findings from epidemiological studies should be interpreted with caution, because of a number of inherent limitations and potential biases in study design (160). Two methodologically sound studies have provided information on this topic.

The first was the largest cohort study conducted thus far to assess the risk of renal dysfunction associated with analgesic use (161). Details of analgesic use were obtained from 11 032 men without previous renal dysfunction participating in the Physicians' Health Study (PHS), which lasted 14 years. The main outcome measure was a raised creatinine concentration defined as 1.5 mg/dl (133 μmol/l) or higher, and a reduced creatinine clearance of 55 ml/minute or less. In all, 460 men (4.2%) had a raised creatinine concentration and 1258 (11%) had a reduced creatinine clearance. Mean creatinine concentrations and creatinine clearances were similar among men who did not use analgesics and those who did. This was true for all categories of analgesics (paracetamol and paracetamol-containing mixtures, aspirin and aspirin-containing mixtures, and other NSAIDs) and for higher risk groups, such as those aged 60 years or over or those with hypertension or diabetes.

These data are convincing, as the large size of the PHS cohort should make it possible to examine and detect even modest associations between analgesic use and a risk of renal disease. Furthermore, this study included more individuals who reported extensive use of analgesics than any prior case-control study. However, the study had some limitations, the most important being the fact that the cohort was composed of relatively healthy men, most of whom were white. These results cannot therefore be generalized to the entire population. However, the study clearly showed that there is not a strong association between chronic analgesic use and chronic renal dysfunction among a large cohort of men without a history of renal impairment.

The second study was a Swedish nationwide, population-based, case-control study of early-stage chronic renal insufficiency in men whose serum creatinine concentration exceeded 3.4 mg/dl (300 μmol/l) or women whose serum creatinine exceeded 2.8 mg/dl (250 μmol/l) (162). In all, 918 patients with newly diagnosed renal insufficiency and 980 controls were interviewed and completed questionnaires about their lifetime consumption of analgesics. Compared with controls, more patients with chronic renal insufficiency were regular users of aspirin (37% versus 19%) or paracetamol (25% versus 12%). Among subjects who did not use aspirin regularly, the regular use of paracetamol was associated with a risk of chronic renal insufficiency that was 2.5 times as high as that for non-users of paracetamol. The risk increased with increasing cumulative lifetime dose. Patients who took 500 g or more over a year (1.4 g/day) during periods of regular use had an increased odds ratio for chronic renal insufficiency (OR = 5.3; 95% CI = 1.8, 15). Among subjects who did not use paracetamol regularly, the regular use of aspirin was associated with a risk of chronic renal insufficiency that was 2.5 times as high as that for non-users of aspirin. The risk increased significantly with an

© 2006 Elsevier B.V. All rights reserved.

increasing cumulative lifetime dose of aspirin. Among the patients with an average intake of 500 g or more of aspirin per year during periods of regular use, the risk of chronic renal insufficiency was increased about three-fold (OR = 3.3; CI = 1.4, 8.0). Among patients who used paracetamol in addition to aspirin, the risk of chronic renal insufficiency was increased about two-fold when regular aspirin users served as the reference group, (OR = 2.2; CI = 1.4, 3.5) and non-significantly when regular paracetamol users were used as controls (OR = 1.6; CI = 0.9, 2.7). There was no relation between the use of other analgesics (propoxyphene, NSAIDs, codeine, and pyrazolones) and the risk of chronic renal insufficiency. Thus, the regular use of paracetamol, or aspirin, or both was associated dose-dependently with an increased risk of chronic renal insufficiency. The OR among regular users exceeded 1.0 for all types of chronic renal insufficiency, albeit not always significantly. These results are consistent with exacerbating effects of paracetamol and aspirin on chronic renal insufficiency, regardless of accompanying disease.

How can we explain the contrasting results of these two studies? A possible explanation lies in the different populations studied. In PHS, relatively healthy individuals were enrolled while in the Swedish study all the patients had pre-existing severe renal or systemic disease, suggesting that such disease has an important role in causing analgesic-associated chronic renal insufficiency. People without pre-existing disease who use analgesics may have only a small risk of end-stage renal disease.

Prevention

While misoprostol has been shown to limit NSAID-induced gastric damage, three studies failed to show that misoprostol prevents NSAID-induced impairment of renal function. However, another showed that it prevents ciclosporin-induced renal damage in renal transplant patients (163). Further studies are therefore required to assess the protective effect of misoprostol on renal function (SEDA-16, 106).

Skin

Skin reactions are often reported with NSAIDs, but the true incidences with individual NSAIDs are unknown. There are very few specific epidemiological studies, and most information comes from single case reports and data from national spontaneous reporting systems. A major study on nearly 20 000 patients showed that 0.3% of 9118 patients taking analgesics and NSAIDs developed skin reactions that could be attributed to these drugs (164).

Although usually mild, skin reactions very often require withdrawal of treatment. At times they can be severe, and isoxicam was withdrawn from the market because of the high frequency of severe adverse skin reactions (SEDA-10, 88).

There are various types of NSAID-induced rashes. The main morphological patterns are urticarial, maculopapular, vesicular, and exfoliative. Skin reactions to NSAIDs are probably of phototoxic origin and can be associated with systemic hypersensitivity or other allergic reactions. More rarely, NSAIDs can exacerbate pre-existing skin disease (for example psoriasis, acne). Phototoxic reactions were very common with benoxaprofen (30–50% of patients treated in the UK), and were one reason why it did not receive licensing approval in Australia or the Benelux countries. Other NSAIDs, such as azapropazone, piroxicam, and fenbufen, have been reported to cause higher than average rates of photosensitivity (165). NSAIDs were among the causal agents of phototoxic reactions most commonly reported to the Australian Adverse Drug Reactions Advisory Committee (166,167).

Widespread use of naproxen, sulindac, diclofenac, and diflunisal probably explains why they were the most frequently implicated, rather than because they have a greater tendency to cause these adverse effects. NSAIDs differ in their ability to cause adverse skin reactions in terms of both frequency and severity: pyrazolones, butazones, and oxicams are most often blamed, and among the arylalkanoic acid derivatives fenbufen and carprofen are most often incriminated.

The types of skin adverse effect also vary with different compounds. The most serious life-threatening reactions, such as erythema multiforme and its variants (Stevens–Johnson syndrome, toxic epidermal necrolysis, exfoliative erythroderma) are uncommon and occur mainly with the butazone derivatives and to a lesser extent with piroxicam, sulindac, and possibly fenbufen. In large series reported in France, Germany, and the USA, NSAIDs are most often implicated: 12 (44%) of the most commonly implicated 29 drugs (168).

Although all NSAIDs can cause urticaria, particularly in aspirin-sensitive patients, it is more common with pyrazolone derivatives. Photosensitivity is principally a problem with azapropazone, carprofen, tiaprofenic acid, and piroxicam (SEDA-9, 84).

The reasons for these different effects of different NSAIDs are poorly understood. The only physicochemical characteristic that seems to be important in determining a particular propensity for adverse skin reactions is lipophilicity (10), which probably affects NSAID distribution to the skin. The longer half-lives of lipophilic compounds may concomitantly facilitate the persistence of skin reactions. Although there are no clear relations between the other pharmacological and kinetic characteristics of NSAIDs and effects on the skin, less lipophilic drugs with short half-lives might be preferable.

There are no clearly identifiable predisposing factors for most adverse skin reactions. Urticaria and photosensitivity are exceptions. Many NSAIDs can cause urticaria (sometimes associated with angioedema) in aspirin-sensitive patients. Probably not immunological in origin, the reaction may be related to prostaglandin inhibition in a patient whose cutaneous mastocytes are more susceptible to the stabilizing effect of prostaglandins. Skin testing in patients with a history of urticarial and/or anaphylactic reactions to analgesics is of little value in identifying patients at risk and can be dangerous (169,170). Skin pigmentation and environmental factors that influence the radiant exposure dose are clearly very important in determining the risk of a phototoxic reaction.

Since the extreme rarity of life-threatening reactions, such as erythema multiforme and toxic epidermal

© 2006 Elsevier B.V. All rights reserved.

necrolysis, suggests individual susceptibility, efforts have been made to identify subjects at risk. In 25 cases of erythema multiforme and toxic epidermal necrolysis there was a slight, non-significant increase in the frequency of the HLA-B12 and DR4 phenotypes, suggesting that genetic factors are involved (171). Genetic predisposition also seems to be confirmed by the finding of a fixed drug eruption in four members of a single family taking feprazone (SEDA-17, 108). From a practical point of view, if a mild reaction occurs it is wise to withdraw treatment, even if the reaction disappears spontaneously in some patients despite continuing treatment. Withdrawal of treatment and prompt referral to hospital is imperative if the reaction is severe and/or tends to progress.

Careful clinical monitoring is probably necessary for all patients with underlying skin diseases (for example acne, psoriasis), as some NSAIDs can exacerbate them (172,173). NSAIDs should not be used for apparently benign inflammatory cutaneous lesions, unless the possibility of infection has been ruled out.

Lichenoid photoeruptions have been reported not infrequently in HIV-positive people, often in association with photosensitizing drugs, especially NSAIDs (174). Facial scars have been described in adults and children treated with NSAIDs, usually in connection with sun exposure (175).

Contact sensitivity to topical NSAIDs

Topical NSAIDs can cause allergic, photoallergic, and phototoxic contact dermatitis. There have been two systematic studies of photosensitivity to these compounds and their cross-reactivity (176,177). Eleven patients with confirmed photocontact dermatitis were photopatch tested with seven topical NSAIDs. Ketoprofen was the commonest cause. In five cases there was cross-sensitivity with fenofibrate, which was explained by a common benzoylketone or benzophenone molecule, and in one patient there was cross-sensitivity to tiaprofenic acid, an arylpropionic acid derivate that is not available in topical form in Europe. There was also one case of photocontact dermatitis from diclofenac, which was discovered by 1% dilution in alcohol, while 5% in petrolatum was negative in the same patient (176). In contrast to these findings, all 12 patients tested in another study reacted to both ketoprofen and tiaprofenic acid, mainly after UVA irradiation, but were negative to other arylpropionic acids (177). Furthermore, there were positive reactions to both ketoprofen and fenofibrate in eight of the 12 patients. The authors concluded that photoallergy to ketoprofen and fenofibrate is due to the molecular benzophenone structure and confirmed cross-reactivity with other benzophenones, used as sunscreens. Cross-reactivity between ketoprofen and tiaprofenic acid was supposed to be due to the benzophenone moiety of ketoprofen, or to the very similar thiophene-phenylketone part of tiaprofenic acid, but not to their arylpropionic function.

The topical use of NSAIDs, such as bufexamac, can provoke contact allergic reactions (178–180) and a case has been reported with bendazac (181).

- A 28-year-old man had been using a bendazac-containing ointment for his atopic dermatitis for 6 months, together with topical corticosteroids. Patch testing showed positive reactions to bendazac in petrolatum on days 2, 3, and 7 and a positive reaction to alclometasone dipropionate.

Contact allergy to topical indometacin has rarely been reported (182).

- A 14-year-old boy had contact allergy to indometacin gel used for a sprained ankle (183). He had previously taken NSAIDs orally, but not topically. Patch tests with the indometacin gel and pure indometacin 1% in petrolatum were positive.

Photocontact allergy to NSAIDs is not uncommon, but the incidence may differ from NSAID to NSAID. A case of photoallergy from local piketoprofen has been reported (184), as have two cases of prolonged photosensitivity after contact photoallergy from ketoprofen, persisting for more than a year after withdrawal (185,186).

Contact pemphigus has been attributed to ketoprofen.

- A 65-year-old Caucasian woman developed a localized skin eruption within hours of using ketoprofen gel on her knees to relieve arthralgia (187). The lesions were pruritic, well-demarcated, and erythematous, and later became studded with vesicles and small bullae. Histology and immunopathology suggested autoimmune pemphigus.

Photosensitivity to topical NSAIDs

The arylpropionic acid derivatives often cause allergic and photoallergic contact dermatitis, and photoallergic dermatitis to ketoprofen, with cross-photosensitivity to benzophenone and tiaprofenic acid, has been reported (188). Photopatch tests to these substances were positive but patch tests were negative.

A case of photoallergic contact dermatitis from aceclofenac has been reported (189). Photopatch tests were positive with aceclofenac 10% in petrolatum, but not with either aceclofenac 1% or 5% in petrolatum or with a series of NSAIDs and other analgesics (benzydamine hydrochloride 3 and 5%, bufexamac 5%, diclofenac 1, 5, and 10%, fepradinol 1%, ibuprofen 5%, indometacin 1, 5, and 10%, ketoprofen 1%, naproxen 5%, paracetamol 1, 5, and 10%, phenylbutazone 1%, piroxicam 1%, salicylic acid 1 and 5%, and thiosalicylic acid 0.1%, all in petrolatum).

Photocontact dermatitis has been reported after topical application of dexketoprofen (Enangel), with positive photopatch tests to dexketoprofen 1% and piketoprofen 2% (190).

Local pharyngeal treatment with benzydamine hydrochloride 0.15% (Tantum verde) by a 67-year-old man resulted in systemic photocontact dermatitis in the third week of treatment (191). Photopatch tests with Tantum verde as is and in 10% aqueous solution were positive: D1+, D2+, D3++.

Photosensitization potentials and cross-reactivities of ketoprofen, suprofen, tiaprofenic acid, and benzophenone have been studied in guinea pigs (192). Ketoprofen and benzophenone were the strongest photosensitizers. Cross-reactivity was most frequent after sensitization with

© 2006 Elsevier B.V. All rights reserved.

ketoprofen. Benzophenone photosensitization did not induce cross-reactivity. The benzoyl radical was identified as the key structure for both photosensitization and cross-reactivity among the NSAIDs.

Pseudoporphyria

Pseudoporphyria is a photodistributed bullous disorder with clinical and histological features similar to those of porphyria cutanea tarda, but without accompanying abnormalities of porphyrin metabolism. Drugs, in particular NSAIDs and sulfur-containing diuretics, often cause pseudoporphyria (193). Pseudoporphyria associated with naproxen (15 mg/kg/day) has been reported in a child (194).

Musculoskeletal

Suspected but unproven harmful effects of NSAIDs on joints, cartilage, and bone have been reviewed (SEDA-11, 87). Inhibition of glycosaminoglycan synthesis in joint cartilage, inhibition of necrotic bone repair by reduced synthesis of vasodilator prostaglandins, which have been shown both in vitro and in animals, and deprivation of protective painful stimuli are possible mechanisms. As these data derive from experimental models, they cannot be extrapolated with certainty to the effects of NSAIDs on the pathophysiological characteristics of the human osteoarthritic joint. Evidence for harmful effects of NSAIDs on the human hip joint comes from single case reports and a small series of clinical observations, two retrospective studies, and two prospective investigations. The first prospective study showed that hip osteoarthritis progressed more rapidly in patients taking indometacin, a potent inhibitor of prostaglandin synthesis, than in those taking azapropazone, a weak inhibitor (195). This suggests that one should be cautious with long-term use of the more potent cyclo-oxygenase inhibitors in patients whose joints are severely compromised by osteoarthritis. The second study showed that the risk of progression of knee osteoarthritis increased in patients treated with indometacin for 1 year (196). Other studies have reported that some NSAIDs have a protective effect on cartilage (197). A study on a small group of patients treated with piroxicam for osteoarthritis of the knee supported the hypothesis that deprivation of painful stimuli lets the patient put more load on the joint, increasing the risk of more rapid progression of the disease (198).

The suggestion that NSAIDs should not be used as analgesics after orthopedic surgery because they might inhibit fracture healing (199) elicited strong disagreement (200,201). The belief that NSAIDs could cause more harm then benefit in patients undergoing orthopedic surgery in based on some experimental data in animals. In diverse rodent models NSAIDs inhibited bone healing, but other animal studies have shown no effect (200,202,203). In humans, published evidence is almost non-existent (200). In the absence of well-designed trials showing important effects on bone healing, NSAIDs should continue to be used as effective analgesics after orthopedic surgery.

Reproductive system

There have been several case reports that non-selective NSAIDs (diclofenac, naproxen, piroxicam) can cause infertility, attributed to "luteinized unruptured ovarian follicles" syndrome (204–206). Women who are trying to become pregnant should avoid taking any NSAIDs if possible, and those who need one for a chronic rheumatic disorder should be aware of possible infertility; in such cases further investigation is not required, as withdrawal of the drug restores fertility.

Immunologic

There is considerable difficulty and controversy in identifying and classifying allergic reactions to NSAIDs, for many reasons (207). First, the difficulty in making a definite diagnosis in patients who have these reactions without provocative challenge with the suspected drug and other NSAIDs. Secondly, reactions are characterized by a large spectrum of target organ responses to NSAIDs, and the same drug may cause different types of reactions in different organs in the same or different individuals. Thirdly, a patient can have a similar reaction to a structurally different NSAID. Finally, reports of these reactions include different, often imprecise, terms, making interpretation difficult.

Anaphylactic or anaphylactoid reactions to NSAIDs are probably relatively rare. Even today, the only data available are from 1981, when the FDA's Division of Drug Experience was notified of 131 cases attributable to various NSAIDs (208). Tolmetin was the most frequently implicated compound. However, the figures are distorted, because some of these drugs are much more widely used than others. A retrospective cohort study using 1980–84 Medicaid billing data from three states in the USA, designed to assess the relative risk of hypersensitivity reactions from different NSAIDs, failed to confirm that tolmetin is associated with a higher risk of hypersensitivity reactions than other NSAIDs (209). However, two drugs (glafenine and zomepirac) have been withdrawn from the market because of their propensity to cause severe hypersensitivity reactions.

The clinical picture of hypersensitivity reactions varies from vasomotor rhinitis, urticaria, and angioedema to serious bronchoconstriction and in some cases anaphylactic shock.

Two pathogenic mechanisms have been proposed: an allergic immunological hypersensitivity reaction and a pseudoallergic reaction characterized by mast-cell degranulation by complement components, histamine liberation by drugs, and interference with endogenous eicosanoid biosynthesis (210). The first mechanism appears to be responsible for anaphylactic shock and/or urticaria after amidopyrine or noramidopyrine, and the second for bronchoconstriction after aspirin, noramidopyrine, or aminophenazone and other pyrazole drugs. It is important to distinguish the two mechanism, since the first type of intolerance is fairly structure-specific and can be avoided by switching from a drug to which the patient has proved sensitive to an NSAID with a distinct structure, whereas pseudoallergic aspirin-sensitive

© 2006 Elsevier B.V. All rights reserved.

patients must avoid all drugs that inhibit fatty acid cyclooxygenase.

There have been reports of exaggerated responses (angioedema and malaise) to bee stings in patients taking NSAIDs (SEDA-11, 88). More recently a report of resensitization to bee stings associated with diclofenac has been received by the Centre for Adverse Reactions Monitoring in New Zealand. The patient, who had been successfully desensitized to bee venom many years before, developed life-threatening anaphylaxis after a bee sting while taking diclofenac (211).

Infection risk

NSAIDs can mask signs of infection, such as fever and pain, which can delay appropriate treatment. Furthermore they can impair the host defence mechanism against infection and can modulate the acute inflammatory response in such a way as to alter the course of infection, predisposing the patient to bacteremia, shock, and multiorgan failure (212,213). Until appropriate studies have defined the relation between NSAIDs and severe soft tissue infections, it is better to avoid using them, if possible, until the cause of the fever is known.

In 11 cases of necrotizing fasciitis (which is usually caused by *Streptococcus pyogenes*) NSAIDs were suspected to have predisposed to the infection and/or to have caused its fulminant evolution (SEDA-12, 79). Sporadic cases continue to be reported (214), but a causal link between this severe infection and NSAIDs is far from proven (215).

Long-Term Effects

Tumorigenicity

Studies on the tumor-inducing effects of heavy use of analgesics, especially those that contain phenacetin, have given contrasting results (SEDA-21, 100) (216,217). There has been a case-control study of the role of habitual intake of NSAIDs on the occurrence of urothelial cancer and renal cell carcinoma (218). In previous studies there was a consistent association between phenacetin and renal cell carcinoma, but inconclusive results with respect to non-phenacetin analgesics. In 1024 patients with renal cell carcinoma and an equal number of matched controls, regular use of analgesics was a significant risk factor for renal cell carcinoma (OR = 1.6; CI = 1.4, 1.9). The risk was significantly increased by aspirin, NSAIDs, paracetamol, and phenacetin, and within each class of analgesic the risk increased with increasing exposure. Individuals in the highest exposure categories had about a 2.5-fold increase in risk relative to non-users or irregular users of analgesics.

Second-Generation Effects

Pregnancy

NSAIDs are among the commonest drugs prescribed for pregnant woman (219). However, the risk of adverse birth outcomes in women who take NSAIDs other than aspirin during pregnancy is largely unknown.

In a comparison, too small to allow firm conclusions, pregnancies in 88 patients with rheumatic diseases in which NSAIDs had or had not been used, there were no differences in pregnancy outcome, duration of labor, complications at delivery, neonatal health, and the health or development of offspring at follow-up (220).

However, there is no doubt that NSAIDs can alter fetal physiology in the last trimester of pregnancy and prolong gestation and labor (SEDA-5, 101) (SEDA-6, 93) (SEDA-7, 108) (SEDA-8, 102) (SEDA-9, 88) (SEDA-11, 88) (SEDA-12, 84) (SEDA-15, 99) (SEDA-21, 96) (SEDA-22, 112).

There has been a study in a Danish county (population about 490 000), including data on all women who between 1991 and 1998 had a live birth or a stillbirth after the 28th week of gestation, or who had a miscarriage (including missed abortions) (221). The researchers performed a case-control study using data from the Danish birth registry, the county hospital discharge registry, and the county's prescriptions database. The risk of miscarriage was examined. The study involved 4268 women who had had their first miscarriage, 63 of whom had filled a prescription for an NSAID in the 12 weeks before being discharged from hospital after the miscarriage, and 29 750 primiparous controls who had live births. There was a significant association with miscarriage both when the prescription for the NSAID was filled during the week before the miscarriage (OR = 7.0; CI = 2.8, 17) and when it was filled at 7–9 weeks before the miscarriage (OR = 2.6; CI = 1.8, 4.0).

The validity of these findings has been challenged on the grounds of possible bias and other methodological problems (222,223). However, according to a statement issued by the UK Royal College of Obstetricians and Gynaecologists (RCOG) NSAIDs should be avoided by women who know that they are pregnant. According to the RCOG, although the study did not establish a causative link between NSAID use and miscarriage, pregnant women should avoid NSAIDs and in the meantime prefer to use effective alternative drugs, such as paracetamol (224).

Teratogenicity

Many NSAIDs have provoked teratogenic effects in animals, but there is no evidence from epidemiological studies that NSAIDs are embryotoxic in humans. The lack of clinical and epidemiological studies makes any firm recommendations about the use of NSAIDs during the first 6 months of pregnancy impossible. However, the possibility of unrecognized dysmorphogenic effects of NSAIDs needs to be considered before prescribing, so it is wise to use compounds with short elimination half-lives and to give them at the longest possible dosage intervals. When NSAIDs are used for dysmenorrhea, administration should be delayed until menstruation has started, so as to avoid ingestion during an unrecognized pregnancy; in any case, there is no need to give them earlier.

There has been a study in a Danish county (population about 490 000), including data on all women who between 1991 and 1998 had a live birth or a stillbirth after the 28th week of gestation, or who had a miscarriage (including

© 2006 Elsevier B.V. All rights reserved.

missed abortions) (221). The researchers performed a cohort study using data from the Danish birth registry, the county hospital discharge registry, and the county's prescriptions database. The risk of an adverse birth outcome (congenital abnormality, low birth weight, and preterm birth) was examined. The study included 1462 women who gave birth after 28 weeks and who had filled a prescription for an NSAID, a total of 1742 prescriptions. The control group consisted of 17 259 pregnant women who did not take any drugs during pregnancy. There was no significant association between the uptake of prescriptions for NSAIDs during pregnancy and the risks of congenital abnormalities, low birth weight, or preterm births.

Fetotoxicity

Several studies have shown that the use of indometacin as a tocolytic agent is associated with severe adverse effects in the fetus (for example fetal ductal constriction, oligohydramnios), which limit this indication (SEDA-16, 108) (225).

Lactation

Although the newer NSAIDs are all secreted into milk, the amounts are probably too small to affect the breast-fed infant. However, serious adverse effects in breast-fed children have been described with pyrazolones and indometacin (SEDA-10, 78). The choice of NSAID, if it is indispensable, should therefore be directed to compounds that have short half-lives. In order to reduce the quantity of drug reaching the child, the mother should take the drug at the time of breast feeding or immediately afterwards, so that the next feed occurs after a time equivalent to the half-life of the drug.

Susceptibility Factors

Genetic factors

Anaphylactic reactions induced by NSAIDs are associated with HLA-DRB1 genes encoding HLA-DR11 molecules, according to the results of a study in 21 patients who suffered from anaphylactic reactions to NSAIDs and 47 patients who had exclusively skin reactions to these drugs (226). A control group of 167 patients was studied. Patients and controls were challenged, single-blind, with aspirin, salsalate, paracetamol, piroxicam, or diclofenac. There were 88 episodes of skin reactions to NSAIDs and 26 episodes of anaphylaxis. The frequency of HLA-DR11 alleles was 59% in the anaphylaxis group compared with 16% in the control group. Neither HLA-DR nor HLA-DQ alleles was associated with NSAID-induced skin reactions.

Drug Administration

Drug administration route

Topical NSAIDs

Despite official approval and wide use as either over-the-counter or prescription drugs, there is skepticism that topical NSAIDs have any action other than as rubefacients (227). There has been a systematic review of the efficacy and safety of these drugs in 86 randomized controlled clinical trials in more than 10 000 patients with acute or chronic pain (228). Topical NSAIDs were significantly more effective than placebo for pain relief. Local tolerability was good: local skin reactions were rare (3.6%) and systemic effects even rarer (less than 0.5%). Local or systemic unwanted effects of sufficient severity to cause withdrawal from the study were also rare (0.5%) and no more common than with placebo.

In two case-control studies, topical NSAIDs were not significantly associated with upper gastrointestinal bleeding or perforation, after adjustment for the confounding effect of concomitant use of oral NSAIDs (229), nor with hospitalization for acute renal insufficiency (157), although renal adverse effects have been described, albeit rarely, with these topical formulations (SEDA-18, 100).

Drug–Drug Interactions

General interactions with NSAIDs

General interactions with NSAIDs are summarized in Table 2 (pharmacokinetic interactions) and Table 3 (pharmacodynamic interactions).

Widespread use of NSAIDs, particularly in the elderly, who often take other drugs at the same time, leads to a high risk of clinically significant drug interactions, both pharmacokinetic and pharmacodynamic. The inhibitory effects of azapropazone, oxyphenbutazone, and phenylbutazone on the metabolism of other drugs, such as oral anticoagulants, oral hypoglycemic drugs, and phenytoin, is an example of a pharmacokinetic mechanism. Other NSAIDs inhibit the renal excretion of lithium (although toxicity is less likely with aspirin, ibuprofen, and sulindac) and methotrexate. Pharmacodynamic mechanisms are exemplified by the interactions between indometacin and other NSAIDs (except perhaps sulindac) and with antihypertensive agents (including beta-blockers, diuretics, and ACE inhibitors). Interactions of NSAIDs with other drugs (230) are summarized in Tables 2 and 3.

To explore the frequency of continuous use of over-the-counter drugs and the potential for harmful interactions between OTC drugs and prescribed drugs, a population-based interview survey was conducted in 10 477 subjects (231). Daily use of over-the-counter drugs was reported by 7% of the subjects and 4% of those who used over-the-counter drugs had taken combinations with potential for clinically significant interactions. Interactions were most common for NSAIDs such as ketoprofen (15% of ketoprofen users), ibuprofen (10%), and aspirin (6%). Unfortunately, this study did not provide information on whether the potential interactions led to actual clinical problems.

Alcohol

The FDA has announced its intention to require alcohol warnings on all over-the-counter pain medications that contain acetylsalicylic acid, salicylates, paracetamol, ibuprofen, ketoprofen, or naproxen. The proposed warnings are aimed at alerting consumers to the specific risks incurred from heavy alcohol consumption

Table 2 Pharmacokinetic drug interactions with NSAIDs

Drug(s) affected by NSAIDs	NSAID(s) implicated	Effect(s)	Management
Oral anticoagulants	Phenylbutazone Oxyphenbutazone Azapropazone	Inhibition of metabolism of *S*-warfarin, increasing anticoagulant effect	Avoid NSAIDs if possible; careful monitoring when unavoidable (note also pharmacodynamic interactions)
Lithium	Probably all NSAIDs (?except sulindac, aspirin)	Inhibition of renal excretion of lithium, increasing lithium serum concentrations and increasing risk of toxicity	Use sulindac or aspirin if an NSAID is unavoidable; careful monitoring of serum lithium concentration and appropriate dosage reduction
Oral hypoglycemic drugs	Phenylbutazone Oxyphenbutazone Azapropazone	Inhibition of metabolism of sulfonylureas, prolonging half-lives and increasing the risk of hypoglycemia	Avoid these NSAIDs if possible; if not, monitor blood glucose closely
Phenytoin	Phenylbutazone Oxyphenbutazone	Inhibition of metabolism of phenytoin, increasing plasma concentration and risk of toxicity	Avoid these NSAIDs if possible; if not, intensive plasma concentration monitoring
	Other NSAIDs	Displacement of phenytoin from plasma albumin, reducing total concentration for the same unbound (active) concentration	Careful interpretation of serum total phenytoin concentration; measurement of unbound concentration can be helpful, if available
Methotrexate	Probably all NSAIDs	Reduced clearance of methotrexate (mechanism unclear), increasing plasma concentration and risk of severe toxicity	Simultaneous dosing is contraindicated; use of NSAIDs between cycles of chemotherapy is probably safe
Sodium valproate	Aspirin	Inhibition of valproate metabolism, increasing plasma concentration	Avoid aspirin; monitor plasma concentration if other NSAIDs are used
Digoxin	All NSAIDs	Potential reduction in renal function (particularly in the very young and very old), reducing digoxin clearance and increasing plasma concentrations and the risk of toxicity; no interaction if renal function is normal	Avoid NSAIDs if possible; if not, frequent checks of serum digoxin concentration and serum creatinine
Aminoglycosides	All NSAIDs	Reduction in renal function in susceptible individuals, reducing aminoglycoside clearance and increasing plasma concentrations	Careful plasma concentration monitoring and dosage adjustment
Antacids	Indometacin (?other NSAIDs)	Variable effects of different formulations: aluminium-containing antacids reduce the rate and extent of absorption of indometacin; sodium bicarbonate increases the rate and extent of absorption of indometacin	No action required, unless a marked reduction in absorption results in a poor response to the NSAID, in which case dosages may need to be increased or the antacid withdrawn
Probenecid	Probably all NSAIDs	Reduction in the metabolism and renal clearance of NSAIDs and their acylglucuronide metabolites, which are hydrolysed back to the parent drug	Can be used therapeutically to increase the response to a given dose of an NSAID
Barbiturates	Phenylbutazone (?other NSAIDs)	Increased metabolic clearance of NSAIDs	May require higher dosages of phenylbutazone
Caffeine	Aspirin	Increased rate of absorption of aspirin	No action required
Colestyramine	Naproxen and probably other NSAIDs	The anion exchange resin binds NSAIDs in gut, reducing the rate (?and extent) of absorption	Separate dosing times by 4 hours; may need higher than expected dosages of NSAIDs
Metoclopramide	Aspirin	Increased rate and extent of absorption of aspirin in patients with migraine	Can be used therapeutically

and its interaction with analgesics. For products that contain paracetamol, the warning indicates the risks of liver damage in those who drink more than three alcoholic beverages a day. For formulations that contain salicylates or the mentioned NSAIDs three or more alcoholic beverages will increase the risk of stomach bleeding (232).

Antihypertensive drugs

All NSAIDs interfere with hypertension control in patients taking diuretics, beta-blockers, or vasodilators, although contrasting data have been published on the effects of these drugs on blood pressure (233). Moreover, they interact diversely with different

Table 3 Pharmacodynamic drug interactions with NSAIDs

Drug affected by NSAIDs	NSAID(s) implicated	Effect(s)	Management
Antihypertensive drugs	Indometacin	Reduction in hypotensive effect, probably related to impaired prostaglandin synthesis (causing salt and water retention) and vascular prostaglandin synthesis (causing vasoconstriction)	Avoid all NSAIDs in treated hypertensive patients if possible; if not, use sulindac preferentially; may need additional antihypertensive therapy
Diuretics	Indometacin	Reduction in natriuretic and diuretic effects; can exacerbate congestive cardiac failure	Avoid NSAIDs in patients with cardiac failure; use sulindac; monitor clinical signs of fluid retention
Anticoagulants	All NSAIDs	Gastrointestinal tract mucosal damage; inhibition of platelet aggregation; increased risk of gastrointestinal bleeding in patients taking anticoagulants	Avoid all NSAIDs if possible
Hypoglycemic drugs	Salicylates (high dosages)	Potentiation of hypoglycemic effects (mechanism unknown)	Monitor blood glucose concentration
Combinations with increased risk of toxicity	NSAID(s) implicated	Effect(s)	Management
All diuretics	All NSAIDs	Combination associated with increased risk of hemodynamic renal insufficiency	Avoid combination if possible
Triamterene	Indometacin	Potentiation of nephrotoxicity, including subjects with normal renal function	Combination contraindicated
Potassium-sparing diuretics	All NSAIDs	Potassium retention and hyperkalemia	Avoid combination; monitor plasma potassium concentration

antihypertensive drugs, antagonizing the effect of beta-blockers and ACE inhibitors more than calcium channel blockers, diuretics, and centrally acting alpha-adrenoceptor agonists (234,235). In one study there was no significant change in blood pressure in patients taking calcium channel blockers (verapamil or nifedipine) with NSAIDs (236). Among ACE inhibitors, perindopril reduces blood pressure in patients taking NSAIDs (237).

Ciclosporin

An interaction resulting in additive deterioration of renal function has been documented in patients taking ciclosporin together with different NSAIDs (SEDA-17, 107). The mechanism is still uncertain, but may involve prostaglandin production, and the known effects of NSAIDs on cyclo-oxygenase suggest an additive effect in the kidney. The concomitant use of NSAIDs and ciclosporin requires caution. Sulindac, which may be less toxic to the kidneys, can increase whole blood ciclosporin concentrations by inhibiting hepatic cytochrome P450 (SEDA-17, 107). Inhibition by ciclosporin of diclofenac first-pass metabolism has been hypothesized (SEDA-21, 104).

Methotrexate

Interactions of NSAIDs with methotrexate have been reviewed (SEDA-20, 89). Severe toxicity has been attributed to different dosages of methotrexate in concomitant use with several NSAIDs. The mechanisms are unclear. Both methotrexate and the NSAIDs are secreted by the organic acid secretory pathway in the kidney and both are highly bound to plasma albumin. In a study on the pharmacokinetics of methotrexate in patients with rheumatoid arthritis there was no significant interaction between a single low dose of methotrexate and piroxicam (238). A second study in patients with rheumatoid arthritis showed no significant differences in the pharmacokinetics of methotrexate 7.5 mg/week with or without NSAIDs. At higher dosages (10–25 mg/week) the renal clearance of methotrexate was reduced by both salicylate and non-salicylate NSAIDs (239). These data confirm that simultaneous dosing of methotrexate (over 7.5 mg/week) and NSAIDs must be avoided, since methotrexate toxicity can be severe. Differences between NSAIDs in interactions with methotrexate require other studies (240).

Misoprostol

Two reports of adverse neurological effects (dizziness, unsteadiness in walking, and ataxic symptoms) in patients treated with misoprostol and NSAIDs require confirmation (SEDA-16, 108).

Noradrenaline

See also Adrenoceptor agonists

General Information

Noradrenaline is a catecholamine with agonist effects mainly at alpha-adrenoceptors. It is still occasionally used to maintain blood pressure in acute emergencies.

Note on nomenclature

Although norepinephrine is the recommended International Non-proprietary Name (rINN), there are good reasons why the name noradrenaline should be preferred, based on usage, history, etymology, and, most importantly, risk of clinical errors (1).

General adverse effects

The systemic adverse reactions of noradrenaline are typically adrenergic, involving primarily the central nervous system and the blood vessels. It has very little effect on beta-adrenoceptors in the heart, but there tends to be some bradycardia as a reflex consequence of the drug-induced rise in blood pressure. Retrosternal pain can occur, as with the amphetamines. A paradoxical but transient engorgement of the thyroid has occurred.

Organs and Systems

Cardiovascular

Like adrenaline, noradrenaline is also sometimes added to local anesthetics (for example in a 1:250 000 concentration) to prolong their effect; it should not be injected into extremities (finger, penis) for this purpose, since dangerous ischemia can result (2).

When infusing noradrenaline the infusion should always be ended very gradually, since otherwise a catastrophic fall in blood pressure can occur.

Drug Administration

Drug administration route

Extraordinary care is needed to avoid local damage at the site of the intravenous infusion, which can readily result in skin necrosis as a consequence of ischemia.

Norastemizole

See also Antihistamines

General Information

Norastemizole is a metabolite of the second-generation antihistamine astemizole (1). Its major advantage is that it is not cardiotoxic and does not interact with drugs that increase the risk of serious dysrhythmias.

Reference

1. Bachmann KA. Norastemizole Sepracor. Curr Opin Investig Drugs 2000;1(2):219–26.

Norfloxacin

See also Fluoroquinolones

General Information

Norfloxacin is a fluoroquinolone antibacterial drug with properties similar to those of ciprofloxacin, although less potent in vitro.

Norfloxacin inhibits CYP1A2 and can therefore enhance the effects of other drugs by reducing their clearance (1).

Comparative studies

In a double-blind, multicenter study 171 patients who had acute pyelonephritis were given intravenous cefuroxime for 2–3 days, followed by ceftibuten 200 mg bd or norfloxacin 400 mg bd for 10 days (2). There were fewer bacterial relapses after oral norfloxacin than ceftibuten. Adverse events were reported by 47% of the patients taking ceftibuten and by 38% of those taking norfloxacin. This difference was not significant, but diarrhea or loose stools occurred more often with ceftibuten.

Organs and Systems

Sensory systems

A corneal ulcer associated with deposits of norfloxacin in the right eye has been reported in a 40-year-old man with right trigeminal and facial nerve palsies and reduced tear secretion. He stopped using norfloxacin ophthalmic solution and recovered (3).

Psychological, psychiatric

There have been reports of hallucinations with norfloxacin (4).

Hematologic

- Eosinophilia occurred in a 35-year-old man with alcoholic cirrhosis taking norfloxacin 400 mg bd for prophylaxis of spontaneous bacterial peritonitis (5).

Gastrointestinal

In a prospective study in women with urinary tract infections treated with pivmecillinam 400 mg bd for 3 days ($n = 483$) or norfloxacin 400 mg bd for 3 days ($n = 471$), 36% of the pivmecillinam-treated patients and 39% of the norfloxacin-treated patients reported adverse events (6). Gastrointestinal symptoms were most frequent. Of the patients who took norfloxacin 4.3% had vaginal candidiasis.

Liver

Acute hepatitis has been reported with norfloxacin (7,8).

Pancreas

Norfloxacin can cause pancreatitis (9).

Urinary tract

Acute interstitial nephritis, probably related to norfloxacin, has been reported (10).

- A 38-year-old woman took norfloxacin (300 mg/day) and tiaramide hydrochloride (300 mg tds) for an infection with *Mycoplasma pneumoniae*. One day after the start of treatment, her symptoms of cough and fever worsened and she developed lumbago and hematuria. The diagnosis was confirmed by percutaneous renal biopsy. She slowly improved without specific treatment. Lymphocyte stimulation tests were negative, but rechallenge with norfloxacin was followed by bilateral lumbago.

The authors identified two previous reports of acute interstitial nephritis associated with norfloxacin.

Musculoskeletal

Myalgia has been attributed to norfloxacin (11).

- A 33-year-old man developed myalgia and rhabdomyolysis while taking norfloxacin for cystitis. He complained of general muscle fatigue, tendon disorders, and articular pain. When norfloxacin was withdrawn, his symptoms abated, with persistence of slight myalgia for 10 days.

Drug Administration

Drug formulations

The stability of norfloxacin in suspensions prepared from two brands of film-coated tablets has been studied (12). The vehicle consisted of tragacanth, saccharin sodium, sorbitol solution, glycerol, parabens concentrate, peppermint spirit, purified water, and syrup USP, yielding a final concentration of norfloxacin of 20 mg/ml. The resulting suspensions were chemically stable for 28 days when stored in amber glass bottles at room temperature.

© 2006 Elsevier B.V. All rights reserved.

Drug–Drug Interactions

Antacids

Norfloxacin can interact with antacids containing aluminium or magnesium salts, by complexation, reducing its solubility and therefore its absorption; this can result in therapeutic failure. In an in vitro study, dissolution rates were markedly reduced in the presence of all antacids studied; however, this phenomenon was practically avoided when a disintegrant (sodium starch glycolate or crospovidone) was included in the tablet (13).

Ciclosporin

In children undergoing renal transplantation and receiving ciclosporin, the mean daily dose of ciclosporin needed to maintain adequate trough concentrations fell when patients were treated with norfloxacin for urinary tract infections (14).

Oral contraceptives

Plasma concentrations of oral contraceptive steroids were unchanged by norfloxacin (15).

Food–Drug Interactions

The systemic availability of norfloxacin was reduced by 38–52% by dairy products (16).

Nortriptyline

See also Tricyclic antidepressants

General Information

Nortriptyline is a tricyclic compound which differs from amitriptyline in being monodemethylated (1).

Reference

1. Jerling M, Bertilsson L, Sjoqvist F. The use of therapeutic drug monitoring data to document kinetic drug interactions: an example with amitriptyline and nortriptyline. Ther Drug Monit 1994;16(1):1–12.

Noscapine

General Information

Noscapine, which is derived from *Papaver somniferum*, has little analgesic or sedative effect. It is thought to be capable of modifying cough (1), but as with other antitussives, it remains difficult to say whether cough is genuinely suppressed or merely better tolerated. Headache and drowsiness can occur in a minority of patients and a skin rash has been occasionally reported.

© 2006 Elsevier B.V. All rights reserved.

Long-Term Effects

Mutagenicity

In vitro experiments have shown that noscapine can produce spindle inhibition and polyploidy, suggesting that it may be genotoxic or carcinogenic (SEDA-17, 210). The degree of risk to humans when noscapine is used in a cough mixture remains to be established. Nevertheless, as there are alternative drugs, noscapine should not be given to women of childbearing potential.

Novobiocin

General Information

Novobiocin is an antimicrobial drug that is structurally related to the coumarins. It is active against Gram-positive bacteria, such as *Staphylococcus aureus* (including meticillin-resistant strains) and other staphylococci; the enterococci are usually resistant. Some Gram-negative organisms, including *Haemophilus influenzae* and *Neisseria* species, are also susceptible, as are some strains of *Proteus*, but most of the Enterobacteriaceae are resistant. Its action is primarily bacteriostatic, although it may be bactericidal against more sensitive species at high concentrations. It inhibits DNA gyrase and is effective in eliminating plasmids, but resistance to novobiocin develops readily both in vitro and during therapy.

Although novobiocin has been used alone or with other drugs, such as rifampicin or tetracycline, in the treatment of infections due to staphylococci and other susceptible organisms, it has largely been superseded by other drugs because of the problems of resistance and toxicity.

Organs and Systems

Hematologic

Reports of drug-induced thrombocytopenia have been systematically reviewed (1). Among the 98 different drugs described in 561 articles the following antibiotics were found with level I (definite) evidence: co-trimoxazole, rifampicin, vancomycin, sulfisoxazole, cefalothin, piperacillin, methicillin, novobiocin. Drugs with level II (probable) evidence were oxytetracycline and ampicillin.

Drug–Drug Interactions

Cytotoxic drugs

Novobiocin potentiates the activity of etoposide in vitro by increasing intracellular accumulation of etoposide. A phase I trial showed that the maximum tolerated dose of novobiocin was 7 g/m^2/day when it was given in combination with etoposide; dose-limiting adverse effects consisted of neutropenic fever and reversible hyperbilirubinemia. Novobiocin did not augment the toxic effects of etoposide on the bone marrow or the gastrointestinal mucosa, and nausea, a dose-limiting adverse effect in other trials of novobiocin, was well controlled by 5-HT3 receptor antagonists (2).

However, in a phase II study of the combination of novobiocin and high-dose cyclophosphamide and thiotepa, followed by autologous bone marrow support in women with chemosensitive advanced breast cancer, there was no significant increase in progression-free survival and overall survival compared with historical controls treated with high-dose alkylating drugs alone (3).

Lactoferrin

Lactoferrin can potentiate the activity of novobiocin against some strains of *Escherichia coli* strains (4).

Sodium polyphosphate

The permeabilizer sodium polyphosphate may enhance the activity of novobiocin against *Pseudomonas aeruginosa* (5).

Noxiptiline

See also Tricyclic antidepressants

General Information

Noxiptiline is a tricyclic compound that differs from amitriptyline in having a longer side-chain, containing an oxyimino-group.

In a double-blind comparison of noxiptiline ($n = 30$) and amitriptyline ($n = 32$) in hospitalized patients with

© 2006 Elsevier B.V. All rights reserved.

primary depressive illness for 3–6 weeks there were no significant differences, but noxiptiline had a faster onset of action (1). A comparison with imipramine also showed no difference in therapeutic efficacy (2).

As regards adverse effects, noxiptiline seemed to cause more mental symptoms, such as delirium (3). In one study in 44 patients, 9 developed delirium, there were mild manic symptoms in 6, dry mouth in 21, disturbed micturition in 2, and difficulty in accommodation in 3 (2), the last 3 being evidence of anticholinergic effects.

Nucleoside analogue reverse transcriptase inhibitors (NRTIs)

See also Individual agents

General Information

The nucleoside analogue reverse transcriptase inhibitors (NRTIs) include abacavir, didanosine, lamivudine, stavudine, tenofovir, zalcitabine, and zidovudine (all rINNs). The following abbreviations have been used and may still be encountered in published papers:

- DDI: didanosine (inosine analog)
- 3TC: lamivudine (cytidine analog)
- D4T: stavudine (thymidine analog)
- DDC: zalcitabine (cytidine analog)
- ZDV: zidovudine (thymidine analog)

The abbreviation AZT should not be used to designate zidovudine, since it can be, and has been, confused with azathioprine (1).

To be converted into an active compound, all the NRTIs have to be phosphorylated intracellularly to the triphosphate form via monophosphates and diphosphates. The triphosphates compete with cellular nucleotides and inhibit HIV reverse transcriptase by introducing a chain terminator into the growing complementary DNA strand during reverse transcription. However, this mechanism also occurs when human DNA is transcribed by the human DNA polymerase. In fact, the first NRTI in clinical use (zidovudine) was initially developed as an anticancer drug, targeting human DNA polymerase in cancer cells. However, all NRTIs have higher specificity for viral reverse transcriptase than for the human DNA polymerase.

Observational studies

Combinations of different NRTIs

In a 24-week open, single-arm trial, 108 antiretroviral therapy-naive, HIV-infected prisoners were given a combination tablet of lamivudine + zidovudine (150 mg/300 mg) and a tablet of abacavir 300 mg bd (2). The plasma HIV-1 RNA concentration remained at 400 copies/ml or less in 85% of the patients and at less than 50 copies/ml in 75%. Nausea was the most common adverse effect ($n = 40$). Four patients withdrew prematurely because of one or more of the following: abdominal discomfort and pain; abdominal distension; neutropenia; malaise or fatigue; nausea and vomiting. Two patients had a suspected hypersensitivity reaction to abacavir and were withdrawn.

A combination of nucleosides analogues, stavudine 2 mg/kg/day plus didanosine 180 mg/m^2/day for 48 weeks, has been assessed in 16 asymptomatic children, median age 6.5 years, with HIV infection (3). They had plasma HIV RNA concentrations below 50 000 copies/ml and CD4 counts above 15%. Plasma HIV RNA was reduced to 400 copies/ml or less in 43% and 44% of cases at 24 and 48 weeks respectively. There were minor adverse effects in two-thirds of the children; none led to drug withdrawal. There were no cases of lipoatrophy. There were no resistance mutations linked to didanosine (L74V or M184V) or stavudine (V75T) nor multinucleoside resistant genotypes (151 complex or 69 inserts). However, four children developed zidovudine-like mutations, T215Y and/or M41L.

Combinations of NRTIs and NNRTIs

The efficacy and safety of abacavir (NRTI) and efavirenz (NNRTI) plus background therapy have been retrospectively evaluated in 50 patients, who had previously been treated with highly active antiretroviral therapy (HAART) (4). There was some immunological benefit, albeit limited, in most of the patients. Adverse effects were not mentioned in detail, but the dropout rate during the first 4 weeks of treatment was high, owing to skin rashes and hypersensitivity reactions.

Of 80 injecting drug users who took two NRTIs + nevirapine (NNRTI), 20 discontinued treatment and 20 had treatment failures (5). Adverse events led to withdrawal of therapy in 10 patients: eight had a rash (in one case Stevens–Johnson syndrome); one had liver failure thought to be unrelated to the drugs; and one had "general intolerance." Two patients taking methadone had opioid withdrawal symptoms, presumably due to induction of methadone metabolism by nevirapine.

Combinations of NRTIs and protease inhibitors

A variable-dose plasma concentration-controlled approach to combination antiretroviral therapy (zidovudine, lamivudine, and indinavir) has been compared with conventional fixed-dose therapy in 40 patients in a randomized, 52-week, open trial (6). Significantly more concentration-controlled recipients achieved the desired concentrations for all three drugs: there was a good response in 15 of 16 concentration-controlled recipients compared with nine of 17 conventional regimen recipients. However, there was no difference in the occurrence

© 2006 Elsevier B.V. All rights reserved.

of drug-related clinical events or laboratory abnormalities between the two regimens. Three patients withdrew because of gastrointestinal adverse effects, one because of a peripheral neuropathy, and one with headache and anemia. There was nephrolithiasis in four cases.

The combination of indinavir + ritonavir 400/400 mg bd plus two NRTIs has been studied in 93 patients in an open, uncontrolled, multicenter trial (7). Raised triglycerides ($n = 78$) and cholesterol ($n = 63$) were the commonest adverse effects, followed by nausea ($n = 22$) and circumoral paresthesia ($n = 9$). Withdrawal was required in four cases of nausea, four of lipodystrophy, one of diarrhea, and one of osteonecrosis.

In a multicenter, open, uncontrolled trial of protease inhibitors in conjunction with NRTIs for at least 96 weeks in 32 children, the pharmacokinetics of indinavir and nelfinavir showed large interindividual differences (8). In all, 17 children suffered adverse events. The most common adverse events in those taking indinavir were diarrhea ($n = 6$), vomiting ($n = 6$), anorexia ($n = 5$), hematuria ($n = 5$), abdominal pain ($n = 4$), and headache ($n = 3$); most were mild and occurred early in treatment. The rates of drug-related adverse effects were 0.4 per patient-year in those taking indinavir and 0.16 per patient-year in those taking nelfinavir.

Combinations of NRTIs, NNRTIs, and protease inhibitors

In an open 48-week, single-arm, multicenter phase II study in 99 patients abacavir 300 mg bd, amprenavir 1200 mg bd, and efavirenz 600 mg/day were associated with rashes in 50 patients, possibly because of abacavir hypersensitivity; 17 permanently discontinued one or more drugs as a result (9). Other adverse effects included nausea ($n = 41$), diarrhea ($n = 27$), sleep disorders ($n = 27$), dizziness ($n = 25$), fatigue ($n = 23$), hypertriglyceridemia ($n = 18$), neutropenia ($n = 8$), hyperamylasemia ($n = 4$), leukopenia ($n = 3$), hypercholesterolemia ($n = 2$), raised alkaline phosphatase ($n = 1$), and raised aspartate transaminase ($n = 1$).

In infants and children assigned to different combinations of one or two NRTIs plus an NNRTI and/or a protease inhibitor, the numbers of patients with moderate or severe adverse events were as shown in Table 1 (10). In cases of rash, the rash was worse in those who were taking nevirapine-containing regimens.

General adverse effects

Almost all NRTIs cause non-specific gastrointestinal and general adverse effects (nausea, sleep disturbances, headache) that are difficult to attribute to a single agent and usually disappear after the first 2–4 weeks of therapy.

Mitochondrial toxicity associated with NRTIs

Initially, most of the adverse effects seen with zidovudine use (in particular hematological effects) were attributed to interference with cellular DNA replication. However, DNA replication also occurs in mitochondria. Mitochondrial DNA encodes some of the enzymes used for oxidative phosphorylation. Only recently has it been hypothesized that inhibition of this pathway could lead to mitochondrial toxicity and be responsible for most of the toxicity seen with NRTIs, including polyneuropathy, myopathy, cardiomyopathy, steatosis, lactic acidosis, exocrine pancreas failure, bone marrow failure, and proximal tubular dysfunction (11). These adverse effects are also a compilation of the clinical features seen in several genetic mitochondrial cytopathies.

In vitro, NRTIs reduce mitochondrial DNA, most likely by inhibiting mitochondrial DNA polymerase gamma. Heterogeneous toxicity profiles of different NRTIs in vivo may be related to variable tissue sensitivity, cell entry, and drug phosphorylation. Therefore, each NRTI has a specific adverse effect profile (Table 2 (11)), but any feature of mitochondrial toxicity must be considered with all NRTIs. A major problem of mitochondrial toxicity is its delayed onset, sometimes after several months of treatment.

Table 1 Numbers (%) of infants and children with moderate or severe adverse events in a study of one or two NRTIs plus an NNRTI and/or a protease inhibitor

System affected by the adverse event	Regimen			
	Stavudine + nevirapine + ritonavir ($n = 41$)	Stavudine + nevirapine + nelfinavir ($n = 44$)	Stavudine + lamivudine + nevirapine + nelfinavir ($n = 44$)	Stavudine + lamivudine + nelfinavir ($n = 52$)

Table 2 Spectrum of adverse effects of nucleoside analogue reverse transcriptase inhibitors

Adverse effects	Didanosine	Lamivudine	Stavudine	Zalcitabine	Zidovudine
Cardiomyopathy	+	−	+	−	+
Neuropathy	++	−	++	++	−
Lactic acidosis	−	−	+	+	+
Bone marrow toxicity	+	−	+	−	++
Hepatic steatosis	−	±	+	+	+
Pancreatitis	−	±	++	+	−
Myopathy	−	−	−	−	++

++ most prominent adverse effect
+ observed adverse effect
± possible adverse effect
− adverse effect typically not observed

Organs and Systems

Cardiovascular

Cardiomyopathy is a rare adverse effect that has been observed in patients treated with didanosine, zidovudine, and zalcitabine (12). In a retrospective, case-control study, cardiomyopathy was 8.4 (95% CI = 1.7, 42) times more likely to develop in children who had previously used zidovudine than in children who had never been exposed to it (13).

Nervous system

Peripheral neuropathy is often observed in patients treated with didanosine, stavudine, and zalcitabine (14,15).

Sensory systems

In a report of ototoxicity in a patient taking three antiretroviral drugs, the authors suggested that nucleoside analogues should be avoided in patients with known neurotoxicity.

- A 23-year-old woman who took stavudine, lamivudine, and nevirapine had nausea and diarrhea during the first few days and within 2 weeks developed sudden bilateral hearing loss, dizziness, and tinnitus (16). The hearing defect was sensorineural. CT and MRI scans were normal. Prednisolone was ineffective.

Metabolism

Lipodystrophy

The prevalence of lipodystrophy has been studied during follow-up for 30 months of previously untreated patients who had been randomized to receive different nucleoside analogue combinations for 6 months in the ALBI–ANRS 070 trial (17). After 30 months 37 of 120 patients who had used nucleoside analogues with or without other antiretroviral drugs had at least one morphological change, and 21 of those had isolated peripheral lipoatrophy; the corresponding values for the patients who used only nucleoside analogues during follow-up were 20 of 66 and 14 of 21 respectively. The factors associated with lipodystrophy were initial assignment to stavudine plus didanosine compared with zidovudine plus lamivudine (OR = 6.7), age below 10 years (OR = 3.6), and HIV RNA concentration at month 30 (OR = 0.4). There were no differences in cholesterol and glucose concentrations. Thus, exposure to stavudine and didanosine was associated with lipodystrophy (predominantly lipoatrophy).

In a well-controlled French comparison of changes in body composition, body fat distribution, and insulin secretion, patients taking stavudine ($n = 27$) or zidovudine ($n = 16$) were compared with controls ($n = 15$) (18). The zidovudine group and the control group had similar body composition and regional fat distribution. Stavudine was associated with a significantly lower percentage of body fat than zidovudine (13 versus 15%), a markedly lower ratio of subcutaneous to visceral fat, and a higher mean intake of fat and cholesterol. Triglyceride concentrations were significantly higher with stavudine than in the controls, but did not differ between stavudine and zidovudine or between zidovudine and controls. Free fatty acids tended to be higher with stavudine. Lipodystrophy was observed in 17 patients taking stavudine, and in three taking zidovudine after a median time of 14 months. The relative risk of fat wasting with stavudine compared with zidovudine was 1.95. Five of twelve patients had a major or mild improvement in their lipodystrophy after stavudine was withdrawn. The authors concluded that lipodystrophy may be related to long-term NRTI therapy, particularly if it includes stavudine.

Lactic acidosis

Lactic acidosis is a severe and potentially fatal form of mitochondrial toxicity. Metabolic stress or vitamin deficiencies (riboflavin, carnitine) might provoke it. There is suggestive evidence of clinical benefit with riboflavin therapy (19).

Antiretroviral nucleoside analogues have been associated with hepatic steatosis and lactic acidosis. These compounds require phosphorylation to active triphosphate derivatives by cellular phosphokinases. The triphosphate nucleotide inhibits the growing proviral DNA chain, but it also inhibits host DNA polymerases, and this can result in compensatory glycolysis and lactic acidosis. Abnormal mitochondrial oxidation of free fatty acids causes the accumulation of neutral fat in liver cells, and this manifests as hepatomegaly with macrovesicular steatosis. Hepatic steatosis and lactic acidosis have been reported previously with zidovudine, didanosine, zalcitabine, Combivir (zidovudine plus lamivudine), and lamivudine.

© 2006 Elsevier B.V. All rights reserved.

Of 349 Australian patients studied for 18 months (516 patient-years) taking NRTIs only two had severe lactic acidosis (20).

Three cases of steatosis/lactic acidosis syndrome associated with stavudine plus lamivudine have been reported (21).

- A 37-year-old HIV-infected woman receiving stavudine, lamivudine, and indinavir developed epigastric pain, anorexia, and vomiting. She had lactic acidosis (serum lactate 4.9 mmol/l), raised liver enzymes, and an increased prothrombin time. She had hepatomegaly and tachypnea and required mechanical ventilation. Her progress was complicated by pancreatitis and acute respiratory distress syndrome. Antiviral medication was stopped and she was treated with co-enzyme Q, carnitine, and vitamin C. The serum lactic acid and transaminases returned to normal over 4 weeks and she was weaned off the ventilator after 4 months.
- A 40-year-old HIV-infected woman receiving stavudine, lamivudine, nelfinavir, and co-trimoxazole developed dyspnea, dysphagia, and vomiting with lactic acidosis (serum lactate 9.4 mmol/l) and hepatomegaly. Despite ventilation for respiratory failure she died after 5 days. Autopsy showed massive hepatomegaly with steatosis.
- A 36-year-old HIV-infected woman who had been receiving stavudine, saquinavir, ritonavir, and didanosine developed lactic acidosis (serum lactate 11.4 mmol/l) and hepatomegaly. She had acute pancreatitis and, despite ventilatory support for respiratory failure, died after 8 weeks.

There have been similar reports related to didanosine plus stavudine (22) and stavudine alone (23).

Routine monitoring of lactate is not recommended, since lactate concentrations do not correlate with symptoms and patients may have asymptomatic lactatemia. Furthermore, technical difficulties in blood collection and processing, and the lack of a standardized definition of lactic acidosis for patients taking NRTIs, prevent any routine monitoring recommendations in the absence of symptoms. In addition, it is possible that NRTIs also cause other forms of mitochondrial dysfunction.

Hematologic

The NRTIs are toxic to hemopoietic progenitor cells in vitro (24) and can cause anemia (25,26), neutropenia (25), and thrombocytopenia (27,28).

Pancreas

Pancreatitis has been observed in patients treated with didanosine, lamivudine, stavudine, and zalcitabine (29), but its incidence is also increased in drug-naive patients with advanced HIV infection (30).

Immunologic

- A man developed several erythematous plaques on his face due to borderline tuberculoid leprosy with a reversal reaction (31). He had severe CD4 T cell lymphocytopenia due to HIV infection and had been given HAART. A fall in viral load and an increase in CD4 count preceded the development of the skin lesions, suggesting immune reconstitution as the underlying mechanism for the reversal reaction.

Paradoxical reactions are often observed in patients with pulmonary and extra-pulmonary tuberculosis being treated with HAART. Clinicians need to distinguish these from other adverse reactions related to drug therapy. Reversal reactions in leprosy are increasingly likely as more patients with HIV infection are treated with HAART in developing countries.

Second-Generation Effects

Pregnancy

Two HIV-1-positive women, both of whom had taken regimens containing stavudine and didanosine for at least 2 years, presented in the third trimester of pregnancy, one with acute lactic acidosis and one with acute pancreatitis and lactic acidosis (32). In the first case both mother and baby died. It is not known whether pregnancy is a risk factor for NRTI-induced lactic acidosis, perhaps in combination with riboflavin deficiency or a metabolic defect in the fetus, or whether NRTIs independently cause lactic acidosis through mitochondrial toxicity.

Drug–Drug Interactions

Methadone

In those who are opioid-dependent, methadone can facilitate adherence to HAART regimens. The pharmacokinetics of the tablet formulations of didanosine and stavudine have been studied in 17 individuals taking stable methadone therapy in comparison with 10 untreated controls (33). Methadone reduced the AUC_{0-6} by 63% for didanosine and by 25% for stavudine and the C_{max} by 66% and 44% respectively. These effects appeared to result primarily from reduced systemic availability. Trough concentrations of methadone were comparable to those seen in historical controls, suggesting that the nucleoside analogues did not affect methadone disposition. The authors concluded that larger doses of the tablet formulation (or another type of formulation) may be necessary to provide HAART in subjects taking methadone.

Nystatin

General Information

Nystatin, the earliest antifungal drug, is used today primarily by the oral route to treat gastrointestinal mycosis and topically for mucocutaneous candidiasis (SED-11, 576). Absorption from the gut is insufficient to produce systemic activity.

An intravenous multilamellar liposomal formulation of nystatin has been developed. Its pharmacokinetics are unique among polyenes and are characterized by high peak plasma concentrations and a rapid clearance rate. In a phase I study it was tolerated well at doses up to 8 mg/kg. It was efficacious in candidemia, invasive aspergillosis, and as empirical antifungal therapy in patients with cancer and neutropenia (1). However, it was subsequently withdrawn by the manufacturers.

Organs and Systems

Gastrointestinal

Nausea, vomiting, and diarrhea have been reported after oral administration, possibly due to the drug but perhaps also ascribable to the underlying disease. These effects are more marked with doses over 5 MU a day (SED-11, 576) (2).

Immunologic

Allergic reactions to topical use are rare (SED-11, 576) (3).

Contact allergy due to topical nystatin has been reported in a woman using a combination of clobetasol and nystatin (4). The contact allergy was demonstrated with a positive patch test on day 4.

In another case, the patient developed a maculopapular rash over the trunk and limbs, associated with fever, arthralgia, malaise, and diarrhea; nystatin patch tests were positive on days 2 and 4 (5).

Oak moss resin

General Information

Oak moss resin is an extract of *Evernia prunasti* found in many after-shave lotions and some perfumes (1).

Organs and Systems

Immunologic

Oak moss resin is usually reported as a contact allergen in those who use perfumed products, but is also reported in rural and forestry workers (2). Perfumes are recognized as being potential sensitizers in soluble oils (3), but oak moss as a specific sensitizer within a coolant has not previously been reported.

- A 47-year-old atopic man gave a 3-year history of dermatitis of his hands, forearms, and face (4). He had worked for 24 years as an engineer, grinding components for printing presses. During an enforced absence from work, he noticed that his rash had resolved, but it relapsed within 2 days of his return. Further remissions were noted during his annual holidays, but the rash would always recur within 2 days of returning to work. His skin eruption continued to deteriorate until the coolant used during the grinding process was withdrawn. His rash subsequently resolved and did not recur. Patch testing with standard series, oils and coolants, the constituents of fragrance mix, and his own coolant gave strong positive reactions to fragrance mix, balsam of Peru (*Myroxylon pereirae*), sodium metabisulfite, diethanolamine, and oak moss, and a smaller reaction to his own coolant. The manufacturer of the coolant was contacted for information on the individual constituents of the oil. Further patch tests were then carried out with these components plus the individual components of the fragrance used within it. There were strong positive reactions to oak moss resin and monoethanolamine.

This case highlights the importance of patch testing with individual components of a suspected product in occupational dermatitis. This reduces the chance of false positive reactions and of missing a relevant allergen.

Ocular dyes

General Information

Fluorescein

Topical fluorescein dye is often used during slit lamp examination, because it helps in identifying corneal epithelial defects (1). Fluorescein retinal angiography was first described in 1961 (2); rapid intravenous injection of fluorescein displays retinal circulation velocity and the fine architecture and integrity of the blood retinal barrier. This is associated with minor adverse events in 21% of cases and potential life-threatening adverse events in 0.5% (3).

Fluorescein angiography using oral sodium fluorescein involves the use of 10 ml of a 10% solution of sodium fluorescein, the same material that is generally used for intravenous injection in conventional fluorescein angiography. Retinal photography starts 15 minutes after ingestion and continues for 1 hour. The camera, the photography, and film processing techniques are the same as those used for conventional fluorescein angiography. In 97% of 2625 eyes, adequate photographs for clinical use were obtained after oral fluorescein (4). Only 1.7% of the patients had minimal itching, discomfort, or nausea after oral sodium fluorescein. There were no anaphylactic or other severe adverse effects.

Complications of the use of fluorescein, all of which were reversible in a few hours or days, have been reported (5,6). Most of the complications were associated with the use of a larger quantity of fluorescein than recommended. The most frequent adverse effect of intravenous fluorescein is nausea; urticaria, hypersalivation, rhinorrhea, and chills have been seen in a few cases.

Serious or fatal accidents during fluorescein angiography have been assessed in an international survey involving 594 687 angiographies. The incidence of fatal accidents was one case per 49 557 angiographies, and of non-fatal but serious accidents one case per 18 020 angiographies. The total number of accidents reported was 45 cases, equal to one per 13 215 angiographies.

Indocyanine green

Indocyanine green, used for infrared angiography of the choroidal vessels, is well tolerated intravenously and its adverse effects are less pronounced than those of intravenous fluorescein (7).

Methylthioninium chloride (methylene blue)

Methylthioninium chloride is somewhat irritating, and topical anesthesia is recommended before its use; prolonged systemic exposure can cause the fundus to turn visibly blue (8).

Rose bengal

Discomfort and irritation are more pronounced with rose bengal than with fluorescein. Discoloration of the skin of the patient's eyelids and the examiner's fingers as well as ocular staining are more persistent than when fluorescein is used (9).

Organs and Systems

Nervous system

Non-convulsive status epilepticus has been attributed to fluorescein.

Hematologic

A study was undertaken to evaluate whether or not fluorescein interferes with erythrocyte properties during the angiographic procedure. In 37 patients, 26 with type II diabetes mellitus with and without retinopathy and 11 without diabetes mellitus, all undergoing fluorescein angiography, blood samples were drawn before and 30 minutes after fluorescein injection. The erythrocyte aggregation index, membrane lipid fluidity, and erythrocyte acetylcholinesterase activity were determined in both groups. After fluorescein injection there was no statistical change in erythrocyte aggregation index or erythrocyte membrane fluidity in either group. However, there was a significant fall in erythrocyte acetylcholinesterase activity, a marker of membrane protein integrity, in the diabetic patients. In other words, in diabetic patients fluorescein seems to interact with the erythrocyte membrane, and may interfere with the blood flow in the microcirculation (10).

Skin

The most common adverse effect of topical fluorescein is local irritation (11).

- A previously healthy 35-year-old man with conjunctival irritation had fluorescein dye instilled using a fluorescein-treated ophthalmic strip and isotonic saline. Within 30 minutes he began to notice a pruritic rash around his eye and on his arms, chest, and legs. His joints felt swollen. He had a diffuse erythematous macular rash with evidence of moderate excoriation over his arms and legs. His wrists and ankles were swollen. There were no oral lesions, and all laboratory studies, including the white blood cell count, were normal. Methylprednisolone succinate 125 mg plus diphenhydramine 50 mg produced rapid improvement.

Three patients out of eighty-four in another study had urticaria, which settled within half an hour of administration of an oral antihistamine, and one had nausea, which subsided without treatment (12). Another case of urticaria due to topical fluorescein has been described (13).

Fluorescein transiently stains the skin and mucous membranes yellow (7).

Immunologic

Most systemic reactions after intravenous fluorescein are allergic, but in the past some were due to contamination with dimethylformamide, an industrial solvent (14). It is difficult to predict adverse effects by intracutaneous testing. A delayed allergic response, developing a few hours after intravenous fluorescein dye injection, can occur (15). It is recommended that a complete allergy evaluation be performed in all patients who have adverse reactions to fluorescein, in order to differentiate true allergic reactions from other types of reactions (16).

Infection risk

Contamination of fluorescein eye drops is a very serious risk (17). *Pseudomonas aeruginosa* is an especially dangerous pathogenic microorganism liable to invade fluorescein eye drops. Fluorescein is most safely dispensed in sterile single-dose units or as sterile fluorescein-impregnated paper strips.

Ofloxacin

See also Fluoroquinolones

General Information

Ofloxacin is a fluoroquinolone antibacterial drug similar to ciprofloxacin.

Comparative studies

The safety and efficacy of topical ofloxacin ear-drops 0.3% (0.25 ml bd) have been compared with that of co-amoxiclav oral suspension (40 mg/kg/day) for acute otitis media in 286 children aged 1–12 years with tympanostomy tubes in place. Topical ofloxacin was as effective as and better tolerated than systemic therapy with co-amoxiclav. Treatment-related adverse event rates were 31% for co-amoxiclav and 6% for ofloxacin (1).

Organs and Systems

Nervous system

Headache was recorded in 9% taking ofloxacin during short-course treatment of urinary tract infections (2).

Seizures have occurred in patients taking ofloxacin (3).

A Tourette-like syndrome developed in a 71-year-old patient, temporally related to ofloxacin; spitting, profuse swearing, echolalia, echopraxia, orofacial and limb automatisms, and hypersalivation all resolved completely after withdrawal (4).

Sensory systems

Compared with aminoglycosides, which caused significant loss of hair cells in the basal turn of the cochlea, ofloxacin caused no loss of hair cells in rats, even at concentrations higher than are achieved clinically (5). Moreover, auditory brainstem testing showed no change in auditory thresholds in the ofloxacin-treated animals, whereas neomycin-treated animals showed substantial threshold shifts. In human studies, topical ofloxacin 0.3% had no demonstrable adverse effects on middle ear or cochlear function and was not associated with any changes in hearing.

Endocrine

Ofloxacin 200 mg bd caused diabetes insipidus in a 25-year-old man (6).

Mouth

Ofloxacin can impair salivary gland function. In rat parotid and submandibular glands intraperitoneal ofloxacin (20, 40, and 80 mg/kg) reduced flow rate, amylase activity, total protein and calcium concentrations; in parotid saliva, sodium and potassium were increased (7). Sodium and potassium concentrations were also increased by a dose of 80 mg/kg in submandibular saliva. Possible mechanisms of these effects include altered intracellular cAMP and calcium concentrations and suppression of DNA, RNA, and protein synthesis in acinar cells.

Liver

Ofloxacin can cause fatal hepatic failure (8).

Urinary tract

Acute renal insufficiency has been caused by ofloxacin (9).

Antimicrobial chemotherapy against diseases caused by *Escherichia coli* producing Shiga toxin has been implicated as a risk factor for progression to the hemolytic–uremic syndrome.

- A 75-year-old woman took ofloxacin and developed the hemolytic-uremic syndrome (10).

In an in vitro study the addition of ofloxacin to a cell culture increased toxin activity by more than 200-fold (11).

Skin

Ofloxacin has been implicated in a case of toxic epidermal necrolysis (12).

- A 75-year-old white man took 24 g of ofloxacin over 51 days for epididymitis. He had a severe skin reaction, diagnosed as toxic epidermal necrolysis, and died from complications.

Drug Administration

Drug formulations

Chitosan, a positively charged polysaccharide, increases the precorneal residence time of ophthalmic formulations that contain active compounds. Two chitosan products of high molecular weights (1350 and 1930 kDa) and low degrees of deacetylation (50%) significantly increased antibiotic availability compared with controls (13). The duration of efficacy of ofloxacin was significantly increased from about 25 minutes to 46 minutes by the chitosan of higher molecular weight.

Drug–Drug Interactions

Antacids

The systemic availability of ofloxacin is reduced by aluminium-containing antacids, but not by antacids containing magnesium or calcium (14).

Glucocorticoids

The antibacterial activity of polymorphonuclear leukocytes is based on the production of superoxide anions and H_2O_2 in the respiratory burst. Combinations of an antibacterial agent and an anti-inflammatory drug are commonly used in immunosuppressed patients whose respiratory burst of polymorphonuclear leukocytes is impaired. An in vitro study has shown that the combination of a glucocorticoid (dexamethasone, methylprednisolone, betamethasone, hydrocortisone) with ofloxacin 10 mg/ml neutralizes the inhibitory effect of the former on the respiratory burst (15).

NSAIDs

The antibacterial activity of polymorphonuclear leukocytes is based on the production of superoxide anions and H_2O_2 in the respiratory burst. Combinations of an antibacterial agent and an anti-inflammatory drug are commonly used in immunosuppressed patients whose respiratory burst of polymorphonuclear leukocytes is impaired. An in vitro study has shown that the combination of an anti-inflammatory drug (phenylbutazone or acetylsalicylic acid) with ofloxacin 10 mg/ml neutralizes the inhibitory effect of the former on the respiratory burst (15).

Oral contraceptives

Plasma concentrations of oral contraceptive steroids were unchanged by ofloxacin (16).

Olanzapine

See also Neuroleptic drugs

General Information

Several reviews have echoed the efficacy and tolerability of olanzapine (1–3). In several reviews it has been emphasized that the most common adverse effects are somnolence and weight gain, since about 40% of patients gain weight (especially if on a high starting dose and if they were underweight before treatment); sexual dysfunction can also be a problem for many patients (4–6).

Clinical trials

A thorough and extensive review has summarized five pivotal clinical trials comprising 3252 patients (7). In some studies olanzapine has failed to show efficacy in treatment-resistant schizophrenia (8,9).

In addition to clozapine (10,11), olanzapine has also been reported to improve tardive dyskinesia (12–14).

- An elderly woman who developed moderately severe neuroleptic drug-induced dyskinetic movements responded to olanzapine 10 mg/day (15).

Placebo-controlled studies

A multicenter, double-blind, placebo-controlled study in patients with Alzheimer's disease and symptoms of agitation/aggression and/or psychosis but few or no psychotic symptoms at baseline, and data from a subgroup of patients have been analysed (16). Three subsets of patients were identified on the basis of their symptoms at baseline: those with no clinically significant hallucinations, those with no clinically significant delusions, and those with no clinically significant delusions or hallucinations. Of the patients without hallucinations or delusions at baseline ($n = 75$), the placebo-treated patients had significantly more of these symptoms than olanzapine-treated patients. Similarly, among the patients without baseline hallucinations ($n = 153$), the placebo-treated patients had higher hallucination scores than olanzapine-treated patients, whereas patients without baseline delusions ($n = 87$) had no significant treatment effects. Abnormal gait, a term comprising leaning, limp, stooped posture, and unsteady gait, occurred in a higher incidence among olanzapine-treated patients (14/72) than placebo-treated patients (0/33). Somnolence was also reported at higher rates with olanzapine (27/72) than placebo (3/33).

Olanzapine has been proposed as a treatment for acute mania. In a randomized, double-blind, placebo-controlled

© 2006 Elsevier B.V. All rights reserved.

study for 3 weeks, patients were assigned to either olanzapine 10 mg/day ($n = 70$) or placebo ($n = 69$) (17). Significantly more olanzapine-treated patients responded (49%) compared with those assigned to placebo (24%). Somnolence, dizziness, dry mouth, and weight gain occurred significantly more often with olanzapine, but there were no statistically significant differences with respect to measures of parkinsonism, akathisia, and dyskinesia.

Observational studies

Olanzapine, mean dose 5.4 mg/day, has been given to 21 patients with apathy in the absence of depression after long-term treatment with selective serotonin reuptake inhibitors for non-psychotic depression in an open, flexible-dose study (18). The more frequent adverse effects were sedation ($n = 12$), increased appetite ($n = 8$), stiffness ($n = 7$), edema ($n = 6$), and dry mouth ($n = 5$).

The efficacy and safety of switching 108 Asian patients from their regimen of neuroleptic medications to olanzapine (initial dose 10 mg/day) for 6 weeks has been studied in an open, multicenter, randomized study (19). They were randomly assigned to one of two groups: the direct switch group ($n = 54$) received only olanzapine, while the start-taper switch group ($n = 54$) received olanzapine and their usual neuroleptic drug in decreasing doses for the first 2 weeks. There were statistically significant improvements from baseline to end-point in both switch groups in the Clinical Global Impressions—Severity of Illness Scale score and the Positive and Negative Syndrome Scale total score. Nevertheless, there were no significant differences between the switch groups in any measure of efficacy. Weight gain occurred in both switch groups and both showed statistically significant improvement from baseline to end-point on the Simpson–Angus Scale and Barnes Akathisia Scale.

In 19 patients previously treated with clozapine, olanzapine was used instead (9). Eight were considered to be responders and the rest decompensated, seven of them enough to require hospitalization. Overall Brief Psychiatric Rating Scale (BPRS) scores increased significantly from baseline to final assessment.

In an open trial to determine the efficacy of olanzapine in the treatment of bipolar mixed state ($n = 9$), the results showed improvement in acute symptoms and the drug was well tolerated (20).

In a study supported by Eli Lilly and Company it was concluded that olanzapine may be effective in a significant number of neuroleptic drug-resistant schizophrenic patients (21). However, of 25 patients who entered an open trial for 6 months, 14 discontinued olanzapine, one because of an adverse effect (depression), two because of lack of compliance, and 11 because of lack of efficacy.

Of 14 consecutive patients with bipolar I disorder, who were inadequately responsive to standard psychotropic agents and who were given olanzapine, 8 improved (22). The most common adverse effects were sedation, tremor, dry mouth, and increased appetite with weight gain.

The response to olanzapine in 150 consecutive patients has been assessed by reviewing their records (23). Patients with a moderate-to-marked response to olanzapine were more likely to be younger, to be female, and to have a diagnosis of bipolar disorder. No information on adverse effects was provided.

The efficacy of olanzapine in treatment-refractory childhood-onset schizophrenia has been examined in eight patients (mean age 15 years) over 8 weeks (24). There was a 17% improvement in the BPRS total score. Olanzapine was moderately well tolerated. The most common adverse events were increased appetite ($n = 6$), constipation ($n = 5$), nausea/vomiting ($n = 6$), headache ($n = 6$), somnolence ($n = 6$), insomnia ($n = 7$), difficulty in concentrating ($n = 5$), sustained tachycardia ($n = 6$), transient rises in liver transaminases ($n = 7$), and increased agitation ($n = 6$).

In contrast, olanzapine was discontinued in five preadolescent children (aged 6–11 years) within the first 6 weeks because of adverse effects or lack of therapeutic response (25). The adverse effects included sedation ($n = 3$), weight gain ($n = 3$), and akathisia ($n = 2$).

Substance abuse is a major complication in the treatment of schizophrenia. Of 60 patients with schizophrenia in an open 7-week trial of olanzapine up to 25 mg/day, there was substance abuse in 23 (26). There were no differences in response between the substance-abusing patients and the others. Baseline rates of extrapyramidal adverse effects did not differ between the groups. Overall the patients did not improve significantly.

The medical records of 151 hospitalized elderly psychiatric patients (mean age 71 years) have been analysed (27). Of 37 patients treated with olanzapine (mean duration of treatment 20 days, mean dose 10 mg/day), 75% responded. Adverse effects were reported in six patients: sedation in four patients and extrapyramidal signs and postural hypotension in one each.

In 16 patients with treatment-resistant schizophrenia (defined as non-responsiveness to at least three antipsychotic drugs from at least two different chemical classes), olanzapine was effective treatment in a significant proportion; no serious adverse events were associated with maintenance doses of 10–40 mg/day, and no subjects dropped out (28).

In five consecutive cases, olanzapine was effective for treatment-refractory psychosis in patients previously responsive to, but intolerant of, clozapine (29).

Olanzapine was effective in an open trial in 10 patients with obsessive-compulsive disorder refractory to selective serotonin reuptake inhibitors, who were given additional olanzapine; they had minimal adverse effects, primarily sedation (29).

In 23 patients with obsessive-compulsive disorder who had not responded to a 6-month course of fluvoxamine (300 mg/day), olanzapine (5 mg/day) was added in an open comparison (30). There was a significant reduction in the mean score on the Yale–Brown Obsessive–Compulsive Scale; concomitant schizotypal personality disorder was the only factor significantly associated with a response. The most common adverse effects were mild to moderate weight gain and sedation.

The use of olanzapine for the psychiatric manifestations of hereditary coproporphyria has been studied (31).

In an open study, eight patients with Lewy body dementia associated with psychotic and behavioral difficulties were given olanzapine 2.5–7.5 mg (32). Three of the eight could not tolerate olanzapine, even at the lowest

© 2006 Elsevier B.V. All rights reserved.

dose, two had a clear improvement in psychotic and behavioral symptoms, and three tolerated olanzapine but gained only minimal benefit. The authors concluded that olanzapine in the doses used conferred little advantage over conventional neuroleptic drugs and should be given only with great caution to patients with Lewy body dementia.

In a prospective open 12-week study in eight children, adolescents, and adults with developmental disorders, the most significant adverse effects of olanzapine were increased appetite and weight gain in six patients and sedation in three (33).

The efficacy and adverse effects of high doses of olanzapine (up to 30 mg/day) have been assessed in seven patients with schizophrenia and schizoaffective disorder (34). None discontinued olanzapine because of adverse effects; the only adverse effects were weight gain and self-limited diarrhea. However, poor design and small sample size precluded definitive conclusions.

In an observational prospective study sponsored by Lilly, 2128 patients were treated with olanzapine as monotherapy (mean dose 13 mg/day) or combined with other drugs, and 821 were treated with other neuroleptic drugs as monotherapy or combined with other drugs (control group) (35). Olanzapine was well tolerated and effective, and the overall incidence of adverse events was significantly lower than in controls, although weight gain (6.9%) was significantly more frequent. Dropouts were statistically similar in the two groups.

To evaluate anticholinergic effects, differences among patients taking olanzapine ($n = 12$; average dose, 15 mg/day) or clozapine ($n = 12$; average dose, 444 mg/day) for at least 8 weeks were measured in an unblinded study (36). Altered salivation was significantly more common with clozapine (increased salivation) and olanzapine (decreased salivation), whereas constipation, urinary disturbances, and tachycardia/palpitation were significantly more common with clozapine. There were no global cognitive problems in either group.

Olanzapine has fewer extrapyramidal effects than typical neuroleptic drugs such as haloperidol (SEDA-24, 66). Even some cases of tardive dystonia have been successfully managed with atypical neuroleptic drugs. The antidystonic efficacy of olanzapine has been studied in an open video-blinded study in four patients with tardive cervical dystonia after several years of neuroleptic drug treatment (37). There was moderate to marked improvement in dystonia in all of them, and no serious adverse effects at the maximum dosage reached (7.5 mg/day).

Two patients, one with treatment-resistant rapid cycling bipolar disorder (38) and the other with severe mood changes during corticosteroid therapy (39), improved with olanzapine.

Comparative studies

Comparison with divalproex

The efficacy and safety of olanzapine in disorders other than schizophrenia have been studied (SEDA-24, 67) (SEDA-25, 64) (SEDA-26, 61). In a 3-week, randomized, double-blind trial, the effects of a flexible dose of olanzapine (5–20 mg/day) and divalproex (500–2500 mg/day) for the treatment of patients with acute bipolar manic or mixed episodes have been compared (40). The olanzapine treatment group ($n = 125$) had significantly greater mean improvements in mania rating and a significantly greater proportion of patients achieved protocol-defined remission. With olanzapine there was significantly more weight gain (12 versus 7.9%), dry mouth (34 versus 6.3%), increased appetite (12 versus 2.4%), and somnolence (39 versus 21%), while more cases of nausea (29 versus 10%) were reported with divalproex.

Combination with valproate or lithium

The efficacy of adding olanzapine to either valproate or lithium alone in acute manic or mixed bipolar episodes has been studied in a 6-week, double-blind, randomized, placebo-controlled trial (41). Compared with valproate or lithium alone, the addition of olanzapine provided better efficacy. Olanzapine was associated with somnolence, dry mouth, weight gain, increased appetite, tremor, and slurred speech.

In another study, 30 patients with mania were randomized to olanzapine or lithium in a double-blind 4-week study (42). Olanzapine did not differ from lithium in terms of efficacy or of extrapyramidal adverse effects, as measured by the Simpson–Angus Scale.

Organs and Systems

Cardiovascular

It has been suggested that olanzapine often causes QT interval prolongation (SEDA-25, 64). However, in an analysis of electrocardiograms obtained as part of the safety assessment of olanzapine in four controlled randomized trials ($n = 2700$) the incidence of maximum QT_c prolongation beyond 450 ms during treatment was approximately equal to the incidence of prolongation of the QT_c beyond 450 ms at baseline (43). The authors therefore suggested that olanzapine does not contribute to QT_c prolongation. This has been supported by the report of a patient in whom QT_c prolongation while he was taking clozapine reversed when he switched to olanzapine (44).

Two cases of light-headedness or "fainting" in patients taking olanzapine have been reported (45). Electrocardiograms showed first-degree heart block and AV conduction delay, which normalized after dosage reduction.

- A 44-year-old man took clozapine 10 mg/day and the dose was increased to 50 mg/day, after which he complained of episodes of light-headedness. An electrocardiogram showed prolongation of the PR interval to 227 ms. The dosage was reduced to 30 mg and the PR interval returned to 187 ms within 2 days.
- A 36-year-old man took clozapine 20 mg/day and within 2 weeks began to complain of intermittent, unpredictable "fainting" attacks. An electrocardiogram showed a prolonged PR interval at 230 ms. The dose of olanzapine was reduced to 17.5 mg/day, and a repeat electrocardiogram 1 week later was normal.

Nervous system

Extrapyramidal effects

To ascertain to what extent olanzapine occupies 5-HT_2 and dopamine D_2 receptors, a positron emission

© 2006 Elsevier B.V. All rights reserved.

tomography study has been conducted in 12 patients with schizophrenia randomly assigned to 5, 10, 15, or 20 mg/day of olanzapine (46). Olanzapine is a potent 5-HT_2 antagonist and has higher 5-HT_2 than D_2 occupancy at all doses. Its D_2 receptor occupancy is higher than that of clozapine and similar to that of risperidone. At the usual clinical dose range of 10–20 mg/day, D_2 receptor occupancy is 71–80%, and this restricted range may explain its freedom from extrapyramidal adverse effects. However, doses of 30 mg/day and higher are associated with more than 80% D_2 receptor occupancy and may have a higher likelihood of extrapyramidal adverse effects.

The relation between extrapyramidal adverse effects and the negative symptoms of schizophrenia has been studied (47). Correlation analysis after 6 weeks of treatment showed that extrapyramidal symptoms correlated significantly in patients taking haloperidol ($n = 10$) but not in those taking olanzapine ($n = 13$). The results of multiple regression analysis suggested that ratings of negative signs were confounded by extrapyramidal symptoms in patients treated with haloperidol. This confusion occurred to a lesser extent with olanzapine.

Acute dystonia

Patients taking olanzapine reported a low incidence of dystonias, which may be about 0.3% (SEDA-22, 56). In the light of two new cases of acute dystonia associated with olanzapine in patients with previous history of dystonia or parkinsonism related to antipsychotic treatment, comparative figures have been reported. Acute dystonia occurred in 1.4% of patients who took olanzapine, compared with 5.0–6.3% of those taking haloperidol (48).

Akathisia

Akathisia has been reported in 16% of patients taking olanzapine (SEDA-21, 56). Three patients developed severe akathisia during treatment with olanzapine (20–25 mg/day) (49). In two, the akathisia resolved after withdrawal of olanzapine and in one of those olanzapine was well tolerated when reintroduced in combination with lorazepam. In the third patient, the akathisia was controlled by dosage reduction. A 33-year-old man with AIDS and a prior history of extrapyramidal symptoms with both typical antipsychotic drugs and risperidone developed dose-dependent akathisia with olanzapine 15–19 mg/day; the akathisia responded to dosage reduction and beta-blockade (50).

- A 30-year-old woman with obsessive-compulsive disorder, who took olanzapine 10 mg/day titrated to 15 mg/day, developed severe akathisia after 3 weeks; the condition resolved on withdrawal and reappeared on rechallenge (51).

Restless legs syndrome shares clinical features with akathisia.

- A 41-year-old man complained of paresthesia in both legs at rest, much worse at night, and was relieved by walking around (52). The reaction occurred during the sixth week of treatment, 36 hours after an increase in dose from 10 to 20 mg/day; no other drug was administered.

Neuroleptic malignant syndrome

Several reports of neuroleptic malignant syndrome associated with olanzapine have been published (53–59).

- A 67-year-old man with bipolar disorder became confused, delirious, and manic (60). His only medications were olanzapine 10 mg/day and divalproex sodium 500 mg bd. On day 6, typical neuroleptic malignant syndrome developed. He had a fever (39.9°C), obtundation, rigidity, tremor, sweating, fluctuating pupillary diameter, labile tachycardia and hypertension, hypernatremia, and raised serum creatine kinase. Olanzapine was withdrawn and the syndrome resolved by day 12.

This patient had all of the major manifestations of this condition and there was no other likely explanation for his illness; he had taken no other drug likely to be associated with the syndrome.

- Another case of possible neuroleptic malignant syndrome associated with olanzapine has been reported in a patient who had taken clozapine for 3 years without incident (61). Symptoms suggestive of neuroleptic malignant syndrome appeared 19 days after the addition of olanzapine.

This severe reaction could have resulted from clozapine alone or from an interaction of clozapine with olanzapine.

- A 23-year-old woman had some of the features of the serotonin syndrome (mental status changes, sweating, tremor, and fever); however, the large rise in creatine kinase activity, extreme lead-pipe rigidity, and the abrupt onset suggested neuroleptic malignant syndrome rather than the serotonin syndrome (62).
- An 85-year-old man developed fever, muscle rigidity, and changes in mental state, but his serum creatine kinase activity was not increased (63).
- A 42-year-old man took olanzapine for 3 weeks and developed hyperpyrexia, tremor, labile blood pressure, and mental changes; he had a metabolic acidosis and an escalating creatine kinase activity (64).
- A 78-year-old woman developed fulminant neuroleptic malignant syndrome complicated by pneumonia while taking olanzapine and levomepromazine. When the neuroleptic drugs were withdrawn she recovered; however, when the combination was restarted later, because of severe agitation and hallucinations, the symptoms of neuroleptic malignant syndrome recurred (65).
- A 30-year-old man who had taken olanzapine 20 mg/day for 10 days developed typical neuroleptic malignant syndrome with raised body temperature (39.7°C), obtundation, tremor, rigidity, sweating, fluctuating pupillary diameter, tachycardia, labile hypertension, raised serum creatine kinase activity, and severe hypernatremia (190 mmol/l) (66).
- A 53-year-old man developed atypical neuroleptic malignant syndrome, with fever, altered mental status, and autonomic dysfunction, but without rigidity (a usual feature of this condition) while taking olanzapine (67).

The authors of the last report pointed out that such atypical cases may support either a spectrum concept of neuroleptic malignant syndrome or the theory that neuroleptic malignant syndrome secondary to atypical neuroleptic drugs

© 2006 Elsevier B.V. All rights reserved.

differs from that caused by conventional neuroleptic drugs. They suggested that more flexible diagnostic criteria than currently mandated in DSM-IV may be warranted.

Following a case of olanzapine-associated weight gain, hyperglycemia, and neuroleptic malignant syndrome in a 64-year-old woman the authors suggested that neuroleptic malignant syndrome might occur more often in patients aged 60 years or older (68). However, this patient had previously had well-documented neuroleptic malignant syndrome secondary to haloperidol, and on another occasion fluphenazine decanoate.

In contrast to these cases, a 34-year-old man, who had had clozapine-induced neuroleptic malignant syndrome, was successfully treated with olanzapine (69).

Parkinsonism

Whether treatment with olanzapine is useful in psychotic patients with neuroleptic drug-induced parkinsonism, or even in dopaminergic psychosis in Parkinson's disease, remains unclear. In a retrospective study of 19 patients with parkinsonism, 10 had some worsening of their parkinsonism after taking olanzapine, 3 had some motor benefit, and 7 had improvement in their psychosis (70).

Olanzapine was given to five patients with idiopathic Parkinson's disease and hallucinosis, and after initial treatment for 9 days, the frequency of hallucinations was significantly reduced; during this early phase of treatment, parkinsonian motor disability increased, which resulted in medication discontinuation in two of the patients (71).

Worsening parkinsonism was observed in two patients after treatment with olanzapine 5 mg/day (72). In contrast, coarse tremors induced by fluphenazine or haloperidol disappeared in three patients within days of the start of treatment with olanzapine (10 mg/day), without discontinuation or reduction in the dosage of fluphenazine or haloperidol (73). Olanzapine is active at muscarinic cholinergic receptors, which may account for the observed suppression of neuroleptic drug-induced tremor; however, two of the three patients had been taking benzatropine, an antagonist at muscarinic acetylcholine receptors, with little tremor relief, suggesting that olanzapine could suppress tremor by means of an action other than muscarinic blockade.

Whether treatment with olanzapine is useful in psychotic symptoms in patients with Parkinson's disease is unclear (SEDA-23, 66). Nine patients of twelve with drug-induced psychosis in Parkinson's disease had worsening of motor function while taking olanzapine (2.5 mg/day and increased in 2.5 mg increments as needed); this worsening was considered dramatic in six of these patients, and only one was still taking olanzapine at the time of the analysis (12 months) (74). In addition, two elderly patients, one with and one without pre-existing parkinsonism, had marked rigidity induced by olanzapine 5 mg/day (75).

Tardive dyskinesias

Anecdotal reports of olanzapine-induced tardive dyskinesia have been described as occurring in 1% of treated patients (SEDA-22, 65). Data from three pivotal trials of olanzapine (SEDA-21, 56) have been reanalysed by investigators from the manufacturers, Eli Lilly, with a focus on tardive dyskinesia (76). In a previous study, they had presented the percentage of patients developing dyskinesia without regard to the time to development: tardive dyskinesia occurred in 1.0% and 4.6% with olanzapine and haloperidol respectively (SEDA-22, 65). They subsequently calculated the number of cases per patient exposure time. When patients were stratified by abnormal involuntary movement scale (AIMS) at baseline, the incidence rate ratios for those with AIMS = 0 was 5.67 (CI = 2.45, 13.1) and for those with AIMS > 0 it was 2.55 (CI = 1.15, 5.68), both favorable to olanzapine. However, since only the highest dosages of olanzapine were as effective as haloperidol in the trials, choosing all the patients treated with olanzapine without regard to the dosages yielded an underestimation of the risk. Since olanzapine has a better profile of extrapyramidal adverse effects, it has been proposed as an alternative in the long-term treatment of schizophrenia (77).

Two cases of olanzapine-induced tardive dyskinesia have been described (78).

- A 55-year-old man with Huntington disease took olanzapine 5 mg/day and rapidly developed tardive dyskinesia (79). After 2 months, his chorea improved markedly, but orofacial dyskinesia, which he had never had in the past, appeared. Olanzapine was withdrawn, and 1 week later the orofacial dyskinesia improved while the chorea worsened.

However, olanzapine may also improve pre-existing tardive dyskinesia (SEDA-22, 65) (SEDA-23, 66) (14,80). A case of remission of tardive dyskinesia after changing from flupenthixol to olanzapine has been reported (82).

- A 59-year-old man with a long history of neuroleptic drug exposure improved markedly when given olanzapine (2.5 mg/day, titrated within 5 days to 17.5 mg/day) (14).
- Respiratory dyskinesia, which was conceptualized as a form of tardive dyskinesia, including grunting, tachypnea, and impaired vocalization, improved after the patient started to take olanzapine 2.5 mg/day (80).

Tardive dystonia

- A 40-year-old woman with bipolar disorder developed tardive dystonia after taking olanzapine 10 mg at bedtime for 7 months (82).

Seizures

Fatal status epilepticus occurred in a patient taking olanzapine with no known underlying cause or predisposing factor for seizures.

- A 41-year-old woman developed seizures that progressed to status epilepticus, and died from secondary rhabdomyolysis and disseminated intravascular coagulation (83). She had been taking olanzapine 10 mg/day for 5 months. No other toxic, metabolic, or anatomical abnormalities were identified pre- or postmortem to explain the seizures. However, her medications also included levothyroxine 0.15 mg/day, clonazepam 1.0 mg qds, and propranolol 20 mg tds.

Non-fatal seizures have also been reported.

- A 31-year-old woman with multiple psychiatric and medical disorders, including a generalized seizure

© 2006 Elsevier B.V. All rights reserved.

disorder (a probable confounding factor in this case), developed seizures when she switched from haloperidol to olanzapine (84).
- A 27-year-old woman had a seizure while taking a stable dosage of olanzapine 15 mg/day 1 day after the introduction of quetiapine 100 mg in the evening (85). She suddenly fell to the ground and had generalized shaking and inarticulate vocalization for about 30–60 seconds.

Seizures associated with olanzapine in premarketing studies have been estimated to occur in 0.88% of patients, a reported incidence probably comparable to that found with many conventional agents.

Speech dysfunction

Four patients taking olanzapine developed speech dysfunction (86). The authors suggested that the incidence of speech abnormalities may be higher than listed in the package insert of olanzapine (impairment of articulation 2% and voice alteration less than 1%).

Sleep-related eating disorder consists of partial arousal from sleep followed by rapid ingestion of food, commonly with at least partial amnesia for the episode on the next day; this disorder has been reported, purportedly for the first time, in association with an atypical neuroleptic drug (87).

- A 52-year-old man with bipolar I disorder and a family history of sleepwalking took olanzapine 10 mg/day and after several days had episodes of sleep-related eating disorder, witnessed by his wife; he had no memory of these episodes. After olanzapine withdrawal, the episodes disappeared rapidly.

Sensory systems

Esotropia (an inward squint) has been reported in a patient taking olanzapine and fluoxetine for psychosis; it resolved promptly on withdrawal of olanzapine (88).

- A 14-year-old girl with psychotic depression took fluoxetine 40 mg/day and olanzapine 5 mg/day, and 6 months later developed a severe headache, menorrhagia, diplopia, and eye irritation; her mother had also noted a "lazy eye." She had corrected visual acuity of 20/20 in both eyes, and intermittent esotropia of 14–16 diopters when fixing at 6 meters, and 8 diopters when fixing at 1/3 meters. A month later, her deviation had increased to 20 and 14 diopters respectively. Olanzapine was withdrawn and within 1 week the diplopia and headaches cleared, and the esotropia resolved.
- A 37-year-old man who had taken olanzapine 10 mg/day at bedtime for 1 week developed an excessive whitish discharge from the eyes (89).

The authors suggested that in some patients olanzapine may cause heavy mucus secretion in any of the mucus-secreting surfaces of the body.

Psychological, psychiatric

Hypofrontal symptoms, with problematic discourtesy and socially inconsiderate conduct, occurred in a 31-year-old man shortly after the introduction of olanzapine 20 mg/day; he had taken typical neuroleptic drugs for 13 years without such symptoms (90).

Anxiety and panic attacks

Anxiety has been reported as a common adverse effect (in 36% of patients) associated with olanzapine (SEDA-22, 65).

- A 36-year-old woman taking olanzapine 5 mg tds had new-onset panic attacks, with feelings of severe anxiety, shortness of breath, trembling, palpitation, and sweating, and felt that she was going to die (91). She had no previous history of panic attacks, which responded to the addition of alprazolam. The authors hypothesized that the 5-HT_2 antagonist action of olanzapine had triggered the onset of this condition.

Mania

Mania has rarely been associated with classic neuroleptic drugs, but has been described in patients treated with new antipsychotic drugs, especially risperidone (SEDA-22, 69). Several cases of mania, presumably associated with olanzapine, have been reported (60,92–99). The mechanism is not clear. It has been suggested that olanzapine could lead to manic symptoms in patients with schizophrenia because of its potent anti-$5HT_{2A}$ action.

- An 85-year-old woman with a 3-year history of delusional disorder developed florid manic symptoms, which resolved 2 weeks after withdrawal (100).
- A 36-year-old woman with paranoid schizophrenia was given olanzapine 15 mg/day and 3 weeks later she had a hypomanic episode (Young Mania Rating Scale, YMRS, score 30). The dosage of olanzapine was reduced to 10 mg/day and then to 5 mg/day, with minimal improvement of her manic symptoms (YMRS score 27). Olanzapine was withdrawn and a conventional neuroleptic drug given instead. The manic episode resolved over the next 4 days (YMRS score 5).

Obsessive-compulsive disorder

Olanzapine-induced de novo obsessive-compulsive disorder has been reported in two cases (101). One of the patients developed de novo obsessive-compulsive symptoms with the introduction of olanzapine, whereas in the other case the patient had undisturbing obsessive symptoms before olanzapine treatment.

Olanzapine-induced worsening of obsessive-compulsive symptoms has also been reported.

- Obsessive-compulsive symptoms worsened in a 35-year-old man who had had a similar response to both clozapine and risperidone in previous trials (102).
- A 35-year-old woman developed obsessive-compulsive symptoms after starting to take olanzapine (103). Her symptoms remitted after withdrawal and recurred on rechallenge, which provides evidence for de novo provocation of obsessive-compulsive symptoms by olanzapine.
- A 42-year-old woman with bipolar II disorder who had taken olanzapine 5 mg/day for 5 weeks began to have severe enduring panic-like anxiety and serious obsessive-compulsive symptoms (104).

In three other cases, olanzapine caused significant exacerbation of obsessive-compulsive symptoms in schizophrenia (two cases) and obsessive-compulsive disorder (one case) (105).

© 2006 Elsevier B.V. All rights reserved.

The aims of a prospective study in 113 consecutively hospitalized young patients (mean age 22 years) were to determine whether the severity of obsessive-compulsive symptoms differs during treatment with olanzapine or risperidone and to establish whether the duration of neuroleptic treatment is related to the severity of obsessive-compulsive symptoms (106). At baseline and week 6 assessments, obsessive-compulsive symptoms were found in 32 of 106 evaluable cases and 16 met DSM-IV criteria for obsessive-compulsive disorder, but there were no differences in patients taking olanzapine or risperidone. However, the severity of obsessive-compulsive symptoms was associated with the duration of treatment with olanzapine.

Paranoia

Paranoia and agitation occurred in two patients, a 34-year-old man and a 30-year-old woman, who had taken olanzapine for a few weeks (107). Their symptoms improved when olanzapine was withdrawn.

Endocrine

Prolactin

Olanzapine can cause increased serum prolactin concentrations and galactorrhea, but probably to a lesser extent than haloperidol (SEDA-22, 65).

- A depressed 27-year-old woman taking mirtazapine developed hyperprolactinemia and galactorrhea after taking olanzapine 10 mg/day for 5 weeks (108).
- A 19-year-old woman with mild mental retardation and a history of birth anoxia who took olanzapine 15 mg/day for 3 weeks developed euprolactinemic galactorrhea (109). Laboratory tests were all normal, including a normal thyroid-stimulating hormone concentration and a prolactin concentration of 13 ng/ml (reference range 3–30 ng/ml). She had mild to moderate akathisia. Both the galactorrhea and the akathisia abated after substitution by quetiapine.

The authors stated that the reason why galactorrhea occurred is unclear but suggested that it may have been due to structural damage and greater sensitivity to prolactin resulting from the patient's anoxia at birth.

However, paradoxical cases of improvement in galactorrhea have also been observed (SEDA-23, 67).

Two women with neuroleptic-drug induced hyperprolactinemia, menstrual dysfunction, and galactorrhea had improvement in these adverse effects during treatment with olanzapine (110).

- A 34-year-old woman, who developed amenorrhea while taking risperidone, regained her normal menstrual pattern along with a marked fall in serum prolactin concentration 8 weeks after being switched to olanzapine, whereas amantadine had failed to normalize the menses and had apparently reactivated the psychotic symptoms (111).

The authors suggested that olanzapine may offer advantages for selected patients in whom hyperprolactinemia occurs during treatment with other antipsychotic drugs.

Improvement in galactorrhea has also been observed in a case of trichotillomania refractory to a selective serotonin reuptake inhibitor (112). The patient only had a positive response with risperidone in combination with fluoxetine, but developed hyperprolactinemia and an intolerable galactorrhea. Olanzapine in combination with fluoxetine was started, with significant clinical improvement and without symptoms of galactorrhea; however, the patient had undesired weight gain of 3.6 kg after 22 weeks.

Metabolism

Diabetes mellitus

Hyperglycemia associated with olanzapine has a frequency of 1/100 to 1/1000. Hyperglycemia and diabetes have been associated with olanzapine, and published cases have suggested that these adverse effects may be caused by a mechanism related to weight gain (SEDA-23, 67) (SEDA-24, 69) (SEDA-25, 65). However, several cases of de novo onset or exacerbation of existing diabetes mellitus in patients treated with neuroleptic drugs have been reported and were not significantly related to weight gain. These included patients taking clozapine (113,114) or olanzapine (114,115).

- A 51-year-old woman with an 18-year history of type II diabetes mellitus developed glucose dysregulation with persistent hyperglycemia within 3 weeks of starting treatment with olanzapine, in the absence of weight gain (116).

The author suggested that olanzapine can cause glucose dysregulation by a mechanism other than weight gain.

- A 32-year-old African-American man with no prior history of diabetes mellitus or glucose intolerance had a raised blood glucose concentration after 6 weeks of olanzapine therapy, and required insulin (117). Olanzapine was withdrawn and blood glucose concentrations returned to normal about 2 weeks later. At rechallenge hyperglycemia occurred again.
- A 50-year-old man developed acute ketoacidosis with de novo diabetes mellitus after 8 months of adjunctive olanzapine (118). His dosage was then gradually titrated to 30 mg/day over 6 months, and after withdrawal of olanzapine his diabetes mellitus disappeared completely.
- A 31-year-old man taking olanzapine 10 mg/day, who had no family history of diabetes and had never had any laboratory evidence of diabetes or glucose intolerance, developed diabetic ketoacidosis; obesity was the only predisposing factor, his BMI being 40 kg/m^2 (119).
- A 45-year-old man with a 4-year history of diet-controlled diabetes had hyperglycemia with polyuria, polydipsia, and blurred vision associated with the use of olanzapine 10 mg/day. Within 1 week after olanzapine was withdrawn his blood glucose returned to normal and insulin was discontinued.
- A 54-year-old woman developed severe glucose dysregulation with exacerbation of type 2 diabetes 12 days after starting to take olanzapine 10 mg/day; she also gained 13 kg (120).

The effects of olanzapine on glucose–insulin homeostasis have been studied in 14 patients in an attempt to elucidate the possible mechanisms of olanzapine-associated weight gain (121). Olanzapine caused weight gain of 1–10 kg in

© 2006 Elsevier B.V. All rights reserved.

12 patients and raised concentrations of insulin, leptin, and blood lipids, as well as insulin resistance; three patients developed diabetes mellitus. The authors concluded that both increased insulin secretion and hyperleptinemia may be mechanisms behind olanzapine-induced weight gain. They also suggested that the metabolite *N*-desmethylolanzapine has a normalizing effect on the metabolic abnormalities.

In an open study in seven men and four women taking olanzapine (mean daily dose 12 mg and mean treatment duration 23 months), although the mean fasting triglyceride concentrations and mean fasting plasma glucose concentrations were similar to those found in the previous study, the mean fasting insulin concentrations were lower (143 pmol/l versus 228 pmol/l), and four of the subjects had hyperinsulinemia, compared with ten in the other study (122). However, the small sample sizes precluded any clear conclusions.

Susceptibility factors, such as family history, obesity, and concomitant medications can predispose an individual taking olanzapine to diabetes mellitus. New-onset diabetes mellitus developed after olanzapine was given to a 31-year-old man and a 44-year-old man (123). In both cases, the family history included diabetes mellitus, type unknown. The patients were taking various psychotropic drugs. In the first case body weight increased by about 12 kg (BMI 32 kg/m^2) 6 weeks after starting olanzapine, when his diabetes mellitus started; in the second case (BMI 26 kg/m^2, weight 81 kg) the previous weight was unknown.

Olanzapine-induced non-ketotic hyperglycemia has also been reported in the absence of obesity (124).

- A non-obese 51-year-old man without a history of diabetes mellitus had a serum glucose concentration of 89 mmol/l and was non-ketotic. Treatment with olanzapine had been started less than 6 months before; about 2 months before the event, his blood glucose concentration was 6.0 mmol/l, and 8 days after withdrawal the glucose concentration returned to normal; he no longer required insulin nor any other hypoglycemic drug.

The authors suggested that olanzapine can cause hyperglycemia by a mechanism other than weight gain.

Glucose concentrations have been studied in 47 patients with non-responsive schizophrenia taking olanzapine (125). Three of them, who had taken olanzapine for 3–6 months, had persistently high blood glucose concentrations. However, this is similar to what would be expected on the basis of the prevalence of diabetes mellitus in US adults.

Death from olanzapine-induced hyperglycemia has been reported (126).

- A 31-year-old man took olanzapine 10 mg/day for 1 week, and his fasting blood glucose rose to 11 mmol/l (200 mg/dl). For more aggressive treatment of his psychosis, the dosage of olanzapine was increased to 20 mg/day, and his fasting blood glucose rose to 16 mmol/l (280 mg/dl). He became progressively weaker and developed polydipsia and polyuria and died 3 weeks after starting to take olanzapine. He had no personal or family history of diabetes mellitus and was taking no other drugs at the time of his death. Death was attributed to hyperosmolar non-ketotic hyperglycemia.

The authors recommended including vitreous glucose and gammahydroxybutyrate analysis as part of postmortem toxicology work-up when the drug screen reveals either olanzapine or clozapine.

On the other hand, seven cases of asymptomatic lowered blood glucose concentrations have also been reported in patients with Tourette's syndrome who were taking olanzapine (mean dose 12 mg/day) during an 8-week, open-label trial (127). The mean serum glucose concentration was 4.8 mmol/l at baseline and 4.1 mmol/l during the study; the average weight gain was 4.5 kg. The authors suggested that increased insulin release may have been responsible for the changes observed; however, non-insulin mechanisms, such as a low carbohydrate intake, may also have played a role.

Weight gain

Significant weight gain occurs more often with olanzapine than with either haloperidol or risperidone (SEDA-22, 64).

Weight gain of 38.5 kg occurred in a 15-year-old adolescent who had taken olanzapine 5–10 mg/day for 14 months (128).

The medical records of ten patients with a DSM-IV diagnosis of cluster B personality disorder (narcissistic personality disorder) who had taken olanzapine 2.5–20 mg/day for 8 weeks have been reviewed (129). The mean Social Dysfunction and Aggression Scale score was 29 for the 8 weeks before olanzapine therapy and improved to 14 after 8 weeks of treatment. Five of the ten patients developed severe weight gain.

In 15 patients with excessive weight gain associated with olanzapine the mean weight gain was 11 (range 3.6–25) kg and the mean duration of treatment was 7 (range 2–11) months (130).

In a retrospective study of 16 patients (7 men, 9 women) taking olanzapine (mean dose 14 mg/day, range 10–30) there was weight gain of over 7% in 15 of them; no change in diet, access to food, or change in exercise pattern had occurred (131).

Weight gain was observed in nine patients (seven men, two women, mean age 41 years) treated with olanzapine (mean dose 19, range 10–30, mg/day) (132). The patients had a mean weight gain of 9.9 kg and triglyceride concentrations (reference range 0.3–2.3 mmol/l) increased from a mean of 1.9 mmol/l (range 0.8–4.3) to a mean of 2.7 mmol/l (range 1.5–4.2).

Average weight gain was 8 kg in patients with refractory schizophrenia ($n = 8$) who were taking olanzapine in high doses (20–40 mg over an average of 40 weeks) (133).

In a retrospective chart review, 20 consecutive patients, who requested a switch from their previous neuroleptic drug therapy to olanzapine, were monitored over 12 months to note changes in weight. After 12 months of olanzapine treatment, 13 had a mean weight gain of 7.3 kg and three had no significant change in weight (134). Paradoxically, four patients lost weight when taking olanzapine, and the authors claimed that this is the first report of patients who had weight loss with olanzapine, although in these cases it is difficult to determine which factors contributed to the weight loss.

Taking advantage of this effect on weight, olanzapine 10 mg has been used in an open trial in 20 patients with anorexia nervosa (135). Of the 14 patients who completed

© 2006 Elsevier B.V. All rights reserved.

the 10-week study, 10 gained an average of 3.9 kg and three of these attained their ideal body weight. The other four patients who completed the study lost a mean of 1.0 kg. The most common adverse effects were sedation ($n = 13$), headache ($n = 5$), fatigue ($n = 4$), and hypoglycemia ($n = 4$).

The genetic basis of some reactions associated with neuroleptic drugs is of particular interest. Different polymorphisms have been studied in connection with atypical neuroleptic drug-induced weight gain (SEDA-26, 57). The relation between the CYP2D6 genotype and weight gain in patients taking atypical neuroleptic drugs has been addressed in a study in 11 Caucasian patients taking a fixed dose of olanzapine 7.5–20 mg/day for up to 47 weeks (136). They had their DNA analysed for the CYP2D6*1, CYP2D6*3, and CYP2D6*4 alleles; six had two *1 alleles and the other five had either *1/*3 or *1/*4. Subjects with a heterozygous genotype (*1/*3 or *1/*4) had a statistically significantly larger percentage change in body mass index than those who were homozygous for the *1 allele.

Histamine H_2 receptor antagonists, like nizatidine, can control appetite in overweight patients (137).

- A 23-year-old man, who had had repeated episodes of weight gain during olanzapine treatment, had good control and subsequent weight reduction after 4–5 weeks of therapy with nizatidine.

Electrolyte balance

Hyponatremia has been reported in patients treated with olanzapine (138).

Hematologic

Neutropenia and agranulocytosis

Although hemotoxicity was not observed during premarketing studies of olanzapine (139), cases of neutropenia (neutrophil count below 1.5×10^9/l) (140) or agranulocytosis (neutrophil count below 0.5×10^9/l) (141) have been published.

Six cases of hematological reactions, including leukopenia, granulocytopenia, and neutropenia, were reported in Canada in the 2 years after the approval of the drug in 1996 (142).

- A 20-year-old man with schizophrenia took olanzapine 5 mg/day increasing to 10 mg/day after 3 days (143). His total leukocyte count fell to 3.9×10^9/l on the fifth day, with an absolute neutrophil count of 1.52×10^9/l. Olanzapine was withdrawn and the leukocyte count normalized within 72 hours. A few days later rechallenge was positive. He was given lithium 900 mg/day and continued to take olanzapine 20 mg/day.

Mechanism

Some explanations of the lower risk of agranulocytosis have been advanced after an in vitro cytotoxicity study (144). Like clozapine, olanzapine is oxidized to a reactive nitrenium ion by HOCl, the major oxidant produced in activated neutrophils. However, the olanzapine-reactive metabolite has a lower propensity to cause toxicity to human neutrophils, monocytes, and HL-60 cells than the reactive clozapine nitrenium ion. The lower toxic potential of the olanzapine reactive metabolite, in conjunction with the lower therapeutic plasma concentrations of olanzapine compared with clozapine, may help to explain this difference between the drugs.

Dose relation

In three cases of leukopenia with olanzapine, a reduction in dose was followed by normalization of the leukocyte count and allowed continued treatment (145). Two of the patients had a previous history of neutropenia and agranulocytosis associated with typical neuroleptic drugs and the third developed neutropenia for the first time while taking olanzapine.

Time course

Of two cases of olanzapine-induced neutropenia, one occurred 17 days after the first dose of olanzapine and the other more than 5 months after the first dose (140); in the second patient, re-exposure to olanzapine caused the neutrophil count to fall again. In neither case was there evidence of infection, and the white blood cell counts increased immediately to the reference ranges after withdrawal of olanzapine, no special treatment being necessary. In addition, two cases of reversible leukopenia during treatment with olanzapine have also been reported (146).

Susceptibility factors

Genetic

Susceptibility factors for neutropenia and agranulocytosis have been investigated in two patients, one of whom had neutropenia after taking other drugs and one of whom was also taking amitriptyline (147). The risk of clozapine-induced agranulocytosis was significantly higher in patients with the HLA haplotypes DQB*01, DQB*05, and DQB*02. One of the patients who had neutropenia had HLA-DQB*05 and both patients had haplotype HLA-A2.

If there is an HLA association for olanzapine, it seems to be different from the HLA antigens incriminated for clozapine (SEDA-25, 66).

- In a 46-year-old man taking olanzapine 10 mg/day, leukopenia and neutropenia were associated with HLA types A1 24, B7, B35, DRB1*15, DRB1*11, DRB3*01–03, DRB5*01–02, a haplotype distinct from that previously observed in clozapine-induced hemotoxicity (148).

Cross-reaction with clozapine

Olanzapine-induced blood disorders have been reviewed and compared with clozapine-induced agranulocytosis (149). Whether clozapine-induced granulocytopenia or leukopenia predisposes a patient to hematological adverse effects during treatment with olanzapine is unclear: three patients who had previously stopped clozapine owing to hematologic adverse effects had improvement with olanzapine that equated to a 16–31 point reduction in rating scale scores during 1 year of follow-up without any hematological abnormalities (150). In contrast, one case associated with clozapine worsened when olanzapine was given (151).

- In a 31-year-old woman clozapine monotherapy 75 mg/day caused neutropenia (neutrophil count 1.1×10^9/l);

© 2006 Elsevier B.V. All rights reserved.

5 days after clozapine withdrawal the neutrophil count normalized (2.6×10^9/l). Olanzapine was then introduced at 5 mg/day and the next day increased to 10 mg/day. After a week the neutrophil count fell to 0.9×10^9/l and olanzapine was withdrawn. The neutrophil count was normal 4 weeks after olanzapine withdrawal.

In another case, olanzapine caused agranulocytosis after clozapine had had no effect on the white cell count (141).

- A 27-year-old man taking clozapine, benperidol, and risperidone developed severe extrapyramidal adverse effects and had insufficient antipsychotic effects and was given olanzapine, rapidly increasing to 40 mg/day. After 9 days of treatment with olanzapine, his total white cell count fell from 5.8×10^9/l to 3.4×10^9/l, and olanzapine was withdrawn; 3 days later his neutrophil count was 0.39×10^9/l. He developed a fever of 39.5°C and was treated with granulocyte colony-stimulating factor.

Prolonged granulocytopenia due to olanzapine occurred in a 39-year-old woman after clozapine withdrawal (152). In contrast, two patients with severe clozapine-induced granulocytopenia and agranulocytosis were successfully treated with olanzapine in a dose greater than 25 mg/day (153). Furthermore, a 65-year-old man who had previously developed leukopenia and neutropenia, first with clozapine and then also with risperidone, took olanzapine (20 mg/day for 2 years with only a transient reduction in leukocyte and neutrophil (but not erythrocyte or platelet) counts) during a flu-like illness (154).

Seven patients, after developing eosinophilia ($n = 1$), agranulocytosis ($n = 2$), or neutropenia ($n = 4$) during neuroleptic drug therapy, were given olanzapine, with improvement and without evidence of blood dyscrasias (155,156). In a review it was suggested that this might reflect the fact that olanzapine shares many pharmacological properties with clozapine, which might make it more likely to prolong the clozapine-induced effect on white cells (157).

Thrombocytopenia

Thrombocytopenia, with a platelet count of 20×10^9/l, possibly associated with olanzapine and subsequently with benzatropine mesylate, has been reported, purportedly for the first time, in a 38-year-old woman (158).

Pancytopenia

Pancytopenia associated with exacerbation of motor disability induced by olanzapine (10 mg/day) in a patient with Parkinson's disease has been reported (159). Olanzapine withdrawal increased the neutrophil, total granulocyte, erythrocyte, and platelet counts to normal in 3 weeks, while the motor disability improved only moderately.

Eosinophilia

Eosinophilia occurred in a 30-year-old man taking olanzapine 22.5 mg/day (160). After 5 weeks, the white blood cell count increased to 15×10^9/l, of which 7.9×10^9/l were eosinophils. Olanzapine was withdrawn, and 5 weeks later the white blood cell count was 8.5×10^9/l with 14% eosinophils.

Gastrointestinal

While hypersalivation is a common adverse effect of clozapine (SEDA-22, 60), dry mouth is associated with olanzapine (SEDA-21, 57) (SEDA-22, 64). Drooling as an adverse effect of olanzapine has been reported in a 20-year-old woman (161). Excessive, chalky-white, frothy, sticky salivation has been reported in a 27-year-old man who had taken olanzapine 10 mg/day at bedtime for 4 days (89).

Pancreas

Acute pancreatitis has been reported in a patient who did not take alcohol and who had undergone a cholecystectomy in the past; other medical causes of pancreatitis were ruled out (162).

Acute pancreatitis was subsequently discussed (163,164). The main points of debate were the interpretation of attributability and the use of the Naranjo probability scale in a case in which the patient was taking another drug that could not be completely excluded as at least a partial contributor to the acute pancreatitis.

Urinary tract

Urinary incontinence has been attributed to olanzapine.

- A 61-year-old man with bipolar disorder treated with olanzapine and lithium developed urinary incontinence 4 days later (165). He was successfully treated with ephedrine 25 mg/day.

The authors suggested that the alpha-blocking effect of olanzapine was involved and that an alpha-adrenoceptor agonist (such as ephedrine) would reduce urinary incontinence in such cases.

Sexual function

Priapism has been attributed to olanzapine.

- A 68-year-old taking olanzapine 5 mg at bedtime developed priapism and required emergency surgery (166).
- In a 46-year-old man taking olanzapine 15 mg/day, priapism remitted after withdrawal (167).
- A 27-year-old man had taken olanzapine 15 mg at bedtime for 12 days for hallucinations and then developed priapism (168). Partial detumescence was followed by recurrence, and he required an operation to insert a glandular shunt. He subsequently required mechanical support to achieve an erection.
- Recurrent priapism during clozapine and then olanzapine therapy occurred in a 43-year-old man (169).
- A 26-year-old man, who had previously taken a variety of psychotropic medications, including typical neuroleptic drugs and risperidone, without sexual adverse effects, took olanzapine 10 mg at bedtime (170). Soon after, he developed priapism; 24 hours after withdrawal of olanzapine, the adverse effect disappeared.
- A 51-year-old man developed priapism 16 hours after attempting suicide by taking olanzapine 100 mg and gabapentin 1500 mg (171). Detumescence was produced by two injections of lidocaine and 8 hours later an intracorporeal shunt.

© 2006 Elsevier B.V. All rights reserved.

Immunologic

Hypersensitivity syndrome, defined as a drug-induced complex consisting of fever, rash, and internal organ involvement, has been associated with olanzapine (172).

- A 34-year-old man took clozapine for several months, but developed a cardiomyopathy. Clozapine was withdrawn and olanzapine 20 mg/day was given instead; 60 days later he developed a recurrent high fever, rash, and pruritus. There was bilateral periorbital edema and generalized erythroderma without target lesions or bullae and no mucosal involvement. He also had an eosinophilia and hepatitis.

Drug Administration

Drug overdose

Fatal overdoses in which novel antipsychotic drugs were the sole ingestant have been reported with olanzapine (173). In two cases blood olanzapine concentrations were 237 ng/ml in one and 675 ng/ml in the other (174). The usual target range for plasma olanzapine concentrations is 9–23 ng/ml.

- A 59-year-old woman died after taking an unknown quantity of olanzapine; the blood concentration was 4900 ng/ml (173).
- A 43-year-old man (175) died within hours of ingestion of 600 mg of olanzapine; the drug concentration in a postmortem analysis of the blood was 12 400 ng/ml.
- A 24-year-old man took a presumed cumulative dose of 420 mg of olanzapine and 10 mg of alprazolam (176). He had a cardiac arrest with asystole, from which he was initially resuscitated. Recurrent cardiac arrest, probably caused by hyperkalemia, occurred in the intensive care unit and he died within 1 hour.

Several non-fatal cases have also been published.

- Profound central nervous system depression and tachycardia without other dysrhythmias occurred within 2 hours of an olanzapine overdose (800 mg; the highest serum concentration was 991 ng/ml) (177). The patient recovered after intubation, gut decontamination, and supportive care.
- A patient took an overdose of 1110 mg of olanzapine and had tachypnea, sinus tachycardia, fluctuating blood pressure, and brief hypoxemia; respiratory and cardiovascular function returned to normal within 16 hours of ingestion with minimal interventions (178).
- A patient attempted suicide by taking 120 mg of olanzapine, but had no serious clinical adverse effects, and only fatigue, dizziness, and headache (179).
- A 22-year-old man took about 800 mg of olanzapine; his olanzapine serum concentration reached a maximum of 200 ng/ml (180). His vital signs were stable at all times, but he started to become progressively somnolent, with short periods of aggressive agitation. Gastric lavage was performed and after 10 hours he was alert and oriented.

In four cases of overdose with up to 1000 mg there was significant central nervous system depression and miosis after acute overdosage of olanzapine (181). Olanzapine concentrations were over 250, 59, 54, and 151 ng/ml. All four patients recovered with supportive care and two required advanced airway support. The authors pointed out that all the patients had marked miosis and depressed mental status, findings that are usually associated with intoxication with opioids or alpha$_2$-adrenoceptor agonists.

Several cases of olanzapine overdose have been reported in children.

- An 11-kg, 1-year-old child developed agitation followed by prolonged lethargy after accidental ingestion of an unknown amount of olanzapine (182).
- An 18-month-old boy took 30–40 mg of olanzapine and had respiratory distress and mental status changes (183).
- Prolonged central nervous system depression occurred after a medication error in a 17-kg, 6-year-old girl who was given Zypresa (olanzapine 10 mg) instead of Zyrtec (cetirizine 10 mg) (184).
- In a dispensing error a 14-year-old boy was given olanzapine 80 mg/day, eight times the recommended dose in adults (185).
- A 2.5-year-old boy took one or two tablets of 7.5 mg and exhibited agitation, aggressive behavior, miosis, hypersalivation, tachycardia, and ataxia (186). A similar dose was well tolerated by an 8-year-old autistic boy (187).

Drug–Drug Interactions

General

Pharmacokinetic and pharmacodynamic profiles of olanzapine have been extensively reviewed (188). Olanzapine does not inhibit CYP isozymes, and no clinically significant metabolic interactions were found of olanzapine with aminophylline, biperiden, diazepam, ethanol, fluoxetine, imipramine, lithium, or R/S-warfarin.

Carbamazepine

Patients co-medicated with carbamazepine had a median dose-corrected plasma olanzapine concentration 36% lower than those taking monotherapy (189).

The pharmacokinetics of two single therapeutic doses of olanzapine have been determined in 11 healthy volunteers, before and after carbamazepine (190). The dose of olanzapine given after pretreatment with carbamazepine for weeks was cleared more rapidly than olanzapine given alone. Olanzapine C_{max} and AUC were significantly lower after the second dose, the half-life was significantly faster, and the clearance and volume of distribution were significantly increased. This interaction may be attributed to induction of CYP1A2 by carbamazepine, leading to increased first-pass and systemic metabolism of olanzapine.

The effect of carbamazepine on the glucuronidation of olanzapine has been studied in 30 patients taking olanzapine monotherapy (dosage 2.5–30, median 15, mg/day) and in 15 patients being co-medicated with carbamazepine (dosage 5–50, median 20, mg/day) (191). The median ratio of unbound olanzapine concentration to daily dose in the carbamazepine group was 38% lower than in the monotherapy group, confirming that carbamazepine accelerates the metabolism of olanzapine. Furthermore, in the carbamazepine group, the median glucuronidated olanzapine fraction was 79% of the unbound fraction,

© 2006 Elsevier B.V. All rights reserved.

compared with 43% in the monotherapy group, which suggests that an increased rate of olanzapine glucuronidation contributes to the increased rate of metabolism of olanzapine induced by carbamazepine.

Ciprofloxacin

The plasma concentration of olanzapine doubled in a patient who also took ciprofloxacin, a potent inhibitor of CYP1A2 (192). The magnitude of the interaction was surprising, because available data suggest that CYP1A2-mediated oxidation of olanzapine accounts for only a small portion of the biotransformation of olanzapine relative to glucuronidation.

Diazepam

There were orthostatic changes when olanzapine and diazepam were co-administered (188).

Ethanol

There were orthostatic changes when olanzapine and ethanol were co-administered (188).

Inhibitors of CYP2D6

Of 56 patients, 22 of whom took olanzapine monotherapy and the rest took other psychotropic drugs, those co-medicated with inhibitors of CYP2D6 and other drugs had a median dose-corrected concentration about 40% higher than those taking monotherapy.

Selective serotonin re-uptake inhibitors (SSRIs)

Olanzapine is metabolized by CYP1A2, and fluvoxamine, which inhibits CYP1A2, increases plasma olanzapine concentrations (SEDA-24, 71).

- A 21-year-old woman had a very high olanzapine plasma concentration (120 ng/ml) during co-administration of fluvoxamine 150 mg/day and olanzapine 15 mg/day; her symptoms included slight tremor, rigid movements, and general discomfort (193).

Pharmacokinetic and pharmacodynamic profiles of olanzapine have been extensively reviewed (188). Olanzapine does not inhibit CYP isozymes, and no clinically significant metabolic interaction was found with fluoxetine.

Tricyclic antidepressants

Clomipramine and olanzapine are both metabolized by CYP1A2 and CYP2D6, and it is therefore possible that raised concentrations of both compounds can result from co-administration.

- Seizures in a 34-year-old man were attributed to an interaction of olanzapine with clomipramine (194).

A pharmacodynamic interaction occurred between olanzapine and imipramine (188).

Smoking

Plasma concentrations of olanzapine and clozapine are lower in smokers than in non-smokers, mainly because of induction of CYP1A2. Two patients who smoked tobacco and cannabis have been reported (195). One took olanzapine and had extrapyramidal motor symptoms after reducing his consumption of tobacco. The second, who was taking clozapine, developed confusion after he stopped smoking tobacco and cannabis, related to increased clozapine concentrations. The authors recommended that when patients stop smoking, appropriate dosage adjustments should be made to ensure that the plasma neuroleptic drug concentrations remain within the usual target range.

Olprinone

See also Phosphodiesterase type III, selective inhibitors of

General Information

Olprinone is an inhibitor of phosphodiesterase type III, and has a positive inotropic effect. It is given intravenously and is mostly eliminated by the kidneys. Its pharmacological effects have been reviewed (1). Its major adverse effects are cardiac dysrhythmias and thrombocytopenia, the latter with a reported incidence of 0.43%.

Reference

Omalizumab

See also Monoclonal antibodies

General Information

Omalizumab (formerly rhuMab-E25) is a humanized monoclonal antibody against IgE, which blocks the interaction of IgE with mast cells. Several phase I and phase II trials have demonstrated its efficacy in patients with allergic asthma (1–4).

In a placebo-controlled study of subcutaneous omalizumab (50, 150, and 300 mg before the ragweed season and every 3 or 4 weeks during the pollen season) in 536 patients with seasonal allergic rhinitis, injection site reactions were mild and infrequent, there were no clinically significant alterations in laboratory values, and anti-idiotypic antibodies to omalizumab were not detected; there was no evidence of immune complex-related adverse events (5–7).

In another placebo-controlled trial in 525 patients with severe asthma, the adverse effects profiles were similar in the treatment and placebo groups (8).

In an extension study in 225 children there were no anaphylactic reactions or adverse events suggestive of serum sickness or immune complex formation; anti-omalizumab antibodies were not detected (9). In cases of re-treatment there were no severe adverse events related to omalizumab (10).

Organs and Systems

Skin

The safety of subcutaneous omalizumab has been assessed in 334 boys and premenarchic girls aged 6–12 years with moderate to severe allergic asthma requiring inhaled glucocorticoids in a randomized, placebo-controlled, double-blind trial (11). There were no serious treatment-related adverse events, and the frequencies of most adverse events were similar with omalizumab and placebo. However, urticaria was more frequent with omalizumab (4 versus 0.9%). It usually resolved spontaneously or with antihistamine therapy and did not recur with subsequent treatment. Urticaria was also reported in a small number of adults (0.5%) given omalizumab for allergic rhinitis (12).

Omeprazole

See also Proton pump inhibitors

General Information

Omeprazole is a proton pump inhibitor. Headache, skin rash, and diarrhea have all been recorded by adverse event registries sufficiently often to suggest causal relations (1). Omeprazole is a modest inhibitor of CYP isoforms. Interactions are less likely than with cimetidine and are probably of no practical importance. However, omeprazole reduces the absorption of drugs that require a low gastric pH (ketoconazole, iron salts, ampicillin) and can inhibit the hepatic clearance of some drugs (diazepam, warfarin, phenytoin) (2).

To test whether omeprazole accelerates healing of standardized gastroduodenal lesions in the presence of diclofenac, 12 healthy volunteers took consecutive 2-week courses of omeprazole 40 mg/day or placebo, with diclofenac given in the second week of each course, in a double-blind, crossover study (3). Omeprazole did not accelerate the healing of pre-existing mucosal lesions or prevent the development of small diclofenac-induced mucosal lesions. Omeprazole increased serum gastrin in all subjects.

Organs and Systems

Psychological, psychiatric

- Delirious psychosis has been attributed to intravenous omeprazole 40 mg bd in a 77-year-old woman with Guillain–Barré syndrome, who also had *Helicobacter pylori*-associated gastritis (4). Delirium developed 2 days after omeprazole was begun and resolved completely after drug withdrawal.

Metabolism

In patients with Zollinger–Ellison syndrome, omeprazole causes significant weight gain, perhaps because of shifts in hormonal balance (SEDA-17, 419) (5,6).

Electrolyte balance

Hyponatremia caused by omeprazole has been reported in a 78-year-old woman who was taking omeprazole 20 mg/day for esophagitis, in a 74-year-old man (7), and in an elderly alcoholic (SEDA-17, 419).

Hematologic

- Iron deficiency anemia has been reported in a 49-year-old man eating a normal diet who had taken omeprazole 40 mg/day for 3 years (8). Two months after withdrawal of omeprazole his anemia improved and his serum ferritin concentration normalized after 4 months. During this period he took his usual diet and was not given any iron supplements.

Prolonged suppression of gastric acid, which plays an important role in the absorption of non-heme iron, was thought to have led to iron deficiency.

Hemolytic anemia occurred with recovery after withdrawal of omeprazole (SEDA-17, 419).

Agranulocytosis in a kidney transplant recipient (9) and neutropenia (10) have been associated with omeprazole.

Thrombocytopenia occurred in a man with a history of chronic alcoholism taking omeprazole; the blood disorder appeared on the fourth day of treatment and resolved after drug withdrawal (11,12).

Gastrointestinal

Moderate nausea, diarrhea, or abdominal pain can occur in patients taking omeprazole (13). There is an increased incidence of the severe interstitial and atrophic forms of gastritis, associated with moderate hypergastrinemia and hyperplasia of the argyrophil cells (1). This is not necessarily an adverse effect; it could represent the natural history of chronic gastritis associated with peptic ulcer disease.

Gastric polyps have been observed in a number of patients, but they disappear spontaneously during follow-up (SEDA-18, 373). Most or all patients taking omeprazole have a non-pathological "pseudohypertrophy" of the parietal cells.

The possibility that, as with H2 receptor antagonists, achlorhydria will increase the risk of gastrointestinal infection has been advanced both on theoretical grounds and in the light of a number of cases, including one of esophageal candidiasis (SED-12, 944) (14,15).

Of 33 patients with severe reflux esophagitis prospectively followed up for 5–8 years six were positive for *H. pylori* (16). There was no evidence of significant enterochromaffin-like cell hyperplasia, gastric atrophy, intestinal metaplasia, dysplasia, or neoplastic changes during 185 patient follow-up years during which 137 gastric biopsies were taken.

Omeprazole 20 mg/day and famotidine 20 mg bd for 4 weeks had equivalent ulcer healing rates in a randomized, endoscopist-blinded study in 16 patients who had undergone endoscopic mucosal resection for early gastric cancer (17). Although concentrations of fibroblast growth factor-2 in biopsy specimens were similar in the two treatment groups, fibromuscular hyperplasia was significantly greater in the omeprazole group on day 28.

Liver

Hepatitis occasionally occurs with omeprazole.

- Severe hepatitis occurred on two occasions when a 30-year-old man with advanced renal insufficiency secondary to diabetic neuropathy took omeprazole for esophagitis (18).
- A 34-year-old woman developed jaundice 11 days after starting to take omeprazole for ulcer dyspepsia (19). Her liver function tests suggested acute hepatitis with large rises in transaminases. Investigations excluded virus infections, autoimmune disorders, copper overload, and alpha$_1$ antitrypsin deficiency. On withdrawal of omeprazole, the transaminases gradually normalized.

© 2006 Elsevier B.V. All rights reserved.

Urinary tract

There have been occasional reports of acute interstitial nephritis attributed to omeprazole (SEDA-20, 318).

- A 31-year-old pregnant woman (35 weeks gestation) developed hypercalcemia and interstitial nephritis possibly associated with omeprazole 20 mg/day for over 8 weeks (20). Investigations excluded other causes of hypercalcemia. She recovered after drug withdrawal and treatment with glucocorticoids.
- Renal insufficiency due to acute interstitial nephritis occurred in a 73-year-old man who had taken omeprazole 40 mg/day for 4 months for severe reflux esophagitis (21). He recovered completely after withdrawal of omeprazole.
- A 36-year-old woman who had taken omeprazole 20 mg/day for 3 months developed acute interstitial nephritis (22). The drug was withdrawn and she made a full recovery after 4 weeks of glucocorticoid therapy.

Skin

Cutaneous adverse reactions attributed to omeprazole are uncommon; they include rashes, urticaria, angioedema, acute disseminated epidermal necrolysis, lichen spinulosus, and contact dermatitis.

- Erythroderma has been reported in a 58-year-old woman with scleroderma who had taken omeprazole 20 mg/day for 6 months (23). She made a full recovery after omeprazole was withdrawn. She was then given pantoprazole 40 mg/day, which was well tolerated.

Hair

Several well-documented case reports have suggested an association between omeprazole and diffuse hair loss (SEDA-22, 392), in one case at least confirmed by rechallenge (24).

Sexual function

Painful erections occurred after each dose of omeprazole in an elderly man (SEDA-17, 419).

Reproductive system

There have been occasional reports of gynecomastia in patients taking omeprazole, regressing after drug withdrawal (25).

Immunologic

Angioedema and urticaria triggered by omeprazole, but not by the enteric granules devoid of the capsule shell, has been described (SEDA-18, 373).

- Cutaneous leukocytoclastic vasculitis has been reported in a 71-year-old woman with epigastric pain who had taken omeprazole 20 mg/day for 4 weeks (26). She made a full recovery after omeprazole was withdrawn.

Anaphylaxis has been attributed to omeprazole (27).

- A 35-year-old alcoholic with pancreatitis developed anaphylaxis after an intravenous infusion of omeprazole. He had raised serum tryptase activity 6 hours after the onset of anaphylaxis. Total serum IgE concentrations were also raised. Intradermal tests 2 months later were positive for both omeprazole and lansoprazole, suggesting cross-reactivity.

Yersinia enterocolitica septicemia occurred in a patient taking omeprazole and heavy oral iron supplementation (28). The authors suggested that intra-luminal iron together with a raised intestinal pH resulting from omeprazole may have contributed to the enhanced proliferation and dissemination of this organism. Since treatment with omeprazole arrests the secretion of gastric acid, it increases the risk of overgrowth with small intestinal bacteria in patients with scleroderma (SEDA-20, 318).

Susceptibility Factors

Age

The use of omeprazole in the treatment of acid-related disorders in children has been reviewed (29). Different formulations have been used in children aged 2 months to 18 years for the treatment of erosive esophagitis, gastric and duodenal ulcer, *H. pylori* infection, and related conditions in dosages of 5–80 mg/day (0.2–3.5 mg/kg/day). The initial dose most consistently reported to heal esophagitis and relieve symptoms of gastroesophageal reflux disease appears to be 1 mg/kg/day. Omeprazole was well tolerated during both acute and chronic use.

Omeprazole, in a starting dose of 0.7 mg/kg/day, was effective in the treatment of severe esophageal reflux after failed fundoplication in 18 children (mean age at presentation 7.8 years) over a mean follow-up period of 4.4 years (30). It was also well tolerated. A hyperplastic polyp was noted in one child after 38 months of treatment and persisted without any dysplastic change. One to three gastric nodules were seen in three children after a mean of 45 months; histology of the nodules showed only mucosal edema.

Hepatic disease

The pharmacokinetics of omeprazole during intravenous infusion in patients with varying degrees of liver dysfunction have been examined in an open study in 13 patients with hepatic cirrhosis (31). Each patient received a bolus of omeprazole 80 mg over 30 minutes, followed by a continuous infusion of 8 mg/hour for 47.5 hours. Exposure to omeprazole after intravenous administration was higher in patients with liver dysfunction. However, even in patients with severely impaired liver function, the plasma concentration of omeprazole did not change by more than 100% and the drug was well tolerated. Adverse effects were infrequent and occurred in three patients: epigastric pain, arthralgia, and hepatic encephalopathy; the last was probably unrelated to the drug.

Drug Administration

Drug formulations

To investigate the pharmacokinetics of omeprazole MUPS tablets and its encapsulated form, 38 healthy

© 2006 Elsevier B.V. All rights reserved.

male volunteers were given a single 20 mg oral dose of each formulation in a crossover study (32). Encapsulation did not influence the extent and rate of absorption of the drug, demonstrating bioequivalence. Both formulations were well tolerated. The most commonly reported adverse effect with both formulations was headache.

Drug dosage regimens

The effect on serum gastrin concentrations of omeprazole 20 mg/day and 20 mg on alternate days given long term has been studied in 53 patients with reflux esophagitis in a controlled trial (33). The mean serum gastrin concentration was significantly raised in the first group. Gastrin concentrations in the alternate day treatment group were similar to controls who did not take omeprazole.

Drug–Drug Interactions

Ciclosporin

Omeprazole increases ciclosporin blood concentrations (SEDA-17, 420).

Clarithromycin

In an open, randomized, crossover study of the effects of oral omeprazole 20 mg/day for 7 days on the distribution of co-administered clarithromycin in the gastric juice in 18 male volunteers with *H. pylori*, short-term omeprazole increased the amount of clarithromycin transferred to the gastric juice, confirming synergy between these two drugs (34).

Digoxin

In an acid-free stomach a different and shorter-acting pattern of metabolites of digoxin is produced, which could change its duration of action (35).

Furazolidone

The effect of acid secretion blockade by omeprazole 20 mg/day for 5 days on the systemic availability of oral furazolidone has been investigated in a randomized, crossover study in 18 healthy volunteers (36). Omeprazole significantly reduced the systemic availability of furazolidone. This could partially explain reports of modest *H. pylori* eradication rates (50%) when the two drugs are used in combination, despite the fact that furazolidone is considered to be highly effective against the bacterium, and low resistance to the drug has been reported.

Itraconazole

The effects of omeprazole 40 mg/day on the pharmacokinetics of itraconazole 200 mg have been studied in 11 healthy volunteers (37). Omeprazole reduced the absorption of itraconazole. As the absorption of itraconazole is pH-dependent (it requires a pH of under 3.0 for complete dissolution and absorption) the likely explanation for this interaction is the effect of omeprazole on gastric pH.

Roxithromycin

The effect of omeprazole on roxithromycin concentrations in plasma and gastric tissue has been investigated in 12 healthy volunteers who took omeprazole 20 mg bd with or without roxithromycin 300 mg bd over 6 days (38). The medications were well tolerated, with only mild adverse events. The more frequent adverse events were nausea, bloating, and diarrhea. Omeprazole and roxithromycin did not alter the systemic availability of each other. However, omeprazole increased the local concentration of the antibiotic in the stomach.

Onagraceae

See also Herbal medicines

General Information

The genera in the family of Onagraceae (Table 1) include evening primrose and fuchsia.

Oenothera biennis

The seeds of *Oenothera biennis* (evening primrose, fever plant, king's cure-all, night willow herb, scabish, sundrop, tree primrose) yield evening primrose oil, which contains gamma-linolenic acid and has been used in various disorders, such as atopic eczema, premenstrual syndrome, and benign breast pain, but is probably not efficacious (1,2).

Adverse effects

Evening primrose oil has generally only minor adverse effects, such as nausea, diarrhea, and headache.

In three patients evening primrose oil triggered temporal lobe epilepsy (3).

Opioid analgesics

See also Individual agents

General Information

Classes of substances

Opioids are naturally occurring or synthetic substances that have morphine-like activity. The term opiate refers only to substances with morphine-like activity that are derived from opium. Substances that bind to opioid receptors but elicit little agonist activity are known as opioid antagonists. Some drugs have both agonist and antagonist effects (partial agonists). The opioids and their antagonists can be divided into three groups: (a) opioid agonists (morphine and morphine-like opioids); (b) opioid antagonists (for example naloxone and naltrexone); and (c) opioid partial agonists (for example buprenorphine and nalbuphine).

Three separate categories of endogenous substances with morphine-like activity have been identified. These families of neuropeptides are known as enkephalins, endorphins, and dynorphins. Each family is derived from a distinct precursor polypeptide (pro-enkephalin, pro-opiomelanocortin, and prodynorfin) and has a characteristic anatomical distribution. The enkephalins and dynorphins found co-exist with other neurotransmitters, such as serotonin (5-HT) and noradrenaline, but details of how the peptides modulate the activity of co-transmitters await elucidation.

Finally, several molecules with chemical structures similar to morphine have been found in mammalian brain, but it is not certain if these molecules have been derived from dietary sources or if they are synthesized in the brain.

The word narcotic was previously used to describe substances with morphine-like activity and is now largely obsolete, although it is still used in legal parlance.

Opioid receptors

There are three main types of opioid receptor: OP_3 (μ), OP_2 (κ), and OP_1 (δ) receptors. They are mainly found within the central nervous system but also in the periphery. Subtypes of each have been identified. Opioids interact with these receptors to produce their effects, primarily by exerting presynaptic inhibition, which results in reduced release of excitatory transmitters. It is thought that analgesia is primarily mediated via activation of OP_3 (μ) receptors at supraspinal sites and OP_2 (κ) receptors within the spinal cord. The finding that morphine is ineffective as an analgesic in knock-out mice without μ receptors confirms the importance of this receptor type. However, structural studies in cloned μ receptors have failed to support pharmacological studies that suggest the existence of separate μ receptor subtypes that independently mediate analgesia and respiratory depression.

The identification of opioid receptors and the discovery of opioid peptides in the 1970s led to the hope that greater understanding of fundamental mechanisms would lead to the development of new drugs with all the valued properties of known opioids but without their unwanted effects. However, these hopes have remained unrealized, although a synthetic enkephalin (pentapeptide 443C81), which penetrates the blood–brain barrier poorly, produces dose-related analgesia without causing significant miosis or reducing minute volume on rebreathing carbon dioxide in healthy volunteers (SEDA-16, 86).

Understanding of nociceptive processing has progressed in recent years, and the pain mechanisms and opioid effects on various receptors and transmission systems have been elucidated (1–3), as have tolerance and physical dependence and the influence of NMDA receptors (4,5).

The peptides endomorphin 1 and 2 have been identified in human brain and show selectivity and affinity for μ receptors. In mice, endomorphin 1 and 2 produce spinal and supraspinal analgesia. They appear to act through regulation of calcium entry into the target cell via voltage-gated channels and also to inhibit cyclic AMP production in μ receptor bearing cells. Clinically they mimic the action of other μ opioids. Their clinical relevance and unique adverse effects profiles await further investigation. Similarly the clinical usefulness of newly discovered receptor systems, such as the orphan opioid receptor for nociceptin (ORL1), which produces analgesia, hyperalgesia, and anti-opioid effects in animals, has yet to be defined.

Differences between individual agents

Morphine remains the gold standard against which all other opioids are compared. Most opioids are used as analgesics, although some are used primarily as antitussives, despite the fact that the cough-suppressing effect of codeine and dextromethorphan has not been demonstrated in children (SEDA-22, 98); others, such as loperamide and diphenoxylate, are used exclusively in the treatment of diarrhea; fentanyl and its congeners are primarily used in anesthesia. Fentanyl, the oldest of the anesthetic opioid agonists, and its derivatives alfentanil and sufentanil, are used either as anesthetic supplements or in appropriate doses as complete anesthetics. Butorphanol and nalbuphine have largely replaced pentazocine in analgesia, because they are less likely to have dysphoric effects and, in contrast to the pure agonists, any respiratory depression that follows their use is not dose-related and reaches a ceiling as the dose increases.

The main characteristics and use of opioid drugs are listed in Table 1. Drugs in widespread clinical use each have a separate monograph.

The use of opioid drugs is continuing to increase, mainly because of the development of alternative routes

© 2006 Elsevier B.V. All rights reserved.

Table 1 Major characteristics and uses of some opioid drugs

Drug	Typical dose	Route of administration	Half-life (hours)	Usual indication	Main adverse effects
Agonists					
Morphine (active metabolite morphine-6-glucuronide)	10 mg and upwards 3–4 hourly	Oral, subcutaneous, intravenous, intramuscular, intrathecal	2–4	Severe pain, anesthesia	Sedation, constipation, nausea, vomiting, itching, respiratory depression, tolerance and dependence, euphoria
Alfentanil	30–50 μg/kg	Epidural, intravenous	1.6–4	Analgesia, anesthesia	As morphine
Codeine (metabolized to morphine by CYP2D6)	30–60 μg 4-hourly	Oral	3–4	Cough, diarrhea, moderate pain	As morphine; lack of effect in poor metabolizers by CYP2D6
Dextromethorphan	10–30 mg 4–8 hourly	Oral	2.7–3.3	Dry cough	
Dextropropoxyphene (active metabolite norpropoxyphene)	65 mg 6–8 hourly	Oral	6–32 (norpropoxyphene 24–42)	Moderate pain	As morphine; cardiotoxicity, not reversible by naloxone; convulsions possible, due to norpropoxyphene
Fentanyl	50–200 μg	Epidural, intravenous, transdermal patch	2–7	Acute pain, anesthesia	As morphine
Methadone	10 mg 6–8 hourly; 30–80 mg/day	Oral, intravenous, intramuscular	15–60	Severe pain; opioid dependence	As morphine
Pethidine (meperidine)	50–150 mg 3-hourly	Oral, intramuscular	3.2	Moderate/severe pain	As morphine; excitement and convulsions
Sufentanil	Up to 8 μg/kg	Epidural, intravenous	2.7–6	Severe pain, anesthesia	As morphine
Partial agonists					
Buprenorphine	300–600 μg 6–8 hourly; 2–32 μg	Sublingual, intravenous Sublingual	5–12	Moderate/severe pain Opioid dependence	As morphine, but less pronounced; less well reversed by naloxone
Pentazocine	30–60 mg 3–4 hourly	Oral, intravenous, intramuscular	2–4	Acute pain	As morphine; dysphoria
Antagonists					
Naloxone	1.5–3 μg/kg repeated according to response	Intravenous	1.1	Reversal of opioid-induced respiratory depression	Nausea, vomiting, hypertension, cardiac dysrhythmias, rarely seizures
Nalmefene	0.25 μg/kg repeated according to response	Intravenous	10	Reversal of opioid-induced respiratory depression	Nausea, vomiting, tachycardia, hypertension, fever, dizziness
Naltrexone	25–50 mg/day	Oral	2.7	Adjunct to prevent relapse in formerly opioid-dependent patients	Nausea, vomiting, abdominal pain, dysphoria, joint and muscle pains, dizziness

of administration and increasing use in the very young. Pharmacological maneuvres have been made in order to improve analgesic potency and reduce adverse effects. Benzodiazepines have been used to improve analgesic effects (SEDA-17, 78), and methylphenidate has been given to patients in order to reduce drowsiness (SEDA-17, 78). Combinations of opioids with non-steroidal anti-inflammatory drugs have been used to provide analgesia postoperatively, with the aim of reducing the amounts of opioid required, with consequent reduction in adverse effects (SEDA-18, 79).

The more novel routes of administration of opioids, including oral, nasal, rectal, transdermal, spinal, and by patient-controlled methods, have been outlined (SEDA-17, 78). Oral transmucosal fentanyl administration, avoiding first-pass metabolism, produces analgesia and sedation in both adults and children undergoing short, painful outpatient procedures. The quality of analgesia is good, and the adverse effects are those typical of the opioids.

Degrees of risk

When the opioids are used correctly, their adverse effects are usually minimal. However, when they are used illicitly, they are often adulterated with other substances, which can cause adverse effects.

A strategy for controlling pain caused by malignant disease has been outlined and the classic effects that can be associated with opioid administration have been reviewed (6). These include constipation, nausea, sedation, pruritus, urinary retention, myoclonus, and respiratory depression. The latter can be life-threatening. Particular care is needed in opioid-naive individuals, those with compromised respiratory function, and elderly patients.

The use of opioids in very young patients is increasing. In a review of pain management in children, various routes of administration of opioids and their associated adverse effects have been discussed (SEDA-17, 78). Attention has been drawn to the adverse effects of intravenous codeine in children and to the risk of convulsions with pethidine in neonates, because of accumulation of its metabolite norpethidine. The risk of respiratory depression with morphine was also highlighted, and morphine is recommended for use only in neonates who are being ventilated or intensively nursed. Routine use of pulse oximetry has been recommended in all children receiving opioids (SEDA-21, 86).

The use of patient-controlled analgesia (PCA) (SEDA-15, 68) highlights the importance of adequate monitoring, in order to avoid potentially catastrophic adverse effects, such as respiratory depression. With PCA, patients generally use less morphine but still achieve the same degree of pain control (7). This supports the view that self-administration of opioids does not put patients at risk of over-medication or drug dependence.

It has been suggested that the risk of producing opioid dependence in the medical setting is greater in those who prescribe and administer them than in those who receive them (8). The likelihood of dependence in patients treated with opioids has been examined. In the treatment of cancer pain, tolerance and physical dependence occur but psychological dependence (addiction) is rare (9,10). In 11882 patients who had received at least one opioid, addiction was reasonably well documented only in four (11).

Of 130 patients with chronic malignant and chronic benign pain attending a pain relief unit over 3 years, 9 (18%) were considered to be addicted to analgesics on subjective evaluation (12). Of 71 patients with chronic pain referred to a pain relief center, 86% were taking analgesics, 58% opioids, and 68% psychotropic agents; 49% of those taking opioids were considered to be dependent (13).

These studies emphasize the need to define the meaning of terms such as addiction and dependence correctly and to distinguish between psychological and physical dependence. Failure to do so could lead to unwitting deprivation of opioids in patients for whom they provide undisputed benefit with minimal harm. These results also suggest that patients receiving opioids for less well-defined pain conditions, quite often for longer periods and sometimes along with other drugs with abuse potential, may be at special risk of dependence and abuse. Thus, withdrawal may be important, but may become extremely difficult. The adverse effects encountered during long-term opioid therapy have been reviewed, as well as the evidence that opioids can cause seizures or seizure-like activity (SEDA-22, 97).

Finally, it must be borne in mind that some of the problems with opioids are treatable: for example, naloxone can reverse respiratory depression, but care must be taken in opioid-dependent individuals, as it may precipitate opioid withdrawal.

General adverse reactions

Opioid agonists

Although opioids share many adverse effects, in some respects they are qualitatively and quantitatively different. They all cause constipation by reducing gastrointestinal motility. Respiratory depression, cough suppression, nausea, vomiting, and urinary retention also occur. With the exception of constipation, tolerance to these effects develops. Physical and psychological dependence is also possible. Interaction with monoamine oxidase inhibitors leads to central nervous excitation and hypertension. Hypersusceptibility reactions are rare, although anaphylactic reactions have occurred after intravenous use and skin phenomena can occur. Tumor-inducing effects have not been described in man, but in vitro experiments have suggested a mutagenic effect of papaveretum in mammalian cell lines apparently related to the noscapine content.

The role of opioids in chronic non-malignant pain has been reviewed (14,15), and reports of randomized, double-blind, controlled studies of opioids in chronic non-malignant pain have been identified (15). Opioids appear to be more effective in patients with well-defined nociceptive pain (that is pain associated with clear evidence of tissue damage) than in patients with chronic non-malignant pain of neuropathic origin (i.e. pain associated with injury, disease, or section of the peripheral or central nervous system in the absence of tissue damage) or psychogenic causes (no organic pathology present). Gastrointestinal and CNS adverse effects (sedation, dizziness, cognitive impairment, respiratory depression,

© 2006 Elsevier B.V. All rights reserved.

myoclonus) were frequent and distressing in most of the studies.

Clinical observations suggest that patients often find adverse effects, particularly nausea and vomiting, more distressing than the postoperative pain for which they are prescribed. Some are even willing to endure pain rather than suffer unpleasant adverse effects. This important aspect of opioid-induced analgesia has been investigated in a randomized, double blind, three-way, crossover study of between- and within-patient variability in response to equianalgesic doses of morphine, pethidine, and fentanyl during postoperative PCA (16). In 82 patients undergoing a variety of surgical procedures, the three opioids were equally efficacious from objective measurements in relieving pain and the subsequent incidence and intensity of adverse effects. However, the responses to the three opioids were highly individual, and there were three types of response. One group of patients tolerated all three opioids, another tolerated none, and a third group was sensitive to one or more of the opioids with no preference for any of the opioids used. The authors suggested that it would be good clinical practice to change from one opioid to another in patients who have intolerable adverse effects during PCA, since there is wide variation in subjective interpretation of pain and adverse effects.

Limitations to the use of opioids in cardiac surgery have been reviewed, highlighting the fact that μ receptor agonists cause dose-related respiratory depression through a reduction in carbon dioxide sensitivity in the respiratory centre (17). This depression, with a reduced respiratory rate and hypoxia, outlasts the analgesic effect of μ receptor agonists. Thoracic muscle rigidity on anesthetic induction with high doses of opioids has also been reported and can further compromise respiration. Hypotension through reduced peripheral vascular resistance occurs, while a negative inotropic effect of opioids acting directly on the heart via κ receptors is proposed, based on evidence from in vitro studies. The above effects have limited the role of opiates in patients with coronary artery disease, although they are of less importance in cardiopulmonary bypass surgery, when the heart is quiescent. In such surgery fentanyl partially blocks the expected tachycardia, hypertension, and release of inflammatory mediators that constitute the stress response, although the block is incomplete, owing to a lack of anesthetic effect.

Opioid partial agonists

There is evidence that in the case of partial opioid agonists, such as buprenorphine, the relative clinical activity of agonist and antagonist actions can differ, depending, among other things, on the dose.

The prevention of opioid-induced adverse effects

Prevention of sedation

The use and possible mechanism of amphetamines to counteract opioid-induced sedation has been reviewed (18). Most studies had methodological problems, including small numbers of patients completing short-term trials (under 1 week) and the small number of randomized, placebo-controlled, crossover trials. The quantitative measure of sedation was highly subjective and no uniform cognitive tests were performed to help compare the results of using amphetamines to reduce opioid-induced sedation. The overall conclusion was that more research is needed to determine the exact role of amphetamines. The use of amphetamine and amphetamine derivatives for the treatment of opioid-induced sedation is not recommended.

Prevention of emesis

Another excellent review has focused on the use of prophylactic antiemetics during PCA (19). A systematic search for relevant randomized controlled trails identified 14 studies involving 1117 adults published between 1992 and 1998. Without antiemetic drugs the incidence of opioid-induced nausea was on average 48% and of vomiting 55%, with a 67% chance of having an emetic episode. The most frequently studied antiemetic was droperidol, which was added to morphine PCA in six placebo-controlled trials in 642 adults and to tramadol in another trial. A wide range of doses of droperidol was used, with a constant degree of antiemetic efficacy. Based on this review, the optimal dose of droperidol is said to be less than 0.1 mg of droperidol per mg of morphine or less than 4 mg/day of droperidol. There were few adverse reactions: 56 in 10 000 patients had extrapyramidal adverse effects when droperidol was added to morphine PCA.

The next most frequently used drugs in the prevention of opioid-induced emesis are the 5-HT_3 receptor antagonists (ondansetron and tropisetron). There is no evidence that they prevent nausea, but the effect on vomiting is satisfactory enough for them to be regarded as second-line choices after droperidol. However, in 109 patients undergoing day-case oral surgery there was a higher incidence of nausea with tramadol plus ondansetron compared with three other treatments (fentanyl plus metoclopramide, tramadol plus metoclopramide, and fentanyl plus ondansetron) (20). There was no difference between the groups in analgesic efficacy.

Other prophylactic antiemetic agents include clonidine, promethazine, hyoscine, propofol, and metoclopramide. However, the data on these drugs are either insufficient or non-existent.

In a randomized, double-blind, placebo-controlled study of 80 patients who required epidural morphine after abdominal hysterectomy, 40 received intravenous dexamethasone (8 mg) (21). The incidence of vomiting with dexamethasone group was 5% compared with 25% with placebo; the total incidence of nausea and vomiting was 16% compared with 56%.

Prevention of pruritus

The incidence of opioid-induced pruritus varies widely, and depends on the opioid used and its mode of administration. The highest incidence (up to 80%) is associated with intrathecal morphine. The pruritus is usually localized to the area of the face that is innervated by the trigeminal nerve. A central encephalinergic mechanism has been proposed to explain this localization. The pruritus is often difficult to treat and responds poorly to conventional treatments, except for naloxone and propofol; 10–15% remain unresponsive. Naloxone reversibility of opioid-induced pruritus supports the existence of an

© 2006 Elsevier B.V. All rights reserved.

opioid-medicated central mechanism. However, naloxone will reverse the analgesic effects of the opioids.

Three studies have suggested the use of ondansetron, a 5-HT_3 receptor antagonist, for the treatment of opioid-induced pruritus (22–24). The articles suggested a possible interaction between the opioid and the serotonergic systems. In one prospective, randomized, double-blind, placebo-controlled study, 80 patients undergoing any type of surgery were given intravenous ondansetron 4 mg or 0.9% saline over 1 minute, with alfentanil as the opioid used in the anesthetic technique (22). The study was inconclusive; there was a significant reduction in the incidence of scratching in patients who received ondansetron compared with placebo but a non-significant incidence of itching in the ondansetron group.

In a prospective randomized, double-blind, placebo-controlled study in 100 patients scheduled for elective orthopedic surgery and presenting with pruritus induced by epidural or intrathecal morphine, intravenous ondansetron 8 mg was effective in 70% of cases and placebo in 30% (23). Ondansetron was well tolerated, did not change the degree of analgesia, and was not associated with adverse effects usually associated with ondansetron, such as headache, abdominal pain, and cardiac dysrhythmias.

In a double-blind randomized study of 130 patients given subarachnoid bupivacaine 0.5% with morphine 0.3 mg for surgical and postoperative analgesia, repeated-dose and single-dose ondansetron were compared (24). The overall incidence of pruritus was 73% in the group not given ondansetron, 63% in those who received intravenous ondansetron 4 mg 20 minutes before the spinal analgesia and 2 ml of saline at 12, 24, 26, and 48 hours after surgery, and only 49% in those who received ondansetron 4 mg 20 minutes before the spinal and 12, 24, 36, and 48 hours after surgery. There were methodological problems—the small number of subjects studied and the lack of an objective scoring system—but these results add to the current discussion of pursuing further studies to determine the effective dose of ondansetron in the treatment of opioid-induced pruritus. Further neurobiological research is needed to determine a "human" model of explaining the role and interactions of the central serotonergic system with the opioid system.

In a prospective, randomized, controlled study, 90 women with moderate to severe pruritus due to intrathecal morphine after cesarean section were given intravenous nalbuphine 2 mg, 3 mg, or 4 mg (25). Nalbuphine 2–3 mg relieved morphine-induced pruritus without increasing pain scores or causing other adverse effects.

Organs and Systems

Cardiovascular

Orthostatic hypotension can occur and is common after intravenous administration. Histamine release sometimes contributes to this.

Respiratory

Opioids cause respiratory depression by virtue of a direct effect on brain-stem respiratory centers (26). The nadir depends on the route of administration, and occurs at about 7 minutes after intravenous opioids, but not until about 30 minutes after intramuscular and 90 minutes after subcutaneous injection. The mechanisms of the respiratory effects of opioids (with special reference to their postoperative use) have been reviewed (SEDA-20, 76) (SEDA-21, 85). Pulmonary granulomatosis has occurred (27), and asthma after opioid inhalation has been described (28).

Nervous system

Opioids produce analgesia without loss of consciousness, although drowsiness, changes in mood, and mental clouding occur. Responses to painful stimuli are blocked at several locations in the brain, resulting in both an alteration in the sensation of pain and a change in the affective response. The ability of a patient to perceive pain can remain the same while tolerance to pain is markedly increased (29).

Opioids cause nausea and vomiting by stimulating the chemoreceptor trigger zone in the medulla, although tolerance to this effect usually develops within a few days (30).

Morphine and most opioids cause papillary constriction, which may be due to an excitatory action on the autonomic segment of the nucleus of the oculomotor nerve. Tolerance to this miotic effect is not usual.

Single therapeutic doses of opioids produce a shift toward increased voltage and lower frequencies in the encephalogram, such as occurs in natural sleep or after very low doses of barbiturates. High doses of morphine can cause sleep disturbances in some children (SEDA-17, 78).

Fentanyl and sufentanil can cause epileptiform activity in patients undergoing coronary artery bypass grafting (SEDA-18, 79).

Catatonia is a rare complication of prolonged epidural opioid administration in cancer pain (SEDA-16, 78). Patients with advanced cancer who were taking opioids had significant but transient cognitive impairment when opioid doses were increased (31). This correlates well with studies of the effects of psychotropic medications on ability to drive (32).

The neuropsychiatric syndrome that results from opioid toxicity consists of cognitive impairment, severe sedation, hallucinations, myoclonic seizures, and hyperalgesia (33). Opioid-induced neurotoxicity is most often seen in patients receiving high doses of opioids for prolonged periods, often in association with psychoactive medications (for example benzodiazepines and tricyclic antidepressants), and in older patients with associated dehydration and renal insufficiency. Strategies for reducing the occurrence of opioid-induced neurotoxicity primarily include opioid rotation and dosage reduction and circadian modulation techniques. Drugs such as amphetamines, amphetamine-like derivatives, and neuroleptic drugs like haloperidol can be used to treat hallucinations and delirium as a result of opioid-induced neurotoxicity and when the minimal dose of opioid that can cause sufficient analgesia also causes excess sedation. Proper assessment of the potential risk factors of opioid-induced neurotoxicity with careful monitoring of early signs is the fundamental principle in prevention.

Opioids and hypnotic drugs are often used to prevent increased intracranial pressure and the subsequent reduction in cerebral perfusion pressure. However, it is still uncertain whether opioids can cause increased intracranial pressure. The effects of a bolus injection and infusion of sufentanil, alfentanil, and fentanyl on cerebral hemodynamics and electroencephalographic activity have been studied in a randomized crossover study in six patients with increased intracranial pressure after severe head trauma (34). All three infusions were associated with a significant increase in intracranial pressure (9, 8, and 5.5 mmHg respectively) 3–5 minutes after the bolus opioid injection. Intracranial pressure gradually fell and returned to baseline after 15 minutes. This increase was associated with significant falls in mean arterial pressure and cerebral perfusion pressure throughout the study period. The electroencephalogram changed from a fast to a reduced activity pattern, with an improvement in background activity. It is therefore advisable to avoid using bolus injections of opioids in patients with head injury and to use continuous infusion for sedation.

Endocrine

Morphine reduces the response of the hypothalamus to afferent stimulation (35). In many species, opioids alter the equilibrium point of the hypothalamic heat-regulatory mechanisms.

In patients undergoing surgery, opioids inhibit the stress-induced release of ACTH (36).

Secretion of luteinizing hormone (LH) and thyrotropin is suppressed by opioids, whereas the release of prolactin and, in some cases, growth hormone is enhanced (37).

Gastrointestinal

Opioids reduce the secretion of hydrochloric acid and have a marked effect on gastrointestinal motility. Gastric emptying is prolonged and the likelihood of esophageal reflux is increased (38). Tone in the antral part of the stomach and first part of the duodenum is increased. The passage of gastric contents through the duodenum can be delayed by as much as 12 hours, retarding the absorption of orally administered drugs (39). In 260 patients with malignant disease, 23–40% vomited and 8–10% felt nauseated (SEDA-17, 79). Transdermal hyoscine (scopolamine) can reduce these problems (SEDA-17, 79).

Biliary and pancreatic and intestinal secretions are reduced by morphine, and digestion in the small intestine is delayed.

Constipation is usual (SEDA-17, 79). The tone of the anal sphincter is increased and the usual reflex relaxation response to rectal distension is reduced.

Biliary tract

Therapeutic doses of opioids constrict the sphincter of Oddi, and biliary tract pressure rises ten-fold. Patients with biliary colic can have exacerbation of pain after morphine. Likewise, opioids such as fentanyl, morphine, and dextropropoxyphene can cause bile duct spasm (SEDA-21, 85).

"It is standard teaching that morphine should not be used to treat patients with pancreatitis because it causes a rise in biliary and pancreatic pressure" (40). From this starting point, this comprehensive review discusses current approaches to opioid analgesia in pancreatitis, pointing out that morphine has been reported to cause biliary colic in individuals without biliary tract disease and that pethidine (meperidine) has become the analgesic of choice. Constriction of the sphincter of Oddi and the basal tone of the sphincter and the frequency of phasic contractions have been measured using endoscopic retrograde cholangiopancreatography (ERCP); an increase in basal tone is believed to be the best indication of sphincter dysfunction. Morphine sulfate in intravenous doses of 2.5–5 micrograms/kg caused increased contractions but no change in basal pressure, while doses of 10 micrograms/kg and over caused a rise in basal pressure. Pethidine increased contractions but not basal tone, while tramadol had no effect on basal pressure in a small study. Among mixed opiate agonist/antagonists, pentazocine increased basal pressure. Buprenorphine, a partial opiate agonist, resulted in no pressure changes, while the antagonist naloxone 0.4 mg intravenously had no effect alone on the sphincter basal pressure and did not stop the increase in pressure caused by morphine. However, case reports have suggested that naloxone reduces sphincter spasm in clinical situations.

Urinary tract

The urinary voiding reflex is inhibited by opioids, and both the tone of the external sphincter and the volume of the bladder increase; urinary retention is therefore common.

Skin

Flushing of the face, neck, and upper thorax can follow therapeutic doses of opioids. These effects may be partly due to release of histamine, which is also implicated in the sweating and pruritus seen after opioid administration. Opioid effects on neurons may partly be involved in the pruritus, as pruritus is provoked by opioids that do not release histamine and is abolished by small doses of naloxone.

Urticaria at the site of injection is due to histamine release. It is seen with pethidine and morphine, but not with oxymorphone, methadone, fentanyl, or sufentanil. Wheal and flare responses to various opioids differ (41).

Sexual function

Although long-term administration of low-dose opioids, especially intrathecally, improves quality of life through improved pain control, it can compromise it by causing impaired sexual function. Low testosterone concentrations have been reported in heroin addicts (42) and subjects in a methadone maintenance program (43).

In prospective non-randomized non-blinded evaluation of the effects of a 12-week course of intrathecal opioids for the control of chronic non-cancer pain on the hypothalamic–pituitary–gonadal axis in 12 men, it was suppressed and serum testosterone concentrations fell (44). This effect not only reduces quality of life through sexual

© 2006 Elsevier B.V. All rights reserved.

dysfunction but can also increase the risk of spinal osteoporosis in men, with an increased risk of vertebral and hip fractures. Patients receiving long-term intrathecal opioid therapy need to be informed of potential hypothalamic–pituitary–gonadal axis suppression as a result of the treatment, and testosterone replacement after hypothalamic–pituitary–gonadal axis surveillance during treatment should be considered if indicated.

Death

Opiates are widely used all over the world, but recently concerns about opiate use (and deaths from such use) have increased in Australia and the UK (45). The rate of opiate overdose deaths in these countries increased dramatically between 1985 and 1995. Throughout that period, it was four to ten times higher in Australia than the UK, but the rate of increase may have been greater in the UK in the latter half of the period, since the difference in rate narrowed substantially during that time. Methadone maintenance treatment, established in Australia in 1969 and in the UK in 1970, has become the main treatment for opiate dependence in both countries. About half of the opiate deaths in the UK were attributed at least in part to methadone. By contrast, considerably fewer (18%) opiate overdose deaths in Australia were attributed to methadone. The authors suggested that the discrepancy in the rates between the two countries could be artefacts of the differences in (a) the documentation of these deaths, (b) the rate of opiate dependence, (c) the route of opiate administration, (d) opiate purity, and, most importantly, (e) the method of delivery of methadone maintenance treatment.

Methadone-related fatalities have been reported from all countries in which methadone has been used for either detoxification or maintenance treatment of opiate users. These fatalities are often defined as cases of poisoning due to methadone or as polydrug intoxication with methadone as the leading cause of death. Methadone maintenance treatment was introduced in Germany in 1989, and 1396 drug-related deaths were reported from 1990 to 1999 in Hamburg (46). While the absolute numbers of drug-related deaths by poisoning did not change over this period, the rise in methadone-associated deaths paralleled a fall in the number of heroin-associated deaths. From 1990 to 1998, the rate of monovalent heroin intoxication in cases of poisoning fell from 60% to 11%, while the rate of polydrug intoxication increased. Poisoning caused by methadone combined with other substances first gained significance 4 years after methadone maintenance treatment was introduced in Hamburg. Since 1994, methadone-related deaths have increased steadily, and by 1997–1998 the numbers had increased exponentially. In the first 6 months of 1999, 60% of all cases of poisoning among drug addicts showed the presence of methadone. When strict guidelines for describing such poisonings were used, 39 poisonings in 1998 (40%) were predominantly caused by methadone, six of them being monovalent methadone intoxication. About two-thirds of all methadone-related poisonings concerned drug addicts who never stayed in methadone maintenance treatment, implying that they obtained methadone from outside of regular treatment. Almost 10 years after the introduction of methadone maintenance treatment in Hamburg, methadone replaced heroin as the leading cause of death due to poisoning. At the same time, however, the absolute number of drug-related deaths and poisonings fell slightly. While methadone maintenance treatment has clearly reduced overall morbidity and mortality in addicts globally, some issues remain unresolved. There are significant differences in the delivery of methadone maintenance treatment from one country to another. The authors reported that in some patients the starting doses of methadone are quite high and potentially lethal. This is especially so when the patients are also using other drugs and attempting to wean off them. Thus, continued polydrug use in treatment is an important risk factor for mortality. Many patients receive take-home doses for a week at a time. While this is useful in a select group of patients, it is not useful in those who sell methadone to buy heroin and combine the two drugs without knowledge of their half-lives and potential complications. The authors suggested changes in methadone maintenance treatment policy, in order to reduce the chances of accidental overdose/poisoning. Specifically, they recommended: a substantial improvement in quality assurance; a more restrictive methadone take-home policy (at least for patients with evidence for concomitant opiate use); and evaluating heroin or long-acting acetylmethadol as alternatives.

Another report from Australia reviewed all the accidental illicit drug deaths that occurred in the Sydney area in 1995–1997 (47). There were 3559 autopsies, of which 4% were considered accidental illicit drug deaths; of these deaths, 121 were men and 22 were women. While the highest number of male deaths occurred in the 25–35 year age group, female deaths were evenly spread from ages 20–35. Almost half (49%) of the deaths occurred from morphine poisoning, 27% from multiple drug toxicity, and 21% from heroin toxicity combined with alcohol. Methadone was detected in 19 cases (13%); 12 of these people were enrolled in a methadone maintenance program. Methadone intoxication alone was responsible for two deaths (1%) only. Methadone was present in the blood in a potentially fatal concentration in 13 cases, while 113 people (80%) had a heroin concentration in the fatal range and 91% had detectable concentrations of heroin. There were no significant neurological findings in the 143 cases studied. More than 50% of those with methadone detected also had heroin in their blood. Unfortunately, this appears to show that some people who participate in a methadone program may still die from accidental heroin overdose. Thus, the authors emphasized the importance of education of heroin users about the risk of accidental overdose.

There is excess mortality in heroin users compared with the general population. The prevalence and experience of heroin overdose in drug users in a general practice in Ireland were examined during 5 months (48). Of the 33 patients identified, 24 agreed to participate. They had had their first overdose on average 5 years after starting to use heroin. Ten had taken an overdose themselves, 23 had witnessed an overdose, 22 knew a victim of fatal overdose, and 4 had been present at a fatal overdose. However, they reported poor understanding of how to deal with an overdose. Despite maintenance treatment

© 2006 Elsevier B.V. All rights reserved.

with methadone, a significant proportion continued to inject heroin; 17% admitted to the use of illicit methadone, but methadone was not implicated in overdose in any case. The authors suggested that overdose prevention and management should become a priority for general practitioners who care for opiate-dependent patients. Factors implicated in overdose include too high a dose, use after a period of abstinence, and mixing with other drugs.

Clostridium novyi type A, a bacterium that was associated with serious infection during the two World Wars, killed 35 injecting heroin users in Britain and Ireland (49). *Clostridium novyi* type A is present in soil and dust and is a well-recognized cause of infection in sheep, cattle, and other animals. Contaminated batches of heroin from a common source were believed to be responsible for the recent outbreak. The bacteria were able to survive the process of preparation for injection. All recent cases occurred after intramuscular injection, which provides the requisite anerobic conditions for infection. This was the first time that this organism caused an outbreak of infection in drug injectors. In all, 74 cases with the same clinical features were reported.

An increase in the number of deaths of all body packers in New York has been associated with an increase in deaths among opiate body packers: of 50 deaths among body packers from 1990 to 2001, 42 were due to opiates (50). Four were related to cocaine and four to both opiates and cocaine. In 37 cases, open or leaking drug packets in the gastrointestinal tract resulted in acute intoxication and death. Five cases involved intestinal obstruction or perforation, one a gunshot wound, one an intracerebral hemorrhage due to hypertensive disease, and one was undetermined. The number of packets recovered was 1–111 (average 46).

An unbound morphine blood concentration of 100 ng/ml or more is considered potentially fatal. However, fatal cases of heroin intoxication occur in patients with blood morphine concentrations below 100 ng/ml. In 62 cases of heroin intoxication, death was associated with unbound morphine heart blood concentrations below 100 ng/ml in 21 cases and 100 ng/ml or over in 41 cases (51). In the 21 with low concentrations, respiratory tract infections occurred more often, and plausible causes of death were identified in 19.

Long-Term Effects

Drug tolerance

The clinical significance of opioid tolerance has been extensively reviewed (4) and the evidence for tolerance in acute and prolonged opioid administration has been presented. The former remains controversial while the latter has been adequately demonstrated. Different patterns of opioid use in chronic cancer-related pain are described, these being essentially escalating prescribing, steady-dose prescribing, and opioid withdrawal. The particular pattern followed by any individual is the result of the balance between physical changes in the level of nociceptive activity, psychological processes, such as increased anxiety and depression, and the degree of tolerance itself. While tolerance to an opiate reduces its clinical effectiveness, the tolerance may be beneficial if it mitigates drug adverse effects. Tolerance to respiratory depression and nausea occurs swiftly, sedation takes longer to resolve, and constipation is relatively resistant to the development of tolerance. Cross-tolerance is partial; hence switching from one opioid to another can relieve particular adverse effects without loss of clinical effect.

Physical dependence on opioids appears to occur in patients who use opioids for long-term pain relief, and cases of addiction have been reported. However, rates of addiction are low and occur mainly in individuals who have a history of substance misuse. The role of long-term opioid medication in non-cancer-related chronic pain remains controversial. "Opiophobia," a fear of the legitimate use of opioid analgesics because of the potential for addiction, remains a significant issue for physicians, patients, and relatives alike. The review is illustrated with a report of a 52-year-old man with multiple myeloma who displayed tolerance to oral morphine over 2 years.

Opioid tolerance in neonates

Tolerance to opioids in neonates has been reviewed (52). There are two forms of neonatal opioid exposure. First, in-utero exposure to opioids of neonates with opiate-addicted mothers; secondly, preterm infants requiring prolonged support in intensive care when opioid administration is used to reduce the stress response. The adverse effects of opioids on neonates are similar to those described in adults (sedation, dysphoria, seizures, nausea and vomiting, urinary retention, reduced intestinal motility, biliary tract spasm, histamine release, and chest wall rigidity), but it has been proposed that differences in the densities of the different opioid receptor subtypes lead to an increased theoretical propensity for respiratory depression with given opioid doses compared with older people. However, clinical studies have not confirmed increased sensitivity to respiratory depression in neonates or young infants. Tolerance may occur more swiftly in neonates due to slower opioid metabolism and a more permeable blood–brain barrier. Opioid withdrawal symptoms in neonates are similar to those for other age groups but can be mimicked by hypoxia, hypercarbia, hypoglycemia, hypocalcemia, or hypomagnesemia. Assessment of tolerance and withdrawal is made using the neonatal abstinence score rating scale and the neonatal withdrawal index.

Management of neonatal opioid withdrawal relies on gradually reducing doses of opioids to reduce the severity of withdrawal symptoms. Paregoric was formerly used as a withdrawal aid but is little used now owing to toxic effects. Tincture of opium (10% solution), consisting of 1 ml in 24 ml of sterile water, 0.05 ml/kg 4-hourly is proposed as the most suitable replacement. Speed of reduction depends on the length of neonatal exposure to opioids and a short reducing regimen (over 2–3 days) can be sufficient. A methadone replacement withdrawal regimen is also discussed, while benzodiazepines, phenobarbital, chlorpromazine, and clonidine are all reviewed as having a potential role in symptomatic relief during withdrawal; however, each has its own associated adverse effects, which limit their usefulness.

Mechanism

At micromolar concentrations opioids cause an increase in the cell membrane threshold, shortened action potentials, and inhibition of neurotransmitter release. At nanomolar concentrations opioid agonists are excitatory and prolong the action potential via the stimulatory G proteins, which act on the adenylate cyclase/cAMP system and on protein kinase A-dependent ion channels. Tolerance is proposed to be the result of an increase in the association of opioid receptors to stimulatory G proteins, to an activation of *N*-methyl-D-aspartate receptors via protein kinase C, and calmodulin-dependent increases in cytosolic calcium, resulting in cellular hyperexcitability.

Drug withdrawal

Chronic administration of opioids produces physical and psychological dependence. A characteristic withdrawal syndrome occurs when the opioid is stopped abruptly or an opioid antagonist is given. In the case of morphine and other OP_3 receptor agonists with a similar duration of action, lacrimation, rhinorrhea, yawning, and sweating occur about 8–12 hours after the last dose. Symptoms peak at about 24–48 hours after withdrawal, with restlessness, irritability, and insomnia, as well as severe sneezing, weakness, anxiety, and depression. Other symptoms include dilated pupils, anorexia, piloerection, nausea, vomiting, diarrhea, pyrexia, hypertension, muscle cramps, dehydration, and weight loss (53).

Treatment of opioid withdrawal

Various regimens were used in the past in an attempt to withdraw patients from opioid addiction (54). The modern scientific basis for the evaluation of opioid withdrawal regimens was established by Kolb and Himmelsbach (55), who concluded that the methods that produced the least discomfort and the best results were either abrupt or rapid withdrawal of the opioid. Rapid withdrawal consisted of gradually reducing doses of morphine over 4–10 days. Such methods were in regular use until the advent of methadone as a heroin substitute in the 1950s.

Antidepressant, anxiolytic, and neuroleptic drugs can allow some patients to participate in treatment programs, especially when drug abuse is associated with psychiatric disorders such as depression, chronic anxiety, or schizophrenia.

Methadone

A widely used technique, pioneered by Isbell and Vogel (56), involves the substitution of methadone for the illicit opioid, followed by a gradual reduction in the amount of methadone taken. Methadone is used to substitute for a variety of opioid drugs. It is well absorbed after oral ingestion, with peak blood concentrations after about 4 hours. Steady-state concentrations are reached after about 5 days. By virtue of its long duration of action (the half-life with regular dosing is about 22 hours), methadone suppresses opioid withdrawal symptoms for 24–36 hours. In the early stages of treatment, patients may report problems such as drowsiness, insomnia, nausea, euphoria, difficulty in micturition, and excessive sweating. With the exception of chronic constipation and excessive sweating, these effects do not generally persist.

British studies have shown that, using methadone, about 80% of inpatients but only 17% of outpatients were successfully withdrawn (57,58). However, the technique is not without problems, one being that the methadone reduces but does not eliminate withdrawal symptoms. The withdrawal response has been described as being akin to a mild case of influenza, objectively mild but subjectively severe (59). The fear of withdrawal symptoms expressed by those dependent on drugs should not be underestimated: these factors are associated with the subsequent severity of withdrawal symptoms, and they are more closely related to symptom severity than drug dosage (60). Methadone substitution can result in a protracted withdrawal response, with patients still experiencing significantly more symptoms than controls 2 weeks after withdrawal (61).

In a study of methadone withdrawal, patients who were withdrawn over 10 days had a withdrawal syndrome that began to increase in severity from day 3, with peak severity of symptoms on day 13; in those who were withdrawn over 21 days, symptoms began to increase about day 10 with a peak on day 20 and abated thereafter, although some patients did not recover fully until 40 days after starting withdrawal (62). Thus, the duration of the withdrawal syndrome is much the same for both treatments in terms of symptom severity. It is possible that an exponential rather than a linear reduction in dosage may improve the withdrawal response. These results may be of clinical significance, in that patients may feel it important that they recover from withdrawal as quickly as possible, in order to participate fully in other aspects of drug withdrawal programs. However, although there was no difference between the 10-day and the 21-day programs regarding completion rates for detoxification (70 and 79% respectively), the dropout rates after detoxification were significantly different. During the 10 days after the last dose of methadone, the dropout rate in the 21-day group was 18% compared with 30% in the 10-day group. These results may also have financial implications in respect of the number of subjects who can be admitted to treatment programs.

In some treatment programs total abstinence is not considered to be a practical objective and treatment may involve the use of drugs such as methadone as maintenance therapy with the expectation of reducing illicit drug consumption (63). Well-organized methadone maintenance treatment can reduce the intake of illicit opioids in many injecting drug users (64,65).

The methadone maintenance treatment was established in 1964 in New York City by Vincent Dole and Marie Nyswander (see the monograph on Methadone). In the initial studies, subjects who were heavily addicted to heroin were evaluated and stabilized on daily methadone doses as inpatients before transfer to an outpatient clinic for continued treatment. With further experience, it was feasible to drop the inpatient phase.

Outcome studies of methadone maintenance treatment have reported favorable results, with high rates of patient retention, reduced criminality, and improved social rehabilitation. However, despite its proved effectiveness, it remains a controversial approach among substance abuse treatment providers, public officials, policy makers, the medical profession, and the public at large.

© 2006 Elsevier B.V. All rights reserved.

Nevertheless, almost every nation with a significant narcotic addiction problem has established a methadone maintenance treatment program.

For patients entering treatment from an institution where they have been drug-free, initial daily methadone doses should be no more than 20 mg. Otherwise initial daily doses of 30–40 mg should be sufficient to obtain the necessary balance between withdrawal and narcotic symptoms. Thereafter, stabilization is achieved by gradually increasing the dose. When methadone is given in adequate oral doses (usually 60 mg/day or more), a single dose in a stabilized patient lasts 24–36 hours, without creating euphoria and sedation. Tolerance to methadone seems to remain steady, and patients can be maintained on the same dose, in some cases for more than 20 years.

The methadone dose must be determined individually, because of individual variability in pharmacokinetics and pharmacodynamics. Maintenance of appropriate methadone blood concentrations is recommended.

Tolerance to the narcotic properties of methadone develops within 4–6 weeks, but tolerance to the autonomic effects (for example constipation and sweating) develops more slowly.

The major adverse effects during treatment occur during the initial stabilization phase. In addition to constipation and sweating, the most frequently reported adverse effects are transient skin rash, weight gain, and fluid retention. Since the main metabolic pathway of methadone is CYP3A4 numerous drug interactions can be expected. Drugs that interact with methadone and other opioid analgesics are listed in Table 2.

Methadone maintenance treatment is considered to be a medically safe treatment with relatively few and minimal adverse effects. However the danger of serious adverse effects and death with the increasing use of methadone as maintenance therapy in drug addicts has been highlighted. It must be emphasized that a daily maintenance dose of 50–100 mg is toxic in a non-tolerant adult, and as little as 10 mg can be fatal in a child. There is an increasing number of reports of the deaths of children of mothers on maintenance therapy from inadvertent ingestion.

Clonidine

Clonidine appears to ameliorate the opioid withdrawal syndrome by reducing central noradrenergic activity. It has been hypothesized that the opioid withdrawal syndrome is due to increased noradrenergic neuronal activity in areas such as the locus ceruleus, which are regulated by both opioid receptors and α_2-adrenoceptors (66). Opioids and clonidine both act at the locus ceruleus, reducing central noradrenergic function. This common pathway hypothesis is supported by the similarity of clonidine and opioid withdrawal in respect to their effects on vital signs, mood, and noradrenergic hyperactivity (67). Since the actions of clonidine are mediated by α-adrenoceptors they are not antagonized by opioid antagonists.

There have been many reports of the use of clonidine in the treatment of acute opioid withdrawal (68). A dose of 500 micrograms/day for 10 days reduced but did not completely abolish withdrawal symptoms in 50 patients dependent on methadone or heroin. The patients still complained of sluggishness, insomnia, and bone pain, but there were none of the usual complaints associated with opioid withdrawal, such as anxiety, abdominal cramps, chills, muscle spasms, irritability, and anger.

Others have reported good results from the use of clonidine (69,70). Of 25 inpatients physically dependent on methadone, 20 were able to withdraw completely from methadone at the end of 2 weeks. In most patients, 10–11 days of clonidine, in a peak dose of 16 micrograms/kg/day, produced a perceived reduction in symptoms compared with previous attempts to become opioid-free. In these dosages, clonidine significantly reduced standing blood pressure without producing clinical problems.

Table 2 Drug interactions involving opioid analgesics

Object drug	Precipitant drug	Clinical consequences	Proposed mechanism(s)
Carbamazepine	Dextropropoxyphene	Increased effect of carbamazepine	Reduced metabolism
Codeine	Quinidine	Reduced analgesic effect	Reduced liver metabolism of codeine to morphine
Dextropropoxyphene	Ethanol	Increased effect of dextropropoxyphene	Reduced metabolism
Methadone	Carbamazepine	Reduced effect of methadone	Increased metabolism
Methadone	Cimetidine	Increased effect of methadone	Reduced metabolism
Methadone	Phenobarbital	Reduced effect of methadone	Increased metabolism
Methadone	Fluvoxamine	Increased effect of methadone	Reduced metabolism
Methadone	Phenytoin	Reduced effect of methadone	Increased metabolism
Methadone	Rifampicin	Reduced effect of methadone	Increased metabolism
Morphine	Cimetidine	Increased effect of morphine	Reduced metabolism
Morphine	Amitriptyline	Increased effect of morphine	Increased systemic availability
Morphine	Clomipramine	Increased effect of morphine	Increased systemic availability
Nortriptyline	Dextropropoxyphene	Increased effect of nortriptyline	Reduced metabolism
Pethidine	Cimetidine	Increased effect of pethidine	Reduced metabolism
Pethidine	Chlorpromazine	Increased toxicity of pethidine	Altered metabolism
Pethidine	Moclobemide	Increased effect of pethidine	Serotonin syndrome reported
Pethidine	Selegiline	Increased effect of pethidine	Serotonin syndrome reported
Phenobarbital	Dextropropoxyphene	Increased effect of phenobarbital	Reduced metabolism
Phenytoin	Dextropropoxyphene	Increased effect of phenytoin	Reduced metabolism

Withdrawal symptoms of anxiety, restlessness, insomnia, and muscle aching were still evident.

In a randomized double-blind, placebo-controlled comparison of clonidine with a reducing dose of methadone, there was no difference in success rate: 42% abstinence with clonidine and 39% with methadone (71). However, patients who received clonidine had more self-rated withdrawal symptoms and a higher percentage of days on which symptoms were severe.

Clonidine has been reported to reduce both diastolic and systolic blood pressure by 10–15 mmHg during treatment for opioid withdrawal. Sedation and insomnia have also been noted. However, it is often difficult to distinguish which symptoms are due to the treatment and which are caused by opioid withdrawal. In a comparison of clonidine and methadone, seven of 14 patients in the clonidine group were withdrawn from the study because they had unacceptable adverse effects, compared with one of 11 in the methadone group. Two of those taking clonidine had severe immediate adverse effects that prevented them from continuing beyond 2 days (72).

One of the limitations of clonidine treatment is that it does not appear to reduce the duration of the opioid withdrawal syndrome. In one study, 10 days of clonidine therapy were required to suppress the symptoms of opioid withdrawal from long-acting opioids such as methadone (70).

The effect of clonidine in the management of opioid-dependent individuals undergoing gradual methadone detoxification over 14 days has been studied (73). In those who completed the course, clonidine did not significantly reduce either the symptoms or objective signs of opioid withdrawal. There was a substantial dropout rate, and several subjects were withdrawn from the study because of symptoms related to hypotension. In those who completed detoxification, clonidine did not reduce either the symptoms or the signs of opioid withdrawal. Clonidine therefore seems to have no place as an adjunct to a program of gradual methadone detoxification.

Clonidine plus an opioid antagonist

In a double-blind study using titrated doses of clonidine and naltrexone, combined clonidine and naltrexone treatment allowed 38 out of 40 patients physically dependent on methadone to withdraw completely in 4–5 days (74). For most patients naltrexone was gradually increased from 1 to 50 mg/day over 4 days. The dose of clonidine was 200–600 micrograms every 4 hours. After the first 48 hours the dose was rapidly tapered without recurrence of withdrawal symptoms. Flurazepam was used for night sedation. Although clonidine reduced the intensity of naltrexone-induced withdrawal symptoms, it did not eliminate them completely. On the first day after withdrawal of methadone and initiation of naltrexone and clonidine the frequencies of craving, anxiety, restlessness, insomnia, muscular aching, anorexia, hot and cold flushes, and diarrhea were significantly higher than whilst taking methadone. However, after 4 days of naltrexone, the patients were considerably less symptomatic. Compared with their feelings whilst taking methadone, they complained of significant increases in irritability, unpleasantness, and lethargy during the first 3 days.

The combined use of clonidine and naltrexone appears to allow successful withdrawal from long-term methadone therapy within 4–5 days of its abrupt withdrawal. Although patient selection may be an important consideration, the apparent success rate compares favorably with other methods and is achieved in a much shorter time (70).

Buprenorphine

In a study designed to assess the safety of buprenorphine for the treatment of cocaine and opiate dependence there were no adverse effects or serious interactions with a single dose of intravenous morphine or cocaine during daily maintenance on buprenorphine (SEDA-18, 85).

Second-Generation Effects

Pregnancy

A major review of the problems of drug dependence in pregnancy and the clinical management of mother and child was published in 1979, and its findings remain valid today (SED-11, 138) (75).

Opioids taken in pregnancy by a drug-dependent mother, or administered to the parturient, can cause respiratory depression in the newborn. Abstinence symptoms have been reported in the infants of mothers who are opioid-dependent at term (76).

The adverse consequences for the neonate of drug abuse in pregnancy can be dramatically reduced by comprehensive medical and psychosocial care for the mothers during pregnancy and delivery (SED-11, 138) (77,78). However, without due care during pregnancy problems are likely.

The long-term consequences of maternal opioid dependency on the child have been examined in detail in 89 infants born to mothers addicted to heroin, morphine, and methadone (SED-11, 138) (79); 20% were preterm and 31% were light for gestational age; 85% of the infants had withdrawal symptoms and 12% had convulsions. The somatic and neurobehavioral findings in children in their first 18 months of life, born to methadone-maintained mothers and to a matched drug-free comparison group of mothers, have been reported (SED-11, 138) (80). At 18 months the methadone children had: (a) a significantly higher incidence of otitis media; (b) a significant incidence of head circumference below the third percentile; (c) neurological findings of tone discrepancies, developmental delays, and poor motor co-ordination; (d) a high incidence of abnormal eye findings; and (e) significantly lower scores on the Bayley mental and motor developmental indices. In a study of 72 such children investigated 1–10 years after birth, only 25% were physically, mentally, and behaviorally normal (79).

In 41 children born to methadone-maintained mothers and 23 children from matched controls at 6 months of age, there was delayed motor development in methadone-exposed infants and greater vulnerability of males to adverse environmental conditions; in adult male rats there was a correlation between early methadone exposure and behavioral abnormalities (SED-11, 138) (81).

Opioid analgesia during the first stage of labor

The 50% and 95% effective doses (ED_{50} and ED_{95}) of intrathecal sufentanil for analgesia in labor have been characterized in several studies (82,83). The same criteria have been applied to fentanyl in 90 women in active early labor (at least 5 cm dilatation), who received a range of doses of intrathecal fentanyl (5–25 micrograms) in a double-blind, randomized study (84). Fentanyl induced rapid and effective dose-dependent analgesia in early labor. Pruritus occurred in 66% of patients and falls in ventilation were dose-related. The ED_{50} and ED_{95} values were 5.5 and 17.4 micrograms respectively.

In 60 women who requested epidural analgesia during labor randomized to sufentanil 10 micrograms, fentanyl 10 μg, or saline in addition to intrathecal bupivacaine 2.5 mg, the combination of sufentanil plus bupivacaine gave a significantly longer duration of analgesia (85). Pruritus was more common in women given sufentanil (80%) and fentanyl (47%) than in those given plain bupivacaine. However, there were no differences in the incidences of gastrointestinal effects, hypotension, or motor blockade between the groups. Adding sufentanil 10 micrograms to intrathecal bupivacaine 2.5 mg provided fast onset, better analgesia for a longer duration than the other treatments.

In another similar study, the adverse effects profile, especially in regard to pruritus, improved if intrathecal sufentanil 2.5 micrograms was added to bupivacaine 1.25 mg and adrenaline 2.5 micrograms, without compromising analgesia in women in the first stage of labor (86).

In 30 women randomized to receive either sufentanil 7.5 micrograms plus bupivacaine 2.5 micrograms, with or without clonidine 50 micrograms, using a combined spinal-epidural technique, analgesia was prolonged in those given clonidine without an increased incidence of adverse effects or worse pain scores (87).

In a prospective, randomized, double-blind comparison of nalbuphine with pethidine in 310 women requiring analgesia during labor, nalbuphine produced a lower incidence of nausea and vomiting (88). There were no differences between the two groups in the other adverse effects of the opioids, and nalbuphine did not afford major analgesic benefits.

Use of opioids in cesarean section

The use of intrathecal or epidural opioids has been recommended for the relief of pain after cesarean section, and there have been several comparisons of intrathecal and epidural opioid use.

In 50 women randomized to intrathecal diamorphine 0.25 mg or epidural diamorphine 5 mg in addition to intrathecal bupivacaine 10 mg, there was no significant difference in the duration or quality of analgesia (89). The incidence of nausea and vomiting was higher in the epidural group (24 versus 4%). There was no difference in the incidence of pruritus, but the incidence was as high as 88% of patients, and it was severe enough to require treatment in 20%.

In a double-blind, randomized study, 55 women undergoing elective cesarean section were allocated to either epidural diamorphine 3 mg or intrathecal morphine 0.2 mg (90). There were no significant differences between the two groups in pain assessed by visual analogue scale or in the incidence of pruritus, sedation, or respiratory depression measured by pulse oximetry during the 28-hour postoperative period. Nausea and vomiting were significantly more common in the intrathecal morphine group (73 versus 41%).

Patient-controlled analgesia with epidural pethidine or a single bolus of epidural morphine 4 mg during the 24 hours after cesarean section has been studied in 78 women (91). There were no differences in the degree of analgesia or opioid adverse effects profiles.

In 66 cesarean section patients the effects of sufentanil (2 micrograms/ml), tramadol (10 mg/ml), or a mixture of the two were compared using patient-controlled extradural analgesia (92). Nausea and vomiting were closely related to the use of tramadol, while pruritus was associated with sufentanil. The combined regimen reduced the dosage requirements of both opioids by 20%. Extradural tramadol cannot be recommended, because of the increased incidence of severe gastrointestinal adverse effects, the high dose required, and inferior analgesia.

Patient-controlled epidural fentanyl (20 micrograms with 10 minute lock-out) has been compared with patient-controlled intravenous morphine (1 mg with a 5-minute lock-out) in 48 women after cesarean section (93). Fentanyl was more efficacious in controlling postoperative pain, with a lower incidence of nausea and drowsiness.

Finally, 60 women undergoing cesarean section were randomly given epidural tramadol 100 mg, epidural tramadol 200 mg, or saline (94). Pain scores and adverse effects were evaluated for 24 hours after surgery. In all three groups there were no opioid-related adverse effects and epidural tramadol 100 mg provided adequate postoperative analgesia.

Fetotoxicity

The pharmacokinetics and effects of various systemically administered analgesics on the uterus, fetus, and neonate have been reviewed (SED-11, 137). Fetal bradycardia lasting up to 7 minutes was reported in 53 of 1910 fetuses (2.7%) after the administration of pethidine (meperidine) 75 mg and promethazine 25 mg intravenously to the mothers during labor (SED-11, 137) (95).

The relation between maternal morphine administration during labor and the Apgar score of the baby at birth has been studied (SED-11, 137) (96). The authors concluded that morphine alone did not seem to cause asphyxia at birth, but that morphine together with other fetal and/or obstetric factors would definitely be a cause for concern with regard to birth asphyxia.

The effect of maternal analgesia on neonatal behavior has been assessed (SED-11, 137) (97). The authors suggested that neonates respond to pethidine in the same way as adults, but the changes observed were relatively subtle, and comparison of these infants with a control group whose mothers had received no drugs showed no differences in behavior.

Opioid analgesia can cause prolonged reductions in the baseline variability of the fetus during monitoring in labor (SEDA-17, 85). This is thought to occur by a direct effect

© 2006 Elsevier B.V. All rights reserved.

on the cardiac centers or fetal myocardium. The danger of this is the risk of misinterpretation of the cardiotocogram as being indicative of fetal distress.

Intramuscular tramadol (50 or 100 mg) during labor is associated with fewer adverse effects than pethidine 75 mg (SEDA-18, 83). Pethidine and the higher dose of tramadol had similar analgesic efficacy, but pethidine was associated with a significantly lower neonatal respiratory rate at birth.

Susceptibility Factors

Age

Neonates, infants, and children are at risk of adverse effects of opioids, owing to pharmacokinetic and pharmacodynamic changes (SEDA-17, 78). Routine use of pulse oximetry is recommended in all children receiving opioids (SEDA-21, 85).

Elderly patients are particularly at risk, as a number of other susceptibility factors can co-exist.

Renal disease

Renal insufficiency can result in clinically significant accumulation of pharmacologically active opioid metabolites and prolonged narcosis; such patients must be monitored for signs of toxicity (SEDA-17, 79) (SEDA-21, 85) (98,99). To date, this effect has only been reported with codeine, morphine, and pethidine. Dextropropoxyphene is not recommended in renal insufficiency, as its metabolite norpropoxyphene, which is eliminated by the kidneys, accumulates, causing cardiac depression (SEDA-17, 79) (SEDA-21, 85).

Other features of the patient

In patients with reduced respiratory reserve, such as those with emphysema, severe obesity, cor pulmonale, and kyphoscoliosis, opioids must be used with caution. The relative benefits and harms of using opioids in patients taking monoamine oxidase inhibitors, those with a history of drug abuse, asthma, hepatic impairment, hypotension, raised intracranial pressure, or head injury, and during pregnancy or breast feeding, should be carefully considered. Dextropropoxyphene, pethidine, and methadone should be used with caution (SEDA-21, 85).

Drug Administration

Drug administration route

Compared with conventional routes, spinal opioid administration carries potentially greater morbidity and can only be justified if it produces equal or superior pain relief compared with conventional methods, with fewer unwanted effects (SED-11, 139).

Although the analgesic effect of spinal opioids is largely due to a spinal effect, the opioid can spread rostrally to the brainstem and higher centers, and can cause delayed adverse effects. Lipid solubility affects the rate at which an opioid is absorbed into the spinal cord from the cerebrospinal fluid (CSF), and therefore predicts the likelihood of rostral spread. Hydrophilic drugs, such as morphine, will linger in the CSF and produce prolonged analgesia that may last 12 hours or more. Such drugs can float rostrally, producing more widespread but less intense analgesia. However, if the drug reaches opioid receptors in the respiratory center in the fourth ventricle, delayed respiratory depression can occur. In contrast to morphine, fentanyl is very lipid-soluble but short-acting; a single dose will produce intense highly segmental analgesia lasting 2–3 hours. These properties make it suitable for continuous epidural infusion.

When an opioid is used as the sole agent by the epidural or intrathecal route, the results are disappointing, because of unwanted adverse effects, such as pruritus, nausea, vomiting, respiratory depression, and effects on the neonate, caused by significant systemic absorption (SEDA-17, 85). Hypotension and changes in fetal heart rate are not uncommon (SEDA-21, 91). Combinations of opioids (alfentanil, fentanyl, morphine, sufentanil) with local anesthetics (for example bupivacaine) have therefore been suggested to yield better results (SEDA-18, 83).

The use of alfentanil with bupivacaine via continuous epidural infusion during labor resulted in a significant reduction in motor blockade compared with bupivacaine alone. There was no respiratory depression in the mothers, although shivering and pruritus were more frequent with alfentanil. There were no differences in the neonatal Apgar scores between the groups (SEDA-18, 83).

There has been a comparison of the effects of fentanyl and sufentanil, combined with bupivacaine and adrenaline, given by PCA after cesarean section (SEDA-18, 83). The numbers of requests were greater in the fentanyl group, but there was no difference between the groups with regard to sedation, pruritus, or nausea. However, those who received sufentanil had a significantly higher incidence of vomiting, light-headedness, and dizziness.

It is uncertain whether the addition of adrenaline to intrathecal sufentanil increases the duration of analgesia during labor. In one study, the addition of adrenaline to intrathecal sufentanil did not prolong the duration of analgesia, but reduced the incidence and severity of pruritus (SEDA-18, 83), whereas in another the addition of adrenaline or morphine to intrathecal sufentanil prolonged the duration of analgesia (SEDA-18, 83). However, those given morphine had significantly more nausea and pruritus.

In another comparison of a single dose of epidural morphine with PCA epidural fentanyl after cesarean section, pain relief and the incidence of nausea were similar, but pruritus was significantly less with fentanyl (SEDA-18, 83).

Epidural methadone and diamorphine are useful analgesics during cesarean section, but oxygen desaturation and nausea are more frequent with diamorphine (SEDA-18, 83).

Combined spinal-epidural administration achieves almost instantaneous analgesia with longer pain relief (100). This method gives a faster onset of analgesia and less motor blockade than standard epidural analgesia (101).

Intrathecal route

Technical problems after intrathecal opioids are rare, although catheter occlusion and leakage of CSF have been reported (SEDA-17, 85) (102–104). In 121 patients with

© 2006 Elsevier B.V. All rights reserved.

mean follow-up of 68 days (maximum 13 months) there was an incidence of less than 10% (105).

Intrathecal opioids used in obstetrics are well tolerated by mother and child (SED-11, 139, 140) (106–108).

Morphine is the opioid most often chosen for intrathecal administration.

Respiratory

Respiratory depression occurs more often after intrathecal than after epidural opioid administration and can be more of a problem in old age or when there is pre-existing respiratory disease (SED-11, 139) (109,110). The time of onset is variable but usually occurs within 6–10 hours of the opioid injection, although delays of up to 11 hours have been reported (111). There have been two cases of prolonged respiratory depression lasting 18 hours after single doses of 3 and 5 mg (111). Repeated doses of naloxone were required, but each incremental dose did not alter the level of analgesia.

It has been suggested that opioid-naive patients may be more susceptible to respiratory depression and that posture may also be important (SED-11, 139) (112).

Return of normal respiration can take up to 23 hours. Peak expiratory flow rate (PEFR) was significantly better in patients who had received intrathecal rather than intravenous morphine after cardiac surgery, but mean $PaCO_2$ was significantly higher in patients given intrathecal morphine 2 mg, rather than intrathecal or intravenous morphine 1 mg (113). The effect was dose-dependent (114).

Nervous system

Central adverse effects are as expected; with the exception of constipation, urinary retention, and respiratory depression, these effects tend to be transient and disappear within a few days of starting therapy.

Drowsiness, miosis, and respiratory depression have been reported after intracerebroventricular administration of morphine in two of 55 patients who received morphine 1–1.5 mg (115). A third patient developed visual hallucinations and behavioral disorders after 1 mg. All effects were rapidly reversed by naloxone.

Myoclonic spasms of the legs have been described after intrathecal morphine, and were abolished by intrathecal bupivacaine (116).

Hyperalgesia and myoclonus were reported after high-dose intrathecal morphine (SEDA-17, 87).

Temporary, totally reversible motor and sensory paralysis has been reported after intrathecal morphine 1.6 mg and was attributed not to a direct spinal action of morphine but to cardiovascular changes occurring as a result of pain relief (117).

Gastrointestinal

There is a high incidence of nausea and vomiting with intrathecal diamorphine, which may not be dose-related (118). Two studies have suggested that the incidence of nausea and vomiting in labor is higher with intrathecal than with epidural opioids (119,120).

Urinary tract

Urinary retention has been described in one of a series of patients who had been given pentazocine 5 mg intrathecally (121); others have since reported similar findings.

Skin

Pruritus is a frequent adverse effect after intrathecal administration, with an incidence of one-third with buprenorphine (122) and diamorphine (123) and over 70% for both diamorphine and morphine (124,125). In one study the incidence of pruritus was higher with morphine than with methadone; analgesia was also superior (124). Pruritus has also been reported with intrathecal pethidine (meperidine). Treatment was not reported to be necessary. This effect is not reported to occur after intrathecal beta-endorphin (126,127). The mechanism of pruritus is not well understood and has been attributed to a disturbance of thiamine metabolism (128) and to a disturbance of afferent input at supraspinal as well as at spinal receptor sites (129).

Infection risk

Reactivation of *Herpes simplex* infection after epidural administration of opioids is well known. However, there have been reports of reactivation of *Herpes simplex* after intrathecal morphine for cesarean section (SEDA-17, 87) (SEDA-18, 84).

Susceptibility factors

Knowledge of the use of spinal opioids in children is limited, but adverse effects are similar to those reported in adults (SEDA-18, 85) (130–132). Dysphoria has also been reported, but attributed to systemic absorption (132).

Epidural route

The adverse effects reported with epidural administration are similar to those reported with the intrathecal route. Again, old age and respiratory disease probably dispose to respiratory depression (133). As can be predicted from pharmacokinetic considerations, delayed respiratory depression is more common with epidural morphine than with fentanyl (134).

Epidural administration of opioids has been reviewed (SEDA-21, 92). Morphine causes less respiratory depression and provides better analgesia when it is given by continuous infusion than by intermittent bolus. The authors concluded that epidural fentanyl offers no advantage over the intravenous route and that the mechanism of analgesia is by a systemic effect due to the vascular absorption of this lipophilic drug. However, the administration of lipophilic opioids together with a local anesthetic offers the advantage of using lower doses of both drugs, giving comparable analgesia with a reduction in adverse effects.

Patient-controlled epidural analgesia (PCEA) with fentanyl gives superior analgesia and reduces opioid doses, but without a reduction in adverse effects. However, PCEA with sufentanil offers no advantage (SEDA-19, 87).

Studies of the use of the partial opioid agonist butorphanol to reduce the adverse effects of epidural morphine have not provided evidence of benefit (SEDA-19, 86). Epidural meptazinol has been described as being well tolerated (135).

Respiratory

Respiratory depression occurs less often after epidural than intrathecal opioid administration (109,110). It has been suggested that older patients and those with increased intrathoracic or intra-abdominal pressure are particularly at risk and require reduced dosages (133). In a retrospective study, in which over 6000 patients received epidural morphine, 220 epidural pethidine, and 90 intrathecal morphine, respiratory depression requiring naloxone occurred in about 0.33% after epidural morphine and 5.5% after intrathecal morphine (110). Only two of the patients who received epidural morphine had respiratory depression later than 6 hours after the last dose of opioid. Only three of the 22 patients who had respiratory depression after epidural morphine had not received opioids in addition to epidural morphine during or after the operation. Ten were over 70 years old and 10 had thoracic injections. In another study of 2000 women who received 9000 doses of epidural pethidine 50 mg there was only one case of respiratory depression; this was due to migration of the catheter into the subarachnoid space (136).

The time taken for diffusion of poorly lipid-soluble opioids, such as morphine, from the lumbar subarachnoid space to the fourth ventricle is the most likely explanation for the delayed onset of respiratory depression. It has been suggested that the frequency of respiratory depression can be influenced by the position of the patient and the form of administration, as well as by the dosage of the opioid and the volume of the solution (112).

Doxapram has been used to treat respiratory depression after epidural morphine (137). However, the patient still required endotracheal intubation and mechanical ventilation to correct severe hypercapnia.

Markedly lipid-soluble opioids have also been reported to cause respiratory depression. There was profound respiratory depression 100 minutes after the administration of fentanyl 100 micrograms epidurally (138), whilst epidural sufentanil caused apnea within a couple of minutes, reversed by nalbuphine (139). Epidural buprenorphine 150 micrograms produced prolonged time-dependent biphasic depression of carbon dioxide response in six healthy volunteers. The second maximum occurred at 8–10 hours after injection (140). Similar cases have been reported by others.

Respiratory depression occurred 3.5 hours after a 2.5-year-old child had been given a caudal epidural of 100 micrograms/kg of morphine (141). The effects were successfully reversed by intravenous naloxone.

The efficacy of up to two doses of epidural hydromorphine 1.5 mg has been evaluated in 10 women after cesarean section (142). The mean duration of analgesia was 19.3 hours. Adverse effects were pruritus (56–70%), nausea (11–20%), and vomiting (less than 10%). There was a significant increase in venous PCO_2 3 hours after the second dose of hydromorphine. There was no delayed respiratory depression.

Extradural diamorphine 5 mg, extradural phenoperidine 2 mg, and intramuscular diamorphine 5 mg have been compared (143). Extradural diamorphine produced more prolonged and intense analgesia and there were no serious adverse effects.

Epidural opioids have a much better safety margin in patients who are already tolerant to such drugs (144). Tolerance has also not proven to be a problem (145).

Cardiovascular

Both severe hypotension and severe hypertension have occurred after epidural pethidine (146,147).

There were symptoms of shock lasting 2–3 hours in two women with advanced cancer who were given epidural buprenorphine 300 micrograms after becoming tolerant to epidural morphine (148). The buprenorphine was given 12 hours after the last dose of morphine. Symptoms started within 2 hours of administration and remitted spontaneously.

Nervous system

Myoclonic seizures after epidural morphine 25 mg/hour and after intrathecal hydromorphone have been reported (149).

- A 30-year-old known epileptic woman who had undergone cesarean section developed a tonic-clonic seizure 6 hours after epidural morphine (150).

Two cases of Menière-like syndrome (SEDA-16, 83) (151), and vertical nystagmus and blurred vision (SEDA-16, 83) (SEDA-17, 86), have been reported after epidural morphine.

Catatonia has been reported after a continuous infusion of epidural morphine (152). Hallucinations were thought to be an important sign of impending intoxication.

Mechanical difficulties, in the form of backflow of solution from epidural catheters, occurred in 31 of 32 patients and there were neurological complications in a further two of eight patients in whom the catheter had been tunnelled and connected to a subcutaneous access port; epidural fibrosis with compression of the spinal cord was presumed to be the cause (144).

Epidural fibrosis is a reported complication after long-term epidural morphine administration (SEDA-17, 85).

Psychological, psychiatric

Psychomotor symptoms have been noted subsequent to epidural buprenorphine (153).

Gastrointestinal

Whereas a high incidence (50%) of delayed (6 hours) nausea and vomiting has been reported in volunteers who received epidural morphine (154), there is a low incidence postoperatively (155). In another series the incidence of nausea (12%) and vomiting (24%) was similar whether morphine was used intramuscularly or epidurally or saline was injected epidurally (156). In labor the incidence of this adverse effect is low with epidural opioids (136,157) compared with intrathecal opioids (119,120). The incidence appears to fall with repeated dosing and is very low in patients with cancer who require long-term opioids (111,158). Nausea and vomiting have also been reported after fentanyl (159,160) and pethidine (161). The effects are abolished by intravenous naloxone without loss of analgesia (162).

Urinary tract

Current evidence suggests that the urodynamic effects of epidural morphine are not dose-related, and the incidence is similar to that reported after intramuscular injections. Urinary retention is more frequent after the use of epidural opioids in volunteers compared with patients

© 2006 Elsevier B.V. All rights reserved.

(163,166). In one series (154) two patients who had failed to respond to bethanechol 5 mg subcutaneously, responded to intravenous naloxone 400 micrograms, and in other studies all subjects responded to naloxone 800 micrograms (164–167), which suggests that the mechanism involves opioid receptors. There was a 22% incidence of urinary retention in 90 postoperative patients who received epidural morphine (168), and in another series a rate of 39% (112). In a dose–response study of epidural morphine in increments of 0.5–8 mg (169) there was a similar incidence of urinary retention at all doses. These results are similar to those in a volunteer study involving 30 subjects who received 2, 4, or 10 mg of morphine epidurally (164).

Skin

Pruritus has been noted after epidural morphine, pethidine (meperidine), diamorphine (heroin), and fentanyl, with a quoted incidence of 1–100%. Troublesome pruritus occurs in only about 1% of cases (SED-11, 139) (102). In one study of postoperative patients who received morphine 10 mg epidurally, pruritus occurred in 28% of patients (112), but in only 1% of patients in other studies who received 5 and 2 mg morphine (SED-11, 139). With pethidine 50 mg epidurally after cesarean section, there was a 50% incidence of pruritus, but it was troublesome in only one patient (136). Pruritus has been reviewed in relation to parturition (170,171). It occurred in 593 cases (43%) in pregnant women compared with 3050 non-parturients (8.4%). These findings are borne out by other comparative work (137). Pruritus after cesarean section was more common with epidural morphine and fentanyl than with buprenorphine or butorphanol (172).

Suggested mechanisms for the difference in the incidence of pruritus in parturients and non-parturients include high plasma concentrations of maternal endorphins during labor together with more distant spread of morphine within the CSF, competition by estrogens for opioid-binding sites, and hormonal modifications of endogenous opioid concentrations at opioid receptors. It has also been suggested that the incidence of all adverse effects after spinal opioids may be higher in pregnant women, for the reasons stated above.

Various approaches have been used to try to eliminate pruritus with opioids. Substitution of epidural buprenorphine for morphine in combination with bupivacaine relieved severe unremitting pruritus in a single case (173). Injection of 10 mg nalbuphine subcutaneously significantly reduced the pruritus induced by epidural fentanyl within 15 minutes in 24 patients (174). Naltrexone 6 mg by mouth significantly reduced the incidence of pruritus after epidural morphine without affecting analgesia, but a dose of 9 mg was associated with a shorter duration of analgesia (175). Naloxone and propofol can reduce pruritus (SEDA-19, 87) (154), and the addition of droperidol to epidural sufentanil reduced the adverse effects of nausea, vomiting, and pruritus (SEDA-19, 88).

Spinal opioids probably cause widespread alterations in sensory modulation, as it occurs when there is evidence of opioid migration over the entire spinal cord to the brain. The dominant feature of facial pruritus, which is often reported, can be explained by rapid penetration of opioid to the superficially placed caudal portions of the nucleus of the spinal tract of the trigeminal nerve (154).

Pruritus is not due to preservatives in formulations, as it occurs with non-preservative-containing opioid solutions (176). It is unlikely to be due to histamine release, as the effect occurs about 3 hours after spinal or epidural administration (154,177–179) and occurs with fentanyl, which does not cause histamine release, in contrast to morphine (180).

Immunologic

An anaphylactic reaction to epidural fentanyl has been reported (181).

Body temperature

Maternal pyrexia has been reported following epidural opioid analgesia during labor. This may be the result of vascular and thermoregulatory modifications induced by the epidural analgesia (182).

Fetotoxicity

The effect of obstetric epidural administration of a mixture of 8 ml of bupivacaine (0.25%) with fentanyl 50 micrograms has been studied in 40 offspring (183). Fetal distress occurred in 11 babies, five of whom needed resuscitation; there was no correlation between fetal distress and plasma fentanyl concentrations in the neonates.

The use of epidural opioids in labor can pose a risk to the fetus (184), but in a series of 40 parturients who received either epidural morphine 2.0–7.5 mg or bupivacaine (10 patients), the opioid did not produce respiratory depression in the neonate (185).

Drug overdose

Acute opioid poisoning involves marked CNS depression, with drowsiness, loss of consciousness, and coma. Other prominent features are a reduced respiratory rate, hypotension, and symmetrical pinpoint pupils (unless the patient has been hypoxic for some time, in which case the pupils can be dilated). Reduced urine output, hypothermia, flaccid skeletal muscles, and pulmonary edema can also be present. Convulsions have occurred in children.

Rhabdomyolysis in association with myoglobinuric renal insufficiency and cardiac failure has been reported with a variety of agents (SEDA-8, 76) (186).

Respiratory depression can be rapidly reversed by clearing the airway, ventilating the patient, and giving intravenous naloxone. The duration of action of naloxone is generally shorter than that of opioids, necessitating periodic repeated administration.

Drug–Drug Interactions

General

For various interactions, see Table 2.

Opioids can reduce or prolong the gastrointestinal absorption of other drugs. The partial opioid agonists, for example buprenorphine and pentazocine, can antagonize the effect of poor opioid agonists.

© 2006 Elsevier B.V. All rights reserved.

Increased respiratory depression can occur if other respiratory depressant drugs, for example hypnotics, sedatives, or alcohol, are taken concurrently. Muscle relaxants and antihistamines with sedative properties have a similar effect.

Monoamine oxidase inhibitors

Opioid analgesics interact with non-selective monoamine oxidase inhibitors, causing nervous system excitation and hypertension (187).

Concomitant use of some opioid analgesics, such as pethidine or dextropropoxyphene, with the selective monoamine oxidase inhibitors selegiline and moclobemide can enhance their nervous system toxicity (188).

Phenothiazines

Hypotensive effects are increased if opioids and phenothiazines are used together (SED-9, 109).

Opioid antagonists

See also Individual agents

General Information

Opioids are naturally occurring or synthetic substances that have morphine-like activity. The term opiate refers only to substances with morphine-like activity that are derived from opium. Substances that bind to opioid receptors but elicit little agonist activity are known as opioid antagonists (1–3). Some drugs have both agonist and antagonist effects (partial agonists). The opioids and their antagonists can be divided into three groups:

(a) opioid agonists (morphine and morphine-like opioids);
(b) opioid antagonists (for example naloxone and naltrexone);
(c) opioid partial agonists (for example buprenorphine and nalbuphine).

Individual drugs are covered in seperate monographs.

General adverse effects

The main adverse effects of the opioid antagonists fall into two groups. The first are those caused by a reversal of opioid actions; these include hypotension, pulmonary edema, atrial and ventricular dysrhythmias, and cardiac arrest. The risk of such effects is increased in patients with pre-existing cardiac abnormalities. The second group of effects results from direct actions of the opioid antagonists and their actions on the central nervous system, that is typical opioid effects, including dependence.

Oprelvekin

General Information

Oprelvekin has thrombopoietic activity and has been licensed to prevent severe thrombocytopenia and reduce the need for platelet transfusion after myelosuppressive chemotherapy (1). Common adverse effects included myalgia and arthralgias, fatigue, headache, and conjunctival injection. Peripheral edema, dyspnea, pleural effusions, tachycardia, and anemia were supposedly the result of oprelvekin-induced fluid retention (SEDA-20, 336) (SEDA-21, 376). Atrial flutter or fibrillation were sometimes noted.

Severe fluid retention resistant to furosemide and fluid restriction was observed in 10 patients randomized to receive subcutaneous oprelvekin 50 μg/kg/day to prevent mucositis and acute graft-versus-host disease after allogeneic stem cell transplantation (2). One patient also had a large but reversible increase in serum transaminases.

A preliminary study of the thrombopoietic effect of oprelvekin (50 μg/kg/day for 21 days) in patients with refractory immune thrombocytopenic purpura was halted, since all of the first seven patients had adverse effects without significant changes in the platelet count (3). Adverse effects consisted of conjunctival injection, diffuse aches and joint pains, marked pedal edema, petechiae, and mild anemia. In addition, one patient had a neuropathy, which resolved more than 1 month after oprelvekin withdrawal.

Orciprenaline

See also Adrenoceptor agonists

General Information

Orciprenaline is somewhat $beta_2$-selective compared with isoprenaline, but is by no means free of cardiac effects (1). Individual susceptibility to these varies, but it would seem that about one individual in 10 will experience tachycardia after usual therapeutic doses. At normal doses (for example 20 mg qds) "jitteriness" and nervousness are not uncommon, and about one patient in 12 suffers from cramps or numbness in the extremities. Lactic acidosis has been described in one patient as a result of concomitant use of orciprenaline, theophylline, and glucocorticoids. Other susceptibility factors and interactions are as for isoprenaline.

Organic solvents

General Information

Lighter fuels, benzene, toluene, cleaning fluids (carbon tetrachloride), petrol, paraffin, and even the fluorocarbon propellants found in various household sprays and medications have all been used, particularly by children, to produce changes in consciousness. They are all inhaled, often with the aid of a plastic bag, and, since they are lipid-soluble, they are readily concentrated in brain tissue. As with many anesthetics there is an early period of hyperactivity, excitement, and intoxication, followed by sedation and confusion. Prolonged or regular use can cause serious toxicity with bone-marrow depression, cardiac dysrhythmias, peripheral neuropathy, cerebral damage, and liver and kidney disorders (SEDA-12, 37) (1).

Orgotein

General Information

Orgotein, an enzyme (CuZn superoxide dismutase) that is present in all mammalian cells, is obtained from bovine liver by several steps, including chromatography. It can be given parenterally or topically. Reliable published clinical experience of its properties is limited. In Germany, marketing approval for orgotein was suspended because of severe reactions and deaths, mostly due to hypersensitivity (SEDA-18, 107).

Organs and Systems

Immunologic

Two anaphylactic reactions have been reported, one after intra-articular injection, the other after submucosal bladder injection of orgotein. An IgE-mediated mechanism was demonstrated in the first case (SEDA-12, 94) (SEDA-14, 96).

Drug Administration

Drug administration route

Painful local subcutaneous reactions, erythema, urticaria, and pruritus have been observed after topical administration (1), as have fever and swelling, redness, heat, and pain at the injection site after intravenous administration (2).

Ornidazole

General Information

Used in single large doses for the treatment of *Trichomonas urogenitalis* or *Giardia* infections, ornidazole can cause gastrointestinal symptoms (SEDA-11, 597) (1).

Organs and Systems

Nervous system

- A meningeal syndrome with fever has been reported in a 65-year-old man on the fourth day of administration of ornidazole (500 mg tds) (2). Spontaneous recovery occurred within a few days and without sequelae.

Liver

Ornidazole can cause hepatotoxic damage resembling acute cholestatic hepatitis (3).

Orphenadrine

See also Adrenoceptor agonists

General Information

Orphenadrine is related to an antihistamine (diphenhydramine), and appears to have been developed in the hope of producing a greater effect in Parkinson's disease by combining both anticholinergic and antihistaminic effects in a single molecule.

In the doses commonly used, any of the well-recognized anticholinergic effects can occur. Some patients become drowsy, whilst others are stimulated. With increasing dosages, some patients go into coma; others have agitation, convulsions, and marked euphoria, perhaps with hallucinations and disorientation.

Organs and Systems

Cardiovascular

Non-sustained ventricular tachycardia has been attributed to orphenadrine (1).

- A 57-year-old woman had been taking a formulation containing orphenadrine 15 mg and paracetamol 450 mg bd for musculoskeletal pain. She was also taking propafenone 600 mg/day for paroxysmal atrial fibrillation. After 5 days she developed severe palpitation. Holter monitoring showed frequent brief episodes not only of atrial fibrillation but also of non-sustained ventricular tachycardia. After the orphenadrine was withdrawn the palpitation ceased.

The authors pointed out the potential problems of anticholinergic drugs like orphenadrine in patients taking antidysrhythmic drugs.

Long-Term Effects

Drug abuse

Orphenadrine abuse has been described (SEDA-14, 122).

Drug Administration

Drug overdose

In overdosage, orphenadrine has been stated to be relatively toxic (SEDA-3, 124). Although some patients have survived doses grossly in excess of the usual maximum of 400 mg/day, the therapeutic margin can vary. On occasion doses of as little as 2–3 g have produced a fatal outcome within 6–12 hours. The clinical picture of intoxication tends to be characterized by coma with seizures, apnea, disturbances of cardiac rhythm, and shock; physostigmine should only be used cautiously and preferably after the most severe toxic phase has been overcome (2).

Osmic acid

General Information

Osmic acid is injected into joints for chemical synovectomy and is associated with local pain, effusions, and fever; skin necrosis is less frequent (1). Nerve damage and abnormal urinary findings (hematuria, proteinuria, and leukocyturia) can occur (SEDA-12, 94). A potentially dangerous drug, it certainly should not be given to young patients.

Oxaceprol

General Information

Oxaceprol, a hydroxyproline derivative, has been used to treat osteoarthritis (1,2). Gastrointestinal reactions, nervous system reactions (headache, dizziness), and skin reactions have been reported (3), but oxaceprol is reportedly tolerated at least as well as diclofenac (1) or better (2).

References

Oxametacin

See also Non-steroidal anti-inflammatory drugs

General Information

The adverse reactions pattern of oxametacin is similar to that of indometacin. In one study, 17% of 771 patients taking oxametacin had adverse effects, which led to withdrawal of treatment in 87. Gastrointestinal adverse effects accounted for 60% and nervous system reactions (headache, dizziness) for 31% (1).

Reference

Oxamniquine

General Information

Oxamniquine, in doses of 15 mg/kg or in a single oral dose of up to 15 mg/kg bd for 2 days, depending on the sensitivity of *Schistosoma mansoni* in the area concerned, is effective with minimal toxicity. It has no effect in *Schistosoma hematobium*. It is no longer given intramuscularly, because of severe pain at the injection site.

Reactions occur in up to one-third of patients and include dizziness, drowsiness, headache, amnesia, occasional behavioral disturbances (hallucinations, excitement), and even seizures (SEDA-14, 262); there is often some nausea, vomiting, and diarrhea (1). Allergic manifestations include fever and pruritic skin rashes. Minor abnormalities of liver function and creatine kinase, proteinuria, and hematuria have been reported.

Organs and Systems

Cardiovascular

Electrocardiographic and electroencephalographic changes have been reported as rare adverse effects of oxamniquine (SEDA-11, 598) (2).

Nervous system

Oxamniquine can cause neurological adverse effects (3). At high doses, somnolence was reported in 25% of cases. Somnolence is reportedly more common if the drug is given just before a meal. In a comparison of oxamniquine with praziquantel, there were adverse effects in 45% of patients treated with oxamniquine and 71% of patients given praziquantel; somnolence occurred less often (11% of cases) with praziquantel (SEDA-12, 709) (4).

Headache and dizziness have also been reported with oxamniquine (5).

Gastrointestinal

Gastrointestinal complaints are common with oxamniquine, and take the form of anorexia, abdominal discomfort, and diarrhea (4).

Liver

Hepatic enzyme changes, initially reported as rare with oxamniquine, may in fact be frequent if sought. In one study, there were changes in 79% of patients, with raised alkaline phosphatase in 36% and a raised eosinophil count in 52% (SEDA-13, 837) (6).

© 2006 Elsevier B.V. All rights reserved.

Immunologic

Fever occurs in about a quarter of patients taking oxamniquine (SEDA-11, 598) (7), and in some 15% of these, a Löffler-like syndrome with eosinophilia and pulmonary infiltrates was seen when it was specifically looked for.

Oxaprozin

See also Non-steroidal anti-inflammatory drugs

General Information

In controlled studies, oxaprozin caused adverse effects in 23–58% of patients (1). It was considered better than aspirin and similar to other NSAIDs in long-term studies (2). However, treatment had to be interrupted owing to adverse effects in 8–31% of patients.

Organs and Systems

Nervous system

Headache, dizziness, vertigo, and tinnitus are less frequent with oxaprozin than with indometacin or aspirin (3,4).

Metabolism

Drug-induced pseudoporphyria has been ascribed to oxaprozin (SEDA-21, 106).

Liver

There were minor rises in transaminase activity in 10–20% of patients taking oxaprozin. Liver function should be monitored, especially during the first 6 months of therapy. Fulminant hepatitis has been reported (5).

Urinary tract

Of 847 patients with different rheumatic diseases who took oxaprozin daily for up to 1 year, 6% developed significant rises in blood urea nitrogen or creatinine, but a severe adverse renal effect occurred in only one patient (SEDA-12, 87). Oxaprozin can cause membranous nephropathy with nephrotic syndrome (SEDA-21, 106).

Skin

Under 5% of patients taking oxaprozin develop rashes. Some have phototoxic reactions (SEDA-12, 87).

Toxic epidermal necrolysis occurred in a 71-year-old man after treatment with oxaprozin for shoulder pain (6).

Immunologic

Life-threatening respiratory distress, facial edema, and lethargy occurred in a woman with a history of severe asthma and aspirin allergy (SEDA-22, 118).

Susceptibility Factors

Age

Older patients are more likely to have gastrointestinal and nephrotoxic reactions to oxaprozin. In this respect, it differs little from other NSAIDs.

Drug–Drug Interactions

Cimetidine

The clinical significance of the reduced renal clearance of oxaprozin when it is given concomitantly with cimetidine is not clear (SEDA-12, 87).

Ranitidine

The clinical significance of the reduced renal clearance of oxaprozin when it is given concomitantly with ranitidine is not clear (SEDA-12, 87).

Oxatomide

See also Antihistamines

General Information

Oxatomide is a second-generation antihistamine (SED-12, 371) (SEDA-18, 185) (SEDA-21, 176).

Organs and Systems

Respiratory

In some cases of asthma exacerbation of bronchospasm has occurred when patients have taken oxatomide (1,2).

Nervous system

Oxatomide caused drowsiness in 37–56% of treated patients (3,4).

Liver

Acute cytolytic hepatitis has been attributed to oxatomide (5). An eruption and liver damage has been described in an elderly woman taking several different antihistamines; oral rechallenge with both terfenadine and oxatomide caused erythema, and there was mild liver dysfunction after oxatomide (6).

Skin

When oxatomide was used topically in a gel in 22 patients with vulvar lichen sclerosus, in a concentration sufficient to relieve pruritus, some patients withdrew from treatment because of a burning sensation (7).

Oxazepam

See also Benzodiazepines

General Information

Oxazepam is a relatively short-acting benzodiazepine with a half-life of about 9 hours. As well as being used as a drug in its own right, it is a metabolite of temazepam and desmethyldiazepam.

Passiflora incarnata extract has been compared with oxazepam in a double-blind, randomized trial in 26 outpatients with DSM-IV generalized anxiety disorder (1). Both were effective, but oxazepam had a more rapid onset of action and caused significantly more problems relating to work performance.

Organs and Systems

Psychological, psychiatric

An important behavioral adverse effect of benzodiazepines, hostility and aggression in response to provocation, is less common with oxazepam than with its closely related analogue lorazepam (2). In a study of the effects of oxazepam on implicit versus explicit memory processes, as a function of time-course the effects of oxazepam (30 mg) or placebo on directly comparable tests of implicit memory and explicit memory were examined at three times in 60 healthy volunteers. Before the plasma concentration had peaked, oxazepam impaired cued recall performance relative to placebo but did not impair priming. At the time of the peak, oxazepam impaired performance in both memory tasks. After the peak, cued recall performance in the oxazepam group remained significantly impaired relative to placebo. However, oxazepam-induced impairments in priming were only marginal, suggesting that oxazepam-induced impairments in implicit memory processes begin to wane after theoretical peak drug concentrations. The results support the hypothesis that benzodiazepines cause impaired implicit memory processes time-dependently (3).

In 30 subjects who were given an acute dose of oxazepam 30 mg, lorazepam 2 mg, or placebo, both drugs impaired explicit memory relative to placebo. Also, both oxazepam and lorazepam impaired priming performance. The results suggested that episodic memory is time-dependently impaired by both benzodiazepines (4).

Oxazolidinones

General Information

The oxazolidinones have a unique mechanism of action, involving inhibition of the first step in protein synthesis. The first marketed member of the class, linezolid, has inhibitory activity against a broad range of Gram-positive bacteria, including methicillin-resistant *Staphylococcus aureus* (MRSA), glycopeptide-intermediate *Staphylococcus aureus* (GISA), vancomycin-resistant enterococci (VRE), and penicillin-resistant *Streptococcus pneumoniae*. It also has activity against certain anerobes, including *Clostridium perfringens*, *Clostridium difficile*, *Peptostreptococcus* species, and *Bacteroides fragilis*. The most frequently reported adverse effects are diarrhea, headache, nausea and vomiting, insomnia, constipation, rash, and dizziness; thrombocytopenia has also been documented in a few patients (about 2%) (1,2).

In controlled phase III studies, linezolid was as effective as vancomycin in patients with infections caused by MRSA and VRE. It is effective both intravenously and orally. Although technically classified as bacteriostatic against a number of pathogens in vitro, linezolid behaves in vivo like a bactericidal antibiotic.

The pharmacokinetics of linezolid in adults are not altered by hepatic or renal function, age, or sex to an extent that requires dose adjustment. Linezolid is metabolized via morpholine ring oxidation, which is independent of CYP450; linezolid is therefore unlikely to interact with medications that induce or inhibit CYP450 enzymes. Plasma linezolid trough concentrations after a 1-hour infusion of 600 mg bd were 0.54–5.3 μg/ml and CSF linezolid trough concentrations were 1.46–7.0 μg/ml; the ratio between CSF and plasma linezolid trough concentrations always exceeded 1 (mean, 1.6; range 1.2–2.3) (3). There was good rapid penetration of linezolid into bone, fat, and muscle (4,5). The mean peak plasma concentration of linezolid was 18.3 μg/ml in six healthy men who took 600 mg orally every 12 hours for five doses. There was good penetration into inflammatory fluid (6,7).

General adverse effects

Linezolid is generally well tolerated (8–10). The most frequently reported adverse events were diarrhea, headache, nausea and vomiting, insomnia, constipation, rash, and dizziness. Thrombocytopenia was also documented in few patients (about 2%). In a phase II, open, multicenter study of intravenous linezolid followed by oral linezolid suspension, both in a dose of 10 mg/kg every 12 hours in 66 children, the most common adverse effects were diarrhea (10%), neutropenia (6.4%), and raised alanine transaminase activity (6.4%) (11).

In children the common adverse events have been similar to those found in adults, although thrombocytopenia has not been as common (12).

Organs and Systems

Nervous system

Peripheral and optic neuropathy occurred in a 76-year-old man after he had taken linezolid for about 6 months (13).

Hematologic

Linezolid has been associated with reversible myelosuppression (14), which appears to be related to the duration of therapy, with a higher risk after more than 2 consecutive weeks of treatment (15). Myelosuppression with red cell hypoplasia has been reported in three patients taking linezolid 600 mg bd. The bone marrow changes were similar to those seen in reversible chloramphenicol toxicity. Another patient had sideroblastic anemia after taking linezolid for 2 months (16,17).

- Red cell hypoplasia and thrombocytopenia occurred in a 66-year-old man who took linezolid 600 mg bd (18).
- Reversible pure red blood cell aplasia occurred in a 52-year-old black man who had taken linezolid for 8 weeks (19).

Pancytopenia in two cases was reported with linezolid 600 mg bd (20).

In 19 patients there was thrombocytopenia in six of those who had taken it for more than 10 days; gastrointestinal bleeding was observed in one patient and four required platelet transfusions (21). Of 71 patients who took linezolid for 1–44 days, 48 took it for more than 5 days; among those 48, thrombocytopenia, with a 32–89% reduction in platelet count, occurred in 23; the platelet count fell to below 100×10^9/l in nine (22).

Susceptibility Factors

Age

In single-dose pharmacokinetic studies children had a greater plasma clearance (0.34 l/hour/kg for children aged 3 months to 16 years) than adults (0.10 l/hour/kg) (12).

Drug–Drug Interactions

Selective serotonin re-uptake inhibitors (SSRIs)

Serotonin syndrome was reported in a 56-year-old white woman who received intravenous linezolid shortly after withdrawal of a selective serotonin reuptake inhibitor, paroxetine (23).

© 2006 Elsevier B.V. All rights reserved.

The serotonin syndrome was reported in a 45-year-old white man who received intravenous linezolid (600 mg 12 hourly) and sertraline (24).

Oxcarbazepine

See also Antiepileptic drugs

General Information

Oxcarbazepine is the 10-keto analogue of carbamazepine and a prodrug for monohydroxycarbazepine, to which it is rapidly reduced. Its efficacy and tolerability profiles are similar to those of carbamazepine, from which oxcarbazepine differs in kinetic profile (lack of autoinduction, linear kinetics, half-life of 10–20 hours, elimination by glucuronidation), lower allergenicity, greater antidiuretic activity, possibly slightly better central nervous system tolerability, and less potential for drug interactions (1). Like carbamazepine, oxcarbazepine can exacerbate absence and myoclonic seizures (SEDA-21, 73).

Oxcarbazepine has not been associated with hepatotoxicity or hematological toxicity. It is less likely than carbamazepine to cause hypersensitivity reactions, but may be more often associated with hyponatremia. It is less likely than carbamazepine to induce CYP450 isozymes, but it may significantly increase the clearance of oral contraceptives and significantly induce CYP450 at higher doses.

The pharmacology, clinical pharmacology, and adverse reactions and interactions of oxcarbazepine have been reviewed (2–6).

Placebo-controlled studies

The safety and efficacy of oxcarbazepine 600–2400 mg/day as adjunctive therapy for uncontrolled partial seizures have been studied in a randomized, double-blind, placebo-controlled study in 694 patients aged 15–65 years (7). During the double-blind phase, 76%, 84%, 90%, and 98% of patients respectively taking placebo or oxcarbazepine 600, 1200, or 2400 mg/day reported one or more adverse events. The most common adverse events were related to the nervous and gastrointestinal systems.

The safety and efficacy of oxcarbazepine 300 and 2400 mg/day have been studied in patients with refractory partial epilepsy in a double-blind, randomized trial (8). Dizziness, fatigue, somnolence, and nausea, mostly transient and mild to moderate, were the most frequent adverse events.

The safety and efficacy of oxcarbazepine have been studied in a randomized, placebo-controlled trial in 267 children with inadequately controlled partial seizures (9). There was at least one adverse event in 91% of those who took oxcarbazepine and 82% of those who took placebo;

© 2006 Elsevier B.V. All rights reserved.

vomiting, somnolence, dizziness, and nausea occurred more often (two-fold or more) with oxcarbazepine.

Two doses of oxcarbazepine have been compared in a double-blind, parallel-group, randomized trial in patients with uncontrolled partial-onset epilepsy who had previously taken carbamazepine monotherapy (10). After two open phases in 143 patients, 96 were randomized to oxcarbazepine 300 or 2400 mg/day for 126 days. The time to meet an exit criterion was significantly in favor of oxcarbazepine 2400 mg/day. In all, 24 of the 47 non-randomized patients withdrew because of an adverse event, most commonly dizziness, ataxia, headache, nausea, vomiting, or fatigue. Three withdrew because of laboratory abnormalities, one each with leukopenia, hyponatremia, and hyperglycemia. Headache, dizziness, and nausea were the only adverse events that occurred in more than 10% in either group. Similar adverse events were reported in the randomized patients, but none withdrew.

Organs and Systems

Nervous system

- A 31-year-old man developed oculogyric crises after starting to take oxcarbazepine, and the frequency of these episodes correlated with the dosage of the drug (11). Similar episodes had occurred in the past after exposure to carbamazepine. The implantation of a vagus nerve stimulator led to the disappearance of the oculogyric crises.

Electrolyte balance

Hyponatremia occurs in an appreciable proportion of patients taking oxcarbazepine (12), perhaps more often than with carbamazepine; it is usually asymptomatic. Among 2166 oxcarbazepine-treated patients in the manufacturer's database, the incidence of sodium concentrations below 135 mmol/l was 22% (13). There was marked hyponatremia (sodium concentrations below 125 mmol/l) in 2.7% overall and the risk increased with age: 0% below 6 years, 0.5% 6–17 years, 3.4% at 18–64 years, and 7.3% above 65 years. The incidence of adverse events was similar in all sodium categories: the absence of symptoms suggests that the fall in sodium concentrations was not precipitous.

Changes in serum electrolyte balance and underlying regulatory mechanisms have been evaluated in 10 men with epilepsy 2 and 6 months after long-term carbamazepine monotherapy had been replaced with oxcarbazepine (14). Serum sodium concentrations fell in four patients (in two below the reference range) and were unaltered in six. Serum aldosterone rose in the six patients whose serum sodium concentrations did not fall, but not in those with low sodium concentrations during oxcarbazepine. The serum concentration of the N-terminal fragment of pro-atrial natriuretic peptide fell in all patients, reflecting the reduced serum sodium concentrations. Thus, compensatory aldosterone release may prevent hyponatremia in some patients taking oxcarbazepine.

In one series in which there were low serum sodium concentrations in patients taking oxcarbazepine, 25% had concentrations below 135 mmol/l and 3% had concentrations below 125 mmol/l (12). In most patients, the hyponatremia was asymptomatic and only rarely resulted in morbidity or led to drug withdrawal.

In a prospective study, 11 patients with epilepsy and 10 controls taking oxcarbazepine 600–1800 mg/day for 3 weeks were subjected to a water-load test (15). Oxcarbazepine significantly reduced serum osmolality and serum sodium concentration after a water-load test in both healthy volunteers and patients with epilepsy. The hyponatremia was hypotonic and not associated with a significant change in serum concentrations of arginine vasopressin; thus, it could not be attributed to inappropriate secretion of ADH. There was a statistically significant negative correlation between the trough plasma concentration of the monohydroxylated derivative of oxcarbazepine and the percentage of the water load excreted at 1 hour. The hyponatremia appears to result from both a relative inability to dilute the urine and a reduction in the percentage of water excreted. The underlying mechanism might be related to a direct effect of the drug on the renal collecting tubules or enhancement of their responsiveness to circulating antidiuretic hormone.

Susceptibility Factors

- A 28-year-old man with porphyria cutanea tarda took oxcarbazepine without adverse effects, suggesting that oxcarbazepine may be used in patients with this disorder (16); most other antiepileptic drugs cannot.

Drug–Drug Interactions

General

Oxcarbazepine is a weaker enzyme inducer than carbamazepine. When it is substituted for carbamazepine, plasma concentrations of concomitant drugs, such as valproate and neuroleptic drugs, can rise, owing to de-induction, leading to potential toxicity (17,18).

Oxcarbazepine metabolism is unaffected by several inhibitors of carbamazepine metabolism.

Ciclosporin

A possible interaction of oxcarbazepine with ciclosporin has been reported after renal transplantation in a 32-year-old man (19). The ciclosporin trough serum concentration and serum sodium concentration fell after oxcarbazepine was added.

Enzyme-inducing anticonvulsants

Enzyme-inducing anticonvulsants cause a modest reduction in monohydroxycarbazepine concentrations (17).

Felodipine

Oxcarbazepine reduces serum felodipine concentrations, although less than carbamazepine does (20).

Lamotrigine

In a retrospective study, in which 376 samples from 222 patients were analysed, oxcarbazepine induced the metabolism of lamotrigine and reduced lamotrigine concentrations by about 29% (21).

© 2006 Elsevier B.V. All rights reserved.

Phenytoin

In human liver microsomes with cDNA-expressed CYP2C19, oxcarbazepine and its 10-monohydroxy metabolite inhibited CYP2C19-mediated phenytoin metabolism at therapeutic concentrations (22). Thus, co-administration of oxcarbazepine with phenytoin could significantly increase serum phenytoin concentrations.

Steroid oral contraceptives

In a placebo-controlled study in healthy women, oxcarbazepine 900 mg/day reduced the serum concentrations of ethinylestradiol and levonorgestrel by about 50% (23). This confirms that oxcarbazepine may reduce the efficacy of the contraceptive pill, as does carbamazepine. Women taking oxcarbazepine should be given a contraceptive that contains 50 μg of ethinylestradiol and they should be monitored for signs of insufficient contraceptive cover, such as breakthrough bleeding.

Warfarin

Oxcarbazepine does not modify the anticoagulant activity of warfarin (17).

Oxitropium

See also Anticholinergic drugs

General Information

Oxitropium is an anticholinergic drug that is used in the treatment of asthma.

In a single blind, randomized, crossover study, in 12 patients the bronchodilator effects of salmeterol 50 micrograms and oxitropium 200 and 400 micrograms were compared with placebo. All treatments were taken from a metered dose inhaler. The peak effect of salmeterol was delayed but the effect was more prolonged than the effect of oxitropium. The response to salmeterol 50 micrograms exceeded the response to oxitropium 200 micrograms over 12 hours. Between 3 and 12 hours the response to salmeterol was greater than the response to oxitropium 400 micrograms, but the difference was not

© 2006 Elsevier B.V. All rights reserved.

significant. There were no significant changes in pulse rate, blood pressure, or the electrocardiogram with any of the four treatments. No patients complained of adverse symptoms and none noticed any difference in the taste of the different inhalers (1).

Organs and Systems

Immunologic

Total serum IgE has been measured in 36 patients with allergic rhinitis and 11 healthy subjects given a submaximal dose of oxitropium bromide 600 micrograms by inhalation (2). FEV_1 was greater than 80% of predicted in all subjects. Baseline FEV_1 correlated negatively with serum IgE concentration. Oxitropium bromide inhalation produced an increase in FEV_1 (mean 155 ml) that was significantly greater in allergic patients with high serum IgE than in healthy subjects (64 ml) or in those with allergic rhinitis and low serum IgE (82 ml). The effect of an inhaled $beta_2$-adrenoceptor agonist (orciprenaline) was similar in all three groups. These findings may explain some of the variation in response to inhaled antimuscarinic drugs in patients with asthma. The data also suggested that IgE may itself modify airway tone by an increase in cholinergic responsiveness.

Oxolamine

General Information

Oxolamine citrate is a synthetic derivative of 3,5-disubstituted 1,2,4-oxodiazole. It has been used to treat cough in some European countries for more than two decades.

Organs and Systems

Psychological, psychiatric

Evidence has accumulated that oxolamine can cause hallucinations in children, especially those under 10 years of age (1,2); some cases have been confirmed by re-exposure to the drug.

Oxybuprocaine

See also Local anesthetics

General Information

Oxybuprocaine is an ester of para-aminobenzoic acid. It is a popular local anesthetic for use in ophthalmology.

Organs and Systems

Cardiovascular

An episode of severe bradycardia, with no perceptible cardiac output, was reported in a previously healthy patient after one drop of 0.4% oxybuprocaine was applied to each eye (1).

Sensory systems

When used in the eye, oxybuprocaine can enter the anterior chamber, and fibrinous iritis and moderate corneal swelling have been described (SED-12, 257) (2). Abuse has often been reported and can lead to keratopathy, severe visual impairment, and even enucleation (3).

Skin

There have been two reports of patients scheduled for tonometry who developed periorbital dermatitis following the topical instillation of local anesthetic eye drops (4). The first patient reacted strongly positive on patch testing to Thilorbin AT (oxybuprocaine, fluorescein, phenylmercuric borate, polysorbate 20, mannitol) and also to oxybuprocaine alone. The second reacted to Conjucain EDO (oxybuprocaine, sorbitol, sodium hydroxide) and to oxybuprocaine alone. The authors believed these to be the only described cases of a delayed hypersensitivity reaction to oxybuprocaine, an ester local anesthetic commonly used for topical anesthesia in the eye.

Oxybutynin

See also Anticholinergic drugs

General Information

Oxybutynin is an anticholinergic drug that is used to treat bladder detrusor instability. It can cause all the adverse effects that would be expected from its anticholinergic action (1).

Oxybutynin 15 mg/day has been compared with a newer anticholinergic agent tolterodine 4 mg/day in a randomized, double-blind, placebo-controlled parallel group study in 293 patients with bladder detrusor instability (2). The efficacies were generally similar, but twice as many patients taking oxybutynin withdrew because of adverse effects (17 versus 8%). Dry mouth was by far the most frequent adverse effect, reported by 86% of patients taking oxybutynin and 50% of those taking tolterodine. Although there was still an excess of adverse effects after halving the dose of oxybutynin, it would not be normal practice to start treatment with this drug in a dose as high as 15 mg/day.

Organs and Systems

Sensory systems

Oxybutynin can precipitate acute angle closure glaucoma (3).

- An 80-year-old woman, who was taking oxybutynin 2.5 mg bd, developed acute angle closure glaucoma but did not suffer permanent visual impairment, despite the very high intraocular pressure (56 mmHg) initially found in the affected eye.

Psychological, psychiatric

Neuropsychiatric adverse effects seem to pose a greater problem with oxybutynin than other anticholinergic drugs. A group of pharmacologists involved in pharmacovigilance have described five spontaneous reports of night terrors associated with oxybutinin (4). Four were children, aged 5–8 years, being treated for enuresis, and the fifth was a 77-year-old woman with incontinence. Total daily doses were 8–12 mg in the children and 10 mg in the elderly woman: these are all toward the upper end of the recommended ranges.

Mouth and teeth

There have been several comparisons of tolterodine and oxybutynin. All agree that oxybutynin, in its standard formulation at a dose of 5 mg bd, while of similar efficacy, produces significantly more adverse effects (5). The incidence of dry mouth reached 60%, and over 75% in patients taking the highest dose of 5 mg tds. Direct measurements of saliva production confirmed that oxybutynin 5 mg/day reduces saliva output significantly more than tolterodine 2 mg or a modified-release formulation of oxybutynin 10 mg, all given as single doses (6). In over 300 patients modified-release oxybutynin once-daily produced less dry mouth (28 versus 33%) than immediate-release tolterodine 2 mg bd (7).

Drug Administration

Drug formulations

An extended-release formulation of oxybutynin has been compared with an immediate-release formulation; it had similar efficacy but fewer adverse effects (8). The overall conclusion of an unsystematic review was that, as expected, dry mouth is very common; it occurred in about two-thirds of those taking the extended-release formulation (up to a dose of 30 mg/day) and in nearly 90% of those who took the immediate-release formulation. In about 25% of those who took the extended-release formulation the dry mouth was classified as severe, compared with nearly 50% of those who took the immediate-release formulation. Other adverse effects were very uncommon and significant toxicity was not reported. In total the two comparative trials involved 331 patients, and an open study of 256 patients was also discussed.

Diagnosis of Adverse Drug Reactions

Means of reducing the adverse effects of oxybutynin have been considered in 226 patients (89% women, mean age 59 years) with urge incontinence and known to be responsive to anticholinergic therapy, who were randomized to take either conventional or modified-release oxybutynin (9). The dosage was titrated up to a maximum of 20 mg/day in both groups. Response rates were similar in both groups, as was the incidence of dry mouth (48% in the modified-release group and 59% in the immediate-release group). However, further analysis showed that at any dose significantly fewer patients complaining of dry mouth in the modified-release group, and this was even more apparent in patients with moderate to severe dry mouth.

Another approach is to try to stimulate salivary flow in patients taking oxybutynin. Malic acid pastilles have been used as a salivary stimulant, but the results were not good, although the study has some design problems (10). Of the 67 women enrolled only 32 completed the 8-week study. It is not clear whether there was any attempt to make the trial double-blind.

Oxycodone

See also Opioid analgesics

General Information

Oxycodone is an opioid analgesic that is 1.5 times as potent as morphine and has a longer duration of action.

Drug studies

Pain relief

The postoperative analgesic effects of intravenous ketamine 10 mg and oxycodone 2 mg have been compared in a randomized, double-blind study in 40 tonsillectomized men (1). There were no significant differences between the two analgesics. The patients found ketamine more acceptable than oxycodone. Oxycodone was associated with more skin problems, especially pruritus. Oxycodone also caused a significantly lower respiratory rate with lower oxygen saturation throughout the recovery period and increased sedation throughout the study.

The effects of modified-release oxycodone in osteoarthritic pain have been evaluated in a placebo-controlled, double-blind trial in 133 patients (2). Oxycodone was effective, and although opioid-related adverse effects were frequent they were considered acceptable by the authors.

In a double-blind, randomized, crossover comparison of the efficacy and safety of modified-release oxycodone bd and immediate-release oxycodone qds in 57 patients with intervertebral disc disease or osteoarthritis, eleven patients withdrew: eight with nausea and constipation while taking modified-release oxycodone and three (one with migraine and two with nausea, vomiting, and headaches) while taking immediate-release oxycodone (3). There were no statistically significant differences in the adverse effects profiles between the two formulations. The overall incidence of adverse effects fell over the three phases of the study: from 89% (51/57 patients) during titration to 77% (36/47 patients) in stage 1 and 62% (29/47 patients) in stage 2. The most common adverse effects were constipation, nausea, pruritus, somnolence, and dizziness, the frequency of which fell with time; the incidence of constipation remained constant.

In a randomized, double-blind, crossover study, previous findings on the adverse effects of oxycodone among sufferers of postherpetic neuralgia were confirmed (4). Oxycodone was analgesic in this group, although 76% of the sample reported adverse effects compared with 49% of the placebo group. Constipation, nausea, and sedation were the most frequently reported adverse effects.

Two studies of oxycodone in patients with cancer pain have been carried out. In the first, modified-release and immediate-release oxycodone were compared (5) in a multicenter, double-blind trial in 180 patients who were given either modified-release oxycodone, mean dose 114 mg bd, or immediate-release oxycodone 127 mg qds, four times a day for cancer-related pain. A 5-day comparison showed no significant difference in the analgesic effects of the two formulations, both of which provided effective relief of pain. However, of the 160 patients who received at least one dose of medication, 104 reported a total of 295 adverse events, significantly fewer being reported with modified-release oxycodone (109) than immediate-release oxycodone (186). Reported adverse effects included: nausea (18 versus 26%), vomiting (11 versus 23%), and constipation (9 versus 17%). With immediate-release oxycodone headache was reported by 7% and anxiety by 5%; neither was reported with modified-release oxycodone. Altogether, 7% of the modified-release group and 11% of the immediate-release group discontinued medication because of adverse effects. It is suggested that the equianalgesic effect is likely to be a factor of the rapid initial release of the modified-release formulation, allowing adequate drug concentrations to establish sufficient receptor activation, followed by a slower release of the remaining drug, which may be responsible for the reduction in adverse effects. Alternatively the peaks achieved with each administration of medication may account for the observed difference in the rates of adverse effects between the two formulations.

The second study was a randomized, double-blind, crossover comparison of the safety and efficacy of oral modified-release oxycodone with modified-release morphine in 32 patients with cancer pain, nine of whom completed the trial (6). The average dose of oxycodone was 47 mg bd compared with 73 mg bd of morphine. There were no significant differences in the degrees of sedation, nausea, or pain intensity experienced by the subjects on the different regimens and the results suggested that oxycodone may be used as an alternative to morphine.

Long-Term Effects

Drug withdrawal

A patient with atypical oxycodone withdrawal had restlessness and delusions (7).

Susceptibility Factors

Age

Children may have a faster rate of clearance of oxycodone than adults, and ventilatory depression may be greater than with comparable opioids in children (SEDA-19, 85).

© 2006 Elsevier B.V. All rights reserved.

Hepatic disease

In end-stage cirrhosis, reduced clearance and prolonged half-life of oxycodone may necessitate dosage reduction (SEDA-22, 101).

Drug Administration

Drug formulations

A double-blind, randomized, crossover comparison of modified-release or immediate-release oxycodone has been carried out in 30 patients with cancer pain (8). There were no significant differences between the two groups with respect to pain intensity or acceptability of therapy. More than 80% of the patients did not require rescue medication. Adverse effects were similar with the two formulations and occurred in relatively low numbers compared with previous morphine studies. The greatest difference in adverse effects was in the incidence of vomiting, which occurred in 6% of those given immediate-release morphine, and none of those given modified-release morphine. The modified-release formulation provided equal analgesia with the benefit of less frequent dosing.

In a systematic review of the safety and efficacy of modified-release oxycodone 16 trials were identified; 7 addressed the safety and efficacy of oxycodone for the treatment of non-cancer pain (9). In these studies, modified-release oxycodone offered no significant advantage over immediate-release oxycodone. There was no consistent beneficial effect on quality of life, despite adequate analgesia. Opioid adverse effects, such as constipation, nausea, vomiting, and drowsiness, were more frequent and severe with oxycodone than with placebo. In six studies, modified-release oxycodone was compared with immediate-release oxycodone in cancer and non-cancer pain. In only one study was modified-release oxycodone superior; in the other five there were no significant differences in analgesic effect. In five randomized, double-blind comparisons there was no advantage in analgesic efficacy nor a consistent reduction in adverse effects with modified-release oxycodone compared with modified-release morphine, hydromorphone, or methadone.

Drug administration route

Oxycodone has been available in oral form for at least 70 years and is rarely given by other routes. In a study of subcutaneous oxycodone hydrochloride 100 mg/ml for opioid rotation in 63 patients with cancer pain (maximum dose 4.5–660 mg in 24 hours for 1–49 days) there was local toxicity in only two cases, and this included central pallor of the skin at the needle site with surrounding erythema and bruising; there was no necrosis (10). The design of the study made it difficult to compare the adverse effects profile of subcutaneous oxycodone with oral oxycodone or other opioids. Randomized controlled trials are needed to support the conclusions that subcutaneous oxycodone is free from adverse effects and is a better vehicle for analgesia in terminal cancer.

Oxyfedrine

See also Adrenoceptor agonists

General Information

Oxyfedrine is a vasodilator and has been used in angina pectoris and myocardial infarction.

Organs and Systems

Sensory systems

Impairment of the sense of taste is a particular complication of oxyfedrine therapy; 21 such cases have been reviewed since 1985 (1) and they continue to be reported to national monitoring centers. This adverse effect usually occurs within 4 weeks after the start of therapy and is slowly reversible after the drug is withdrawn.

Oxygen

General Information

The duration and extent of hyperoxygenation during anesthesia are generally limited. However, in intensive care, a patient's exposure to oxygen can become prolonged and dangerous. Oxygen toxicity can cause adverse effects in numerous tissues, including the lungs, nervous system, eyes, red blood cells, and liver, because of their susceptibility to chemical toxicity by mechanisms such as lipid peroxidation (SED-12, 242) (1).

Organs and Systems

Respiratory

The adverse effects of high-dose oxygen on the lungs take the form of an initial exudation of blood and fibrinous fluid into the alveoli followed by proliferation of fibroblasts and alveolar cells (2). The proliferative phase can be permanent (3). It is reflected in a reduced vital capacity and a reduced diffusion capacity (4) and appears to be proportional to the units of pulmonary toxic dose (UPTD) administered; 1 UPTD is equivalent to 1 absolute atmosphere $\times$ 1 minute of exposure. If exposure exceeds 1000 UPTD it can be difficult to predict the outcome (5), owing to inter-patient differences in susceptibility.

Nervous system

High doses of oxygen can cause convulsant activity resembling tonic-clonic seizures (6) and is associated with reduced concentrations of GABA in the brain. Such fits may not be apparent in sedated patients.

Sensory systems

Oxygen toxicity in the eye can cause tunnel vision by an effect on the retina (7) and, in neonates, retrolental fibroplasia (8) (SED-12, 242).

Hematologic

Oxygen toxicity in red blood cells can cause hemolysis (SED-12, 242) (9).

Oxygen-carrying blood substitutes

General Information

The development of oxygen-carrying blood substitutes, which can act as alternatives for allogenic erythrocyte transfusions, has progressed significantly in the last decade. It is important for the laboratory medicine community to be aware of their effects on routine laboratory testing and the settings in which they might be used (1).

The characteristics of an ideal emulsion for use as a blood substitute are absence of red cell incompatibility, absence of a risk of transmission of infectious diseases, a long duration of conservation, easy access, and rheological parameters similar to those of blood (2).

Oxygen carriers can be divided into two classes: hemoglobin-based oxygen carriers, prepared from hemoglobin of human or bovine origin, and synthetic perfluorocarbons.

Hemoglobin-based oxygen carriers

There are three sources of hemoglobin from which oxygen carriers have been developed: human, bovine, and recombinant. Hemoglobin-based oxygen carriers have benefits, such as the lack of pathogen transmission, no need for cross-matching, and increased stability and storage time; however, compared with erythrocyte transfusions, they have a short half-life. Of various hemoglobin-based oxygen carriers under development, two (Polyheme and Hemopure) have been tested in phase III studies. One product, Hemopure—polymerized hemoglobin of bovine origin—has been licensed for human use in South Africa. The tetrameric hemoglobin easily dissociates in vivo into dimers and monomers that are quickly eliminated by the kidneys. As the administration of tetrameric hemoglobin is associated with renal insufficiency, intermolecular cross-linking of hemoglobin has been performed using different agents to polymerize hemoglobin. Newly developed hemoglobin-based oxygen

© 2006 Elsevier B.V. All rights reserved.

carriers are conjugated hemoglobin or packed hemoglobin in nanocapsules or lipid vesicles (3–6).

Perfluorocarbons

Perfluorocarbons are synthetic, fluorinated hydrocarbons that increase the amount of oxygen dissolved in the fluid phase of the blood. Perfluorocarbon emulsions are heavy, low-viscosity liquids, inert, and optically clear, with a high specific gravity and good surface tension. Their chemical and physical properties make them a suitable temporary intraoperative tool to flatten the retina during surgery, and they have gained wide acceptance in the surgical management of complicated retinal detachment (7). Perfluorocarbons have a transport capacity that is greater than that of blood under hyperoxic conditions (2).

The available formulations include perfluoro-octyl bromide, perfluoro-octylethane, perfluorodichloro-octane, Fluosol-DA (70% perfluorodecalin plus 30% perfluorotripropylamine), Oxygent™ (perflubron, perfluoro-octyl bromide) (5), and LiquiVent (perflubron). Second-generation perfluorocarbons are now used in anemia, trauma, high blood loss surgery, perioperative hemodilution, ischemia, and organ conservation for transplantation. Phase III studies of one of the perfluorocarbons, Oxygent™, are proceeding in cases in which tissue oxygenation is required and when it is desirable to avoid allogeneic blood transfusion.

General adverse effects

Hemoglobin-based oxygen carriers

Hemoglobin-based oxygen carriers bind endogenous nitric oxide, thereby causing transient hypertension, esophageal dysfunction, and abdominal discomfort. In a phase II study using *O*-raffinose cross-linked hemoglobin (Hemolink™) in patients undergoing coronary artery bypass grafting surgery raised blood pressure, probably caused by binding of *O*-raffinose cross-linked hemoglobin to nitric oxide, and jaundice were observed (8). Jaundice was expected, owing to metabolism of cell-free hemoglobin.

Perfluorocarbons

Perfluorocarbon blood substitutes are reported to have several adverse effects, the clinical significance of which is not currently fully understood. They include a dose-related, flu-like illness 4–6 hours after infusion (2,9). Symptoms included back pain, malaise, flushing, and transient fever (10); arterial hypotension, tachycardia, a high leukocyte count, and thrombocytopenia can also occur. These symptoms are most likely cytokine-mediated, as the perfluorocarbon particles are cleared by cells of the reticuloendothelial system (11). The most important adverse effect of LiquiVent is the risk of intravascular passage of the perfluorocarbon. Phagocytosis by alveolar macrophages has been demonstrated by cytology. Larger doses of emulsion particles can lead to hepatic engorgement and temporary impairment of immune defences (2).

Third-generation emulsions are currently in early preclinical development (2). The absence of toxicity of these new emulsions has been demonstrated in endothelial cell cultures and in animal organ preservation studies.

In a phase II study in 25 patients undergoing ardiac surgery a perflubron emulsion (AF0144) was well tolerated (12).

Organs and Systems

Cardiovascular

A modified hemoglobin solution, DCLHb, has been associated with an increase in mean arterial pressure. This has been proposed to be due to binding to nitric oxide, stimulation of the production of endothelin, and sensitization and/or potentiation of beta-1 and beta-2 adrenoceptor responses to catecholamines (2).

It has been suggested that cell-free hemoglobin, particularly low molecular weight hemoglobin, such as tetrameric hemoglobin, has the ability to come more closely to the endothelial cell lining of blood vessels than erythrocytes and to extravasate into the subendothelial space. There, hemoglobin might scavenge nitrous oxide and so induce vasoconstriction and hypertension (3,5,9). A randomized, controlled phase II study has suggested that hemoglobin raffimer (Hemolink) is safe and effective in patients undergoing coronary artery bypass surgery. The incidence of hypertension was higher in the treated group, but blood pressure management prevented serious hypertension-related events (13).

Another hemoglobin substitution product, liposome-encapsulated tetrameric hemoglobin, can exacerbate the manifestations of septic shock (2).

Respiratory

In premature neonates and children with respiratory distress syndrome treated with a perfluorocarbon, pneumothorax has been observed (2).

Sensory systems

Corneal epithelial damage has been attributed to a perfluorocarbon (14).

- An elderly man underwent vitreoretinal surgery for retinal detachment. Perfluorodecalin was used to repair the retina and was left in situ for 8 weeks and removed via the pars plana. One month later he developed a non-healing corneal epithelial defect associated with limbitis. Perfluorodecalin was found under the superior conjunctiva. A biopsy showed vacuoles in the conjunctival stroma surrounded by inflammatory cells. On surgical removal of the perfluorodecalin from the subconjunctival space, the epithelial defect healed.

Although the high surface tension of perfluorocarbons allows closure of retinal breaks and prevents them from flowing into the subretinal space, particularly during intraocular manipulation, they can gain entry into the subretinal space, resulting in residues in the eye (15,16). The removal of perfluorocarbons is recommended at the end of surgery, but they can be left in the eye for limited periods of time (17).

- A 29-year-old man with a high degree of myopia developed a rhegmatogenous retinal detachment due to a giant retinal tear following blunt trauma (18). After

© 2006 Elsevier B.V. All rights reserved.

surgical treatment perfluorodecalin was left in the eye as a tamponade; 2 weeks later it was removed and 20% sulfahexafluoride was injected. On the following day the retina was flat and residual perfluorodecalin was not detected in the vitreous cavity. A week later he developed severe pain in the operated eye and his vision worsened. There was a marked cellular response in the vitreous cavity and total retinal detachment. Examination with retroillumination showed that there was residual perfluorocarbon trapped in the retrolental space. There also appeared to be a precipitate of pigmented cells adherent to the vitreous surface of the posterior lens capsule, as seen on slit lamp biomicroscopy. Posterior capsulotomy removed the obstruction caused by the deposits, confirming the suspicion of the site of the pigmentary infiltration. A small amount of heavy liquid was found subretinally and removed. Although retinal reattachment was not possible due to very severe proliferative vitreoretinopathy, the intravitreal inflammation resolved.

Hematologic

Administration of erythrocytes can cause neutrophil priming, which leads to a dysfunctional inflammatory response. This neutrophil priming, which has been associated with the occurrence of multiple organ failure after trauma, was not observed after administration of Polyheme, a glutaraldehyde-cross-linked hemoglobin product (3).

In a randomized, double-blind, placebo-controlled study in healthy volunteers coagulation responses (using bleeding time) and hemostasis were examined for 14 days after dosing with either saline or perfluorocarbon emulsion (1.2 or 1.8 g/kg) (19). There were no postinfusion changes in bleeding time or differences in in vivo agonist-induced platelet aggregation. There was a fall in platelet count, but this recovered to baseline within 7 days. The intravascular half-life of perfluorocarbon for the first 24 hours was dose-dependent (9.4 hours and 6.1 hours with 1.8 and 1.2 g/kg respectively). The authors concluded that perfluorocarbon does not affect coagulation, at least in healthy volunteers.

Transient thrombocytopenia can occur 3–4 days after perfluorocarbon (10). In several studies the fall in platelet count was 30–40%, and platelet counts returned to normal in 7–10 days. The use of radioactively labelled platelets showed increased platelet clearance, thought to be due to alteration of the platelet surface by the perfluorocarbon emulsion.

Gastrointestinal

Occasionally, gastrointestinal disorders have been related to the use of hemoglobin-based oxygen carriers, possibly through binding of nitrous oxide, causing gastrointestinal smooth muscle spasm (9,20).

Liver

In a single-blind, randomized study, four of 55 surgical patients who were treated with Hemopure developed jaundice without an increase in serum bilirubin (21). Similarly, in a double-blind, randomized study of 98 patients undergoing cardiac surgery, Hemopure was related to some cases of jaundice (22).

Urinary tract

Purification of haemoglobin avoids free hemoglobin, which can cause nephrotoxicity (2).

Skin

In a single-blind, randomized study, two of 55 surgical patients who were treated with Hemopure had ecchymotic rashes (21).

Immunologic

Hemoglobin solutions do not have the antigenic properties of the blood groups.

Drug Administration

Drug contamination

The main limitation of bovine hemoglobin is the risk of transmission of bovine spongiform encephalopathy and the development of antibodies to bovine proteins (2).

Oxymetazoline and xylometazoline

General Information

Oxymetazoline and xylometazoline are alpha-adrenoceptor agonists, which seem to be better tolerated than other topically used drugs of this sort.

Organs and Systems

Ear, nose, throat

Nasal irritation, with dryness of the mouth and throat, can occur; a rebound effect on the nasal mucosa was found in some 5% of cases studied (1).

Sensory systems

The development of an acute retinal artery obstruction in a young, otherwise healthy man was associated with excessive use of an oxymetazoline nasal spray. Platelet coagulation studies indicated a platelet aggregation hypersensitivity to adenosine diphosphate and adrenaline. Predisposition to sympathomimetic drug-induced platelet fibrin embolus formation may have played a role in this case (2).

Oxymetazoline has a vasoconstrictor effect and this has been reported to have caused an ischemic retinopathy (3).

- A 43-year-old woman with hypertension and diabetes mellitus used 2–3 puffs of oxymetazoline nasal spray and experienced painless blurring of vision in the right eye, with a corrected acuity of 20/400 (20/50 on the left). Apart from background diabetic retinopathy she had edema of the optic disk. Several weeks later she used the spray again and this time developed blurred vision in the left eye. There was disk pallor on both sides and acuities were 20/400 on the right and 20/70 on the left. There were also segmental inferior field defects in both eyes. After 6 weeks both eyes had recovered somewhat, but only to 20/200 and 20/50 respectively: there was no further improvement after a year.

The authors concluded that this was sequential bilateral ischemic retinopathy due to oxymetazoline.

Long-Term Effects

Drug withdrawal

The interruption of a high dose nasal spray therapy precipitated a prolonged panic disorder in a healthy man (SEDA-13, 109).

Second-Generation Effects

Fetotoxicity

Repeated use of an oxymetazoline nasal spray has been associated with changes in fetal heart rate demonstrated as a non-reactive, non-stress test and late decelerations in a patient at 41 weeks of gestation; 6 hours after the last dose these changes gradually disappeared (4).

Susceptibility Factors

Age

Systemic adverse reactions of ocular administration have been reported in young children (5).

Drug Administration

Drug overdose

An unusual response to an overdose of oxymetazoline (0.05% nasal spray) occurred in an elderly patient who used the product several times daily; the patient, who had pre-existing cerebellar degeneration and peripheral neuropathy, developed severe bradycardia and oscillations in systolic pressure between 236 and 60 mmHg. Withdrawal of the spray resulted in complete recovery (6).

Oxyphenbutazone

See also Non-steroidal anti-inflammatory drugs

General Information

Oxyphenbutazone is a parahydroxylated analogue of phenylbutazone, and is one of its active metabolites. It has the same spectrum of activity, therapeutic uses, interactions, dangers, and contraindications. In April 1985, Ciba-Geigy decided to stop sales of systemic dosage forms of oxyphenbutazone worldwide. They stated that they had reached this decision because a survey had shown that although the recommended limitations on the use of phenylbutazone had been widely respected, the same could not be said of oxyphenbutazone. Evidence that oxyphenbutazone was more likely to cause death due to bone marrow failure than phenylbutazone (1) was provided by data from the UK's Committee on Safety of Medicines. Furthermore, according to Ciba-Geigy's re-assessment in January 1984, deaths per million prescriptions of oxyphenbutazone were 5.5 (USA) to 12.8 (UK) compared with phenylbutazone (3.8–7.6 deaths per million prescriptions) (SEDA-9, 87).

Oxyphencyclamine

General Information

Oxyphencyclamine is an anticholinergic drug, which is claimed to act for some 12 hours. However, the wide range of oral doses used (10–50 mg/day) indicate doubt about its potency.

Oxyphenonium

See also Anticholinergic drugs

General Information

Like methanthelinium, oxyphenonium is an anticholinergic drug with relatively marked ganglion-blocking effects, but it seems to have little effect on the central nervous system; an oral dose of 5–10 mg given several times a day produces typical anticholinergic effects. Its efficacy is rather poor (1).

Oxytocin and analogues

General Information

Oxytocin is a hypothalamic nonapeptide that selectively stimulates the smooth muscle of the uterus and mammary glands. It is used in the induction or augmentation of labor and to prevent postpartum hemorrhage, and is well tolerated and effective in a wide range of infusion rates and concentrations. Contraindications to its use include placenta previa or vasa previa, a previous classical uterine incision, pelvic structural deformities, and an abnormal fetal presentation. Large fetal size and high maternal parity are relative contraindications. Prior nonclassical cesarean delivery should not preclude oxytocin therapy.

Uterine contractions and fetal heart rate should be monitored during oxytocin administration (SEDA-13, 1310) (1,2). There is no significant increase in uterine complications or in fetal morbidity or mortality in women with a previous cesarean section, although oxytocin-treated patients had a higher rate of failed trial of labor for reasons that are unclear (3). Oxytocin is structurally similar to vasopressin, and like the latter has water-retaining properties when used in pharmacological doses.

Oxytocin is in common use during induction of labor and in the third stage of labor to prevent uterine atony and postpartum hemorrhage. Carbetocin, a synthetic analogue with a half-life 4–10 times longer than the native hormone, has been studied in trials; both agents cause a small transient fall in blood pressure (less than 4 mmHg) (4). Common mild adverse effects of both drugs include headache, flushing, a feeling of warmth, a metallic taste, and abdominal pain.

© 2006 Elsevier B.V. All rights reserved.

Organs and Systems

Cardiovascular

Tachycardia and a fall in blood pressure are common and usually short-lived after oxytocin administration during labor. There has been one reported maternal death after a hypovolemic woman was given a bolus dose of oxytocin 10 units (5).

In 34 women undergoing cesarean section at full term under spinal anesthesia, heart rate and cardiac output increased significantly within 2 minutes of the rapid administration of either 5 or 10 units of oxytocin, with an associated 10 mmHg fall in mean arterial pressure in those who received 10 units (6). There were significant ST segment changes in 11 of 26 women undergoing cesarean section, with raised concentrations of troponin I in two; however, the relationship to oxytocin administration was not clear in this report (7).

- A previously fit 19-year-old woman had severe ST segment depression and increased troponin concentrations after a bolus dose of oxytocin 5 units (8).

Ventricular tachycardia has been reported in two patients with pre-existing prolongation of the QT interval, immediately after oxytocin was begun (9).

Fluid balance

Fluid retention causing severe hyponatremia and convulsions has been observed in neonates after administration of oxytocin and salt-poor fluids to the mother during labor.

Acute water intoxication has produced maternal cerebral edema and convulsions in under 50 reported cases, both with intravenous and intranasal administration (10). The risk is higher in women given high doses of the drug in combination with salt-poor intravenous fluids. In rare cases this has been fatal.

Hematologic

Maternal oxytocin administration increases the rate of neonatal physiological jaundice in a dose-dependent manner (SEDA-13, 1310) (11). This effect may be due to hemodilution and an increased rate of hemolysis.

Second-Generation Effects

Pregnancy

In a retrospective analysis of 2774 women who had had one prior cesarean delivery, there was a 1% incidence of uterine rupture in women who were given oxytocin, compared with 0.4% in non-augmented controls with spontaneous labor (12). Six women needed emergency hysterectomy. The odds ratio for uterine rupture in the oxytocin-treated women was 4.6 by logistic regression analysis (CI = 1.5,14). The small number of events limited the study: it had only 30% power to detect changes of that magnitude. However, it is reasonable to proceed cautiously, with close clinical observation, given the potentially severe outcome.

- Uterine rupture occurred when oxytocin was started 5 hours after the administration of a second misoprostol tablet for induction of labor, although the usual recommendation is to wait at least 12 hours (13).
- A 36-year-old multiparous woman had a ruptured uterus after labor was induced at 24 weeks with misoprostol 200 μg and augmented with oxytocin (14).

The risk of uterine rupture is increased by previous cesarean section, fetal weight over 4 kg, and the use of oxytocin (SEDA-24, 506) (15,16). In 24 women with uterine rupture after oxytocin, the dose and duration of use of oxytocin were 10% higher than in controls; this difference was not statistically significant, but the power of the study was limited by the small sample size (17).

Paclitaxel

See also Cytostatic and immunosuppressant drugs

General Information

Paclitaxel is a complex plant product derived from the bark of the yew tree, *Taxus brevifolia*. It has been used for the treatment of metastatic carcinoma of the ovary and breast. It has also been investigated in the treatment of other carcinomas, including non-small-cell lung cancer, malignant melanoma, head and neck cancers, acute leukemias, and Kaposi's sarcoma. The recommended dosage for the treatment of ovarian and breast carcinoma is 175 mg/m^2 given intravenously over 3 hours every 3 weeks. However, various dosage and administration schedules have been investigated.

Mechanism of action

Paclitaxel acts by enhancing microtubule assembly and stabilizing microtubules (1,2). Microtubules consist of polymers of tubulin in dynamic equilibrium with tubulin heterodimers. Their principal function is the formation of the mitotic spindle during cell division, but they are also active in many interphase functions, such as cellular motility, intracellular transport, and signal transmission. Paclitaxel inhibits the depolymerization of tubulin, and the microtubules formed in the presence of paclitaxel are extremely stable and dysfunctional. This stabilization impairs the essential assembly and disassembly required for dynamic cellular processes, and death of the cell results through disruption of the normal microtubular dynamics required for interphase processes and cell division. In tumor cells, cytotoxicity is represented by the appearance of abnormal microtubular bundles, which accumulate during G2 and mitosis, blocking the cell cycle (3).

Pharmacokinetics

Paclitaxel has non-linear kinetics: peak plasma concentrations and drug exposure increase disproportionately with increasing doses and the pharmacokinetics depend on the schedule of administration. Saturation is reached with high-dose short infusions (4). Paclitaxel has been reported to follow both biphasic (5) and triphasic models (6). The half-life has been estimated at 6–13 hours after intravenous administration (7).

After intravenous administration, paclitaxel is extensively distributed, despite extensive binding to plasma proteins (89%), presumably albumin (2). Its routes of elimination have not been fully elucidated, but renal clearance accounts for an insignificant proportion of total systemic clearance, suggesting that metabolism, biliary excretion, or excretion via other routes are responsible for elimination (6). High concentrations of paclitaxel and its hydroxylated metabolites have been found in rat and human bile, suggesting hepatic metabolism (8). In all, 11 metabolites of paclitaxel have been identified, and paclitaxel metabolism to 6-α-hydroxypaclitaxel is an important detoxification pathway (6,9).

The effects of renal and hepatic dysfunction on paclitaxel elimination have not been studied extensively. Since renal clearance accounts for a small proportion of total clearance, dosage modifications are not considered necessary in patients with renal dysfunction.

One study has shown that patients with existing liver dysfunction have a reduced total body clearance of paclitaxel and require dosage reductions (10). A dosage reduction of 50% has been suggested in patients with moderate or severe hyperbilirubinemia or increased serum transaminases (4).

Paclitaxel is formulated in a mixture of ethanol and Cremophor EL (polyethoxylated castor oil). Cremophor reduced the electrophoretic mobility of serum lipoproteins along with the appearance of a lipoprotein dissociation product. After serum was exposed to Cremophor in vitro or in vivo there was substantial binding of paclitaxel to the lipoprotein dissociation product(s), and this could represent an important factor in the distribution of paclitaxel (11).

General adverse effects

A summary of the incidences of the adverse effects of paclitaxel in single-agent studies in 402 patients is given in Table 1 (12).

Organs and Systems

Cardiovascular

Paclitaxel causes disturbances in cardiac rhythm, but the relevance of these effects has not been fully elucidated. Originally, all patients in trials of paclitaxel were under continuous cardiac monitoring, owing to the risk of hypersensitivity reactions, and cardiac disturbances were therefore more likely to be detected. Many trials limited eligibility to patients without a history of cardiac abnormalities and to those who were not taking medications likely to alter cardiac conduction. The incidence of cardiac dysrhythmias in the population under study not treated with paclitaxel is unknown, and it is therefore not always possible to attribute dysrhythmias to paclitaxel in these patients. The Cremophor EL vehicle does not appear to be implicated in the incidence of dysrhythmias, although hypotension associated with hypersensitivity reactions may occur (13).

The most common effect of paclitaxel is asymptomatic bradycardia, which occurred in 29% of patients in one phase 2 trial (14) and in 9% of patients in a further assessment of 402 patients in phase 2 trials (15). One phase 1 trial showed no significant cardiac dysrhythmias (16), while another reported cardiac toxicity in 14% of patients, 74% of these being due to asymptomatic bradycardia (17). Bradycardia is not an indication for discontinuation of treatment, unless it is associated with atrioventricular conduction disturbances or clinically significant effects (for example symptomatic hypotension). More significant bradydysrhythmias and atrioventricular conduction disturbances have been reported during clinical trials, including Mobitz I (Wenckebach syndrome) and Mobitz II atrioventricular block (14,18).

Any symptoms	55
Severe symptoms	4
Immunologic reactions (with premedication)	
Any	41
Severe	2

One patient died in heart failure 7 days after receiving paclitaxel by infusion; this patient had no prior history of cardiac problems, apart from mild hypertension (19).

The authors of a review of the cardiac toxicity associated with paclitaxel in a number of studies concluded that the overall incidence of serious cardiac events is low (0.1%) (20). Heart block and conduction abnormalities occurred infrequently and were often asymptomatic. Sinus bradycardia was the most frequent, occurring in 30% of patients. The causal relation of paclitaxel to atrial and ventricular dysrhythmias and cardiac ischemia was not entirely clear. There did not appear to be any evidence of cumulative toxicity or augmentation of acute cardiac effects of the anthracyclines.

In an attempt to clarify further the cardiotoxicity of paclitaxel, its effect on cardiovascular autonomic regulation has been investigated in 14 women (21). The authors concluded that autonomic modulation of heart rate is impaired by paclitaxel, but they were unable to say whether it would return to normal on withdrawal. They also investigated the effect of docetaxel on neural cardiovascular regulation in women with breast cancer, previously treated with anthracyclines (22). They concluded that docetaxel did not impair vagal cardiac control. The changes that they observed in blood pressure suggest that docetaxel changes sympathetic vascular control, although these changes seemed to be related to altered cardiovascular homeostasis rather than peripheral sympathetic neuropathy.

Continuous cardiac monitoring is recommended for patients with serious conduction abnormalities; however, routine cardiac monitoring is considered unnecessary in patients without a history of cardiac conduction abnormalities (7). Further studies are needed to determine the risk in patients treated with paclitaxel with predisposing cardiac risk factors.

Respiratory

Effects of paclitaxel on the respiratory system are generally related to hypersensitivity reactions. One case of pneumonitis was possibly due to a hypersensitivity reaction to either paclitaxel or its vehicle Cremophor EL; treatment with corticosteroids resulted in improvement (23). One patient developed tachypnea and cyanosis and subsequently died of pulmonary edema 7 days after receiving an infusion of paclitaxel (19).

Nervous system

The most common nervous system effect is peripheral neuropathy, although one patient developed tonic-clonic seizures whilst receiving paclitaxel and required treatment with benzodiazepines and barbiturates (14). Motor weakness has occasionally been reported (24).

Neurotoxicity associated with paclitaxel is dose-dependent, cumulative, and characterized principally by a sensory and motor peripheral neuropathy. Neuropathy appears to be related to axonal degeneration and demyelination (25). Neurological toxicity is usually reversible after termination of therapy, and although it rarely requires withdrawal of therapy, it has been the dose-limiting adverse effect in some phase 1 trials (5,26). This effect became more apparent as higher doses of paclitaxel were used, particularly in combination with growth factors, which allow escalating doses of paclitaxel to be administered. A high-dose study has shown dose-related toxicity, with a dose-limiting ceiling at 775 mg/m^2, when paresthesia occurs (27). Patients with co-existing medical illnesses associated with peripheral neuropathy, such as diabetes mellitus and alcohol abuse, may be more prone to develop peripheral neuropathy.

Peripheral neuropathy presents as numbness, burning, and tingling in a glove-and-stocking distribution. Symptoms usually begin 24–72 hours after treatment with paclitaxel, with a symmetrical distal loss of sensation. Most cases occur at doses over 200 mg/m^2 and particularly after multiple courses (24–26). Mild to moderate sensory neuropathy has occurred in 52% of patients treated with doses of 175 mg/m^2, while only 36% experienced neuropathy at doses of at least 135 mg/m^2 (17,24,28,29). At the lower dose of 135 mg/m^2, the effects are usually limited to a mild sensory neuropathy (17,29).

The incidence of peripheral neuropathy increases substantially at doses above 250 mg/m^2 (14,16,18–20,

© 2006 Elsevier B.V. All rights reserved.

25,29–32). Neuropathy was the dose-limiting adverse effect in one phase 1 trial with doses of 275 mg/m^2, and patients experienced grade 2–3 neurotoxicity 1–3 days after treatment (5). The symptoms generally subsided within several weeks to months. A study of adverse effects in patients in phase 2 trials showed that peripheral neuropathy occurred in 62% of 402 patients (15). Of patients receiving higher doses (190 mg/m^2 or more), 80% had symptoms that were mild or moderate. In severe cases of peripheral neuropathy a dose reduction of 20% is recommended for subsequent courses (7).

Previous treatment with other neurotoxic agents may compound the problem. In one study symptoms of neurotoxicity were observed in one patient who received concomitant cisplatin with paclitaxel (33). However, signs and symptoms of neurotoxicity have been insignificant in combination treatments of cisplatin and paclitaxel in other trials (1). Pre-existing neuropathy as a result of previous therapy is not a contraindication to paclitaxel (7).

Tricyclic antidepressants, in particular amitriptyline, and venlafaxine are helpful in relieving symptoms of paclitaxel-induced peripheral neuropathy (1,26,33,34).

Sensory systems

Transient scintillating scotomata have been observed in the visual fields of both eyes in nine patients receiving paclitaxel infusions in doses of 175 and 225 mg/m^2 (35). Involvement of the optic nerve was confirmed, and this is likely to have been related to optic nerve conduction abnormalities associated with the neurological effects of paclitaxel. The abnormalities were not progressive and there was some degree of recovery, although one patient sustained a permanent reduction in vision.

Hematologic

Bone marrow suppression is a dose-limiting adverse effect often encountered with paclitaxel. Neutropenia occurs most commonly 8–10 days after treatment, and recovery usually occurs on days 15–21. Paclitaxel is relatively platelet-sparing, and thrombocytopenia and anemia are rare (26). There is no evidence that neutropenia is cumulative, suggesting that paclitaxel may not irreversibly damage hemopoietic stem cells (1).

Neutropenia is dose- and schedule-related and is less common with shorter infusion schedules. At doses of 110–250 mg/m^2 over 24 hours, neutropenia is usually severe, and grade 4 neutropenia develops in a large proportion of patients. Paclitaxel given as a 3-hour infusion causes less severe neutropenia (17,24,29). An analysis of patients receiving either a 3-hour or 24-hour infusion of 175 or 135 mg/m^2 showed that severe neutropenia was more common with the 24-hour infusions: 75% of patients developed severe neutropenia (absolute neutrophil count below 500×10^6/1) and episodes of fever (29). Doses of 200–250 mg/m^2 also cause severe neutropenia when paclitaxel was given as a 24-hour infusion, but recovery of neutrophil count was fairly rapid (13,14,26,33,36,37).

The duration of neutropenia is usually brief and treatment delays for unresolved adverse hematological effects at day 21 are rare. Paclitaxel-induced neutropenia does not always lead to infectious complications, and therefore a dosage reduction for neutropenia alone is not considered necessary (14,16,18–20,29,30).

Prior myelotoxic chemotherapy and/or radiotherapy appear to be major risk factors in determining the severity of neutropenia (1,13). Doses of 200 and 250 mg/m^2 over short infusion times induce minimal myelosuppression in patients who have had minimal prior therapy (26,30); however, seven patients (1.6%) died because of toxicity in another trial in patients with ovarian cancer who had received extensive previous chemotherapy; deaths were due to sepsis or severe neutropenia (13).

Other data suggest that neutropenia may be related to pharmacological exposure, and phase 1 studies have shown that the severity of paclitaxel-induced neutropenia correlates with the area under the paclitaxel concentration–time curve (36).

The incidence of neutropenia has also been investigated in combination schedules. Patients receiving paclitaxel in combination with cyclophosphamide have severe neutropenia more often than with single treatment (72% of patients). Paclitaxel given as a 24-hour infusion before cyclophosphamide is more likely to cause severe neutropenia compared with patients who receive cyclophosphamide first (31).

Attempts to overcome neutropenia include the use of human granulocyte colony stimulating factor (GCSF). The absolute neutrophil counts are generally higher and the duration of severe neutropenia is shorter when GCSF is given 24 hours after paclitaxel and continued until there is recovery of the neutrophil count. When paclitaxel is given in combination with GCSF, doses of 250 mg/m^2 given over 24 hours every 3 weeks are possible without inducing dose-limiting neutropenia (16). Three-hour infusion schedules have also been successful using doses of 250 mg/m^2 in combination with GCSF and doxorubicin (32). Other dose-limiting adverse effects tend to predominate when paclitaxel is given in higher doses in combination with GCSF.

Recommendations currently specify that patients should not be retreated with paclitaxel until the neutrophil count recovers to 2.5×10^9/1 and the platelet count recovers to over 100×10^9/1 (7).

Gastrointestinal

Severe nausea, vomiting, and diarrhea are uncommon with paclitaxel (1). Although about half of the patients in one study had vomiting or diarrhea, under 5% were severe events (15). In another phase 2 trial, there were 11 episodes of nausea and vomiting in 281 courses (14). Four patients developed diarrhea, but this was not clinically significant. Generally, symptoms of nausea, vomiting, and diarrhea associated with paclitaxel therapy are mild.

Mucositis and stomatitis have been reported with paclitaxel. Mucositis is characterized by ulceration of the lips, pharynx, and oral cavity, occurring 3–7 days after paclitaxel treatment (1,13,14,17,24,26,29,33,36–38). Mucositis appears to be more common during treatment of acute leukemias rather than solid tumors, when doses above 390 mg/m^2 are used (24). Severe mucositis occurred during second and third courses, suggesting a cumulative effect, and was more severe if treatment was given at 15 days or less after previous courses. Patients

© 2006 Elsevier B.V. All rights reserved.

with hematological malignancies are more prone to breakdown of the mucosal barrier, and this may account for the increased incidence of mucositis. Narcotic analgesics are effective in controlling the pain associated with mucositis (1).

Severe abdominal pain occurred in 25 patients treated with intraperitoneal paclitaxel in doses over 175 mg/m^2 (39).

Transient paralytic ileus occurred in two patients in one study (29). Both patients were diabetic, and these symptoms may have been an additional manifestation of autonomic neuropathy.

Postmortem examinations of patients treated with paclitaxel have shown mucosal ulceration of the esophagus, stomach, small intestine, and colon (40). Changes associated with epithelial necrosis and mitotic arrest were most prominent in patients who had recently been treated with paclitaxel. These findings suggest that paclitaxel causes transient mitotic arrest associated with cell necrosis.

Urinary tract

Reversible renal insufficiency has been reported in one patient who was treated with paclitaxel by the intraperitoneal route (39).

Skin

Local venous effects, including erythema, tenderness, and discomfort, can occur at the injection site during paclitaxel infusion (13). Inflammation is evident within hours and usually resolves within 21 days. Inflammation occurs in areas of drug extravasation along with prolonged soft tissue injuries, and necrotic changes have been reported in one patient at the site of extravasation (41). Inflammation is most likely to be due to the drug, but the Cremophor EL vehicle may be implicated, as it produces mild inflammation in animals (41).

There is little information on the treatment of extravasation of paclitaxel, as it has not been common during clinical trials. However, a soft-tissue injury occurred in one patient at the site of previous extravasation after treatment with paclitaxel in a different limb (42). This resolved within 7 days.

Radiation dermatitis has been reported in a patient who received a single infusion of paclitaxel (43). This was attributed to the potentiation of radiation effects by paclitaxel because of the close time relation between the radiotherapy and paclitaxel therapy.

Hair

Alopecia occurs in nearly all patients who receive paclitaxel, but it has unique characteristics. Hair loss is sudden and complete, and many patients often experience loss of all body hair, including axillary and pubic hair, eyelashes, and eyebrows (28,44). The loss of body hair often occurs with cumulative therapy and is more severe after longer infusion times.

Nails

Onycholysis occurred in five of 21 patients who received more than six doses of paclitaxel 100 mg/m^2/week (45). The authors also provided a useful review of onycholysis caused by other chemotherapy.

Musculoskeletal

An arthralgia/myalgia syndrome occurs 2–5 days after chemotherapy in about 20–30% of patients receiving paclitaxel and is possibly dose-related (1). It commonly occurs at doses above 170 mg/m^2 (29). Symptoms of myalgia usually involve the shoulder and paraspinal muscles, while arthralgia is common in the large joints of the arms and legs (1,13). Symptoms can be controlled by nonsteroidal anti-inflammatory drugs (13) and perhaps gabapentin (46). The incidence of arthralgia and myalgia is also increased in patients who receive GCSF, with symptoms occurring more frequently in 86% of patients compared with patients who receive similar doses without growth factor support (28%) (16).

The severity of myalgia and arthralgia correlated significantly with the total cumulative dose of paclitaxel 210 mg/m^2/cycle by 3-hour infusion in 247 patients with a median cumulative dose of 630 mg/m^2 (47).

Immunologic

Acute hypersensitivity reactions were common during phase 1 trials of paclitaxel, and this caused delays in the completion of many trials. Reactions were mild to severe and consisted of cutaneous flushing, bronchospasm, bradycardia, and hypotension; the reactions occurred after either the first or second dose (48). The mechanism of these reactions is uncertain, but they are thought to be non-immunologically mediated, and direct histamine release by mast cells is probably responsible. A large dose of Cremophor EL is used in the formulation of paclitaxel, and this may play an important part in these hypersensitivity reactions; Cremophor EL induces similar reactions in dogs by direct release of histamine (4).

In a study of 32 patients, 84% of those who received paclitaxel developed hypersensitivity reactions characterized by hypotension, respiratory distress, and urticaria (35). These symptoms further confirm that histamine is likely to be the cause of the reaction. The majority of reactions (53%) occurred within 2–3.minutes after the administration of paclitaxel and 78% within 10 minutes. There was one fatal reaction, characterized by hypotension and asystole. Most reactions to paclitaxel occurred after the first or second dose, and hypersensitivity reactions were more common with shorter infusion schedules. Since the duration of the infusion affected the incidence of hypersensitivity reactions, an extension of the infusion duration was investigated. Longer infusion schedules were associated with a reduced incidence of hypersensitivity reactions, the frequency of severe reactions being reduced from 12% or more to 5% with longer infusion times (5,15,49).

Premedication regimens of glucocorticoids and histamine H_1 and H_2 receptor antagonists have been used in an attempt to prevent hypersensitivity reactions in other phase 1 trials. These trials were successfully completed using infusion schedules of 1–120 hours and doses of 135–390 mg/m^2, with a lower incidence of hypersensitivity reactions (15,17,28,29,37,44,48). However, the use of premedication did not completely prevent such reactions.

© 2006 Elsevier B.V. All rights reserved.

There were incidences of 16, 13, and 7% with 3-hour, 6-hour, and 24-hour infusion schedules respectively, despite premedication (48), while only 1.5% of patients developed reactions in a trial with doses of 125–250 mg/m^2 over 24 hours with glucocorticoids and histamine receptor antagonists (29). Only one patient out of 26 developed a hypersensitivity reaction with doses of 150–250 mg/m^2 over 24 hours (26). The relative merits of longer infusion times and premedication are not entirely clear.

In one study of infusion of doses of 175–275 mg/m^2 over 6 hours without premedication, there was only one hypersensitivity reaction in 32 patients (49), while patients who received paclitaxel administered over 1 hour with premedication developed no serious hypersensitivity reactions (37). There were no hypersensitivity reactions in 40 patients who received fractionated doses of paclitaxel administered over 3–5 days, with cumulative doses of 120–250 mg/m^2 (36). In a randomized comparison of two doses of paclitaxel given by 3-hour or 24-hour infusions, premedication alone was sufficient to prevent hypersensitivity reactions with either infusion duration (29).

Premedication, consisting of dexamethasone 20 mg intravenously, 12 and 6 hours before the infusion, and diphenhydramine 50 mg and cimetidine 300 mg, intravenously 30 minutes before the infusion, are now routinely given before patients are treated with paclitaxel, and this, as well as a recommended infusion time of 3 hours, has reduced the incidence and severity of hypersensitivity reactions. A single dose of dexamethasone 16 mg given 30 minutes before paclitaxel was effective in preventing hypersensitivity reactions in 43 patients (38); however, whether a single dose of a glucocorticoid is sufficient for prophylaxis is controversial.

About 2% of all patients who receive paclitaxel with preventive premedication will develop a severe hypersensitivity reaction, characterized by dyspnea, hypotension, angioedema, and urticaria, and requiring treatment. Minor reactions occur in 39% of patients but do not require therapeutic intervention (7).

There was a 9% incidence of clinically important hypersensitivity reactions to paclitaxel in 450 women with gynecological malignancies treated with paclitaxel either alone or in combination regimens (50). There was a significant association between bee sting or animal allergy and paclitaxel hypersensitivity in 57 patients with a variety of tumors (51).

Drug–Drug Interactions

General

Drug interactions with paclitaxel have been reviewed (52). The most important of these are the pharmacodynamic interactions with other cytostatic drugs, but pharmacokinetic interactions have also been described.

Paclitaxel is metabolized by the cytochrome P_{450} isoenzymes CYP2C and CYP3A4 (53), and drugs that inhibit or induce these isozymes would be expected to alter the metabolism of paclitaxel. In vitro ranitidine, diphenhydramine, vincristine, vinblastine, and doxorubicin had little or no effect on the metabolism of paclitaxel, but barbiturates stimulated hydroxylation of the side-chain by induction of CYP3A isoforms (53).

Anthracyclines

The combination of doxorubicin plus paclitaxel is cardiotoxic. Various authors have suggested that after a median cumulative dose of 480 mg/m^2, 50% of patients will have a reduced left ventricular ejection fraction and 20% will develop congestive heart failure.

In 36 women with previously untreated metastatic breast cancer, paclitaxel dose-dependently increased the plasma concentrations of doxorubicin and its metabolite doxorubicinol; this was attributed to competition for biliary excretion of taxanes and anthracyclines mediated by *P*-glycoprotein (54).

Two studies of the combination of epirubicin plus paclitaxel have shown less reduction in left ventricular ejection fraction and no clinical evidence of cardiac failure (55,56).

Ketoconazole

In patients with ovarian cancer, ketoconazole, 100–1600 mg as a single oral dose 3 hours after paclitaxel 175 mg/m^2 as a 3-hour continuous intravenous infusion, did not alter plasma concentrations of paclitaxel or its principal metabolite, 6-alpha-hydroxypaclitaxel (57).

Platinum-containing cytotoxic drugs

In 21 patients with advanced non-small cell lung cancer carboplatin had no effect on the pharmacokinetics of paclitaxel 135–200 mg/m^2 as a 24-hour intravenous infusion (58). Peripheral neuropathy occurred in 13 of 37 patients treated with paclitaxel 175 mg/m^2 and carboplatin (59). The authors concluded that clinically important neurotoxicity increases with every cycle of chemotherapy. The peripheral neuropathy mainly affected sensory fibers without involving motor nerves. The same paclitaxel/carboplatin chemotherapy in 28 women caused no signs of acute central neurotoxicity or neuropsychological deterioration; however, 11 patients had a peripheral neuropathy (60).

Palivizumab

See also Monoclonal antibodies

General Information

Palivizumab is a humanized monoclonal antibody that inhibits an epitope at the A antigenic site of the F protein of respiratory syncytial virus subtypes A and B (1).

Palivizumab is generally well tolerated (2). Its most common adverse effects (over 5%) are rhinitis, cough, fever, pharyngitis, bronchiolitis, and diarrhea (3).

In 565 patients with respiratory syncytial virus infections palivizumab caused injection site reactions (2.3%), fever (1.5%), and nervousness/irritability (under 1%); no other adverse effects were reported (4).

Organs and Systems

Immunologic

The estimated risk of anaphylactic reactions to palivizumab is under one per 100 000 infants (5). No second-season subjects had a significant antipalivizumab antibody response (titer over 1:80) (6).

Pancreatic enzymes

General Information

Pancreatic enzyme supplements are used to treat people who lack pancreatic secretions. Pancreatin, the British Pharmacopoeia standard, is an extract of pancreas, and contains enzymes with proteinase, amylase, and lipase activity; most commercial formulations are similar or identical (SEDA16, 358).

The effect of oral pancreatic enzyme supplementation (Creon 10 000 in a dose of 1000 units of lipase per gram of ingested dietary fat) on fat malabsorption has been evaluated in an open study in 24 patients with HIV infection (1). Pancreatic enzyme supplementation was highly effective in reducing fecal fat loss. There were no clinical adverse effects or changes in serum biochemistry attributable to the drug.

Organs and Systems

Metabolism

The effects of pancreatic exocrine supplements (four capsules with meals, two with snacks; each capsule containing lipase 10000 units, protease 37500 units, amylase 33200 units) on glucose metabolism have been studied in a 2-week parallel, randomized, placebo-controlled trial in 29 patients with chronic pancreatitis who had stool fat excretion of over 10 g/day, 18 of whom were diabetic and 15 of whom were malnourished (2). There were major problems with blood glucose control in 28 of the 29 patients.

Gastrointestinal

Colonic toxicity due to pancreatic enzyme supplements in children with cystic fibrosis has been reviewed (3). Since it was first reported in 1994, an increasing number of cases of fibrosing colonopathy due to pancreatic enzymes have been reported in children with cystic fibrosis in the UK, USA, and continental Europe. The disorder is not affected by age or sex, and the age at diagnosis is 9 months to 13 years.

- Fibrotic injury of the entire colon has been reported in an 8-year-old boy with cystic fibrosis who took pancreatic enzymes 12 000 IU/kg at each meal (SEDA23.36.65). He had earlier been taking 5000 IU/kg. The first colonic symptoms occurred 1 year after the increase in dose.

Evidence implicates high-strength formulations, which provide at least 22 000–25 000 IU of lipase per capsule (compared with low-strength and medium-strength formulations which provide up to 10 000 IU), and the association between pancreatic enzymes and colonopathy is clearly dose-related: the higher the dose greater the risk. There are several hypotheses about the pathogenesis of the condition. They include the following:

- toxicity due to the enteric coating (Eudragit L30D-55) used in high-strength pancreatic capsules;
- prolonged exposure of the colon to high-strength pancreatic enzymes because of the abnormally low small intestinal pH in cystic fibrosis, causing delay in dissolution of the enteric coating of the capsule (which occurs only above pH 5.5) until the enzymes reach the distal small intestine or even the large intestine;
- a colon-specific immune-mediated disorder or primary dysregulation of collagen synthesis in the colonic wall.

High-dose pancreatic enzyme formulations are no longer recommended for use in children because of the risk of fibrosing colonopathies (SEDA-19, 330) (SEDA-20, 322). A consensus meeting between the Cystic Fibrosis Foundation and the FDA in 1995 recommended that weight-based dosing should start at 1000 lipase units/kg per meal for children under 4 years and that the upper limit of the usual dosage should be 2500 lipase units/kg per meal and about half for snacks. This translates to a daily intake of 12 000–15 000 lipase units/kg, and the doses of other enzymes, such as protease, would be proportional (SEDA-21, 366).

Having reviewed the available epidemiological data, the UK's then Medicines Control Agency recommended that high-strength pancreatic enzymes coated with Eudragit L-30D-55 should be contraindicated in children under 15 years, that all high-strength formulations should be available only on prescription, and that no formulation should be used in a dosage over 10 000 IU/kg/day.

Pancreas

The effect of high-dose pancreatic enzymes on pancreatic function has been assessed in a double-blind study in 12 healthy volunteers, six of whom were given 18 capsules of Panzytrat (20 000 units of lipase, 18 000 units of amylase, and 1000 units of protease per capsule) daily for 4 weeks (4). There were no morphological or functional changes in the pancreas in those treated. None of the subjects had severe adverse effects. Two had transient mild nausea, epigastric pain, and heartburn. There were no abnormalities in liver function tests.

Drug Administration

Drug contamination

Pancreatic preparations can be bacterially contaminated (5).

Some formulations of pancreatic enzymes contain monohydroxy bile acids, which should not be administered to patients with liver disease (6).

Pancuronium bromide

See also Neuromuscular blocking drugs

General Information

Pancuronium bromide is a non-depolarizing muscle relaxant (1) with two quaternary ammonium groups on a steroid (androstane) skeleton. It is about 5–7 times as potent as D-tubocurarine. Protein binding occurs to both albumins and globulins, probably only to a relatively slight extent (10–20%), although reports vary from 10 to 90%. In contrast to most other non-depolarizing relaxants, pancuronium is metabolized at about 10–20%. Deacetylation in the liver probably accounts for the greater part of this biotransformation. The major metabolites are 3-monohydroxypancuronium, 17-monohydroxypancuronium, and (3,17)-dihydroxypancuronium; they are active pharmacologically, 3-monohydroxypancuronium being half as potent and the other two having 2% of the potency of pancuronium. About 40–50% of a dose is normally excreted in the urine and 5–10% in the bile over 24 hours as pancuronium plus its metabolites.

Pancuronium is reported to inhibit plasma cholinesterase (2) and this may be partly why the action of suxamethonium, given after a small dose of pancuronium, is prolonged. It also weakly inhibits acetylcholinesterase.

For tracheal intubation the usual dose is 0.1 mg/kg. When given after suxamethonium, 0.05 mg/kg is sufficient for good abdominal relaxation. Further doses of about one-quarter to one-third of the initial dose are given at intervals of 30–40 minutes to maintain relaxation. Reversal is easily achieved with neostigmine, provided there is some spontaneous return of neuromuscular transmission beforehand. If the evoked twitch height is less than 10% of the control value, there can be difficulty in reversing the blockade; this applies to all non-depolarizing relaxants, except perhaps vecuronium and atracurium.

The onset time for complete neuromuscular blockade is similar to that of D-tubocurarine and other non-depolarizing agents, namely 2–4 minutes. However, this is to some extent dose-dependent, and because of the relative lack of cardiovascular effects and histamine release, pancuronium can safely be given in higher dosages, thus producing good intubation conditions within 2 minutes. The dose of D-tubocurarine required to achieve similar conditions in 2 minutes would result in hypotension. As with D-tubocurarine, repeated doses can lead to accumulation and prolonged blockade.

In burned patients resistance to the neuromuscular blocking action of pancuronium may be encountered (3), as with other non-depolarizing relaxants.

Patients in whom pancuronium bromide is of value (4) include:

- patients with hypoxemia resisting mechanical ventilation and so cardiovascularly unstable that the use of sedatives is precluded;
- patients with bronchospasm unresponsive to conventional therapy;
- patients with severe tetanus or poisoning when muscle spasm prohibits adequate ventilation;
- patients with status epilepticus unable to maintain their own ventilation;
- shivering patients in whom metabolic demands for oxygen should be reduced;
- patients requiring tracheal intubation in whom suxamethonium is contraindicated.

Organs and Systems

Cardiovascular

Cardiovascular adverse effects are minimal with pancuronium. Ganglion blockade does not occur. Slight dose-dependent rises in heart rate, blood pressure, and cardiac output are common (5), but are often masked by the actions of other co-administered agents, such as fentanyl or halothane, which cause bradycardia or hypotension. These adverse effects of pancuronium are thus often beneficial and can be deliberately harnessed. Several mechanisms contribute: vagal blockade via selective blockade of cardiac muscarinic receptors (6), release of noradrenaline from adrenergic nerve endings (7), increased blood catecholamine concentrations (8), inhibition of neuronal catecholamine reuptake (9–11), and direct effects on myocardial contractility (12). These have been reviewed (13–15).

Occasionally nodal rhythm, atrioventricular dissociation, and tachydysrhythmias (such as ventricular extra beats or even bigeminy) develop, but these usually occur in association with halothane.

Supraventricular tachycardia has been reported after 8 mg pancuronium in a patient taking aminophylline (800 mg/day) (16).

Nodal rhythm can occur after injection of pancuronium. This dysrhythmia and bradycardia appear to be more common when neostigmine (plus atropine) is given for reversal of pancuronium-induced neuromuscular blockade than for reversal of D-tubocurarine or alcuronium (17); cholinesterase inhibition by pancuronium may contribute to the bradycardia in these circumstances.

Respiratory

Histamine release and bronchospasm are relatively rare with pancuronium but have been reported (SEDA-12, 117) (18–21).

© 2006 Elsevier B.V. All rights reserved.

Nervous system

Accidental injection into the cerebrospinal fluid of 4 mg of pancuronium resulted in generalized hypotonia, weakness, and hypoventilation (SEDA-15, 126) (22). Neostigmine given intravenously led to prompt recovery.

Sensory systems

Neonates with congenital diaphragmatic hernia often develop respiratory failure. To facilitate mechanical ventilation, neuromuscular blocking agents may be used. Sensorineural hearing loss can occur in survivors, with a reported incidence of up to 60%. It has been associated with the use of pancuronium. In a historical cohort study of 37 survivors of congenital diaphragmatic hernia, children with hearing loss had received significantly higher doses of pancuronium during respiratory failure than children without hearing loss (23). In addition, the cumulative dose of pancuronium correlated with the intensity of hearing loss in decibels. There were no differences with regard to oxygenation and ventilation parameters or to the cumulative dose of aminoglycosides, vancomycin, or furosemide, but children with hearing loss had received a higher cumulative dose of etacrynic acid. The authors admitted that the retrospective study design and the small sample size demanded cautious interpretation of their observations. For the time being, this report is not reason enough to avoid pancuronium if neuromuscular blockade is required. However, it should be remembered that the risk of severe neuromuscular disturbances associated with long-term administration of neuromuscular blocking agents militates against the routine use of these drugs in patients in intensive care, both children and adults. If muscle relaxants are given in this setting for more than a few hours, their effect should be monitored by a peripheral nerve stimulator to avoid overdose and drug accumulation. This may prove technically difficult in neonates.

Liver

Significant hyperbilirubinemia has been reported to occur more frequently in critically ill neonates given pancuronium than in a control group (24). The hyperbilirubinemia increased in the 4 days after withdrawal of pancuronium, whereas during the administration period the hyperbilirubinemia was less in the pancuronium group.

Body temperature

Malignant hyperthermia, possibly triggered by pancuronium, has been described (25), although pancuronium is generally considered to be safe in patients who are susceptible to the syndrome (26).

Second-Generation Effects

Fetotoxicity

There is placental transfer of pancuronium, but no untoward effects have been reported in neonates.

In a comparison of the onset and duration of paralysis produced by 0.2 mg/kg pancuronium ($n = 8$) or pipecuronium ($n = 8$) injected into the thighs of fetuses at 30–38 weeks gestational age, tachycardia occurred in four out of eight fetuses given pancuronium, and there was loss of beat-to-beat variability in two. No such changes were observed in any of the eight fetuses given pipecuronium (27).

Susceptibility Factors

Renal disease

Pancuronium appears to depend more on renal function for its elimination than D-tubocurarine does. Its action is, in most cases, significantly prolonged in renal insufficiency (28); in particular, spontaneous recovery is slow and adequate reversal of the block with neostigmine takes much longer than is generally expected (29). The response to pancuronium is much more unpredictable in renal insufficiency, with great interindividual variation in duration of blockade. Occasionally resistance to neuromuscular blockade with pancuronium is encountered (SEDA-13, 103) (28,30). This may be because of an increase in the volume of distribution. High plasma and tissue concentrations of 3-monohydroxypancuronium, sufficient to produce significant neuromuscular blockade, have also been measured in anuria (31). Monitoring of neuromuscular function is required in patients with appreciable renal dysfunction.

Hepatic disease

In hepatic disease, pancuronium seems to be more problematic than D-tubocurarine. Patients with cirrhosis have a prolonged half-life, a reduced clearance, and a markedly increased apparent volume of distribution (32). This is likely to result in the need for larger initial doses for adequate relaxation and prolongation of recovery of neuromuscular function.

Cholestasis can prolong the action of pancuronium, reducing its plasma clearance by 50%. This may be a result of raised bile salts, reducing the hepatic uptake of pancuronium (which is an important factor contributing to the total plasma clearance in normal patients) (SEDA-6, 130).

In patients undergoing liver transplantation, the dosage requirements for pancuronium and vecuronium by intravenous infusion were reduced by 57 and 50% respectively during the anhepatic phase (SEDA-17, 153), whereas atracurium requirements were not altered by exclusion of the liver from the circulation.

Other features of the patient

As with all muscle relaxants, abnormal reactions can occur in patients with neuromuscular diseases. In addition, muscle fibrillation has been reported, possibly due to pancuronium, in a patient with metachromatic leukodystrophy (33).

Pancuronium is relatively contraindicated, particularly in combination with halothane, in patients who may have raised catecholamine concentrations, or who are receiving drugs with sympathomimetic effects. Severe hypertension together with tachycardia can occur when pancuronium is given to a patient with a pheochromocytoma (34,35).

© 2006 Elsevier B.V. All rights reserved.

Caution should also be exercised in patients with thyrotoxicosis and with valvular stenosis, coronary artery insufficiency (36), or other conditions in which a tachycardia is hazardous.

Drug–Drug Interactions

Aminophylline

Aminophylline facilitates neuromuscular transmission, perhaps by increasing neurotransmitter release, through raising cyclic AMP concentrations at the neuromuscular junction via phosphodiesterase inhibition (37). This would account for the antagonism of pancuronium-induced blockade that has been reported in the presence of very high serum concentrations of theophylline (38).

Anticonvulsants

The long-term use of phenytoin has been associated with increased pancuronium requirements during neurosurgical operations (39), although the opposite effect might be expected from the quinine-like membrane-stabilizing activity of phenytoin.

Azathioprine

Azathioprine reduces sensitivity to pancuronium in experimental animals, possibly as a result of phosphodiesterase inhibition, increasing transmitter release (SEDA-4, 87) (40), (SEDA-13, 104).

Carbamazepine

Resistance to pancuronium, with a considerable shortening of recovery time, has been seen in patients taking long-term carbamazepine (SEDA-12, 118) (41); there was an inverse correlation between the daily dose and the recovery time.

Ciclosporin

Ciclosporin can cause considerable prolongation of the neuromuscular paralysis induced by pancuronium (42) in one patient (and also in another given vecuronium). Reversal required both neostigmine and edrophonium. Subsequently, recurarization occurred (SEDA-14, 116). Contributing factors could have been the solvent Cremophor EL in the ciclosporin formulation (Sandimmun) and minor renal dysfunction.

Corticosteroids

Corticosteroids have been reported to antagonize neuromuscular blockade due to pancuronium (43,44). In vitro studies in rats have shown a direct facilitating action of prednisolone on neuromuscular transmission (45), so that one would expect some antagonism of non-depolarizing relaxants in general.

Furosemide

Furosemide (1 mg/kg) shortened the recovery time from pancuronium blockade in neurosurgical patients with normal renal function (46). Phosphodiesterase inhibition and increased pancuronium excretion were suggested as possible explanations.

General anesthetics

Halothane anesthesia increases the risks of tachydysrhythmias when pancuronium is used (47).

Pancuronium lowers the MAC for halothane by 25% (48), although this has been disputed (SEDA-15, 124) (49).

Glyceryl trinitrate

Experiments in cats have demonstrated a significant prolongation and potentiation of the neuromuscular blockade induced by pancuronium during glyceryl trinitrate infusion (1 mg/kg/minute) started before the muscle relaxant was given. No prolongation was seen if suxamethonium, D-tubocurarine, or gallamine were used instead of pancuronium. Neostigmine reversal of the pancuronium block was not affected and neither was the plasma clearance of pancuronium changed over the 2 hours after the injection (50,51). The cause of this phenomenon, and whether it is applicable to humans, remains to be elucidated. However, more recent experiments (also in cats), using only moderate doses of pancuronium (and vecuronium), have failed to elicit any potentiation by glyceryl trinitrate (52).

Lithium carbonate

Prolonged neuromuscular blockade has been reported in patients taking long-term lithium given pancuronium (53). In animal experiments, lithium prolonged neuromuscular block due to pancuronium, suxamethonium, and decamethonium, but not that due to D-tubocurarine and gallamine (54); on the other hand, lithium was reported to have no or minimal effects on the blockade produced by pancuronium or D-tubocurarine (55). The mechanism of this interaction is not known, although possible mechanisms have been discussed (54). Caution, and monitoring are advisable.

Tricyclic antidepressants

The use of both halothane and pancuronium in patients taking tricyclic antidepressant has been reported as resulting in severe tachydysrhythmias. Experiments in dogs have shown that this combination can produce ventricular fibrillation and cardiac arrest (56). Enflurane also resulted in tachycardias in dogs given both imipramine and pancuronium acutely, but not when the imipramine was given chronically for 15 days beforehand. Pancuronium should not be used in patients taking tricyclic antidepressants.

Interference with Diagnostic Tests

Radiography

Complete relaxation in artificially ventilated neonates has resulted in apparent "gasless abdomens" on radiography and confusion in diagnosis. On discontinuation of paralysis, the normal appearance of gas-filled bowel was restored (57).

Pantoprazole

See also Proton pump inhibitors

General Information

Pantoprazole is a proton pump inhibitor.

Comparative studies

Pantoprazole 40 mg/day and ranitidine 150 mg bd for 8 weeks have been compared in the treatment of grades II and III reflux esophagitis in a randomized, double-blind trial in 256 patients (1). Symptom relief and healing rates were significantly better with pantoprazole. The incidences of adverse effects were similar in the two groups; the most commonly reported were diarrhea and somnolence with pantoprazole (2–3%) and headache, diarrhea, dizziness, increases in liver enzymes, and pruritus (2–4%) with ranitidine.

Pantoprazole 20 and 40 mg/day and nizatidine 150 mg bd for 8 weeks have been compared in the treatment of reflux esophagitis (grade II or worse) in a multicenter, randomized, double-blind trial in 221 patients (2). Both doses of pantoprazole were more effective in relieving symptoms and healing erosive esophagitis than nizatidine. The incidences of adverse effects were similar in the three groups; the most commonly reported were diarrhea and headache.

Pantoprazole 20 mg/day and ranitidine 300 mg/day for 12 months have been compared in the relief of symptoms in a multicenter, randomized, double-blind trial in 307 patients with symptomatic gastro-esophageal reflux disease in primary care (3). Symptom control was significantly more effective and faster with pantoprazole than ranitidine. Adverse effects were similar in the two groups; the most common adverse effects were headache, diarrhea, nausea, constipation, and vomiting.

Pantoprazole 40 mg/day and pantoprazole 40 mg/day plus cisapride 20 mg bd for 8 weeks have been compared in the treatment of gastro-esophageal reflux disease in a multicenter, randomized, double-blind trial in 350 patients (4). The addition of cisapride did not significantly improve symptom control or healing rates. The frequency of adverse effects in the two groups was similar. Compliance was worse in the pantoprazole plus cisapride group.

Pantothenic acid derivatives

See also Vitamins

General Information

The pantothenic acid derivatives include pantothenic acid (BAN), pantothenol (BAN), dexpanthenol (rINN), and hopantenic acid (rINN).

Pantothenic acid (vitamin B_5) has been proposed as a treatment for hair loss. It has been used to treat pantothenic acid deficiency, acne, and rheumatoid arthritis. Over

© 2006 Elsevier B.V. All rights reserved.

the past 30 years, only mild adverse reactions, such as rash and diarrhea, have been reported.

Hopantenate (calcium D-(+)-4-(2, 4-dihydroxy-3, 3-dimethylbutyramido)butyrate hemihydrate), or calcium hopantenate, is a homoanalog of l-pantothenate and has been used in Japan for the treatment of mental retardation with behavioral abnormalities. It represents one of the many attempts that have been made, so far unsuccessfully, to develop derivatives of substances belonging to the vitamin B group as agents for the treatment of brain or nervous disorders (SEDA-12, 328) (SEDA-13, 347).

Adverse effects, sometimes fatal, have been reported in patients taking calcium hopantenate, notably encephalopathy with metabolic acidosis and semicoma (1) and a Reye-like syndrome (2); this may be due to pantothenic acid deficiency, as hopantenate is a pantothenic acid antagonist. In elderly people, liver dysfunction and gastrointestinal upsets have been reported (3,4). In Japan, where the product was introduced in 1978, the control authorities in 1988 issued a series of warnings with respect to problems caused by hopantenate (5).

Organs and Systems

Cardiovascular

Eosinophilic pleural effusion with eosinophilic pericardial tamponade has been attributed to concomitant use of pantothenic acid and biotin (6).

- A 76-year-old woman developed chest pain and difficulty in breathing. She had no history of allergy and had been taking biotin 10 mg/day and pantothenic acid 300 mg/day for 2 months for alopecia. Chest X-rays showed pleural effusions and cardiac enlargement. Blood tests showed an inflammatory syndrome, with an erythrocyte sedimentation rate of 51 mm/hour and an eosinophil count of 1.2–1.5 $\times$ 10^9/l. Pericardiotomy showed an eosinophilic infiltrate. There was no evidence of vasculitis. Serological studies were negative for antinuclear antibodies, rheumatoid factor, viruses, bacteria, and Lyme disease. Stool examination and parasitological serologies were negative. A malignant tumor was excluded by mammography, thoracoscopy, and a CT scan. Myelography, a biopsy specimen of the iliac crest bone, and the concentrations of IgE, lysozyme, and vitamin B_{12} were also normal. A week after withdrawal of pantothenic acid and biotin she improved dramatically and her eosinophilia resolved.

Metabolism

As a pantothenic acid analogue, hopantenate can affect lactate generation, glucose metabolism, and ammonia disposal, and there have been two fatal cases in elderly people who developed disturbances of consciousness with lactic acidosis, hypoglycemia, and hyperammonemia (7).

Immunologic

Contact allergy to dexpanthenol is rare, but it occurs more often in some patients (for example those with eczema of the lower leg). Between 1992 and 1999, only 163 of 13 216 patients tested in the Information Network of Departments of Dermatology had a positive reaction to dexpanthenol. There have been no previous cases of occupational dexpanthenol sensitization caused by occupational exposure, but one has been reported in a junior nurse (8).

- Six weeks after starting training a 29-year-old nurse developed flushing and pruritus on the back of both hands and fingers, spreading to the forearms. Because of increased skin sensitivity she had been recommended to use skin protection measures; however, she did not use the skin protection cream that was available at the hospital but used a "Hand- und Hautsalbe" that had been designed for use especially in hairdressing salons. In addition to the lesions on her hands and arms she had periorbital shadowing, angular cheilitis, palmar hyperlinearity, and slightly generalized xerosis of the skin. She also reported seasonal rhinoconjunctivitis, intolerability of metals, and rhagades on the ears. After withdrawal of all supposed allergenic substances and local antieczematous therapy, the hand and arm lesions healed within a few days. Skin tests were positive for nickel-II-sulfate, imidazolidinyl urea, phenyl mercury acetate, and the hand cream, in which pantothenol (5% in vaseline) was identified as the allergen. She avoided the cream and the eczema did not recur.

Papaveraceae

See also Herbal medicines

General Information

The genera in the family of Papaveraceae (Table 1) include a variety of poppies and the greater celandine.

Chelidonium majus

Chelidonium majus (celandine, common celandine, greater celandine) contains a number of alkaloids, including chelidonine, chelerythrine, chelidocystatin, coptisine, sanguinarine, berberine, and sparteine.

Greater celandine was traditionally used to improve eyesight and in modern times has been used as a mild sedative, and antispasmodic in the treatment of bronchitis, whooping cough, asthma, jaundice, gallstones, and gallbladder pain. The latex is used topically to treat warts, ringworm, and corns. A semisynthetic thiophosphate derivative of alkaloids from *C. majus*, called Ukrain, has cytotoxic and cytostatic effects on tumor cells (1).

Adverse effects

Hematologic

Hemolytic anemia has been reported after the oral use of a celandine extract; there was intravascular hemolysis, renal insufficiency, liver cytolysis, and thrombocytopenia; a direct antiglobulin test was positive (2).

Liver

Hepatitis has been attributed to celandine (3).

- A 42-year-old woman had been admitted twice to hospital with hepatitis (4). No toxic agent could be identified during the first episode, but detailed questioning during the second showed that in both cases she had self-prescribed a commercially available medication of common celandine. Withdrawal of this herbal remedy was followed by an unremarkable recovery.

Table 1 The genera of Papaveraceae

Arctomecon (bear poppy)
Argemone (prickly poppy)
Bocconia (bocconia)
Canbya (pygmy poppy)
Chelidonium (celandine)
Dendromecon (tree poppy)
Eschscholzia (California poppy)
Glaucium (horn poppy)
Hunnemannia (hunnemannia)
Macleaya (macleaya)
Meconella (fairy poppy)
Papaver (poppy)
Platystemon (cream cups)
Platystigma (queen poppy)
Roemeria (roemeria)
Romneya (Matilija poppy)
Sanguinaria (bloodroot)
Stylophorum (stylophorum)
Stylomecon (wind poppy)

- A 42-year-old woman developed acute hepatitis several weeks after taking a herbal formulation containing greater celandine and curcuma root for a skin complaint (5). After withdrawal recovery was rapid and hepatic function returned to normal within 2 months.

Ten cases of acute hepatitis induced by formulations of greater celandine were observed over 2 years in a German University hospital (6). Perhaps ironically, this product is popular in Germany for gastric and gall-bladder problems. In five cases there was marked cholestasis but no liver failure. After withdrawal of the product, the symptoms subsided and the liver enzymes normalized within 2–6 months. Unintentional rechallenge led to a further episode of acute hepatitis in one patient.

In addition to about 15 published cases, some 40 cases of liver damage from *C. majus* have been reported to the German regulatory authorities (7). The course of the hepatitis can be severe and can include cholestasis and fibrosis, but acute liver failure has not been observed. Based on these data, celandine has been banned for oral use in several countries.

Skin

Contact sensitivity has been attributed to *C. majus* (8).

Susceptibility factors

Some authors caution that the use of celandine in children should be discouraged because of an early fatal colitis in a 3-year-old boy (9); however, this report does not provide convincing evidence that the victim had indeed taken *C. majus*.

Papaver somniferum

Papaver somniferum (opium poppy) contains a variety of opioid and related alkaloids, including codeine, morphine, noscapine, papaverine, and thebaine. Crude opium is the air-dried latex obtained by incising the unripe capsules of *P. somniferum*. Paregoric is ammoniated tincture of opium (Scotch paregoric) or camphorated tincture of opium (English paregoric). The use of these formulations has largely been replaced by use of the purified compounds.

Adverse effects

The adverse effects of opium are generally the same as those of the pure compounds.

Respiratory

Of 28 workers in a pharmaceutical factory that produced morphine and other alkaloids extracted from the shells of *P. somniferum*, six had symptoms of sensitization and positive skin tests (10). A bronchial provocation test was positive in four of them, and in all six there was a specific IgE, detected by ELISA and RAST tests using an aqueous extract of *P. somniferum*.

Nervous system

- A young man dependent on "Kompot" or "Polish heroin", a domestic product produced from poppy straw or the juice of poppy heads (*P. somniferum*) and given intravenously, developed Guillain–Barré syndrome after severe intoxication induced by home-made heroin, barbiturates, and benzodiazepines (11).

© 2006 Elsevier B.V. All rights reserved.

"Kompot" contains variable amounts of morphine, heroin (diacetylmorphine), 3-monoacetylmorphine, 6-monoacetylmorphine, acetylcodeine, and codeine, in addition to papaverine, thebaine, and narcotine.

Papaveretum

See also Opioid analgesics

General Information

Papaveretum (Omnopon, Pantopon) is a mixture of several opium alkaloids.

Organs and Systems

Urinary tract

Renal insufficiency has been reported in a 60-year-old patient after the use of papaveretum for perioperative analgesia (SEDA-17, 83).

Second-Generation Effects

Teratogenicity

Because of possible teratogenicity, papaveretum is no longer recommended for women of child-bearing age (SEDA-17, 83).

Susceptibility Factors

Age

There was a 56% incidence of nausea and vomiting with papaveretum in 129 children 24 hours after circumcision with caudal epidural blockade (1).

Reference

1. Wilton NC, Burn JM. Delayed vomiting after papavaretum in paediatric outpatient surgery. Can Anaesth Soc J 1986; 33(6):741–4.

Papaverine

General Information

Papaverine is an alkaloid present in opium, although it is not related chemically or pharmacologically to other opium alkaloids. It has a direct relaxant effect on smooth muscle, partly attributable to inhibition of phosphodiesterase.

Systemic adverse effects reported are hypotension and dizziness and, in rare cases, abnormal results of liver function tests (SEDA-15, 3).

Organs and Systems

Sexual function

Intracavernous administration of papaverine with phentolamine has been used in the diagnosis and treatment of erectile dysfunction. The major local adverse effect is prolonged erection, which usually occurs early during diagnostic testing and is reduced after dose adjustment; furthermore, local hematomas have been reported in a number of patients. It may be that patients most susceptible to priapism can be identified in advance by testing their erectile abilities in response to erotic stimulation (1). Long-term therapy can also cause intracavernous fibrosis but it can also lead to development of tolerance to the desired effect.

Parabens

See also Disinfectants and antiseptics

General Information

Parabens (methyl, ethyl, propyl, and butyl esters of parahydroxybenzoic acid) are used as preservatives in concentrations of 0.1–0.3% in pharmaceutical formulations and in concentrations of 0.01–0.1% in cosmetics and foods. In such concentrations they are devoid of systemic toxic effects, but allergic reactions have been reported.

Organs and Systems

Immunologic

Parabens can cause allergic contact dermatitis that can run an insidious course, especially when the parabens are in glucocorticoid ointments. In such cases, treatment leads to a protracted dermatitis without acute exacerbation, so that neither the patient nor the physician suspects parabens as a possible cause. A sensitization index of 0.8% was found in 273 patients with chronic dermatitis (1).

In 1973, in a multicenter study of 1200 individuals carried out by the North American Contact Dermatitis Group, there was a 3% incidence of delayed hypersensitivity reactions to parabens. General allergic reactions have also been reported after the injection of parabens-containing formulations of lidocaine and hydrocortisone and after oral use of barium sulfate contrast suspension, haloperidol syrup, and an antitussive syrup, all of which contained parabens (SEDA-11, 484).

Paracetamol

General Information

A century after its introduction, acetylsalicylic acid (aspirin) is by far the most commonly used analgesic, sharing its leading position with the relative newcomer paracetamol (acetaminophen), and notwithstanding the fact that other widely used compounds, such as ibuprofen, have in recent years been introduced in over-the-counter versions. Both are also still being prescribed by physicians and are generally used for mild to moderate pain, fever associated with common everyday illnesses, and disorders ranging from head colds and influenza to toothache and headache. However, their greatest use is by consumers who obtain them directly from the pharmacy, and in many countries outside pharmacies as well.

Perhaps this wide availability and advertising via mass media leads to a lack of appreciation by the lay public that these are medicines with adverse effects. Both have at any rate been subject to misuse and excessive use, leading to such problems as chronic salicylate intoxication with aspirin and severe hepatic damage with paracetamol overdose. Both aspirin and paracetamol have also featured in accidental overdosage (particularly in children) as well as intentional overdosage.

In an investigation of Canadian donors who had not admitted to drug intake, 6–7% of the blood samples taken were found to have detectable concentrations of acetylsalicylic acid and paracetamol (1). Such drugs would be potentially capable of causing untoward reactions in the recipients.

To offer some protection against misuse of analgesics, many countries have insisted on the use of packs containing total quantities less than the minimum toxic dose (albeit usually the one obtained for healthy young volunteers and thus disregarding the majority of the population), and supplied in child-resistant packaging. Most important, however, is the need to provide education for the lay public to respect such medicines in general for the good they can do, but more especially for the harm that can arise, but can be avoided. There is a definite role for the prescribing physician, since informing the patient seems to prevent adverse events (2).

The sale of paracetamol or aspirin in dosage forms in which they are combined with other active ingredients offers considerable risk to the consumer, since the product as sold may not be clearly identified as containing either of these two analgesics. Brand names sometimes obscure the actual composition of older formulations that contain one or both of these analgesics in combination with, for example, a pyrazolone derivative and/or a potentially addictive substance. For instance, in Germany, with the EC harmonization of the Drug Law of 1990, the manufacturers of drugs already marketed before 1978 had the opportunity of exchanging even the active principles without being obliged to undergo a new approval procedure or to abandon their brand name. Combination formulations are still being promoted and sold, and not exclusively in developing countries. Consequently the patient who is so anxious to allay all his symptoms that he takes several medications concurrently may without knowing it take several doses of aspirin or paracetamol at the same time, perhaps sufficient to cause toxicity. It is essential that product labels clearly state their active ingredients by approved name, together with the quantity per dosage form (3).

The antipyretic analgesics share with the non-steroidal anti inflammatory drugs (NSAIDs) a common mechanism of action, namely the inhibition of prostaglandin synthesis from arachidonic acid and their release. More precisely their mode of action is thought to result from inhibition of both the constitutive and the inducible isoenzymes (COX-1 and COX-2) of the cyclo-oxygenase pathway (4). However, aspirin and paracetamol are distinguishable from most of the NSAIDs by their ability to inhibit prostaglandin synthesis in the nervous system, and thus the hypothalamic center for body temperature regulation, rather than acting mainly in the periphery.

Endogenous pyrogens (and exogenous pyrogens that have their effects through the endogenous group) induce the hypothalamic vascular endothelium to produce

© 2006 Elsevier B.V. All rights reserved.

prostaglandins, which activate the thermoregulatory neurons by increasing AMP concentrations. The capacity of the antipyretic analgesics to inhibit hypothalamic prostaglandin synthesis appears to be the basis of their antipyretic action. Neither aspirin nor paracetamol affects the synthesis or release of endogenous pyrogens and neither will lower body temperature if it is normal.

While aspirin significantly inhibits peripheral prostaglandin and thromboxane synthesis, paracetamol is less potent as a synthetase inhibitor than the NSAIDs, except in the brain, and paracetamol has only a weak anti-inflammatory action. It is simple to ascribe the analgesic activity of aspirin to its capacity to inhibit prostaglandin synthesis, with a consequent reduction in inflammatory edema and vasodilatation, since aspirin is most effective in the pain associated with inflammation or injury. However, such a peripheral effect cannot account for the analgesic activity of paracetamol, which is less well understood.

The use of paracetamol as an antipyretic increased rapidly once phenacetin was no longer available and has received a boost more recently with wide acknowledgement of the role of aspirin as a causative agent in Reye's syndrome, resulting in the virtual disappearance of children's dosage forms of aspirin. While the incidence of adverse effects is reassuringly low, satisfaction must be tempered by appreciation of the relatively short duration of extensive clinical experience with paracetamol, its close relation to phenacetin, its low potency as an analgesic, and low public awareness of its potential adverse effects.

General adverse reactions

Although paracetamol is acceptably safe in usual dosages, there have been some reports that in patients with significant hepatic dysfunction or those taking substances that induce hepatic enzymes (for example ethanol, phenobarbital, isoniazid) even these doses may aggravate liver dysfunction, sometimes to the point of causing hepatic failure. The problem of overdosage is substantial. Allergic reactions, including urticaria, are seen occasionally. Anaphylactic shock has been reported.

Organs and Systems

Cardiovascular

Despite the high prevalence of the use of minor analgesics (aspirin and paracetamol) there is little information available on the association between the use of these analgesics and the risk of hypertension. A prospective cohort study in 80 020 women aged 31–50 years has provided some useful information (5). The women had participated in the Nurses' Health Study II and had no previous history of hypertension. The frequency of use of paracetamol, aspirin, and NSAIDs was collected by mailed questionnaires and cases of physician-diagnosed hypertension were identified by self-report. During 164 000 person-years of follow-up, 1650 incident cases of hypertension were identified. Overall, 73% of the cohort had used paracetamol at least 1–4 days/month, 51% had used aspirin, and 77% had used an NSAID. Compared with non-users of paracetamol the age-adjusted relative risk (RR) of hypertension was significantly increased even in women who had used paracetamol for only 1–4 days/month (RR = 1.22; CI = 1.07, 1.39). There seemed to be a dose–response relation, as the RR of hypertension compared with non-users was 2.00 (CI = 1.52, 2.62) in women who had taken paracetamol for 29 days/month or more. For women using aspirin or NSAIDs at a frequency of 1–4 days/month the RRs were 1.18 (CI = 1.02, 1.35) and 1.17 (CI = 1.02, 1.36) respectively. However, after adjusting for age and other potential risk factors, only paracetamol and NSAIDs, but not aspirin, remained significantly associated with a risk of hypertension. In summary, the data from this study support the view that paracetamol and NSAIDs are strongly associated with an increased risk of hypertension in women, the risk increasing with increasing frequency of use. Aspirin did not seem to be associated with an increased risk. This conclusion contrasts with the results of some short-term studies that have shown no effect of paracetamol on blood pressure (6,7).

This study suggests that paracetamol can raise arterial blood pressure in a dose-related fashion, interfere with the actions of antihypertensive drugs, and prompt the need for new antihypertensive therapy. However, these results must be interpreted with caution, as there were some limitations: the assessments of analgesic use and hypertension were made using a self-reported questionnaire; relative risk can be influenced by many potentially confounding variables; the results are relevant only for young women and cannot be extrapolated to the general population.

Respiratory

Paracetamol can aggravate bronchospasm in patients who are sensitive to aspirin and other analgesics (8). In severe poisoning, paracetamol depresses respiratory function centrally through metabolic acidosis and coma (9).

An observational study, part of a population-based case-control study of dietary antioxidants and asthma, has shown an association between the regular use of paracetamol and the incidence of asthma and rhinitis in adults (10). After controlling for potential confounding factors the OR for asthma in daily users, compared with never users, was 2.38 (CI = 1.22, 4.64). Not unexpectedly, there was also an association in users and non-users of aspirin, strongest when cases with more severe disease were compared with controls. This adverse effect of paracetamol may be due to depletion of the antioxidant glutathione in the lungs. However, further studies are needed before paracetamol can be blamed for an increase in the prevalence and severity of asthma.

Nervous system

In patients who suffer from recurrent headaches, for example migraine, cluster headache, or tension headache, temporary relief for the constant or intermittent pains is obtained from each analgesic dose, but wears off after a few hours with the arrival of a new episode. The patient gets accustomed to this pattern and may use excessive doses of analgesics. This in turn can cause, worsen, and perpetuate headaches, leading to what is called analgesic-induced or rebound headache. Like

© 2006 Elsevier B.V. All rights reserved.

migraine, analgesic-induced headache is more likely to occur in women and is associated with depression.

It is postulated that the mechanism by which analgesic abuse transforms a primary headache into a rebound headache involves serotonin: both platelet serotonin concentrations and uptake were lower in patients with analgesic-induced headache compared with migraine sufferers and non-headache sufferers. At the same time, there was upregulation of serotonin receptors on the platelet membrane (11,12). Extrapolating these findings to the nervous system, it has been suggested that excessive analgesic use suppresses serotonin pathways, contributing to aggravation of headaches. Paracetamol and codeine were the major culprits of the analgesics investigated.

Analgesic-induced headache has also been described in children. One report (13) described 12 children, aged 6–16 years, who gave a history of headaches on at least 4 days a week, for 3 months to 10 years. Eleven of the children had been taking paracetamol, six in combination with codeine, and one was taking ibuprofen alone. They were taking at least one dose of an analgesic for each headache and eight were taking analgesics every day. The headaches presented with increasing frequency and were related to overuse of analgesics, a typical finding in analgesic-induced headache. The analgesics were withdrawn; in six children the headaches resolved completely, another five children experienced a reduced frequency of headaches, and one resumed analgesic abuse.

A second report (14) was of a retrospective study of patients seen in a pediatric headache clinic. During 8 months, 98 patients were seen for headache; 46 of them suffered from daily or near daily headache and 30 were consuming analgesics daily. Follow-up information was available in 25. The average number of doses of analgesics per week they consumed was 26. The most commonly used medications were paracetamol and ibuprofen. In addition, a minority were taking combinations that contained aspirin, codeine, caffeine, propoxyphene, or butalbital, or other NSAIDs. Abrupt withdrawal of all analgesics concomitant with the use of amitriptyline 10 mg/day (in 22 patients) prompted a significant reduction in the frequency and severity of headache.

The data from these studies are comparable to previous observations reported in adults (SEDA-21, 95) and suggest that daily use of analgesics can cause daily or near daily headaches in children and adolescents. However, additional controlled prospective studies are needed to address the true frequency of analgesics rebound headache among children and to evaluate possible treatments.

Metabolism

Hypoglycemia has been recorded with paracetamol, particularly in children (15).

Hematologic

Agranulocytosis was recorded in a series in France (16), but does not appear to have been a significant clinical problem elsewhere.

Two patients developed immune thrombocytopenia attributed to metabolites of paracetamol (17).

- A 30-year-old man and a 66-year-old woman had taken paracetamol 1 g intermittently for headaches and other non-specific indications. Routine blood testing showed thrombocytopenia (50×10^9/l and 45×10^9/l respectively). They both stopped taking paracetamol, and their platelet counts rose to normal within 7–10 days. Their sera contained antibodies (IgG or IgA) that recognized normal platelets in the presence of the metabolite paracetamol sulfate.

This suggests that in patients with drug-induced immune thrombocytopenia, tests for metabolite-dependent antibodies can be helpful in identifying the responsible agent.

A hemolytic crisis has been recorded in a patient with glucose-6-phosphate dehydrogenase deficiency (18).

Gastrointestinal

In normal doses, paracetamol, in contradistinction to aspirin and the NSAIDs, is well tolerated by the gastrointestinal tract.

Liver

Paracetamol is directly hepatotoxic and can cause severe hepatic damage in dosages over 6–10 g (12–20 tablets).

Biliary tract

Acute biliary pain with cholestasis is an occasional complication (19,20).

Pancreas

Pancreatitis has been reported, but only in overdose (21).

Urinary tract

Apart from renal tubular necrosis, which is usually associated with hepatic toxicity, but is occasionally seen without hepatic damage, there have been reports of a nephropathy similar to that seen with phenacetin, after prolonged use of paracetamol alone or in combination with other NSAIDs (22–27).

Analgesic nephropathy

DoTS classification (BMJ 2003;327:1222–5)

Dose-relation: collateral effect

Time-course: delayed

Susceptibility factors: age (over 65); sex (women)

In a series of papers that appeared from 1950 onwards (28), Spüler and Zollinger in Switzerland recognized analgesic nephropathy as a condition resulting from prolonged excessive consumption of analgesic mixtures, usually containing phenacetin. The disease is characterized by renal papillary necrosis and interstitial nephritis. The prevalence is variable, being especially high when the use of minor analgesics is intensive. The evidence linking the disorder primarily to phenacetin has been reviewed extensively (SED-8, 169) (SED-8, 178) (SED-9, 123) (SED-10, 135) (SEDA-9, 75).

Over the last 50 years there has been a steady evolution in our knowledge of drug-related renal pathology, including the role of prostaglandins in the kidneys and the concept of two cyclo-oxygenase isozymes. In the 1960s a distinct clinical entity was identified, separate from

© 2006 Elsevier B.V. All rights reserved.

NSAID-induced renal toxicity, comprising interstitial nephritis and renal papillary necrosis. The condition, named analgesic nephropathy, was not uncommon and was serious. In a number of cases malignancies in the urinary tract also occurred.

The relation between long-term heavy exposure to analgesics and the risk of chronic renal disease has been the object of intensive toxicological and epidemiological research for many years (SEDA-24, 120) (29). Most of the earlier reports suggested that phenacetin-containing analgesics probably cause renal papillary necrosis and interstitial nephritis.

Nephropathy due to non-phenacetin-containing analgesics

There is no convincing epidemiological evidence that non-phenacetin-containing analgesics (including paracetamol, aspirin, mixtures of the two, and NSAIDs) cause chronic renal disease. Findings from epidemiological studies should be interpreted with caution, because of a number of inherent limitations and potential biases in study design (30). However, two methodologically sound studies have provided information on this topic.

The first was the largest cohort study conducted thus far to assess the risk of renal dysfunction associated with analgesic use (31). Details of analgesic use were obtained from 11 032 men without previous renal dysfunction participating in the Physicians' Health Study (PHS), which lasted 14 years. The main outcome measure was a raised creatinine concentration defined as 1.5 mg/dl (133 μmol/l) or higher and a reduced creatinine clearance of 55 ml/minute or less. In all, 460 men (4.2%) had a raised creatinine concentration and 1258 (11%) had a reduced creatinine clearance. Mean creatinine concentrations and creatinine clearances were similar among men who did not use analgesics and those who did. This was true for all categories of analgesics (paracetamol and paracetamol-containing mixtures, aspirin and aspirin-containing mixtures, and other NSAIDs) and for higher risk groups, such as those aged 60 years or over or those with hypertension or diabetes.

These data are convincing, because the large size of the PHS cohort should have made it possible to examine and detect even modest associations between analgesic use and a risk of renal disease. Furthermore, this study included more individuals who reported extensive use of analgesics than any prior case-control study. However, the study had some limitations, the most important being the fact that the cohort was composed of relatively healthy men, most of whom were white. These results cannot therefore be generalized to the entire population. However, the study clearly showed that there is not a strong association between chronic analgesic use and chronic renal dysfunction among a large cohort of men without a history of renal impairment.

The second study was a Swedish nationwide, population-based, case-control study of early-stage chronic renal insufficiency in men whose serum creatinine concentration exceeded 3.4 mg/dl (300 μmol/l) or women whose serum creatinine exceeded 250 μmol/l (2.8 mg/dl) (32). In all, 918 patients with newly diagnosed renal insufficiency and 980 controls were interviewed and completed questionnaires about their lifetime consumption of analgesics. Compared with controls, more patients with chronic renal insufficiency were regular users of aspirin (37 versus 19%) or paracetamol (25 versus 12%). Among subjects who did not use aspirin regularly, the regular use of paracetamol was associated with a risk of chronic renal insufficiency that was 2.5 times as high as that for non-users of paracetamol. The risk increased with increasing cumulative lifetime dose. Patients who took 500 g or more over a year (1.4 g/day) during periods of regular use had an increased odds ratio for chronic renal insufficiency (OR = 5.3; 95% CI = 1.8, 15). Among subjects who did not use paracetamol regularly, the regular use of aspirin was associated with a risk of chronic renal insufficiency that was 2.5 times as high as that for non-users of aspirin. The risk increased significantly with an increasing cumulative lifetime dose of aspirin. Among the patients with an average intake of 500 g or more of aspirin per year during periods of regular use, the risk of chronic renal insufficiency was increased about three-fold (OR = 3.3; CI = 1.4, 8.0). Among patients who used paracetamol in addition to aspirin, the risk of chronic renal insufficiency was increased about two-fold when regular aspirin users served as the reference group (OR = 2.2; CI = 1.4, 3.5) and non-significantly when regular paracetamol users were used as controls (OR = 1.6; CI = 0.9, 2.7). There was no relation between the use of other analgesics (propoxyphene, NSAIDs, codeine, and pyrazolones) and the risk of chronic renal insufficiency. Thus, the regular use of paracetamol, or aspirin, or both was associated dose-dependently with an increased risk of chronic renal insufficiency. The OR among regular users exceeded 1.0 for all types of chronic renal insufficiency, albeit not always significantly. These results are consistent with exacerbating effects of paracetamol and aspirin on chronic renal insufficiency, regardless of accompanying disease.

How can we explain the contrasting results of these two studies? A possible explanation lies in the different populations studied. In the PHS study, relatively healthy individuals were enrolled, while in the Swedish study all the patients had pre-existing severe renal or systemic disease, suggesting that such disease has an important role in causing analgesic-associated chronic renal insufficiency. People without pre-existing disease who use analgesics may have only a small risk of end-stage renal disease.

As up to 10% of about 42 000 dialysis patients have suffered from renal insufficiency due to analgesic nephropathy (in the postphenacetin era), German nephrologists have demanded the withdrawal from the market of medications that contain fixed combinations of analgesics (paracetamol, aspirin, or propyphenazone) plus caffeine, following the example of their American colleagues in the National Kidney Foundation (33).

Despite the fact that a careful evaluation of all epidemiological studies on non-narcotic analgesics showed no evidence that phenacetin-free combination drugs are more nephrotoxic than simple analgesics (29), the Belgian Public Health Authorities decided that combination analgesics are to become "prescription only" (34), as they have a "devastating" effect on the kidneys. However, contrasting opinions have been published (30,35).

© 2006 Elsevier B.V. All rights reserved.

The effect of the withdrawal of phenacetin in Germany in 1986 and its replacement with paracetamol in most analgesic mixtures resulted in a significant fall in the incidence of end-stage analgesic nephropathy from 30% in 1981–82 to 21% in 1991–92 and 12% in 1995–97 (36). However, whether this reduction can be taken as proof that only phenacetin and not paracetamol is nephrotoxic in compound analgesics is debatable (37). In fact, the German authors found that other factors, such as advanced age and an increasing prevalence of type II diabetes mellitus, affected the relative frequencies of primary renal disease in patients with end-stage renal disease to such a degree that the observed relative reduction in analgesic nephropathy may not have been related to a change from phenacetin to paracetamol. Thus, the relative reduction in the incidence of analgesic nephropathy cannot be used as an argument for the non-toxicity of compound analgesics that contain paracetamol.

Furthermore, despite withdrawal of phenacetin from the market, analgesic nephropathy has continued to occur. It has been estimated that analgesic-associated nephropathy still accounts for 20% of patients in the USA with interstitial nephritis. As recently as the mid-1990s, a German study showed that up to 10% of dialysis patients had suffered from renal insufficiency owing to analgesic nephropathy (SEDA-20, 89). There is evidence that paracetamol, which replaced phenacetin in analgesic combination formulations, is nephrotoxic as well (38,39). The withdrawal of combination analgesic products from over-the-counter sales in Sweden and Australia has markedly reduced analgesic nephropathy as a cause of end-stage renal disease in those countries (SEDA-21, 99). It is therefore not surprising that nephrologists on both sides of the Atlantic have suggested a ban on the advertising and over-the-counter sales of these medications.

Symptoms and signs

Clinical evidence suggestive of analgesic nephropathy includes nocturia, renal insufficiency with severe acidosis, persistent urinary tract infection with colic, hematuria, and hypertension (40,41). Nocturia resulting from failure to concentrate urine is usually the earliest functional defect, but like the other symptoms it is non-specific, rendering the diagnosis of analgesic nephropathy difficult. A CT scan showing bilateral small kidneys with bumpy contours, and papillary calcification is accepted to be of sufficient specificity (38,39).

Epidemiology

Analgesic nephropathy is mostly diagnosed between the ages of 30 and 70 years, with a peak in the fourth decade, and there is a familial predisposition (SEDA-6, 80).

The prevalence of analgesic nephropathy is particularly high when there is intensive use of analgesics. There is evidence from animal and clinical work to suggest that hypovolemia plays a part, and that the risk of nephropathy is greatest in women and the elderly. Because of the long latent period of over 10 years, the condition has continued to appear despite the withdrawal of phenacetin.

In Australia, where phenacetin was withdrawn from antipyretic analgesic formulations during 1962–75 (42), analgesic nephropathy continued to be a major problem for a considerable time thereafter, reflecting the long latent period before the disorder develops; 22% of patients newly admitted to the Australian Kidney Foundation's dialysis and transplant registry in 1980 had analgesic nephropathy. The consumption of phenacetin-containing analgesics increased the risk of renal papillary necrosis in Australian women some 17-fold compared with non-consumers, while analgesics not containing phenacetin did not increase the risk of kidney damage (43).

In Belgium, the distribution of analgesic nephropathy in patients with terminal renal insufficiency was well correlated with the sale of drugs containing either aspirin + phenacetin or paracetamol + caffeine (SEDA-7, 75), and it is estimated that Belgium, after Australia, had the second highest incidence of analgesic nephropathy in the world.

Statistics published in 1981 from the European Dialysis and Transplant Association on the causes of chronic renal insufficiency suggested that in Europe about 3.1% of cases up to that time had been drug-induced; the figures cited varied from 0.4% in Spain to 17.5% in Switzerland. Some of the best-documented reports were those from Switzerland, where per capita consumption of phenacetin reached a peak of some 10 g annually between 1955 and 1968 (44). Between 1962 and 1978 the proportion of phenacetin users coming to autopsy increased from 1.8 to 3.1%.

In the USA only a very small proportion of phenacetin patients (in one series 2.8%) have a history of analgesic abuse (45).

True geographic differences cannot be proven from such figures, since the variation from country to country is largely due to inconsistent classification and differences in the selection of patients for dialysis and transplantation (46).

By the early 1980s, most countries had severely restricted or entirely prohibited the sale of phenacetin. Subsequent data from several of these countries suggested that the number of new patients with analgesic nephropathy fell as a result of the prohibition of phenacetin in analgesic mixtures.

Cause

It soon became clear that the major causative agent in analgesic nephropathy was phenacetin, improperly used long-term and especially in combinations with other analgesics, and this identification led to its virtual disappearance in the mid-1970s, following regulatory action.

In recent years it has become obvious that many of the NSAIDs are associated with renal disorders arising de novo or by aggravation of existent renal dysfunction. Inhibition of prostaglandin synthesis intrarenally leads to reduced vasodilator activity of PGE_1, which normally contributes to the maintenance of renal functional balance and protection against the vasoconstrictor effects of noradrenaline and angiotensin-II and the action of antidiuretic hormone. Some experimental work suggests a tendency for phenacetin and its metabolite paracetamol to concentrate in the renal medulla, possibly accounting for the papillary lesions most often associated with them.

There is no evidence that short-term use of cyclooxygenase inhibitors has any major deleterious effect on renal function in healthy individuals.

© 2006 Elsevier B.V. All rights reserved.

Although some authors have stressed the possible role of aspirin as a causal factor (SED-8, 169), a study of the safety of long-term ingestion of large cumulative doses did not confirm this (47). The patients in question, with seropositive rheumatoid arthritis, had taken aspirin continuously for 10 or more years (mean total dose per patient 36 kg, range 16–82 kg). Their normal creatinine and BUN concentrations, with maximum recorded specific gravities of urine greater than 1019 in 93% of patients, suggested that long-term salicylate ingestion does not cause renal damage or that the magnitude and long-term clinical significance of such damage is not significant. The fact remains, however, that the overwhelming sale of phenacetin was in the form of fixed combinations with aspirin (and sometimes with caffeine, codeine, and other components), and the possibility of some additive effect cannot retrospectively be excluded.

As the debate developed, the safety of paracetamol and its combination with aspirin, which had only come to the fore on a large scale as phenacetin disappeared, also came to be questioned. The difficulty in assigning specific roles to the various analgesics is partly related to the use of drug combinations but largely because of the prolonged time over which the disorder develops.

Susceptibility factors

The association between analgesic abuse and renal papillary necrosis is well established, but the existence of other unrecognized factors is highly probable (SEDA-6, 80). The female/male ratio of analgesic abusers as a whole in the Australian community is 2:1, but the ratio in analgesic nephropathy is about 6.5:1. Swiss data also point to a higher incidence than expected in women and in elderly subjects (28). Climatic factors and fluid intake have also been incriminated, since dehydration can aggravate the risk. Reports of an association between HLA genotype and analgesic nephropathy might explain why only a few of the many individuals who take large quantities of analgesics develop renal insufficiency (48).

Pathology

The primary renal lesions in phenacetin abusers are those involving the capillaries (49,50). In some 80% of cases there is capillary sclerosis, with reduplication of laminar transformation of the intima, due to reduplication of the basement membrane in the capillaries just below the urothelium in the papillae, renal pelvis, and lower urinary tract. It is these changes that make it possible to diagnose analgesic abuse from surgical or postmortem specimens, even when the clinical history is unknown. A morphological study of 21 transitional cell carcinomas in an Australian histopathology department disclosed 16 cases with papillary changes of the analgesic type. Of these patients, only two were known to be analgesic abusers (SEDA-6, 82).

The renal cortical and medullary tubules are similarly affected, since overuse of analgesic-containing formulations can affect the metabolism of the basement membranes of capillaries and tubules and result in thickening of the walls. In skin biopsy specimens from patients with a history of excessive intake of analgesics, thickening of dermal capillaries suggested that the microangiopathy was not confined to the renal tract but also occurred in other organs (SEDA-6, 81).

Associated disorders

In the prospective Swiss Analgesic Study the risk of bacteriuria was about three times higher in those who abused analgesics heavily than in matched controls (51). The primary causes of mortality in this study were tumors and cardiovascular disease; only 7.5% died from primary renal disease due to pyelonephritis.

Renal papillary necrosis with retroperitoneal fibrosis secondary to analgesic abuse (involving aspirin, propoxyphene, and numerous other analgesics taken in large quantities for many years) has also incidentally been reported (SEDA-7, 94).

Patients with analgesic nephropathy have an increased risk of atherosclerosis. In a retrospective study their serum cholesterol and triglyceride concentrations were significantly higher than in a control group of similar age and with a similar degree of renal insufficiency due to other renal diseases (SEDA-6, 81). Some possible mechanisms of hyperlipidemia in analgesic nephropathy have been discussed, as this phenomenon is not sufficiently explained by end-stage renal insufficiency or by protein loss, as in the nephrotic syndrome (SEDA-7, 94).

Urinary tract tumors Renal carcinoma has been associated with analgesic abuse an order of magnitude greater than in non-abusers (52–54), and the causal association has been recognized since 1965 (SEDA-6, 81) and repeatedly confirmed. In 1984 an authoritative consensus conference in the USA pointed to the evidence that very heavy and sustained use of some analgesic mixtures without phenacetin can also predispose to cancer of the urinary tract, particularly transitional cell carcinoma of the renal pelvis (55).

Of 422 inhabitants of Basel with malignant tumors of the lower urinary tract, 18.5% were users of phenacetin-containing analgesics, which means that carcinomas and sarcomas of the lower urinary tract were nearly 13 times as common in abusers as in non-abusers (54). Carcinoma of the renal pelvis was increased 77-fold, carcinoma of the ureter 89-fold, and carcinoma of the urinary bladder 7-fold. In Australia, in 274 urological patients who had abused phenacetin-containing products, renal symptoms appeared after an average latent period of 10 years; within the last decade of the period studied, 8% of this group (22 patients) had tumors of the urothelium.

In an Australian investigation of renal papillary carcinoma (SEDA-6, 81) the overall crude incidence rate was 1.6 per 100 000 population per year; 47% of the tumors were associated with analgesic abuse and analgesic nephropathy. The risk of renal papillary carcinoma among patients who regularly took analgesics was estimated to be 8 per 100 000 patients per year. Renal papillary carcinoma had a female-to-male ratio among analgesic abusers of 2.6:1, compared with 1:2 among those without analgesic-associated nephropathy. A similar epidemiological study from the USA (53) supported this association between analgesic nephropathy and tumors; 5.2% of patients with transitional carcinoma of the urinary tract diagnosed over 3 years had analgesic-

© 2006 Elsevier B.V. All rights reserved.

associated nephropathy. The patients were predominantly younger women, who had renal pelvis tumors instead of bladder tumors and a higher mortality rate. In a historical prospective study of 146 patients with interstitial nephritis, 84 cases were associated with analgesics and in four patients transitional cell carcinoma developed. None of the 98 nephritic patients without analgesic-associated nephropathy developed transitional cell carcinoma. In 300 urological patients (75% women) in whom renal and extrarenal manifestations appeared after an average latency period of 20 years, 31 patients had a tumor of the urothelium.

Studies on the tumor-inducing effects of heavy use of analgesics, especially those that contain phenacetin, have given contrasting results (SEDA-21, 100) (56,57). Two case-control studies have been published on the role of habitual intake of analgesics on the occurrence of urothelial cancer and renal cell carcinoma.

In the first study, 647 cases of urothelial cancer (571 bladder, 25 ureter, and 51 renal pelvis) and an identical number of controls were enrolled (58). Exposure to compound analgesic (at least 1 kg of analgesic substances lifelong) showed a substance-specific association, with an increased risk ratio for renal pelvis cancer but not for cancers of the ureter or bladder. Among the different analgesics, anilide derivatives (intake over 1 kg) were associated with the highest risks of renal pelvis cancer, with respective odds ratios of 5.28 for phenacetin (CI = 0.34, 81) and 3.27 for paracetamol (CI = 0.25, 43); however, these odds ratios were not statistically significant. This lack of significance was due mainly to two factors, the high proportion of heavy analgesic use in controls and the low number of cases with renal pelvis cancer, which had the highest risk.

The second study (59) was aimed at clarifying the possible relation between analgesic use and renal cell carcinoma. In previous studies there was a consistent association between phenacetin and renal cell carcinoma, but inconclusive results with respect to non-phenacetin analgesics. In 1024 patients with renal cell carcinoma and an equal number of matched controls, regular use of analgesics was a significant risk factor for renal cell carcinoma (OR = 1.6; CI = 1.4, 1.9). The risk was significantly increased by all four major classes of analgesics (aspirin, NSAIDs, paracetamol, and phenacetin) and within each class of analgesic, the risk increased with increasing exposure. Individuals in the highest exposure categories had about a 2.5-fold increase in risk relative to non-users or irregular users of analgesics. However, exclusive users of aspirin who took aspirin 325 mg/day or less for cardiovascular problems were not at an increased risk of renal cell carcinoma (OR = 0.9; CI = 0.6, 1.4).

In contrast to these results, another large case-control study (60) in 1732 patients with renal cell carcinoma and 2039 controls showed no increase in the risk of renal cell carcinoma among regular users of phenacetin, paracetamol, and aspirin. There is no clear explanation of these disparate findings.

Conclusions

The history of analgesic nephropathy must not be dismissed as involving only a drug now obsolete. Phenacetin, alone or in combination with other analgesics, was unwisely taken chronically by a large section of the public, and unless such misuse of analgesics can be avoided, there is much reason to fear that the story will be repeated with other agents and combinations.

If analgesics are discontinued in the early phases of nephropathy, there is a reasonable possibility of a return to normal renal function. It is wise to ensure that the dosage of aspirin or paracetamol, or of any NSAID, is kept as low as possible, that renal function is regularly assessed, and that prolonged use is avoided, especially in patients over 65 years of age, who seem to be at particular risk of analgesic nephropathy and who may also have pre-existing renal dysfunction, including marginally compensated asymptomatic renal insufficiency (40).

There is no evidence that short-term use of single cyclooxygenase inhibitors has any major deleterious effect on renal function in healthy, non-hypovolemic individuals, but even short-term use of a compound of this class is never a guarantee that nephropathy will not occur.

Skin

Rashes, usually erythematous, occur occasionally (61–63).

Paracetamol can rarely cause fixed drug eruptions (64,65), including an unusual non-pigmented fixed drug eruption (66).

Immunologic

Acute hypersensitivity reactions due to paracetamol are rare (SEDA-22, 114), but can be life-threatening (67).

Long-Term Effects

Mutagenicity

Animal studies have indicated a carcinogenic effect when paracetamol has been administered for prolonged periods in relatively high dosages. However, no clinical data are so far available to corroborate this. The matter cannot be dismissed entirely for the time being, in view of a report (68) of the development of chromosomal aberrations after prolonged use.

Second-Generation Effects

Fetotoxicity

Paracetamol crosses the placenta readily. However, there has been no published evidence of a teratogenic effect in the offspring of mothers who have taken paracetamol during pregnancy. A case of fetal death after a maternal overdose of paracetamol (30 g) has been described (SEDA-10, 73), but in another similar case, in which 22.5 g was taken in the 36th week, the fetus survived (SEDA-9, 96). Preliminary data from a longitudinal study have shown no adverse effects of therapeutic doses of paracetamol on either pregnancy or infant development (69).

Susceptibility Factors

Hepatic disease

It is generally considered inadvisable to use paracetamol in patients with active liver disease or severe liver dysfunction, patients with cachexia, or chronic alcoholics. Stable mild chronic liver disease does not seem to be a contraindication (70).

Drug Administration

Drug overdose

Paracetamol is one of the most commonly ingested medications in deliberate self-poisoning and accidental ingestion by children.

Fulminant hepatic failure occurs in 1–5% of cases of paracetamol overdosage 3–6 days after ingestion (71), with frequent deaths in people who take 20–25 g. There is only a narrow margin between the normal maximum 24-hour dosage and that which can cause liver damage and acute hepatic failure. Undoubtedly, some people are more susceptible than most to paracetamol toxicity, since although 6 g has been reported as toxic in some cases, most toxicity is seen with 12 g upwards (72,73). Nomograms have been developed to show the relation between plasma paracetamol concentrations over time and the risk of a serious outcome (SEDA-18, 94).

Epidemiology

Paracetamol is a widely-used, effective, and well-tolerated analgesic, but thanks also to its ready availability, it is the most commonly used substance in self-poisoning (SEDA-18, 94) (74) and a frequent cause of accidental overdose, especially in children (SEDA-22, 114), although children of 6 years and under are rarely subject to hepatotoxicity, even with accidental overdosage (75), possibly owing to age-dependent differences in paracetamol kinetics (76).

From prospective data (74,77), it has been estimated that around 58 000 people take paracetamol in overdose each year in England and Wales and that these episodes of poisoning prompted 3.3% of inquiries to US regional poisons centers (78), 10% of inquiries to the UK National Poisons Information Service (79), and up to 43% of all admissions to hospital with self-poisoning in the UK (80). Despite the availability of effective antidotes for patients who seek medical intervention early after an overdose, in the USA paracetamol alone accounted for 4.1% of deaths from poisoning reported to American poison centers in 1997 (78).

Paracetamol plus dextropropoxyphene, the combination known as co-proxamol, is available as a prescription-only analgesic in many countries. Self-poisoning can be lethal, as respiratory depression can occur from an excessive dose of dextropropoxyphene. In England and Wales, co-proxamol alone accounts for 5% of all suicides, and overdose is more likely to result in death than overdose with paracetamol alone or tricyclic antidepressants (81). Furthermore, although it is often prescribed, it is no more effective than paracetamol for short-term relief of pain. It should not be prescribed without good reason.

Symptoms and signs

While damage to the liver is effected within hours of ingestion, major clinical manifestations are seldom seen until some 24–48 hours. However, they can be prevented by early treatment. Thus, early history taking, a high index of suspicion, and prompt and repeated assays of plasma paracetamol concentrations are essential in emergency management. Primary signs, when they do appear, are those of liver failure, for example abdominal pain and tenderness, followed by jaundice, raised serum transaminases, and reduced concentrations of coagulation factors, resulting in a prolonged prothrombin time. It may be up to a week before severe liver failure ensues. Consciousness is not usually lost early on, but resistant cerebral edema can intervene in a few days secondary to hepatic failure.

Acute renal tubular damage occurs in association with the liver damage, together with muscle necrosis and hyperkalemia. The muscle necrosis, as demonstrated at autopsy in fatal cases (82), can itself exacerbate the severe electrolyte derangement, particularly marked hyperkalemia, that occurs in liver failure. The measurement of serum concentrations of coagulation factors V (below 10%) and VIII (VIII/V ratio over 30) can have predictive value and can thus be helpful in selecting patients who require liver transplantation (SEDA-17, 99).

- A 29-year-old woman with a psychiatric disorder took an overdose of paracetamol on nine separate occasions. On the last three occasions she developed a dose-dependent, late-onset, delayed hypersensitivity reaction, characterized by an erythematous rash over the entire body (83).

Risk factors

Alcohol

Alcohol abuse can predispose to paracetamol hepatotoxicity (84–91), even in moderate social drinkers who take therapeutic or modestly excessive doses (92), and there have been anecdotal reports of severe hepatotoxicity in chronic ethanol abusers after ingestion of 4 g/day (93). Alcoholics are more likely to exceed the recommended dosage of paracetamol and consequently may be at higher risk of hepatotoxicity than non-alcoholics (91,94).

The theory behind this effect involves induction by alcohol of CYP2E1, which metabolizes about 5% of a typical dose of paracetamol, producing the reactive hepatotoxic metabolite named *N*-acetylparabenzoquinone-imine (NAPQI), which is normally metabolized by glutathione (95). The rest of a therapeutic dose of paracetamol is conjugated to non-toxic forms of glucuronide and sulfate. Saturation of the detoxification pathway occurs with overdose of paracetamol (72), or sometimes in certain individuals who make long-term use of normal dosages (96), in patients with compromised hepatic function, with certain drug combinations, and in other conditions of glutathione deficiency. Ingestion of alcohol induces the activity of CYP2E1 and therefore predisposes the alcoholic patient to injury even at therapeutic doses of paracetamol (97).

Despite this theory, the evidence that therapeutic doses of paracetamol can produce liver injury in alcoholics is scanty (98,99). There has been only one study of the

© 2006 Elsevier B.V. All rights reserved.

hepatotoxicity of paracetamol in therapeutic doses in alcoholic patients, a double-blind, randomized, placebo-controlled study in which 200 long-term alcoholic patients took placebo or paracetamol 1 g qds on two consecutive days (100). Paracetamol was not given until alcohol had been eliminated from the body. Liver injury, documented by increased serum transaminases, was not detected. Mean aspartate transaminase activity on day 4 was 38 U/l with paracetamol and 38 U/l with placebo. Only five patients who took placebo and four who took paracetamol had an increase in serum aspartate transaminase to greater than 120 U/l, and it did not exceed 200 U/l in any patient. Thus, repeated administration of the maximum recommended daily doses of paracetamol to alcoholic patients was not associated with liver damage. An older report also provided evidence that alcoholic patients are not at risk from therapeutic doses of paracetamol (70). The researchers concluded that the usual recommendations that alcoholic patients should use reduced doses of paracetamol or avoid it entirely are not based on firm evidence. However, the study had some limitations, as paracetamol was given for only 2 days in doses that did not exceed the maximum therapeutic daily dose. Moreover, the alcoholic patients enrolled in the study may not have been representative of those who would be at increased risk of paracetamol toxicity (101–103). It therefore seems wise to suggest that caution is still warranted with paracetamol in alcoholic patients.

Other drugs

Analgesic cocktails or the concurrent use of potentially hepatotoxic drugs increase the risk of paracetamol toxicity.

Drugs that induce liver microsomal enzymes, such as phenobarbital, phenytoin, carbamazepine, rifampicin, and isoniazid, can make paracetamol poisoning more severe (104,105). In patients taking such drugs the serum paracetamol concentration should be doubled before consulting the usual treatment nomogram.

Fasting

Potentiation of the toxic effects of paracetamol by fasting has been previously shown in animals. In 21 cases of paracetamol hepatotoxicity not due to intentional overdosage, fasting was significantly more common than recent alcohol use among patients who developed hepatotoxicity after a dosage of 4–10 g/day (SEDA-20, 96).

Prevention

Restricting supplies

The easy availability of paracetamol is reported to be the most common reason for its common use in overdose (106), and so reducing its availability might be an effective strategy. Therefore, in September 1998 legislation was introduced in the UK limiting the pack size of paracetamol to 20 units of 500 mg; at the same time nearly all formulations became available only in blister packs. The justification for this legislation was that analgesic self-poisoning is highly impulsive and is associated with both low suicidal intent and limited knowledge of the possible consequences; it was expected that the number of cases of paracetamol overdose might be reduced by limiting its availability.

The impact of this legislation on mortality from paracetamol overdose has been assessed in a prospective study of mortality from paracetamol overdose before and after the new legislation (107). The evaluation included the number of patients referred to liver units or listed for liver transplantation, the number of episodes of overdose and tablets taken, the plasma concentration of paracetamol, and sales of paracetamol to pharmacies. In the years after the legislation the number of tablets of paracetamol formulations per packet fell markedly, as did the number of deaths from self-poisoning with paracetamol, the number of liver transplants and admissions to liver units with hepatic damage after paracetamol poisoning, and the number of episodes of overdose in which a large number of tablets was taken. On the basis of these results it seems that the legislation was relatively successful. The results suggested that the main factor was the reduction in the number of tablets per pack available for impulsive self-poisoning. However, the study had some limitations. The period assessed may have been too short for a full assessment of the impact of the legislation (108), and the effect of legislation on self-poisoning with other drugs was not examined (109).

It may be that limiting access to one type of drug simply increases the incidence of overdose with other potentially more dangerous medicines. If that is so, unless the availability of other medications is also controlled, the removal of one readily available medication, such as paracetamol, could lead to an increase in the use of other compounds with similar or even greater toxicity (for example aspirin, ibuprofen).

In Australia, paracetamol-containing medications were recalled during two periods in 2000, presenting a unique opportunity for a retrospective observational study of the effect of reduced availability of paracetamol on the incidence of deliberate self-poisoning and accidental pediatric poisoning with paracetamol and other over-the-counter analgesics (110). During the recall periods there was a significant increase in ibuprofen deliberate self-poisoning (RR = 1.86; 95% CI = 1.41, 2.44), while there was no statistically significant change in paracetamol and aspirin deliberate self-poisoning. In children there was a significant increase in the proportion of ibuprofen accidental poisoning but no significant change for aspirin and paracetamol.

These results suggest that reduced paracetamol availability increased poisoning with alternative analgesics (in particular ibuprofen) but had little effect on the incidence of paracetamol poisoning. Restriction of paracetamol-containing medications should be critically reconsidered as an effective strategy for preventing deliberate and accidental poisoning.

Adding antidotes to oral formulations

Because restricting the packet size cannot completely resolve the problem of paracetamol overdose, alternative measures have been proposed (SEDA-22, 114). Because of the beneficial effect of acetylcysteine in paracetamol overdose, it has been suggested that toxicity caused by paracetamol overdoses, whether intentional or not, could

© 2006 Elsevier B.V. All rights reserved.

be prevented by formulating paracetamol with added acetylcysteine. It has been estimated that including 200 mg acetylcysteine for every 500 mg of paracetamol would prevent toxicity (111,112). Methionine has previously been added to oral paracetamol formulations for the same reason. For example, Paradote contains paracetamol 500 mg and methionine 100 mg, and the combination is called co-methiamol. However, adding methionine to every paracetamol tablet prompted contrasting opinions (SEDA-22, 114) (113,114). Pameton (paracetamol 500 mg + methionine 250 mg) was voluntarily withdrawn in the UK because of safety concerns, before any evaluation of its impact on overdose had been carried out (113). Paradote remains available in the UK, but similar formulations are not currently available in the rest of Europe or the USA.

Treatment

Gastric lavage, especially in the first hour after ingestion, is recommended.

Glutathione donors

Since the mechanism of damage appears to be the exhaustion or depletion of sulfhydryl groups, as available in glutathione, treatment consists of early replacement of those groups by administration of an alternative source of glutathione, either oral methionine or, better, *N*-acetylcysteine, either orally or intravenously. To be most effective, a glutathione donor should be given within 8–12 hours of ingestion of the overdosage, but even up to 24 hours administration can improve the outcome (115). Acetylcysteine is usually given intravenously, but a 20-hour treatment protocol for acute paracetamol overdose using oral acetylcysteine has also been proposed (116) and was effective in preventing hepatic injury after an acute overdose of paracetamol when therapy was begun within 8 hours after ingestion.

To reduce the chance of liver damage and death in cases of paracetamol overdosage, guidelines have been produced in many countries (74,117,118) to identify patients at high risk who need to be treated soon with acetylcysteine.

In general, such guidelines recommend that the antidote should be given to all patients with a serum paracetamol concentration over 200 μg/ml (1.32 mmol/l) 4 hours after ingestion. A nomogram, in which this value is joined to an end-point of 25 μg/ml (0.16 mmol/l) at 16 hours, allows identification over this period of the patients who must receive the antidote. If acetylcysteine is not administered, it has been calculated that over 60% of patients with serum concentration of paracetamol above the described treatment line develop serious liver damage and of these about 5% will die (119). No deaths have been reported in any of the major treatment trials, however high the initial serum paracetamol concentrations, provided acetylcysteine was given within 10 hours of paracetamol ingestion. These data support the hypothesis that serious liver damage and death should be very uncommon if treatment guidelines are followed and if the patient presents for medical advice within the critical time of 10 hours from poisoning.

However, a report (119) has described fatal overdose of paracetamol in four patients who presented within 10 hours with serum paracetamol concentrations below the treatment line who, in accord with the established guidelines, were not treated with the antidote and developed fatal acute liver failure. The report generated considerable debate by advocating changing the treatment line for the use of antidotes in patients at standard risk from paracetamol poisoning from that currently recommended to a lower line passing through 150 μg/ml at 4 hours and 30 μg/ml at 12 hours.

A second "high-risk patient" line, at about half the concentration of the conventional treatment line, has already been adopted in some guidelines for patients considered at adjunctive risk of liver damage, such as those taking long-term enzyme-inducing drugs, abusing alcohol chronically, or with poor nutrition and cachexia.

However, an absolute cut-off point between a non-toxic and a toxic paracetamol overdose does not exist. Many factors should be taken into consideration in correctly interpreting the measured serum concentrations. First, the timing of the blood sample in relation to the overdose is often uncertain, and when using treatment nomogram clinicians should assume the longest interval between poisoning and blood sampling that is consistent with the history. Secondly, the current treatment nomogram is useless when paracetamol overdosage has occurred over several hours or more rather than as a single episode. Thirdly, apart from the already mentioned known risk factors, some individual differences in susceptibility to paracetamol are not well understood.

Therefore, owing to these uncertainties, it seems wise to suggest that in judging whether or not to use an antidote, clinicians should always err on the side of caution: "If there is doubt about the timing or the need of treatment, treat" (74).

Other methods of treatment

The only alternatives to glutathione donors are charcoal hemoperfusion and hemodialysis, which can be effective up to 18 hours after dosage. However, the longer the time from ingestion to treatment, the less likely the condition is to be reversible and the more likely a fatal outcome.

Theoretically, inhibitors of cytochrome P450, like cimetidine, might be of value in the treatment of paracetamol overdosage, and preliminary animal data also suggest this (115).

Drug–Drug Interactions

Alcohol

The FDA has announced its intention to require alcohol warnings on all over-the-counter pain medications that contain acetylsalicylic acid, salicylates, paracetamol, ibuprofen, ketoprofen, or naproxen. The proposed warnings are aimed at alerting consumers to the specific risks incurred from heavy alcohol consumption and its interaction with analgesics. For products that contain paracetamol, the warning indicates the risks of liver damage in those who drink more than three alcoholic beverages a day. For formulations that contain salicylates or the mentioned NSAIDs three or more alcoholic beverages will increase the risk of stomach bleeding (120).

© 2006 Elsevier B.V. All rights reserved.

Argatroban

The thrombin inhibitor argatroban had no effect on the pharmacokinetics of five oral doses of paracetamol 1 g 6-hourly in 12 healthy volunteers; the argatroban was given as an intravenous infusion of 1.5 μg/kg/minute from hours 12 to 30 (121).

Oral contraceptives

Oral contraceptives accelerate the renal excretion of paracetamol, reducing its effect (SEDA-9, 90).

Phenytoin

Paracetamol is metabolized in part by CYP2E1, and inducers of CYP2E1 predispose patients to paracetamol hepatotoxicity. However, a possible interaction leading to hepatotoxicity with phenytoin has been reported in a 55–year-old woman taking paracetamol 1300–6200 mg/day over 10 days (122). Phenytoin induces CYP2C and CYP3A4 but not CYP2E1. As CYP3A4 may participate in paracetamol metabolism the induction of this isoform may also be responsible for paracetamol-induced hepatotoxicity.

Rifampicin

The addition of rifampicin in patients taking paracetamol can reportedly cause liver failure and encephalopathy (123).

- A 32-year-old woman, who had been taking paracetamol 2–4 g/day for several weeks, was given rifampicin 600 mg bd, and 2 days later developed agitation, confusion, and laboratory abnormalities indicative of severe liver injury. Both rifampicin and paracetamol were withdrawn and she was given acetylcysteine. Her liver dysfunction resolved.

The severe hepatotoxicity in this case was probably due to induction of CYP3A4 by rifampicin, but rifampicin-induced liver damage could not be excluded.

Warfarin

The anticoagulant effect of warfarin is potentiated by concomitant long-term paracetamol administration.

In an early, double-blind, placebo-controlled study of the interaction between coumarin anticoagulants and paracetamol, there was a statistically significant lengthening of the prothrombin time (124). The effect, although statistically significant, was very small and was considered to be clinically unimportant.

However, in a case-control study of the risk factors for excessive warfarin anticoagulation the investigators studied 289 patients prospectively, 93 with an International Normalized Ratio (INR) over 6.0 and 196 with an INR of 1.7–3.3 during warfarin therapy (125). Paracetamol intake was independently associated with a high INR and the effect was dose-related. At a dosage of about 2–4 g/week the adjusted odds ratio (OR) for having an INR over 6 was 3.5 (95% CI = 1.2, 10) compared with no intake of paracetamol. At an intake of 4–9 g/week the adjusted OR was 6.9 (95% CI = 2.2, 22), and at an intake over 10 g/week the OR was 10 (95% CI = 2.6, 38).

However, the results of this study must be interpreted with caution, for many reasons. First, despite these data and the widespread use of paracetamol as an analgesic in patients taking warfarin, only few reports from the literature have described serious hemorrhagic complications due to potentiation of anticoagulant effect of warfarin or acenocoumarol by paracetamol (126,127). Secondly, numerous factors in the Hylex study were independently associated with an increased likelihood of having an INR over 6.0 and it is therefore possible that overlap could have occurred between these factors and paracetamol intake. Thirdly, the biochemical mechanism by which paracetamol may interfere with warfarin is not well understood. The normal metabolism of warfarin, which occurs via hepatic cytochrome P450, is a complex mechanism that can be competitively and non-competitively inhibited by many drugs. The normal metabolism of paracetamol, particularly when large doses of paracetamol are ingested, also involves cytochrome P450. Thus, paracetamol can exhaust the capacity of cytochrome P450 and prevent the normal metabolism of warfarin. When the normal metabolism of warfarin is prevented by paracetamol, the amount of active, non-protein bound warfarin promptly increases and may double or triple in concentration in the blood. Some pharmacological data, however, makes this explanation uncertain. CYP2E1 and CYP1A2 partially metabolize paracetamol. CYP2E1 is not involved in warfarin metabolism, CYP1A2 partially metabolizes paracetamol and is responsible for metabolism of *R*-warfarin, the less potent anticoagulant of the two warfarin stereoisomers. While *R*-warfarin and paracetamol may compete for metabolism, it is unlikely that a drug that competes for or inhibits metabolism of the less potent *R*-warfarin would significantly increase the INR. Finally, despite sporadic case reports this potential interaction has been suggested to be clinically irrelevant on the basis of the extensive collective experience of many clinicians in managing patients who require anticoagulation (128,129).

Some pharmacokinetic studies have failed to show such an interaction (130). However, if this interaction happens in only a few individuals at risk, a formal pharmacokinetic study in a small number of subjects would probably fail to include enough of such individuals to detect an effect. A case-control study, on the other hand, would be the appropriate design for detecting this type of interaction.

Thus, the key message from this study is that in patients taking a stable warfarin regimen who begin to take repeated doses of paracetamol a possible interaction should be considered. The dose and duration of paracetamol therapy should be as low as possible and INR values should be monitored.

Zidovudine

Concomitant administration of paracetamol and zidovudine leads to inhibition of glucuronidation and to potentiation of the toxicity of each drug (131,132).

Interference with Diagnostic Tests

YSI glucose analyser

Paracetamol can cause false-positive reactions for glucose in serum and blood specimens examined using the YSI glucose analyser. The effect could be of considerable importance in patients admitted with suspected paracetamol overdosage.

Paraffins

General Information

Paraffin is a name that is commonly used to denote a group of saturated alkane hydrocarbons with the general formula C_nH_{2n+2}, n being greater than 20. They take both solid and liquid forms. The solid form known as paraffin wax was discovered by Karl Reichenbach in 1830. Paraffins are mostly obtained from petroleum. Paraffin oil, used as a fuel, is also known as kerosene.

Hard paraffin

Hard paraffin is a mixture of solid hydrocarbons, also known as paraffin wax. It is used to stiffen ointments and creams and to coat capsules and tablets. At one time it was used for cosmetic enhancement, for example of the breasts, before silicone was introduced. It is also used in bismuth iodoform paraffin paste (BIPP) (see the monograph on bismuth).

Soft paraffins

White soft paraffin and yellow soft paraffin are mixtures of semi-solid hydrocarbons. They are used as bases for ointments, as emollients in skin diseases, and as lubricants in treating dry eyes. Soft paraffin is also known as petroleum jelly, petrolatum, and Vaseline.

Liquid paraffin

Liquid paraffin is a mixture of liquid hydrocarbons. Its main use has been as a lubricant laxative but it is not recommended, because of its adverse effects. Nevertheless, it continues to be used for this purpose and is reportedly as effective as lactulose (1). However, the erstwhile Committee on Safety of Medicines in the UK recommended the following precautions (2):

- pack sizes to be limited to 160 ml;
- liquid paraffin to be used only for the symptomatic relief of constipation;
- prolonged use to be avoided and the package label to state "repeated use is not recommended";
- to be contraindicated in children under 3 years of age.

Liquid paraffin has also been used in ointments, as an emollient in skin diseases, and as a lubricant in treating dry eyes. Injection of liquid paraffin into the pleural cavity (oleothorax) was a widely used treatment for pulmonary tuberculosis before effective antituberculosis drugs became available. Long-term complications continue to be reported (3–10).

Organs and Systems

Respiratory

Liquid paraffin can cause a lipoid pneumonia or pneumonitis if inhaled (11). This has been treated with bronchoalveolar lavage (12). Lipoid pneumonia in a 34-year-old fire-eater who inhaled liquid paraffin was treated with prednisolone, antibiotics, and urinastatin (13).

Nutrition

Liquid paraffin impairs the absorption of fat-soluble vitamins (A, D, E, and K). This has rarely been reported to be of clinical significance, although one case of rickets has been reported (14).

Hematologic

Reticulolymphoblastosarcomatosis with acquired hemolytic anemia and cryoglobulinemia complicated a paraffinoma after 50 years (15,16).

Gastrointestinal

Liquid paraffin leaks from the anus and can cause local irritation.

Immunologic

Although soft paraffin has been used to treat irritant contact dermatitis (17) and to protect the skin from other sensitizers (18), hypersensitivity reactions can occur, but are rare (19–26). Yellow soft paraffin is slightly more antigenic than white soft paraffin (24). Contact sensitization to a neat cutting oil containing chlorinated paraffin occurred in 12 men (27). Contact urticaria mimicking dermatitis has also been reported (28).

Sensitization to soft paraffins can cause false-positive drug patch tests (29).

- A 31-year-old woman with a long history of presumed atopic dermatitis actually had contact dermatitis due to the soft white paraffin that was present in the several medicaments (glucocorticoids, tacrolimus, pimecrolimus, and ciclosporin) that she had used to treat the skin (30).

Long-Term Effects

Tumorigenicity

There have been many reports of so-called paraffinomas, benign tumors due to granulomatous reactions, in patients using paraffin.

Paraffin used for breast enhancement can cause mammary paraffinomas, and there have been many such

© 2006 Elsevier B.V. All rights reserved.

reports in men and women (31–51). The tumors can calcify but are benign; in one case there was no evidence of malignant transformation after 60 years (52), although in another case there was an associated malignancy (53). Lymphatic spread of paraffin has been described (54), as has sarcoid formation (55).

Paraffinomas have also been reported after the use of paraffin to enhance the male and female external genitalia (51,56–71).

When liquid paraffin is used as a laxative, paraffinomas can occur in the colon and rectum (72–75).

Paraffin used as packing after nasal surgery can cause nasal paraffinomas (76–81).

Other tissues in which paraffinomas have been reported include the orbit and eyelids (82–86), the lungs (87–94), the limbs (95–97), sometimes with subsequent calcification (98), the face (99–101), nose (102), and scalp (103), muscle (104), the bladder (105), and the ureter (106).

Although in most cases paraffinomas occur at the site of injection, remote deposition can occur, for example in the mediastinum (107–109).

- A 55-year-old woman, who had undergone intrapleural injection of paraffin for pulmonary tuberculosis 15 years before, developed a large left-sided chest wall mass and spinal paralysis (110). A paraffinoma had invaded the vertebral canal.

Paraffin deposition has also been reported in the retinal fundi, the liver, and the spleen, in addition to the lungs (111).

There is epidemiological evidence linking the use of liquid paraffin to gastrointestinal cancer (112). Malignant transformation of a paraffinoma has occasionally been suggested.

- An 82-year-old woman who had taken long-term liquid paraffin as a laxative, developed a lipoid pneumonia and a mesothelioma (113).

Susceptibility Factors

Age

Liquid paraffin is contraindicated in children under 3 years of age (2).

Drug–Drug Interactions

Anticoagulants

It is often stated that liquid paraffin should interact with oral anticoagulants because it inhibits the absorption of vitamin K. However, no evidence of such an interaction has been published.

Paraldehyde

General Information

Paraldehyde is the cyclic trimer of acetaldehyde, a colorless or slightly yellow-colored liquid. It has been used as an anticonvulsant, but because of its adverse effects and because it is difficult to use it has been replaced by more modern agents. However, it is still sometimes used to treat status epilepticus that is resistant to first-line drugs (1). The usual adult rectal dose is 10–20 ml.

Paraldehyde is a solvent for rubber, polystyrene, and styrene acrylonitrile co-polymer, and if parenteral administration is required it should ideally be given via a glass syringe (2). Plastic syringes start to break down after exposure of about 2 minutes (3). However, some plastic syringes are resistant to its effects for a few hours (4), and intravenous tubing is reportedly unaffected (5); in an emergency it has been given rapidly by plastic syringe.

Organs and Systems

Cardiovascular

Paraldehyde caused microembolization in a neonate immediately after the injection of 0.3 ml/kg (6). The skin below the waist became red, large purple vesicles formed, and there was loss of skin and sloughing of two toes.

Respiratory

Non-cardiac pulmonary edema has been reported with paraldehyde. In one case it followed the intravenous administration of 23 ml of paraldehyde over 10 hours (7) and in another 2 ml of undiluted paraldehyde followed 30 minutes later by 0.1 ml of a 10% solution (8).

Acid–base balance

Paraldehyde can cause a metabolic acidosis, due to inability of the renal tubules to acidify the urine; several cases have been described (9–15).

- A 35-year-old man who regularly took paraldehyde 15–20 ml/day took 200 ml and developed a metabolic acidosis (pH 7.12) and acute renal insufficiency (12). He was successfully treated with intravenous alkali and peritoneal dialysis.
- A 41-year-old woman took paraldehyde 20–50 g on three different occasions and developed a metabolic acidosis that mimicked diabetic ketoacidosis (13).
- A 49-year-old woman took paraldehyde 100 ml in 4 days; she became comatose and acidotic and required hemodialysis (14).
- A 30-year-old man taking anticonvulsants was given paraldehyde 40 ml intramuscularly; 6 hours later he collapsed and was found to have a lactic acidosis (15).

Drug Administration

Drug formulations

Paraldehyde easily oxidizes to acetic acid and acetaldehyde. It should be stored in an airtight container and protected from the light. It should not be used if it has a brown color or if it smells vinegary. It solidifies when cooled and may need to be warmed before use.

Drug administration route

Paraldehyde can be given orally, rectally, intramuscularly, or intravenously.

Oral and rectal administration can cause gastric and rectal irritation.

Intramuscular administration can cause sterile abscesses (16). Peripheral nerve injury has also been reported (17), but that is a hazard of any intramuscular injection (18).

Intra-arterial administration in one case caused generalized arterial and venous thrombosis (19).

Drug overdose

A 20-year-old man died after taking paraldehyde 16 g (20).

Drug–Drug Interactions

Alcohol

Paraldehyde has been used to treat delirium tremens, but eight patients with alcohol intoxication died unexpectedly after they were given paraldehyde 30–60 ml (21).

Disulfiram

Paraldehyde is metabolized in the liver to acetaldehyde (22), and the metabolism of aldehyde by aldehyde dehydrogenase is inhibited by disulfiram, causing aldehyde toxicity. The adverse effects of this have been shown in experimental animals (23) and there have been reports of confusional psychosis in patients given disulfiram and paraldehyde (24).

Intravenous fluids

About 10–16% of paraldehyde in 5% dextrose or 0.9% sodium chloride is lost when it is delivered from PVC bags through standard intravenous administration sets and burettes over 6 hours (25).

Parathyroid hormone and analogues

General Information

Both intact parathyroid hormone and smaller *N*-terminal fragments are used. No adverse reactions have been reported with single infusions of up to 60 mg of synthetic human parathyroid hormone in diagnostic procedures (SEDA-13, 1307) (1,2). Although bone resorption increases if the hormone is given continuously or in high doses, it has an anabolic effect on bone when given intermittently. Synthetic parathyroid hormone fragments have therefore been used in the treatment of slow turnover osteoporosis. However, no improvement in fracture risk has been documented, and the anabolic effect may only be present in the first 12 months (3). The use of parathyroid hormone in the treatment of hypoparathyroidism is also under investigation, with the optimum dosage and target calcium concentrations yet to be determined.

The adverse effects of parathyroid hormone that have been reported in clinical trials are mild and include transient bone pain, nausea, and local irritation at the injection site (4).

Parathyroid hormone has potent anabolic effects on the skeleton if given intermittently; being used in clinical trials. Initial concerns about the development of osteosarcoma in rats after prolonged treatment with high doses of parathyroid hormone have not been confirmed in human trials, but surveillance continues (5). In one study there was a mild increase in creatinine, which was thought not to have clinical significance (6). Mild nausea (7) and arthralgia (7,8) have also been reported.

Nausea was reported in 18% and headache in 13% of 552 women who took parathyroid hormone 40 micrograms, compared with 8% of the 544 women who took placebo (9).

Organs and Systems

Cardiovascular

Parathyroid hormone lowers the blood pressure by a direct effect on vascular smooth muscle, and there are isolated instances of hypotension or tachycardia (10). Pre-injection blood pressure was normal in 1093 women randomized to parathyroid hormone ($PTH_{1–34}$), and dizziness was reported infrequently in 541 women taking 20 micrograms/day but not in 552 taking 40 micrograms/day (9).

© 2006 Elsevier B.V. All rights reserved.

Mineral balance

Mild asymptomatic hypercalcemia is common during treatment with parathyroid hormone (11). The hypercalcemia is persistent, and requires dosage reduction in 3% of patients using 20 micrograms/day and in 11% using 40 micrograms/day (12). Transient mild hypercalciuria and increased serum phosphate are common but do not usually limit therapy.

In a randomized study in premenopausal women also treated with nafarelin, four of 23 women randomized to $PTH_{1–34}$ 500 IU/day had a serum calcium concentration over 2.67 mmol/l 4 hours after the injection; the concentration normalized after the dose of parathyroid hormone was reduced and other treatment was continued (7).

In another study, two of 10 men who were randomized to receive subcutaneous $PTH_{1–34}$ 400 IU/day for 18 months had serum calcium concentrations over 2.6 mmol/l after 1 or 3 months; the concentrations normalized after reduction of the dose of parathyroid hormone (8).

Hypercalcemia was present in 11% of 541 women 4–6 hours after parathyroid hormone 20 micrograms/day and in 28% of 552 women after 40 micrograms/day (9). The dose was halved because of hypercalcemia in 3 and 11% of the women taking 20 and 40 micrograms/day respectively. Nine of the women taking 40 micrograms/day stopped treatment because hypercalcemia persisted after dosage reduction.

Combining parathyroid hormone with antiresorptive agents may prevent or minimize hypercalcemia. None of 27 women randomized to estrogen plus parathyroid hormone $PTH_{1–34}$ 25 micrograms/day became hypercalcemic during a 3-year study (13).

Skin

Local reactions at sites of subcutaneous injection are common but are usually limited to transitory redness (7,8).

Subcutaneous nodules at the injection site developed in two of 17 women after more than 2 years of administration in a clinical trial (14). Two of 27 women randomized to parathyroid hormone developed nodules at injection sites; however, this could have been due to a contaminant, as both women received parathyroid hormone from the same batch (13).

Immunologic

Dose-dependent antiparathyroid hormone antibodies developed in under 10% of 1093 women in one study; however, there was no reduction in efficacy (9).

Long-Term Effects

Tumorigenicity

The rate of osteosarcoma in animal and human trials of parathyroid hormone has been reviewed (15). Rats treated with parathyroid hormone for 2 years had a high dose-dependent rate of osteosarcoma, up to 48% in animals given 75 micrograms/kg; human trials were therefore interrupted (16). However, the anabolic effect of parathyroid hormone is much greater and occurs much earlier in rats than in humans, possibly because of fundamental differences in bone biology: moreover, osteosarcoma has never been associated with primary, secondary, or tertiary hyperparathyroidism in humans (15). There has been no evidence of osteosarcoma in several hundred patients involved in parathyroid hormone clinical trials lasting up to 3 years, after 5 years minimum follow-up (15).

Drug–Drug Interactions

Bisphosphonates

Alendronate significantly reduced the anabolic effect of parathyroid hormone when the two were used in combination, both in postmenopausal women (17) and in men (18). It seems likely that this interaction will also apply to other bisphosphonates, although the mechanism has not been determined.

Parecoxib

See also COX-2 inhibitors

General Information

Parecoxib sodium is an injectable COX-2 inhibitor developed for the treatment of acute pain. It is a prodrug of a sulfonamide-based COX-2 inhibitor, valdecoxib, a potent anti-inflammatory and analgesic drug. The published information on this compound is inadequate to draw any conclusion about its tolerability. Single-dose and multiple-dose studies have not shown any safety problems compared with placebo (1–4). In small short-term endoscopic studies parecoxib was much better tolerated than the non-selective NSAID ketorolac (5,6). However, it should be noted that valdecoxib was withdrawn in 2005 (7).

Parenteral nutrition

General Information

Parenteral nutrition should be tailored to the needs of the individual, but on average should provide about 25 kcal/kg/day. Solutions for long-term parenteral nutrition should contain:

- about 30% carbohydrate, usually in the form of glucose, providing 60% of the energy requirements
- 30–50% fat in the form of a lipid emulsion such as soya oil
- amino acids, 150–250 kcal/g of nitrogen
- sodium and potassium
- calcium, phosphate, and magnesium
- bicarbonate
- vitamins
- trace elements (chromium, cobalt, copper, fluoride, iodide, iron, manganese, molybdenum, selenium, zinc)

The benefits and safety of parenteral nutrition have been considerably improved in recent years by innovative strategies, such as supplementation with medium-chain triglycerides, glutamine, or branch-chain amino acids.

Observational studies

GAB-88 is an infusion solution containing amino acids (3%), dextrose (7.5%), and electrolytes in a dual-chamber plastic bag. It has been evaluated in 39 non-operative patients who were unable to tolerate oral feeding or to take adequate amounts by mouth (1). When it was given in a daily dose of 1.0–2.5 liters for 7–19 days, there was an improvement in nutritional status without obvious adverse effects. There was mild vascular pain in four patients, but no phlebitis. There were no other clinically significant adverse reactions.

© 2006 Elsevier B.V. All rights reserved.

In 28 Japanese institutions, GAB-88 was infused continuously via a peripheral vein at a rate of 30–45 ml/kg/day for 5 postoperative days after partial gastrectomy for gastric cancer in 92 patients and compared with a similar commercial formulation; no particular adverse events emerged (2,3).

No serious adverse effects were noted in a phase 1 clinical study of GAB-88 aimed at determining its safety and pharmacokinetics in eight healthy men who were given three different doses (0.15 g/kg/hour, 0.3 g/kg/hour, and 0.5 g/kg/hour) at 1-week intervals. Serum electrolytes did not change significantly, except for zinc (4).

General adverse effects

Many of the safety issues in parenteral nutrition relate to the fact that the process is inherently unphysiological (5). Instead of periodic ingestion of nutrients via the gastrointestinal tract resulting in gradual entry of nutrients into the blood, nutrients are infused directly at a constant rate. The gastrointestinal tract as a mediator of nutrient absorption, the periodicity of nutrient administration, and the natural biorhythms of hormone secretion are all lost.

Common problems in the past were fat overload syndrome, metabolic acidosis, hyperglycemia, and hypertriglyceridemia (6). These problems are now rare. Increasing efforts have been made to avoid adverse effects such as central venous catheter infection and hepatic dysfunction. Major developments in the future are likely to be achieved with the identification of nutrients, hormones, or other active compounds that can positively influence outcome beyond the safe provision of 40 essential nutrients in proper amounts, which is what principally has been achieved to date (7). Liver damage is still a major problem. The most common micronutrient deficiency is of thiamine.

In an assessment of the clinical use of nutrients, and the tendency that has been noted in the past to overfeed with carbohydrate, lipid, and micronutrients, attention has been drawn to the adverse effects of oversupply (8).

The emerging discipline of nutritional pharmacology and the related legislative and ethical issues require expert attention and analysis. Scientific study of the nutritional and pharmacological aspects of these substances will provide new and safer forms of therapy in a number of medical conditions.

Organs and Systems

Cardiovascular

Infusion phlebitis presents a problem in parenteral nutrition. Various alternative techniques of administration have been compared in order to identify means of countering this problem (9). Mechanical trauma appears to be a causative factor; it can be reduced by limiting the time of exposure of the vein wall to nutrient infusion and by minimizing the amount of prosthetic material within the vein (10). This is likely to be even more important in small veins. In one study the addition of heparin (500 U/l) and hydrocortisone (5 micrograms/ml) significantly reduced the risk of thrombophlebitis from 0.43 to 0.11 episodes per patient-day, and a reduction in osmolality of the solution resulted in a further ten-fold fall in the incidence of thrombophlebitis (11). Other work has concluded that the incidence of infusion phlebitis is minimized during parenteral nutrition by cyclic infusion of nutrient solutions and by rotation of venous access sites (12).

Respiratory

The clinical differentiation of chylothorax from leakage of parenteral nutrition fluid into the pleural space can be difficult. However, in one case the diagnosis of leakage of parenteral nutrition fluid was made by additional tests of electrolytes, showing very high concentrations of potassium (11.3 mmol/l) and glucose (128 mmol/l), ruling out chylothorax (13).

In an acute experiment, infusion of fat emulsion (Intralipid) for 60 minutes (mean dose 0.07–0.16 g/kg/hour) in neonates with lung disease was found to lead consistently to a 10% fall in transcutaneous PO_2 (transcutaneous oxygen tension). There was no change in PCO_2. This is evidence that Intralipid contributes to the hypoxia of respiratory distress in neonates; it should be used with caution in this group, and not at all in infants with pulmonary disease (14).

Nervous system

Two children developed neurological complications of fat emulsion therapy, including focal and generalized seizures, weakness, and altered mental status, before any systemic findings were in evidence (15). Biopsy and autopsy findings included cerebral endothelial and intravascular lipid deposition. These complications are potentially reversible with alteration of the parenteral nutrition content, highlighting the importance of their early recognition.

- Acute hemiplegia and seizure developed in a 24-year-old patient following accidental catheterization of the right common carotid artery for parenteral nutrition infusion (16). Magnetic resonance imaging of the brain showed lesions in the frontal lobe and putamen, consistent with an ischemic stroke.

Considerable interest has been stimulated in the pathogenesis of critical illness polyneuropathy during artificial nutrition (17). This condition (initially functional, but proceeding to an axonal polyneuropathy, demonstrable postmortem by histological evidence of axonal degeneration) is familiar to intensive care units, and it is an important cause of weaning failure. The neurological disability can last for some 6 months, but it is likely to be reversible if the cause is recognized early and treatment withdrawn before permanent axonal changes occur. There is a strong association with sepsis and multiple organ dysfunction syndrome, the nervous system being yet another focus of organ failure. The autonomic nervous system is commonly involved, and patients are likely to show early cardiovascular instability requiring antihypotensive medication. It seems that artificial feeding after starvation leads to reduced activity of the enzymes involved in glucose oxidation, with the result that nutrient glucose causes accumulation of phosphorylated glycolytic

© 2006 Elsevier B.V. All rights reserved.

intermediates; this in turn causes a block in the energy cascade that is an essential element in the development of axonal polyneuropathies. Although the exact chain of events is not known, there is evidence that there are disturbances of the microcirculation and increased microvascular permeability, which can lead to endoneural edema with resulting primary axonal degeneration of peripheral nerves (18). A sensitive bioassay capable of identifying a low molecular weight fraction toxic to rat spinal motor neurons has been identified in the sera of these patients (19,20).

Cases of Wernicke's encephalopathy caused by thiamine deficiency during parenteral nutrition are reported (21).

- A 13-year-old girl with acute myeloid leukemia received parenteral nutrition and chemotherapy. After a second cycle of chemotherapy she developed persistent nausea and vomiting, nystagmus, ophthalmoplegia, and brisk deep tendon reflexes on the left. Her level of consciousness deteriorated progressively. A CT scan was normal, but an MRI scan showed caudate nucleus lesions, cortical involvement, and typical diencephalic and mesencephalic abnormalities. She was given mannitol and dexamethasone, but without improvement. However, after intravenous thiamine her symptoms gradually improved; she recovered within 1 month and the MRI abnormalities disappeared.

The authors suggested that this case showed how MRI can play a role in the diagnosis of Wernicke's encephalopathy, but that there was unusual involvement of the frontal and parietal cortex and the caudate nuclei.

Metabolism

Ammonium

Hyperammonemia has occurred during parenteral nutrition as a component of therapy for renal insufficiency (22). The hyperammonemia presented as a change in mental status, developing about 3 weeks after initiation of parenteral nutrition therapy; in most cases the episodes are of increasing duration and paroxysmal. In three of the patients, serum amino acid analysis in the acute phase showed reduced concentrations of ornithine and citrulline (the respective substrate and product of condensation with carbamyl phosphate at its entry into the urea cycle). Concentrations of arginine, the precursor to ornithine, were raised.

Carbohydrates

The effects of parenteral nutrition on endocrine and exocrine functions of the pancreas have been investigated in experimental rats (23). The conclusion was that after parenteral nutrition treatment the insulin secretory response to glucose is impaired, the exocrine pancreas is hypoplastic, and the storage pattern of pancreatic exocrine enzymes is altered.

Lipids have an adverse effect on carbohydrate metabolism under basal conditions. The infusion of 20% triglyceride emulsion with heparin during basal insulin and glucose turnover conditions resulted in a rise of plasma free fatty acids from 0.4 to 0.8 mmol/l at a low rate of infusion (0.5 ml/minute for 2 hours) to between 1.6 and 2.1 mmol/l at a high rate (1.5 ml/minute for 2 hours). There were similar increases in plasma concentrations of glycerol, acetoacetate, and hydroxybutyrate. The infusions resulted in significant increases in C-peptide concentrations, but had no effects on any of the other indices of carbohydrate metabolism that were examined (plasma glucose, lactate, and pyruvate concentrations), or on carbohydrate oxidation rates. By blocking the compensatory release of insulin by the intravenous administration of somatostatin and by simultaneous replacement of basal insulin and glucagon concentrations, these workers found that there was a significant increase in plasma glucose and in hepatic glucose output, and reduced glucose clearance. It was concluded that exogenous lipids may have adverse effects on carbohydrate metabolism under basal conditions, and that healthy individuals normally compensate for this by additional secretion of insulin (24).

Preoperative parenteral nutrition can be a major cause of hyperglycemia, which has been associated with an increased risk of postoperative infection. The frequency of hyperglycemia and infectious complications has been studied in a prospective, randomized, controlled, nonblind trial in 40 patients who required parenteral nutrition for at least 5 days (25). They were given either a hypocaloric regimen (1 liter containing nitrogen 70 g and dextrose 1000 kcal) or a standard weight-based regimen begun with similar amounts initially but with gradual increases in calorie and nitrogen contents to 25 kcal and 1.5 g nitrogen/kg, up to one-third of the calories being given as fat. There were no significant differences between the two groups with regard to hyperglycemia or infections. The higher calorie regimen provided significant nutritional benefit in terms of nitrogen balance compared with the hypocaloric regimen.

Some children receiving parenteral nutrition have abnormal glucose tolerance. When this was studied in 12 patients, aged 5.7–19 years, receiving cyclic nocturnal parenteral nutrition, patients with normal glucose tolerance had an insulin response to intravenous glucose tolerance testing similar to that of normal people of the same age (26). Two patients with abnormal glucose tolerance had a reduced capacity to release insulin, whereas insulin sensitivity was unchanged in one of them. Patients with a limited capacity to release insulin, either constitutional or acquired, may not be able to produce enough insulin in these conditions and they may develop glucose intolerance during parenteral nutrition. Insulin sensitivity was not a key factor in the alteration of glucose tolerance in this study.

In five patients with multiple trauma given sodium lactate as part of parenteral nutrition there was a 20% fall in glycemia, a 43% fall in insulinemia, a 34% reduction in net carbohydrate oxidation (assessed by indirect calorimetry), and a 54% fall in plasma glucose oxidation (assessed using $^{13}CO_2$). Respiratory oxygen exchange was increased by 3.7% owing to a 20% thermic effect of lactate, but respiratory CO_2 exchange was not altered. PaO_2 fell by 11.3 mmHg, suggesting that the increased oxygen consumption was matched by an appropriate increase in spontaneous ventilation. Arterial pH increased from 7.41 to 7.46. It appears that sodium lactate given in parenteral nutrition during short intravenous

© 2006 Elsevier B.V. All rights reserved.

nutrition in critically ill patients as a metabolic substrate limits hyperglycemia but contributes to metabolic alkalosis and does not spare ventilatory demand (27).

Lipids

The fat overload syndrome, characterized by a sudden rise in serum triglycerides, hepatosplenomegaly, intravascular coagulopathy, and end-organ dysfunction, is today an uncommon complication of intravenous administration of fat emulsion. Its higher incidence in the past may have been due to the greater phospholipid content of intravenous solutions in use at the time. The syndrome is a consequence of fat sludging within the microvasculature in organs such as the spleen, liver, kidney, lungs, brain, and retina. Necrosis in these organs suggests that emboli are responsible for the clinical symptoms and functional impairment that results. Plasma exchange has been successfully used in a patient with this syndrome who had not responded adequately to conventional medical therapy (28).

Critically ill patients are at greatest risk of fat overload syndrome when they are given lipid emulsions intravenously. Some of these patients already have impaired lipid metabolism and they are at risk of developing fat intolerance. These are the very patients who are likely to be given parenteral nutrition, including fat emulsions. Patients with increased serum triglyceride concentrations (for example, in hypothyroidism, with inborn errors of lipid metabolism, renal insufficiency, and severe sepsis, especially gram-negative sepsis) are at greatest risk. There is impaired metabolism of fats in advanced liver disease. Continuous heparin infusion may also lead to a decreased elimination capacity (29).

Fatty acids

Patients undergoing home parenteral nutrition for severe malabsorption or reduced oral intake can exhaust their stores of essential fatty acids, causing clinical effects, mainly dermatitis. In a comparative study of fatty acid profiles in 37 healthy control subjects and 56 patients receiving home parenteral nutrition, reduced small bowel length was associated with aggravated biochemical signs of essential fatty acid deficiency (30). This applied to total *n*-6 fatty acids and not to *n*-3 fatty acids. There were skin problems in 25 of the 56 patients receiving home parenteral nutrition. Patients receiving home parenteral nutrition had biochemical signs of essential fatty acid deficiency. Parenteral fluids did not increase the concentration of essential fatty acids to values comparable with those of control subjects. However, 500 ml of 20% fat emulsion (Intralipid) once a week was sufficient to prevent an increase in the Holman index (an indicator that reflects optimum proportions of polyunsaturated fatty acids).

Linoleic acid and alpha-linoleic acid are essential fatty acids that are provided in any long-term parenteral nutrition by administering fat emulsions at least twice a week. Fatty acid deficiency is a common complication of severe end-stage liver disease. The ability of short-term intravenous lipid supplementation to reverse fatty acid deficiencies has been studied in patients with chronic liver disease and low plasma concentrations of fatty acids (31). Short-term supplementation failed to normalize triglycerides.

Phospholipids

Although choline is not regarded as an essential nutrient for humans, it has been described as being "conditionally essential" in patients receiving parenteral nutrition. Choline is a methyl-group donor, a component of phospholipids, and a precursor of acetylcholine and lecithin. In animal models and healthy human beings, choline deficiency impairs liver function. Studies in patients receiving long-term parenteral nutrition have shown that low levels of plasma choline are common and are associated with hepatic steatosis.

- Choline deficiency developed in a 41-year-old woman with advanced cervical cancer who underwent prolonged parenteral nutrition (32). Her liver function tests became abnormal and she became jaundiced and complained of nausea and vomiting. The serum choline concentration was 5.77 mmol/l and there was histological evidence of hepatic steatosis. There was steady improvement with oral choline supplementation, 3 g/day, and with oral glutamine 15 g/day. There was a 45% improvement in serum choline concentration over baseline.

Intravenous fat emulsions contain choline, but not in sufficient amounts to prevent choline deficiency (32,33).

Nutrition

Amino acids

Carnitine

In septicemic patients with multi-organ dysfunction syndrome serum carnitine concentrations are in the reference range, and they remain unchanged over treatment for 10 days with parenteral nutrition without carnitine supplementation. This has been established in 28 septicemic patients, mean age 53 years, whose mean APACHE II score on admission was 17. Of these patients, 10 had septicemia with multi-organ dysfunction syndrome and 18 had uncomplicated septicemia. There were no differences in patients given long-chain triglycerides ($n = 16$) and a 1:1 mixture of long-chain and medium-chain triglycerides ($n = 12$). It does not appear from these findings that carnitine deficiency plays a significant role in the pathogenesis of multi-organ dysfunction syndrome complicating septicemia, whether or not parenteral nutrition is given in the acute phase of the illness (34).

Deficiency of carnitine has been described in all of a series of surgical neonates receiving parenteral nutrition (35); carnitine intake was far below the recommended minimal need of 11 mmol/kg per day. Although only three of the infants had clinical symptoms suggestive of carnitine deficiency, the authors recommended carnitine supplementation for all neonates receiving parenteral nutrition for more than 2 weeks. It has been suggested that a deficiency of l-carnitine may be responsible for steatosis and steatohepatitis in patients on parenteral nutrition, but one experimental study in adult women throws much doubt on this theory (36). However, in another series of patients who had depletion of erythrocyte and plasma glutathione peroxidase activity during parenteral nutrition (37), supplementation with selenium resulted in normalization of glutathione peroxidase activity within 3–4 months, which is consistent with the time-course for bone marrow erythrocyte production.

© 2006 Elsevier B.V. All rights reserved.

Glutamine

Animal studies have shown that raised plasma glutamate concentrations increase cerebral edema whenever the blood–brain barrier is disturbed. In a prospective study of 23 neurosurgical patients requiring parenteral nutrition, glutamine-containing regimens were compared with parenteral nutrition regimens that excluded glutamine (38). The former doubled plasma glutamine concentrations compared with controls, and the authors concluded that glutamine-containing solutions cannot be recommended for patients with a disturbed blood–brain barrier.

In a study of the safety and efficacy of l-glutamine when added to parenteral nutrition solutions of patients being treated at home, glutamine was stable in home parenteral nutrition solutions for at least 22 days. Supplementation of home parenteral nutrition solutions with l-glutamine in a dose of 0.285 g/kg for 4 weeks in seven stable patients resulted in increases in hepatic enzymes in two patients, requiring withdrawal of the glutamine/parenteral nutrition mixtures at the end of weeks 2 and 3. A third patient's liver enzymes rose at the end of week 4. These abnormalities subsided after withdrawal. Plasma concentrations of glutamine rose during the first 3 weeks of supplementation, but these increases were not statistically significant. It appears that hepatic toxicity can be associated with supplementation of home parenteral nutrition solutions with l-glutamine, without a demonstrable beneficial effect on intestinal absorptive capacity, as measured by d-xylose absorption (39). Other work seems to confirm the lack of benefit from adding glutamine in the form of its dipeptide, though it proved harmless (40).

Thiamine

Thiamine deficiency has been reported (41).

- A young man developed marked deterioration in his vision and oscillating vision, despite normal optic fundi, during parenteral nutrition; he went on to develop a characteristic Wernicke's encephalopathy, confirmed by characteristic findings on MRI brain scan (42). The serum vitamin B_1 concentration was 110 pg/ml (reference range: 200–500). He responded fully to thiamine 300 mg/day in addition to betamethasone for 4 weeks.
- Parenteral nutrition was used to support a patient requiring autologous blood stem-cell transplantation, but vitamins were excluded (the reason was not identified). After about 28 days, the patient suddenly developed severe metabolic acidosis, heart failure, and deep coma. Thiamine was immediately infused, with rapid improvement.

In the second case, the authors were unsure if the associated graft failure was due to the acute metabolic acidosis or thiamine deficiency, since the absence of thiamine in the diet leads to poor glucose oxidation, resulting in accumulation of lactic acid and metabolic acidosis, which is refractory to any treatment except thiamine supplementation.

Vitamins

More than 40 cases of fulminant beriberi have been described in patients receiving parenteral nutrition (43). The condition becomes evident 4–40 days after the start of parenteral nutrition, and is more likely to develop in patients with malignancies, ulcerative colitis, and short bowel syndrome, and in those receiving chemotherapy. The severity of metabolic acidosis is very high and refractory to bicarbonate administration, but it responds quickly to intravenous thiamine. Rapid intravenous administration of thiamine is imperative, and the patient should be transferred urgently to an intensive care unit when parenteral nutrition-induced fulminant beriberi develops.

A further consequence of thiamine depletion during parenteral nutrition can be severe lactic acidosis (44). Six cases have been described from Japan with associated hypotension, Kussmaul's respiration, and clouding of consciousness, as well as abdominal pain not directly related to the underlying disease. During parenteral nutrition administration there was blockade of oxidative decarboxylation of alpha-keto acids such as pyruvate and alpha-ketoglutarate, resulting in pyruvate accumulation and massive lactate production. None of the patients responded to sodium bicarbonate or other conventional emergency treatments for shock and lactic acidosis. Thiamine replenishment with intravenous doses of 100 mg every 12 hours resolved the lactic acidosis and improved the clinical condition of three patients.

These various reports stress the need to supplement parenteral nutrition with thiamine-containing vitamins unless there is adequate dietary intake, and to monitor serum thiamine and erythrocyte transketolase activity so that supplementary thiamine can be given in good time, if necessary intravenously (45). Giving thiamine will not rectify the various disorders if hepatic function is severely disturbed, because then thiamine is not phosphorylated and hence remains physiologically inactive.

Electrolyte balance

Hyperkalemia in one published case was attributed to combined treatment with octreotide and heparin (enoxaparin) in parenteral nutrition (46). It was suggested that both enoxaparin and octreotide had contributed in this case to the development of hyperkalemia since they reduce urinary potassium excretion.

Mineral balance

Calcium

Calcium is normally considered to be safe in parenteral nutrition, and relatively high quantities are often included in neonatal and pediatric formulations. However, there is a risk of hypercalciuria. The pathogenesis of hypercalciuria is not readily explicable on the basis of endocrine or metabolic effects, but it has been postulated to be due to excessive calcium or vitamin D intake or aluminium overload.

- A 6-year-old girl with Hirschsprung's disease had jejunostomy at 1 month followed by parenteral nutrition (47). Her calcium intake was 1–1.5 mmol/kg/day. Her urinary calcium rose from 3 months of age; her serum calcium concentrations remained within the reference range but started to rise when she was 3–4 years old. At 5–6 years of age she showed growth retardation and deteriorating renal tubular function with bilateral

© 2006 Elsevier B.V. All rights reserved.

nephrocalcinosis. The calcium content of the parenteral nutrition was reduced, her serum and urinary calcium concentrations stayed within the reference ranges, and her renal function and growth rate improved.

After persistent hypercalciuria, osteopenia can develop, causing "metabolic bone disease," pathological fractures, and immobilization. Hypercalciuria can also lead to nephrolithiasis and nephrocalcinosis, factors that can impair renal function. Intravenous chlorothiazide has been successfully used for its hypocalciuric effect, with remarkable effect over a period of 6 months in a 13-year-old child who had received parenteral nutrition for 6 years. Calcium excretion and tubular reabsorption of phosphate returned to normal (48). What is not clear from this study is whether the drug actually has a positive long-term beneficial effect on metabolic bone disease.

Increasing the inorganic phosphorus content of parenteral nutrition formulas reduces hypercalciuria due to parenteral nutrition in experimental animals and humans. Urinary calcium excretion is significantly lower when patients receive higher inorganic phosphorus formulae, without changing the load of ultrafilterable calcium or filtered calcium, but significantly reducing fractional calcium excretion. There were no differences in serum concentrations of ionized calcium, parathyroid hormone, 25-hydroxycolecalciferol, 1,25-dihydroxycolecalciferol, or urinary cyclic AMP between different treatments with inorganic phosphorus formulae. Thus, increasing the inorganic phosphorus content of the parenteral nutrition formula reduces urinary calcium content by increasing renal tubular calcium resorption. This effect is not due to alterations in the parathormone/1,25-dihydroxycolecalciferol axis, but more probably reflects a direct action of inorganic phosphorus on the renal tubules (49).

Phosphate

Since chronic renal insufficiency is frequently complicated by rises in serum potassium, phosphate, and magnesium, parenteral nutrition solutions used to treat malnourished patients with chronic renal insufficiency are usually prepared with little supplementation of these cations. Four patients with chronic renal insufficiency developed significant hypophosphatemia 3–5 days after starting parenteral nutrition. Other electrolyte abnormalities included hypomagnesaemia ($n = 1$) and hypokalemia ($n = 3$) (50). Hypophosphatemia may be the most significant of the electrolyte risks in this clinical setting, and the electrolytes of such patients should be monitored closely when nutritional support is begun.

Hypophosphatemia has received continued attention, resulting in the need to recognize the importance of maintaining awareness of the possibility of low phosphate concentrations, monitoring phosphate concentrations closely during the first week of therapy, and supplementing with phosphate cautiously while serum concentrations remain in the reference range (51,52).

Excess phosphate is only likely to be administered as a result of medical error.

- Hyperphosphatemia complicated by calcification of subcutaneous arteries and skin infarcts has been reported in a patient with sepsis who received an unintended excess of phosphate in parenteral nutrition (53). The patient had unintentionally received total elemental phosphorus infused over a 7-week period in the daily amount of 1.8–4.2 g (median 3.1 g), over three times the normal daily requirement. Serum phosphorus increased to 3.02 mmol/l (reference range 0.76–1.46 mmol/l). Calcification of subcutaneous arteries was complicated by widespread infarcts of the anatomically related skin and subcutis, apparently the result of hypoperfusion of these vessels during an episode of septic shock. The infarcts were characterized by blotchy skin discoloration.

Metal metabolism

Aluminium

Over the years, problems have arisen as a result of the presence of significant amounts of aluminium in parenteral nutrition solutions; in particular they have been held responsible for hypercalciuria and its consequences (54). Parenterally administered aluminium bypasses the gastrointestinal tract, which normally serves as a protective barrier to aluminium entry into the blood. In the past, aluminium contamination of casein hydrolysate, which was used as a source of protein in parenteral nutrition solutions, was associated with low-turnover osteomalacia and with encephalopathy in uremic patients. Premature infants are still at risk of aluminium accumulation as a result of prolonged parenteral nutrition (as are patients receiving plasmapheresis with albumin contaminated in its preparation with aluminium). Metabolic bone disease can result (54).

Deposition of aluminium in bone seems to relate to the appearance of bone disorders (55), although it is probably not the only cause and some studies have failed to detect a clear relation. In one critical study the bone response to parenteral nutrition containing high amounts of aluminium and ergocalciferol (25 micrograms/day), administered for 6–72 months, was compared with that to parenteral nutrition containing amino acids with reduced amounts of aluminium and ergocalciferol (5 micrograms/day) for 9–58 months, and various other solutions. Bone formation varied inversely with both plasma aluminium and bone surface aluminium, suggesting that plasma or bone surface aluminium, acquired during parenteral nutrition, reduces bone formation and leads to patchy osteomalacia (56). One should add, however, that in this study the switch to amino acids rather than casein not only influenced aluminium intake but also that of protein and ergocalciferol, both of which could be relevant to bone responses.

No effective treatment has been established for aluminium-loaded patients other than identifying the primary source of aluminium contamination and reducing or eliminating it with an appropriate substitute constituent. Prospective studies of serum aluminium concentration and urinary aluminium excretion in children receiving long-term parenteral nutrition would allow better definition of the extent to which aluminium loading remains a problem (5).

Copper

Patients who develop cholestatic jaundice during chronic parenteral nutrition can develop significant hematological complications due to hypocupremia.

- A 36-year-old woman with short bowel syndrome developed progressive liver dysfunction 6 months after

© 2006 Elsevier B.V. All rights reserved.

the start of parenteral nutrition (57). Trace elements had been omitted because of cholestasis and persistent hyperbilirubinemia. After 15 months she became dependent on erythrocyte transfusions and her neutrophil and platelet counts fell steadily. After 19 months her serum copper concentration was 4 ng/ml (reference range 11–24 ng/ml, 0.17–0.38 μmol/l). Provision of trace elements for 2 months was associated with increased serum copper concentration and neutrophil and platelet counts, independent of erythrocyte transfusions. When the serum copper concentration reached 30 μmol/l copper was discontinued. Over the next 3 months, the copper concentration fell to 1.6 μmol/l and neutrophil and platelet counts fell precipitously. Once again, the copper concentration and neutrophil and platelet counts recovered with copper supplementation.

Because copper is excreted primarily in the bile, some experts advocate reducing or curtailing copper supplementation in patients with chronic hyperbilirubinemia. The earliest signs of copper deficiency are peripheral blood cytopenias (typically anemia and neutropenia) and occasionally thrombocytopenia, caused by reduced bone marrow production. The authors recommended that serum copper should be monitored quarterly and that copper should be included in the parenteral nutrition mixture three times a week, adjusting the frequency in response to serum copper concentrations.

Three adult cases in which copper deficiency developed during long-term parenteral nutrition without copper supplementation have been described. All three patients were suffering from malabsorption when therapy was instituted, and overt symptoms of copper deficiency developed an average of 5.8 months after the start of parenteral nutrition. Leukopenia with neutropenia and low plasma concentrations of copper and ceruloplasmin were seen in all cases (58).

- Copper deficiency has been reported in a patient with Crohn's disease after removal of copper from the parenteral nutrition because of severe cholestasis (59). The patient developed pancytopenia with severely depressed serum copper concentrations after 8 weeks. Bone-marrow biopsy confirmed the cause as copper deficiency. Although intravenous replacement of copper improved the patient's anemia and other markers, he suddenly died of cardiac tamponade.

Manganese

The dangers of hypermanganesemia as a result of parenteral nutrition are well documented. They are mainly associated with neurological toxicity. The causes of hypermanganesemia are poorly understood, but cholestasis is suspected as a key factor. There has been an attempt to identify the main factors associated with increased plasma manganese in a prospective study in 21 subjects (60). Hypermanganesemia was not only related to increased quantities infused but also to persistent inflammation (which can alter manganese metabolism) and cholestasis (causing reduced manganese biliary excretion). Neurological complications appeared to be marginal, despite the fact that manganese brain deposition is frequent. The authors suggested that manganese status must be regularly monitored during long-term parenteral nutrition.

When oral intake is precluded, the recommended daily parenteral supplementation of manganese is 0.15–0.8 mg. Manganese is mainly excreted in the bile; during cholestasis serum manganese levels may rise, and manganese toxicity can result. Hypermanganesemia after parenteral nutrition when first reported was linked to portosystemic encephalopathy. Patients with liver disease were particularly at risk.

- Manganese deposition in the brain has been reported after 28 days of parenteral nutrition including manganese 20 μmol/day (61). The serum manganese concentration was raised (4.9 μmol/l) 34 days postoperatively, 13 days after stopping parenteral nutrition. MRI scans showed symmetrical hyperintense lesions in the globus pallidus, which gradually improved as serum manganese concentrations fell to normal.

The authors concluded that even short-term perioperative parenteral nutrition can result in manganese deposition, especially if there is liver impairment.

Excess manganese can accumulate in the brain, resulting in toxic psychosis ("manganese madness") and parkinsonism. One striking report involves a middle-aged woman receiving parenteral nutrition supplemented with trace elements from the first postoperative day after a Whipple's procedure; she developed obstructive jaundice, and her serum bilirubin concentration peaked at 179 μmol/l on the ninth postoperative day (62). She simultaneously developed increasing confusion, aggression, and choreoathetoid movements. The serum manganese concentration was 26 ng/ml (reference range below 10 ng/ml). When supplementation of manganese was substantially reduced there was progressive improvement in her confusion and other neurological signs. On the basis of this experience the authors warned against the use of standard dosages of manganese in patients with obstructive jaundice.

In manganese madness, neuroleptic drugs may be ill-advisedly administered. However, they themselves can potentiate manganese toxicity and have serious adverse effects of their own. Trivalent manganese promotes oxidation of phenothiazines, increasing free-radical formation, and may increase a patient's susceptibility to haloperidol (63). MRI brain scans in 13 of 57 children aged 6 months to 10 years receiving long-term parenteral nutrition who were being investigated because of hypermanganesemia showed characteristic increased signal intensity on T1-weighted images in seven cases, with no abnormalities on T2-weighted images. All the patients had increased whole blood manganese concentrations, suggesting that the basis for the MRI abnormality was deposition of manganese within the basal ganglia and other cerebral tissues (64). In other studies these MRI changes disappeared or abated after withdrawal of manganese supplements or exposure, but the Parkinson-like neurological manifestations appear to be permanent.

Serum manganese concentrations are not a reliable indicator of the concentrations attained in the brain. However, in one reported case with neurological complications in which alterations in basal ganglia and cerebral signal intensity had been detected during life by magnetic

© 2006 Elsevier B.V. All rights reserved.

resonance, postmortem showed raised concentrations of manganese in the radiologically abnormal areas (65).

The relation between dose and erythrocyte concentrations of manganese has been studied in patients receiving parenteral nutrition, including manganese 500 micromol/day, for periods varying from a few days to many months (66). While concentrations during short-term parenteral nutrition were normal, patients who had been receiving parenteral nutrition for up to 30 days had raised concentrations. Of 21 patients who had been receiving parenteral nutrition for over 1 month, 15 had raised erythrocyte manganese concentrations, although in this group there was no clear relation with liver test abnormalities or renal function. In three patients there was evidence of neurological damage. The authors recommended that all patients receiving parenteral nutrition for more than 30 days should be monitored for serum manganese concentrations, that the recommended dose of manganese should not exceed 100 micrograms/day, and that manganese should be eliminated from nutrition solutions when the serum concentration is raised. The authors also recommended that manganese should not be added to parenteral nutrition solutions for patients with chronic liver disease.

It is not known with certainty whether manganese accumulation is hepatotoxic in humans, but in rats it causes mild though reversible intrahepatic cholestasis. Manganese may prove to be an overlooked cause of hepatotoxicity, as it is excreted via bile. Of 53 children who had been given parenteral nutrition for over 6 weeks, 35 had biochemical evidence of cholestatic liver disease, and in all those cases the serum manganese concentration was over 360 nmol/l (67). The highest serum manganese concentrations were found in children under 2 years of age; it is possible that biliary excretion of manganese at this age is less efficient.

The possible link between hypermanganesemia and cholestasis has been investigated in patients receiving long-term parenteral nutrition (68). The authors concluded that cholestatic liver disease does not contribute to increased blood manganese concentrations in such patients, and that plasma concentrations reflect recent manganese exposure and impaired excretion when cholestasis is present. They also emphasized that serum concentrations are a poor marker and that erythrocyte manganese concentrations should be used instead.

Selenium

The signs of selenium deficiency include skeletal myopathy and cardiomyopathy, and selenium deficiency continues to be reported in cases in which this essential element has not been added to parenteral nutrition solutions during long-term administration (69).

In a report dating from 1987, low selenium concentrations were found in four children receiving long-term parenteral nutrition. There was erythrocyte macrocytosis ($n = 3$), loss of pigmentation of hair and skin ($n = 2$), raised transaminase and creatine kinase activities ($n = 2$), and profound muscle weakness ($n = 1$). Intravenous supplementation with selenium for 3–12 months resulted in progressive improvement in all these (70).

Selenium deficiency caused by parenteral nutrition can cause heart failure.

- A 38-year-old man with Crohn's disease had been receiving parenteral nutrition for 16 years, from the age of 22 years (71). After 6 years of parenteral nutrition he developed heart failure and ventricular extra beats associated with selenium deficiency. A serum concentration of 62 ng/ml was measured (reference range 80–230). Selenium supplements improved his condition but did not normalize left ventricular function. He was given selenium supplements and was free from heart failure for 11 years, but the echocardiographic findings gradually deteriorated and he died of congestive heart failure at the age of 38 years. At autopsy, his heart showed linear fibrosis in the interventricular septum, confined to the right side. The subendocardial region and the right ventricular free wall were relatively spared.

The authors proposed that the cardiac changes in this case were characteristic of the cardiomyopathy related to selenium deficiency. Once fully developed, left ventricular dysfunction may be irreversible, even after the use of selenium supplements.

Selenium deficiency has also been reported to have caused a myopathy.

- A 35-year-old man developed selenium deficiency after repeated administration of parenteral nutrition for 13 years (72). The deficiency syndrome manifested as muscle weakness but not pain in both arms and legs, especially the thighs. There was a dominant proximal muscle weakness and reduced deep tendon reflexes. There was a progressive rise in serum creatine kinase activity, mainly of the MM type. Serum aldolase and lactate dehydrogenase were significantly raised. Peripheral muscle electromyography showed a myogenic pattern of short duration and amplitude. Muscle biopsy showed myopathic changes, with mild variation in size, regeneration of muscle fibers and muscle cell necrosis. There was no infiltration of inflammatory cells. The serum concentration of selenium was very low (1 ng/ml, reference range 97–160). After treatment for 3 months with selenium infusions the muscle weakness began to resolve and the creatine kinase activity improved. The muscle weakness did not disappear completely and serum selenium concentrations did not return to normal for more than 4 months after treatment. Eventually, and after about 5 months, there was virtually complete resolution of the muscle weakness and serum creatine kinase abnormality.

Selenium is a constituent of glutathione peroxidase, an enzyme that catalyses the oxidation of reduced glutathione by hydrogen peroxide and other hydroperoxides to form oxidized glutathione and water. In addition, glutathione peroxidase reduces phospholipid hydroperoxide in cell membranes. Selenium deficiency, as well as glutathione depletion, reduces resistance against oxidative stress, resulting in lipid peroxidation. Selenium via glutathione peroxidase may be one of the key mediators in response to oxidative stress. Cardiomyopathy and hyperglycemia are additional possible complications of selenium deficiency, but they were not noted in this case.

© 2006 Elsevier B.V. All rights reserved.

Acid–base balance

Lactic acidosis can occur through thiamine deficiency during parenteral nutrition (73).

- A 13-year-old boy underwent bone marrow transplantation and received parenteral nutrition without vitamins. After 15 days he had acute life-threatening lactic acidosis refractory to bicarbonate and Tris. Intravenous thiamine 100 mg produced satisfactory clinical and biochemical responses.

The authors suggested that in any patient receiving parenteral nutrition without added vitamins who develops lactic acidosis, thiamine deficiency should be suspected.

Hematologic

Erythrocytes

The major cause of megaloblastic anemia in children is folate deficiency. The following case indicates the importance of including regular supplementation of parenteral nutrition with folate (74).

- A Japanese boy, born at 34 weeks with congenital microvillous atrophy, was given parenteral nutrition 7 days after birth. The mixture included trace elements and most vitamins, but not folate. At 3 months he became lethargic, with facial pallor and hepatosplenomegaly. He had a hemoglobin of 6.9 g/dl with thrombocytopenia and a normal white blood cell count. Bone marrow showed typical megaloblasts. The serum folate concentration was 0.6 (reference range 2.4–9.8) ng/ml and vitamin B_{12} was 290 (249–938) pg/ml. These findings indicated megaloblastic anemia due to folate deficiency. Daily intramuscular folate 30 micrograms/kg and vitamin B_{12} 40 micrograms/kg improved his anemia and thrombocytopenia and his serum folate concentration returned to normal after 14 days. Both vitamins were then added daily and there was no recurrence of anemia, but he died at 4 months because of sepsis.

It is estimated that the minimum daily requirement of folate is 5 micrograms/kg. Liver stores are about 160 micrograms in premature children, and 220 micrograms in full-term infants. Infants who require parenteral nutrition will rapidly become folate deficient unless folic acid is included in the regimen. Since many multivitamin supplements do not contain folic acid, its inclusion should be ensured by the addition of folic or folinic acid.

Iron deficiency anemia can also be an important adverse effect of long-term parenteral nutrition. It is usually caused by partial or complete absence of iron from the regimen, inadequate absorption if oral iron is substituted, or chronic iron loss from gastrointestinal lesions. In a retrospective study, the records of 55 patients on long-term parenteral nutrition (more than 6 months) were examined for evidence of iron deficiency anemia (75). All had received home parenteral nutrition, comprising amino acids, glucose, and fat emulsion, with appropriate electrolytes, vitamins, and trace elements, but without iron. All had taken substantial amounts of food despite malabsorption. Iron deficiency anemia was identified in patients whose hemoglobin concentration was less than 12 g/dl and who had at least one the following: serum iron less than 600 ng/ml and TIBC less than 3500 ng/ml; iron to TIBC ratio (or transferrin saturation) 16% or less; or serum ferritin less than 15 ng/ml. Iron studies had been monitored at about 3-monthly intervals, reduced to yearly if no problems were found. In 30 patients there was evidence of iron deficiency anemia; ten of these were detected at the start of home parenteral nutrition, and the other 20 developed iron deficiency anemia during treatment. Many had evidence of acute blood loss, for example from the gastrointestinal or genitourinary tracts. The time between the start of parenteral nutrition and the development of anemia was 2–97 (mean 29) months. Mild iron loss from the gastrointestinal tract was identified as the predominant cause. Regular treatment with small amounts of iron (10–15 mg/day had been used in these patients) added to the parenteral nutrition regimen appeared to be safe and efficacious, with no reported adverse effects. In contrast, total dose infusion of iron (for example, iron dextran infusion) had adverse effects in 25% of patients.

Iron is an essential element in nutrition, and its inclusion in any long-term parenteral nutrition regimen should be mandatory. However, it is not included in all trace element formulations, although this varies from country to country; most European products include 20 μmol of iron in trace element formulations. While it might be considered unnecessary to include iron as a daily supplement, because of safety and pharmaceutical considerations, there is ample evidence that the use of iron-containing trace element formulations is both safe and efficacious, with no associated adverse effects.

Histiocytosis

Sea-blue histiocytes containing granulations and hemophagocytosis can be seen on bone marrow smears, and there can be bone marrow sequestration of radiolabeled autologous erythrocytes. The constellation of hematological abnormalities suggests an activation of the monocyte-macrophage system by the fat emulsion (76).

Sea-blue histiocytes have been reported in bone marrow secondary to parenteral nutrition including fat-emulsion sources in seven patients with severe thrombocytopenia undergoing long-term parenteral nutrition required by extensive small-bowel resection (77). All patients received intravenous fat emulsion (Intralipid 20%) for 3–18 months. Bone marrow biopsy showed sea-blue histiocytes dispersed amongst hemopoietic cells or arranged in aggregates adjacent to osseous lamellae and blood vessels or separated from bone trabeculae. The significance of these histological findings in association with parenteral nutrition and thrombocytopenia is not known.

When one young woman on chronic parenteral nutrition for short bowel syndrome presented with hepatosplenomegaly and pancytopenia (78), bone marrow examination showed the sea-blue histiocytes to be lipid-laden macrophages. The total amount of fat in the regimen was subsequently reduced, and there was partial hematological improvement. The condition observed in this patient is analogous to that which occurs in Gaucher's disease and Niemann-Pick disease.

© 2006 Elsevier B.V. All rights reserved.

Leukocytes

Septic complications associated with total parental nutrition may be partly due to neutrophil dysfunction, though this has not been demonstrated (79).

Platelets

Hematological abnormalities have been found to be associated with prolonged administration of intravenous fat emulsion in children on a program of long-term cyclic parenteral nutrition. Recurrent thrombocytopenia is common and platelet lifespan is reduced. In one study (80), thrombocytopenia occurred in 66% of patients, but most of these had taken drugs that might have interfered with platelet function. Hypercoagulability was not found in the majority of cases.

It seems clear that platelet counts should be performed on a regular basis in patients receiving prolonged parenteral nutrition with fat emulsion (Intralipid). If a low platelet count develops, reduction or termination of administration is indicated (76). Clinical findings further point to hyperactivity of the macrophage in the reticuloendothelial system related to long-term treatment with Intralipid.

Coagulation

The activation of coagulation that occurs during parenteral nutrition is thought to be aggravated by coincidental infection; experimental work in healthy humans provides evidence that in patients receiving parenteral nutrition bacterial infection may facilitate the occurrence of venous thrombosis by synergistic stimulation of the coagulation system. Warfarin resistance has been found to develop during high dose propofol infusion, which contains 10% soybean oil as an emulsified preparation (81). Despite increasing the daily dose of warfarin to 30 mg, anticoagulation was not achieved until propofol was withdrawn. Lipid emulsions interfere pharmacodynamically with warfarin activity by enhancing the production of clotting factors, facilitating platelet aggregation, or supplying vitamin K; they may also facilitate warfarin binding to albumin. It follows that where patients with intestinal absorptive deficiencies who receive high-dose lipid emulsions require reliable anticoagulation heparin rather than warfarin should be used. If warfarin is given, the response should be monitored daily.

To test the hypothesis that infection facilitates activation of coagulation during parenteral nutrition, healthy subjects were injected intravenously with endotoxin (2 ng/kg) after they had received either standard parenteral nutrition for 1 week ($n = 7$) or normal enteral feeding ($n = 8$) (82). Compared with enteral feeding, parenteral nutrition was associated with selectively enhanced activation of the coagulation system (plasma concentrations of thrombin-antithrombin III complexes) during endotoxemia. Activation of the fibrinolytic system (plasminogen activator activity, tissue-type plasminogen activator, plasminogen activator inhibitor type 1) proceeded similarly in both groups. Bacterial infection, a common complication in patients receiving parenteral nutrition, may aggravate the occurrence of another common complication (venous thrombosis) by synergistic stimulation of the coagulation system. Lipids were not included in the parenteral nutrition in this study, and it is possible that the shift towards thrombogenesis may be even more pronounced in patients receiving parenteral nutrition containing lipids.

Gastrointestinal

The proportion of patients on parenteral nutrition in whom cholestasis is accompanied by necrotizing enterocolitis has increased markedly in the past ten years. Little is known about the nature of this association. In one study, directed primarily to cases of necrotizing enterocolitis and bowel necrosis or perforation who required surgical intervention, it was found that the incidence of accompanying cholestasis was much higher in those patients who had received parenteral nutrition; necrotizing enterocolitis may make the liver more susceptible to the hepatotoxic effects of parenteral nutrition (83). In an animal study using neonatal piglets (84) parenteral nutrition produced a significant reduction in weight and length of the gastrointestinal tract, particularly in the proximal small bowel. The proximal small-bowel weight was reduced by 67–72% compared with controls; similar, but less marked, differences were found in the distal small bowel. If these findings apply to man they mean that parenteral nutrition, while necessary for survival, is at least temporarily detrimental to intestinal growth and development and thus to enteral absorption of nutrients.

Normal enterally-administered nutrition prevents the development of gut barrier failure through several mechanisms which fail to come into play when nutrition is provided parenterally (85).

Liver

Both short-term parenteral nutrition and long-term parenteral nutrition can cause liver damage (86,87). Some adult patients develop cirrhosis (88), but there is a particularly high prevalence of hepatic complications of parenteral nutrition in children (89). The clinical spectrum includes cholestasis, cholelithiasis, hepatic fibrosis with progression to biliary cirrhosis, and the development of portal hypertension and liver failure in a significant number of children who are totally parenterally fed. The pathogenesis is multifactorial and is related to prematurity, low birth weight, and the duration of parenteral nutrition. The degree and severity of the liver disease is related to recurrent sepsis, including catheter sepsis, bacterial translocation, and cholangitis. Lack of enteral feeding leads to reduced gut hormone secretion, reduced bile flow, and biliary stasis, all of which may be important in the development of cholestasis. Even in the absence of frank gallstones, there is a high incidence of biliary tract sludge and microlithiasis in patients receiving parenteral nutrition, highlighting the necessity for preventive measures and for vigilance for acute pancreatitis (90). There is evidence in rats that hepatic steatosis may be an early marker of liver toxicity caused by parenteral nutrition, preceding biochemical disturbances (91). If so, reversal of early hepatic steatosis should spare the liver from further damage. There is an inverse relation between the incidence of parenteral nutrition-associated cholestasis and both gestational age and birth weight (92).

© 2006 Elsevier B.V. All rights reserved.

Intestinal transplantation is combined with liver transplantation in 46% of cases, because of terminal liver failure (93). Of 78 patients who had received parenteral nutrition for more than 2 years ($n = 66$) and/or had short bowel syndrome and could not be weaned from parenteral nutrition ($n = 12$), 58 developed chronic cholestasis and 37 developed one or more severe liver complication (serum bilirubin concentration 60 μmol/l, factor V (proaccelerin) 50%, portal hypertension, encephalopathy, ascites, bleeding from the gastrointestinal tract, or histological findings consisting of extensive fibrosis and cirrhosis) after 6 (3–132) months and 17 (2–155) months respectively. Liver disease was responsible for deaths in 6.5% of the patients (22% of deaths).

Patients treated with interleukin-2 (IL-2) develop profound anorexia, malaise, loss of energy, mucositis, nausea, and vomiting, which can contribute to poor nutrition. In 21 patients who took a normal diet (controls) and 16 who received parenteral nutrition during IL-2 treatment, parenteral nutrition improved serum calcium and potassium concentrations, particularly during spontaneous diuresis after completion of IL-2 treatment (94). Unexpectedly, parenteral nutrition reduced the frequency and severity of cholestatic jaundice caused by IL-2, the pathophysiological basis of which is unknown. A brief period of parenteral nutrition during IL-2 treatment was well tolerated and it corrected the calorie and protein malnutrition. Parenteral nutrition also improved control of serum electrolytes, particularly calcium, potassium, and magnesium concentrations, although there was more marked hypophosphatemia during IL-2 treatment. The reason for this change is not clear.

Frequency

In a prospective prevalence study of liver disease in 90 patients with permanent intestinal failure receiving parenteral nutrition liver biopsy was performed in 57 (95). Chronic cholestasis developed in 58 patients after a median of 6 (range 3–132) months, and 37 developed complicated liver disease after a median of 17 (range 2–155) months. Chronic cholestasis was significantly associated with a risk of liver disease independent of parenteral nutrition, a bowel remnant shorter than 50 cm, and a lipid intake of 1 g/kg/day or more; liver disease related to parenteral nutrition was significantly associated with chronic cholestasis and a parenteral lipid intake of 1 g/kg/day or more. The authors concluded that the prevalence of liver disease increased with the duration of parenteral nutrition and was one of the main causes of death in patients with permanent intestinal failure. Parenteral intake of long-chain lipid emulsion should be restricted to less than 1 g/kg/day.

Mechanisms and susceptibility factors

Several mechanisms have been proposed to explain the cholestasis that occurs during parenteral nutrition, but there is little direct evidence to support any of them. Nutrient deficiencies that may be critical for hepatic uptake, biotransformation, and secretion of bile may be involved. Deficiency of taurine, which is important for bile acid conjugation, may cause cholestasis in premature infants. Certain amino acids may act as toxins. Reduced hormonal and neural stimulation of hepatic bile secretion may be a factor in patients who are not receiving nutrition enterally. Increased production by intestinal bacteria of lithocholate, which is a hepatotoxic bile acid, or retention of lithocholate in the liver, might account for the cholestasis. It is unclear whether it is the lipid or the carbohydrate component of parenteral nutrition solutions that determines the development of cholestasis during parenteral nutrition (96). In one study in neonates receiving parenteral nutrition the number of operations (amongst other factors) was significantly related to the development of cholestasis, possibly because of the stress of surgery itself or to the repeated administration of anesthetic agents or morphine (97). Some animal work suggests that gallbladder sludge and cholestasis during parenteral nutrition result from a reduction in both the bile salt-dependent and bile salt-independent fractions of canalicular bile flow (98). Another possible causal factor is an accumulation in the body of phytosterols derived from soya oil and/or soya lecithin used to make the intravenous lipid emulsion. There is a close association between phytosterolemia and cholestatic liver disease; animal work provides evidence that increasing the content of phytosterols in cell membranes can interfere with the function of important transport proteins involved in the secretion of bile (99,100). Phytosterol-induced changes in neutrophil function also lead to impaired phagocytosis of bacteria and an increased risk of sepsis; the latter is responsible for further damage to hepatocytes. Finally, in neonates who are at high risk of developing parenteral nutrition-associated cholestasis when receiving a prolonged course of parenteral nutrition lack of gastrointestinal hormone formation, including cholecystokinin, may be responsible. In a prospective controlled study, patients who received cholecystokinin prophylaxis had concentrations of direct bilirubin significantly lower than in the non-treated group (101).

Increased hepatic lipogenesis and reduced transport function are important in the fatty liver associated with parenteral nutrition. Providing ample quantities of essential amino acids mitigates but does not prevent this. This highlights the importance of total caloric intake. If insufficient amounts of amino acids are taken together with adequate non-protein calories, protein deficiency analogous to kwashiorkor can develop. Hepatic lipid accumulates, but lipoprotein synthesis is limited. Carnitine supplementation minimizes fatty infiltration of the liver in patients receiving dextrose-based parenteral nutrition, which supports the idea that carnitine deficiency plays a role in the development of this complication. However, carnitine can ordinarily be synthesized from the essential amino acids methionine and lysine, which are present in all commercially available parenteral nutrition formulae. Hepatic tissue requirements may be increased under conditions of stress, contributing to the development of a fatty liver by impairment of transport and oxidation of fatty acids by mitochondria.

Raised concentrations of lithocholate, portal bacteremia, and/or endotoxemia have all been suggested as contributing to hepatic triaditis in patients with inflammatory bowel disease receiving parenteral nutrition. Toxic amino acids or their metabolic products, excessive calorie administration and a disturbed carbohydrate/protein

© 2006 Elsevier B.V. All rights reserved.

ratio may also influence the development of triaditis. Steatonecrosis is also known to occur when nutritional depletion develops. Inadequate administration of a critical nutrient or combination of nutrients might be involved in the pathogenicity of this lesion.

The high incidence of cholestatic liver disease associated with long-term parenteral nutrition in infants who have undergone major gut resection is linked to high plasma concentrations of phytosterols, compounds that resemble cholesterol but have an alkylated side-chain (99). The phytosterols that accumulate in patients receiving parenteral nutrition are derived from the soya oil and/or soya lecithin that is used to make the intravenous lipid emulsion. There is a strong association between phytosterolemia and cholestatic liver disease, which suggests a possible causative association. Experiments in neonatal piglets have suggested that phytosterols, given without any of the other components of parenteral nutrition, can reduce bile flow. The authors suggested that increasing the content of phytosterols in cell membranes may interfere with the function of important transport proteins involved in the secretion of bile. If a 20% lipid emulsion is infused at a rate of more than 50 ml/kg/week into a premature neonate who has had a major gut resection, and if this rate of infusion is continued for 2 months, the plasma phytosterol concentration is likely to rise to a value close to 25% of the total plasma sterols. The mechanism of the liver injury and effect on bile flow caused by parenteral nutrition is likely to be more complex than a simple sterol-induced change in membrane fluidity. Intravenous lipid emulsions that do not contain phytosterols may be safer.

The possible link between cholestasis and intravenous fat emulsions has been investigated in five patients (aged 2 months to 15 years) receiving parenteral nutrition, all of whom had signs of liver disease (102). In particular, the possible role of phytosterols, natural contaminants of fat emulsions, in causing liver disease was evaluated. Three developed steatosis with non-icteric hepatic dysfunction. High plant phytosterol concentrations in patients receiving parenteral nutrition were related to liver dysfunction and depended on the degree of cholestasis and the dosage of fat emulsion. However, this evidence does not prove that plant phytosterols contribute to the development of liver disease in susceptible individuals, and the authors concluded that in patients with steatosis associated with parenteral nutrition, lipid emulsions should not be withdrawn.

In a retrospective study of the incidence of cholestasis and liver failure in 42 patients with intestinal resection in the neonatal period who subsequently became dependent on parenteral nutrition support, the effect of various associated clinical factors on the incidence and severity of cholestasis was determined (103). Cholestasis developed in 28 while they were receiving parenteral nutrition. In 21 patients, the raised direct bilirubin concentration returned to normal while they continued to receive parenteral nutrition. Seven patients progressed to liver failure. Patients without cholestasis had been dependent on parenteral nutrition for longer than patients with cholestasis. It was clear from this study that cholestasis in neonates with intestinal resection is not simply a function of the duration of exposure to intravenous nutrition. The results instead suggested that infection early in life, when the developing liver may be uniquely sensitive to cholestatic injury and additionally stressed by intravenous nutrition, may play an important role.

The role of lipid emulsions in cholestasis associated with long-term parenteral nutrition has been investigated retrospectively in 10 children with a total of 23 episodes of cholestasis, associated with thrombocytopenia in 13 cases (104). Changes in lipid delivery, associated with increased daily amounts, preceded complications in more than half the cases, while temporary reduction in lipid administration led to normalization of bilirubin in 17 episodes. The authors concluded that lipid supply is one of the risk factors for cholestasis associated with parenteral nutrition. They recommended that when cholestasis occurs, lipid should be temporarily withdrawn, especially if there is associated thrombocytopenia.

In a randomized, controlled study of 244 infants one group ($n = 123$) received lower concentrations of manganese (0.0182 micromol/kg/day as Peditrace 1 ml/kg/day) while the second ($n = 121$) received 1 micromol/kg/day (as Ped-el 4 ml/kg/day) (105). All other components of the parenteral nutrition regimen were standardized. Monitoring comprised whole-blood manganese and serum direct bilirubin concentrations, the indicator for the development of cholestasis being a peak bilirubin concentration over 50 micromol/l. Those who were given extra manganese had higher peak whole blood manganese concentrations and higher peak serum direct bilirubin concentrations, but the differences were not significant. The two groups did not differ in terms of the occurrence of cholestasis (63/121 versus 57/123), but more infants in the high manganese group developed a more severe degree of hyperbilirubinemia. The authors concluded that the pathogenesis of cholestasis during parenteral nutrition is probably multifactorial, and that a high manganese intake is a significant contributory factor.

The link between cholestasis during home parenteral nutrition and inflammatory markers has been investigated in 17 patients on long-term home parenteral nutrition and 10 age-matched and sex-matched controls (106). Liver enzyme concentrations were used as markers of liver disease. Circulating inflammatory and immune markers were determined as measures of inflammatory activity. There were abnormal liver function tests in 14 of the patients. Alkaline phosphatase was positively correlated with markers of persistent inflammation and immune activation. Liver enzyme activities were also related to the amounts of total intravenous calories and calories originating from carbohydrates, but not lipids, in contrast to other recent data. The authors suggested that these results confirm that the number of infused calories contributes to liver toxicity in patients receiving home parenteral nutrition and strongly imply that sustained inflammation is probably a key factor in worsening the associated cholestasis.

Management

There is no effective treatment of liver damage during parenteral nutrition, except for using enteral nutrition as soon as possible. However, the benefits of ursodeoxycholic acid, a naturally occurring non-toxic hydrophilic bile acid,

© 2006 Elsevier B.V. All rights reserved.

have been evaluated in a retrospective chart review of six infants who received oral ursodeoxycholic acid 15–30 mg/kg/day for at least 1 month (107). Ursodeoxycholic acid was safe and led to some early reduction in bilirubin concentrations, although there was no improvement in other markers of liver function. Clearly, the possible benefits have yet to be firmly established. Ursodeoxycholic acid may prevent or reduce the hepatocyte damage and cholestasis caused by high concentrations of hydrophobic bile acids by increasing the concentrations of hydrophilic non-hepatotoxic bile acids in the bile, by reducing histocompatibility antigens displayed by hepatocytes, or by a direct cytoprotective effect (108).

One cause of deteriorating liver function resulting from long-term parenteral nutrition is attributable to excessive or persistent calorie intake. Cyclic parenteral nutrition is a procedure of intermittent delivery (either during the day or at night over 10–12 hours). During the non-infusion period the central venous catheter is heparin-locked. In a prospective study the effect of early use of cyclic parenteral nutrition on deterioration of liver function has been studied in 65 patients with impaired liver function (109). The patients were divided into three groups based on bilirubin concentrations (over 85 μmol/l, 170 μmol/l, and 340 μmol/l). Each of the subgroups was divided into control (continuous parenteral nutrition) or test (cyclic parenteral nutrition). Patients on non-cyclic parenteral nutrition had significantly increased bilirubin and alkaline phosphatase, but the difference between the control and test groups was not significant in those patients with the most severe liver failure before the study. The authors were therefore unable to confirm the possible value of cyclic parenteral nutrition in reducing deterioration in liver function, although the results suggested that, at least in mild or moderate liver failure, there may be some benefit in reducing hepatocellular damage and progressive jaundice.

Urinary tract

There was a profound reduction in renal function associated with very long-term parenteral nutrition (continuing for periods longer than 10 years) in 29 of 33 patients studied: a reduction in estimated creatinine clearance of 0.6–15.4% per year (110). Tubular function, as determined by the tubular reabsorption of phosphate, was impaired in 52%. Although nephrotoxic drug use, bacteremia, fungemia, age, and infection rate accounted for part of the decline in renal function, most of it was unexplained.

In some infants receiving parenteral nutrition nephrocalcinosis occurs. Parenteral nutrition solutions contain the oxalate precursors ascorbate and glycine, and in one study of very low birth weight infants (111) administration of parenteral nutrition protein of about 0.5 g/kg/day was associated with an increased urinary oxalate/creatinine ratio; the effect was dose-dependent. Raised urinary oxalate concentrations may be a factor in the pathogenesis of nephrocalcinosis in these infants.

Musculoskeletal

There is massive evidence that parenteral nutrition therapy itself can affect bone adversely, especially bone density (5,112,113). Depletion of bone mineral is common in patients dependent on long-term parenteral nutrition (114). It is difficult to identify the role of a single nutrient in the development of bone disease during parenteral nutrition. The pathogenicity may be multifactorial and different in patients at different ages: in growing infants increased mineral requirement can be of particular importance, whereas other factors (such as aluminium toxicity) can occur in both adults and children. Since mineral status can be critical, particularly in small preterm infants, non-nutritional factors, including chronic use of potent loop diuretics and altered acid-base status, can affect urine mineral loss, cell metabolism, and consequently bone mineralization. Other factors that can play a role in the pathogenesis of bone disease associated with parenteral nutrition make reports confusing; they include lack of periodic enteral feeding, underlying intestinal disease including malabsorption and inflammation, neoplasm, and drug-induced alterations in calcium and bone metabolism.

In adults receiving long-term parenteral nutrition, despite its anabolic effects on other tissues, there is no improvement in bone density. Infants treated with parenteral nutrition from birth also develop low bone density for age, suggesting that parenteral nutrition treatment in some way contributes to the osteopenia (5). A 17% long-term increase in spinal bone mineral content has been shown in patients who have received parenteral nutrition solutions without vitamin D. However, this rise was nearly balanced by a 15% fall in hip bone mineral content (115). In a Danish study of bone mineral content in adults receiving home parenteral nutrition for short bowel syndrome, despite the fact that all were on free oral intake as a supplement to the parenteral nutrition, 47% had mandibular osteoporosis while 33% had osteoporosis in the forearm and radiographic changes of osteoporotic fractures in the vertebral column. Dental and periodontal tissues were normal (116).

In general, the question of whether parenteral nutrition adversely affects calcium regulation is unclear. Human studies are confounded by uncontrolled variables, including the degree to which food is taken orally; gut absorption; underlying disease; medications that adversely affect bones, including glucocorticoids; and aluminium contamination of parenteral nutrients. Calcium loss in the urine is often described, but the pattern is not consistent. Non-human primate work can provide some insight, but here too the findings are difficult to interpret. In one such study it was not possible to show a negative calcium balance with the use of parenteral nutrition in the absence of underlying disease (114). However, at higher rates of intravenous nutrition negative calcium balance has been demonstrated in such a model (117), while in other work evidence has been obtained that there is initial calciuria (and a negative calcium balance), which improves within 2 weeks (5). Some evidence seems to show that in premature infants receiving parenteral nutrition the mixture should contain higher calcium and phosphorus concentrations in prematurity than in childhood in order to avoid rickets and to promote improvement in existing rickets (118).

Cytokines such as interleukin-1, interleukin-6, and tumor necrosis factor alfa influence bone resorption and have been invoked as a cause of type 1 osteoporosis.

© 2006 Elsevier B.V. All rights reserved.

Parenteral nutrition in experimental rats enhances the catabolic effect of tumor necrosis factor alfa (119). The role of parenteral nutrition-induced cytokine release or activity, especially of IL-1, IL-6, and tumor necrosis factor alfa, in causing hypercalciuria and reduced mineralization in patients receiving parenteral nutrition needs to be clarified (119).

Metabolic bone disease in children receiving parenteral nutrition manifests primarily as osteopenia and, on occasion, fractures (5). The etiology is multifactorial: calcium and phosphate deficiency play a major role in the preterm infant but the part played by aluminium toxicity in this population is unknown. Lack of reference values of bone histomorphometry in the premature infant, as well as lack of reference data for biochemical markers of bone turnover in these patients, contributes to the uncertainty. Other factors that may play a role in the pathogenesis of bone disease associated with parenteral nutrition include lack of periodic enteral feeding; underlying intestinal disease, including malabsorption and inflammation; the presence of neoplasms; and drug-induced alterations in calcium and bone metabolism. However, the true incidence and prevalence of parenteral nutrition-associated bone abnormalities in pediatric patients are unknown.

Sexual function

Priapism has been reported as a complication of parenteral nutrition (160).

- A man developed a persistent painful penile erection 12 hours after the administration of a 12% fat emulsion (120). This was thought to have been caused by venous thrombosis in the corpora cavernosa, and the priapism was immediately relieved by bilateral corpora cavernosa spongiosa shunts, although the patient remained impotent.

Three different mechanisms have been postulated for this complication of parenteral nutrition:

1. an increase in blood coagulability
2. adverse effects on erythrocytes
3. fat embolism

In this case it was felt that the 20% fat emulsion had increased platelet activity, which was already increased before the start of therapy, and that this had predisposed to the development of priapism. The authors pointed out that a shunt procedure should be performed as soon as possible if erectile capacity is to be preserved.

Immunologic

Parenteral nutrition can adversely affect the immune system, thereby increasing the risk of infection and sepsis, for example by impairing neutrophil function, blocking the function of the reticuloendothelial system, and altering cell-mediated immunity. However, much of the evidence has been obtained in experiments using large bolus doses; the immunological effects of more conservative doses administered as continuous infusions over 12–24 hour/day are less clear. As the chylomicron-like lipid is metabolized, increased triglyceride concentrations may alter the function of macrophages by reducing chemotaxis and phagocytic capacity, although this has not been consistently demonstrated. Excessive parenteral administration of lipid may overload the mononuclear cells of the reticuloendothelial system, resulting in an inability to clear bacteria from the bloodstream. Studies of the alterations in cellular immunity associated with intravenous infusions of lipid emulsions have produced mixed results. Increases in B lymphocyte and T lymphocyte counts, increased lymphocyte mitogenesis, and increased production of interleukin-2 have been reported in patients receiving parenteral lipids. Others have reported no change or reductions in natural killer cell counts, helper-to-suppressor cell ratios, and antibody-dependent cellular cytotoxicity compared with patients not receiving intravenous lipids. No significant changes in serum immunoglobulin or complement concentrations have been observed secondary to intravenous lipid administration.

A growing area of interest is the use of intravenous medium-chain triglycerides, which have a different metabolic fate to long-chain triglycerides and may not have similar detrimental effects on the reticuloendothelial function, leukocyte activity, and eicosanoid production. Another focus of research is the differences observed between the various lipid components and fatty acids. The polyunsaturated fatty acid content of cell membranes, an important factor in the structural and functional integrity of the cell, can be altered by the provision of increased amounts of *n*-3 fatty acids in place of *n*-6 fatty acids. In a 1987 study, the effects of different parenteral nutrition solutions on in vitro lymphocyte reactivity and measured lymphocyte responsiveness were investigated in patients during treatment (121). In vitro lymphocyte responses were significantly depressed by a fat emulsion at concentrations similar to those achieved in clinical practice, but were unaffected by dextrose or amino acid solutions. These and similar finding by others indicate that careful consideration should be given before using fat emulsions in patients whose cell-mediated immunity is already impaired.

Immune function has been studied in ten surgical infants (aged under 6 months) requiring parenteral nutrition in two consecutive phases: (a) after 31 days with no enteral feeding (parenteral nutrition) and (b) after 4.7 days from the addition to parenteral nutrition of small volumes of enteral feeding. Host bactericidal activity against coagulase-negative staphylococci, measured by an in vitro whole blood model, was lowest in the patients who received parenteral nutrition, and it increased significantly after the addition of small enteral feeds, approaching the levels measured in controls. Production of tumor necrosis factor-alfa was low during parenteral nutrition and rose significantly after the addition of small enteral feeds in patients on parenteral nutrition. The increase in killing of coagulase-negative staphylococci after the addition of small enteral feeds correlated significantly with the duration of enteral feeding. The mechanism causing impaired immune function during parenteral nutrition is not known, and it is probably multifactorial. Neither is it understood how small additional enteral feeds affect host bactericidal activity (122).

© 2006 Elsevier B.V. All rights reserved.

Allergic reactions

Severe allergic reactions can occur to parenterally administered lipid solutions. Such reactions may be mistaken for symptoms of the underlying disease or adverse effects of cytostatic chemotherapy (123). There is some evidence that the presence of soya bean proteins is responsible.

In 1989 the Perioperative Anaphylactic Reactions Study Group began an epidemiological survey of anaphylactoid reactions during anesthesia. Details recorded about patients who have suffered an anaphylactic reaction include demographic information and the results of allergy testing. In the most recent survey 1750 patients were reported from 27 diagnostic centers during January 1992 to June 1994 (124). Plasma substitutes accounted for 5.0% of the reactions observed. Intravenous infusions carry a comparatively small risk of anaphylaxis in the perioperative period. Other surveys come to a similar conclusion (125).

Allergic reactions have been reported infrequently in children receiving parenteral nutrition. The length of exposure before the reaction, the severity of the response, and the component responsible are variable.

- Anaphylaxis has been reported in a 4-year-old child when parenteral nutrition was resumed after a 5-day interruption in therapy after prior treatment 16 days after surgery for Wilms' tumor.

The authors considered the reaction to have been a type 1 IgE-mediated allergic response, although the causative agent was not identified. It was considered unlikely that individual amino acids had stimulated the allergic response, although the possibility of aggregated amino acids acting as a potential sensitizing agent could not be excluded. A component of the multivitamin mixture was considered the more likely explanation; the substances administered were vitamin E, vitamin K_1, the preservatives butylated hydroxyanisole (BHA) and butylated hydroxytoluene (BHT), and polysorbate emulsifiers (126).

Anaphylaxis linked to vitamin B complex in a parenteral nutrition regimen has been reported (127).

- An 8-year-old girl had a diaphragmatic hernia repaired at 7 days of age and had two episodes of adhesion ileus at 8 months. After laparotomy she was given all-in-one parenteral nutrition and after 21 days developed a reddish rash on her face and chest. The rash was pruritic and resolved quickly after intravenous diphenhydramine. She was readmitted 15 days after discharge because of malnutrition. Parenteral nutrition was restarted and she rapidly became irritable and developed an itchy rash over her face and trunk and swelling of her lips and eyelids. Parenteral nutrition was discontinued, diphenhydramine was given, and her symptoms abated rapidly. The possibility of hypersensitivity to a component of the parenteral nutrition was considered, and by a process of elimination the cause of the reaction was identified as the vitamin product MVI No 1. This was further confirmed by a skin test 1 year after the anaphylactic episode, but using a vitamin B complex solution.

Previous reports of anaphylactic reactions to parenteral nutrition have been identified as being caused by fat emulsion, vitamin K, iron dextran, and in particular multivitamins. This appears to be the first report of a reaction to vitamin B complex injection. However, neither the source of the vitamin B complex test product nor its formulation was identified by the authors, and there is doubt about the specific allergens responsible for the allergic response in this case.

Infection risk

Infection has long been recognized as a risk of parenteral nutrition and it has proved impossible to eliminate it (SEDA-22, 379). Once established, sepsis can increase the risk of fat overload syndrome. In an extensive study in Taiwan there was sepsis with positive blood cultures in 56 of 378 children receiving parenteral nutrition; the risk factors were longer duration of parenteral nutrition, age under 3 months, the use of central venous catheters, gastrointestinal disease as an indication for parenteral nutrition, low birth weight, and short gestational age in prematurity (128).

Various explanations have been offered for the occurrence of sepsis during parenteral nutrition, quite apart from the fact that the solution itself may be contaminated. Phytosterols can cause changes in neutrophil function. Cholestasis may play a role and then be further aggravated by the sepsis, creating a vicious circle. And fat emulsion may reduce hepatic phagocytosis. In vitro evidence using material from preterm infants suggests that administration of Intralipid may interfere with the binding of IL-2 to the specific receptors on their activated lymphocytes, with suppression of the immune response (129).

However, the clinical significance of these various mechanisms has been questioned. Some experimental in vitro work on human white cells suggests that the effect is markedly dose-dependent; it has been suggested that very few inhibitory effects on phagocytic cells will be found if lipid emulsion rates are kept at around 0.08 g/kg/hour (20). It is also notable that in one large series of premature very low birth weight infants in whom the use and duration of treatment with parenteral nutrition were associated with short gestational age and low birth weight, children treated with parenteral nutrition had a higher risk of sepsis usually caused by *Staphylococcus epidermidis* or *Staphylococcus aureus* (130). Thus, although the risk of sepsis in this age group appears to be significantly increased by parenteral nutrition, the causative organisms were fairly benign. It was concluded that the advantages of parenteral nutrition outweighed the risk of sepsis in this group of infants.

The incidences of bacteremia and fungemia during the first month after bone marrow transplantation for hematological malignancies have been studied in a prospective comparison in 512 patients. The patients were randomly assigned to receive 6–8% (low dose) or 25–30% (standard dose) of total energy as a 20% lipid emulsion. An adaptive randomization scheme, stratified for various treatments and transplant type, ensured that confounding treatment variables did not differ between the groups. Of 482 evaluable patients, 55 in the standard-dose group developed bacteremia or fungemia compared with 54 in the low-dose group. There was no association

© 2006 Elsevier B.V. All rights reserved.

between the incidence of bacteremia or fungemia and intravenous lipid. Similar results were obtained when the results were analysed according to intention to treat, when bacterial or fungal infections at all sites were included, and when the observation period was extended to 60 days. These results suggest that moderate amounts of intravenous lipid rich in linoleic acid are not associated with an increased incidence of bacterial or fungal infections in patients undergoing bone marrow transplantation and receiving parenteral nutrition (131).

In infants of very low birth weight, fungal colonization and the association between fungal colonization and systemic fungal diseases was significantly linked to prolonged administration of antibiotics, parenteral nutrition, and fat emulsion (Intralipid) (132). Of 116 infants with birth weights under 1500 g, fungal colonization was detected in 25, of whom 17 developed colonization by 2 weeks of life. *Candida albicans* (61%) and *Candida parapsilosis* (29%) were the two most common organisms. The rectum (76%) was the most frequent site of colonization. Cultures were taken from the oropharynx, rectum, skin (groin and axilla), urine, and endotracheal aspirates in the first 24 hours after birth and weekly thereafter. There was an association between colonization and subsequent fungemia in one infant, representing 4% of colonized infants. It was also noted that although fungal colonization represents a risk factor for invasive candidiasis in infants of very low birth weight, candidiasis in this population is not invariably associated with prior colonization. Factors other than fungal colonization can also contribute to the occurrence of invasive candidiasis.

In a study of the independent risk factors for nosocomial coagulase-negative staphylococcal bacteremia among neonates of very low birth weight, after adjusting for the severity of the underlying illness, there was a significant association between coagulase-negative staphylococcal bacteremia and exposure during hospitalization to intravenous lipids (133). The study was conducted in 590 consecutively admitted neonates with birth weights under 1500 g, in two neonatal intensive care units, with a case-control study of 74 cases of coagulase-negative staphylococcal bacteremia and 74 pairs of matched controls. The independent risk factors for bacteremia were intravenous lipids (odds ratio 9.4), mechanical ventilation (OR = 2.0), and short peripheral venous catheters (OR = 2.6). It would appear that exposure to intravenous lipids at any time during hospitalization remains, and has possibly become an increasingly important risk factor for coagulase-negative staphylococcal bacteremia. In neonates of very low birth weight 85% of these bacteremias are now attributable to lipid therapy. In contrast, the relative importance of intravenous catheters as an independent risk factor has declined. Mechanical ventilation in the week before bacteremia has emerged as a risk factor for bacteremia.

There is evidence that lipid emulsion, which is cleared by the Kupffer cells of the reticuloendothelial system, can adversely affect reticuloendothelial function by reducing its ability to remove blood-borne bacteria. In a study of the blood clearance and organ localization of viable ^{35}S-radiolabelled *Escherichia coli* after slow intraperitoneal and more rapid intravenous administration of 20% fat emulsion in Sprague-Dawley rats, although there was rapid bacterial blood clearance in control and test animals, there was a significant change in the organ localization of bacteria as a result of the administration of lipid emulsion. There was a slight increase in lung localization of bacteria in rats that received intraperitoneal fat emulsion, and a significant increase in lung trapping of bacteria in rats that received intravenous fat emulsion. Liver localization of bacteria was reduced in all groups after fat emulsion. The data are understood to indicate that intravenous fat emulsion reduces hepatic phagocytosis and increases pulmonary localization of *E. coli*, and it is thought that this may produce greater susceptibility to infection. Patients with underlying sepsis are at greatest risk. The capacity of the lungs to kill sequestered bacteria is not known. Thus, increased bacterial lung localization may result in local inflammation and other pulmonary complications, and in the re-emergence into the blood of *E. coli*, with systemic sepsis as a result (134).

Second-Generation Effects

Teratogenicity

The developmental toxicity of a 20% lipid emulsion containing a 3:1 ratio of medium-chain to long-chain triglycerides has been examined in animals. Administration was once-daily intravenously to rats and rabbits during organogenesis. Maternal and embryo/fetal toxicity were also assessed. There were no adverse effects on fetal parameters for rats even in the presence of maternal toxicity. However, embryo and fetal toxicity (resorptions) and skeletal abnormalities were noted in rabbits (135). The adverse fetal effects were probably the result of dietary deprivation, maternal toxicity, or both rather than representing a direct teratogenic effect.

Susceptibility Factors

Age

Since lipoprotein lipase activity is reduced in premature babies and babies who are small for gestational age, and since bacterial and viral infections adversely affect lipoprotein lipase activity and can precipitate fat overload, it follows that fat emulsion should be administered with great caution, or even temporarily withheld, in small infants with proven or suspected sepsis (134).

Cholestatic liver disease is a frequent complication of prolonged parenteral nutrition, especially in preterm infants, with an occurrence rate that can approach 60% after 2 weeks of parenteral nutrition. In a retrospective survey of the incidence of liver dysfunction in 94 children (mean age 5 years) receiving parenteral nutrition over 2 years, liver disease was identified in over 50% of cases, with a nadir during the second week of parenteral nutrition (50). The most closely associated factors were length of parenteral nutrition and sepsis. In premature low birth weight infants hepatobiliary dysfunction with histological changes has been attributed to parenteral nutrition (48). Other risk factors include high baseline serum bile acids, reduced hepatic extraction, and an underdeveloped ileal transport system for conservation of bile acids. These lead to a reduced pool of bile acids and consequent exposure

© 2006 Elsevier B.V. All rights reserved.

of the liver to toxic bile acids. The liver damage is aggravated by sepsis, ischemia, necrotizing enterocolitis, or surgery.

The pattern and prognosis of liver injury in children is distinct from that seen in adults, despite some overlap; liver disease develops in 40–60% of infants who require long-term parenteral nutrition for intestinal failure (89). The longer parenteral nutrition is used in neonates the greater is the risk of developing cholestasis, and the risk approaches 100% in neonates who receive parenteral nutrition for more than 8 weeks, especially if parenteral nutrition has been started very early in life (83,136). The particularly high risk in infants can be explained by factors that are specific to this age group; namely, immaturity of the enzyme systems responsible for hepatic conjugation, disturbance in the physiological patterns of enteral nutrition, and excessive secondary bile acid production and absorption from a contaminated small bowel. The bile of premature and newborn infants differs in its composition from that of adults, and this may account for the differences in solubility (137). Histologically one is likely to find cholestasis (intracellular or canalicular), periportal inflammation, fibrosis, and bile ductular proliferation (138). Sepsis can make cholestasis more severe. The clinical manifestations of cholestasis in infants include a progressively rising conjugated bilirubin concentration starting after 2 weeks of parenteral nutrition. Liver biopsy characteristically shows bile duct proliferation, bile plugs, and congestion. The clinical consequences include increased rates of sepsis, cirrhosis, liver failure, and death (139), though if parenteral nutrition can be withdrawn the condition is in principle reversible (138). Cholelithiasis is much less common in these children, but the administration of large amounts of amino acids and a high ratio of non-protein (kcal/ml) increased the risk of formation of gallstones and sludge. Conversely, these are prevented by the administration of appropriate amounts of fat (140). It has been recommended that ultrasound examination of the gallbladder be performed in children maintained on parenteral nutrition for longer than 30 days, and early elective cholecystectomy performed if parenteral nutrition-associated cholelithiasis develops (141).

A theory has been proposed regarding a possible mechanism by which parenteral lipid solutions injure preterm infants; namely, by free radical-induced lipid peroxidation in the lipid solution (142,143). How this happens is not explained. The result can be pulmonary damage and chronic lung disease. Premature infants are thought to be at particularly high risk. However, others (144,145) have suggested that Cooke's interpretation (142) was not based on solid clinical evidence, and that the data that he derived from his observations should be tested in controlled studies before parenteral nutrition is prescribed for infants of very low birth weights.

Other features of the patient

Thrombosis can occur, especially (for unclear reasons) in patients suffering from AIDS. The incidence of symptomatic central venous thrombosis in patients with AIDS receiving home parenteral nutrition has been estimated at 0.009 per patient-month (80). However, in one retrospective study of malnourished patients with AIDS, none of whom had had a previous venous thrombosis, and who were treated with parenteral nutrition for a long period, the rate of central venous thrombosis in patients taking warfarin was 0.016 thromboses per patient-month, both in those taking warfarin and in those not so treated; in this series no hypercoagulability was found.

In a prospective study of the effects of parenteral medium-chain and long-chain triglycerides on lymphocyte subpopulations and function in severely malnourished patients with acquired immunodeficiency syndrome (AIDS), long-chain triglycerides were compared with a balanced emulsion of long-chain and medium-chain triglycerides (146). Administration was over 6 days. With 2 g/kg/day of lipids, long-chain triglycerides caused significant abnormalities in lymphocyte function, expressed as a reduction in phytohemagglutinin A response. Such abnormalities were not observed with long-chain plus medium-chain triglycerides, which reduced IgM and increased the C3 fraction.

Drug Administration

Drug formulations

Precipitates can develop in parenteral nutrition admixtures because of a number of factors such as the concentration, pH, and phosphate content of the amino acid solutions, the calcium and phosphorus additives, the order of mixing, or the mixing process. The consequences can be serious. In one cohort study of hospitalized patients who received peripheral parenteral nutrition, a subgroup developed unexplained chest pain, dyspnea, cardiopulmonary arrest, or new interstitial infiltrates on chest radiograph. A change in the amino acid source of a parenteral nutrition mixture was associated with respiratory adverse events that ranged from interstitial infiltrates to sudden death. The events apparently resulted from infusion of calcium phosphate precipitate in an opaque admixture, and the deposition of the crystals in the pulmonary microvasculature (147).

The United States Food and Drug Administration issued a safety alert in 1994 regarding the potentially life-threatening formation of precipitates in parenteral nutrition admixtures (148). They had received reports of two deaths and at least two cases of respiratory distress during intravenous infusion of a three-in-one parenteral nutrition mixture (amino acids, carbohydrates, lipids). The mixture contained 10% FreAmine III (amino acids + magnesium acetate + phosphoric acid + potassium chloride + sodium acetate + sodium chloride), dextrose, calcium gluconate, potassium phosphate, other minerals, and a lipid emulsion. The solution may have contained a precipitate of calcium phosphate. Autopsies revealed diffuse microvascular pulmonary emboli containing calcium phosphate.

The FDA has recommended the following steps to decrease the hazard of injury through precipitation (149):

1. The amounts of phosphorus and calcium added to the admixture are critical. The solubility of the added calcium should be calculated from the volume at the time that the calcium is added. It should not be based on the

© 2006 Elsevier B.V. All rights reserved.

final volume. The line should be flushed between the addition of any potentially incompatible components.
2. A lipid emulsion in a three-in-one admixture obscures the presence of a precipitate. Therefore, if a lipid emulsion is needed, either use a two-in-one admixture with the lipid infused separately, or add the calcium before the lipid emulsion according to the recommendations in 1 above. If the amount of calcium or phosphate which must be added is likely to cause a precipitate, some or all of the calcium should be administered separately. Such separate infusions must be properly diluted and slowly infused to avoid serious adverse events related to the calcium.
3. During the mixing process, parenteral nutrition admixtures should be periodically agitated to check for precipitates. This check should be conducted both before and during the infusion. Patients and caregivers should be trained to inspect for signs of precipitation. They should also be trained to stop the infusion and seek medical assistance if precipitates are noted.
4. A filter should be used when infusing either central or peripheral parenteral nutrition admixtures. Data are not available to determine which size filter is most effective in trapping precipitates.
5. Parenteral nutrition mixtures should be administered within the following time frames: if stored at room temperature, the infusion should be started within 24 hours after mixing; if stored at refrigerated temperatures, the infusion should be started within 24 hours of rewarming. Because warming parenteral nutrition mixtures may contribute to the formation of precipitates, once administration begins, care should be taken to avoid excessive warming of the mixture.

Mirtallo has added to the FDA guidelines, stressing the need to ensure that an appropriate dose of calcium is prescribed, to follow appropriate procedures when mixing parenteral nutrition solutions and to use automatic mixing devices strictly in accordance with the manufacturer's instructions (150). He has stressed the fact that more information is needed to substantiate the usefulness of filters in preventing adverse effects caused by the infusion of particulate matter present in parenteral nutrition admixtures.

It has been pointed out that calcium phosphate precipitates more readily in warm than in cold solutions. Precipitation can occur in solution at room temperature, even if an identical cold solution is clear. A precipitate can also form when a clear solution, stored refrigerated or at room-temperature, is warmed to body temperature. Thus, visual inspection and even in-line filters, if they are distal to the side of precipitation, may not prevent infusion of the precipitate (151).

Drug contamination

Since the introduction of parenteral nutrition in hospital care the potential microbiological risks associated with the manufacture, preparation, and administration of these products have abated but not disappeared (133,152). Fatal infectious complications still occur. The parenteral nutrition mixture is a good growth medium for microorganisms, more conducive to microbial growth than glucose or amino acid solutions. Storage of mixtures allows time for microbial multiplication, often to counts of millions per ml. Commonly isolated organisms from parenteral nutrition solutions are coagulase-negative staphylococci, *S. aureus*, *Candida* species, *Serratia* species, and *Enterobacter* species. Infection with *Malassezia furfur* is a rare but serious complication strongly associated with parenteral nutrition in young children, now documented in some 50 reports (153). *Candida* infection is a particular problem in patients receiving parenteral nutrition. Even organisms such as *S. epidermidis* and *Bacillus* species, relatively non-pathogenic in normal circumstances, can multiply in the infusion to such large numbers as to have disastrous effects. Many of these commensal organisms tend to be insensitive to antibiotics. In an open-system aseptic process of preparation the estimated risk of contamination, according to the World Health Organization, is one in 3000. Microbiological and environmental quality control assurance needs to be continuous.

The average rate of episodes of catheter-related bacteremia in patients receiving parenteral nutrition is 3–5%. Higher rates are reported for long-term patients. Patients with a nosocomial infection have an 11-fold higher risk of acquiring an additional nosocomial infection compared with those with no infection. Prompt removal of the catheter and targeted antimicrobial treatment remains the standard approach for febrile episodes in these circumstances. However, many catheter-related infections caused by coagulase-negative staphylococci can successfully be treated with the catheter still in place (154).

Drug administration route

Local extravasation of parenteral nutrition fluid can occur. Two patients developed an intense inflammatory reaction that was successfully controlled with repeated local administration of the hyaluronidase analogue chondroitin sulfatase (155). Although the exact mechanism of tissue toxicity by extravasated parenteral nutrition is not understood, it seems likely to be related to osmolarity, pH, and ions. The area affected may become blistered, with darkening of the skin, or ischemic, depending on whether the skin thickness is partially or fully damaged. In children, extravasation can have devastating consequences, such as deep necrosis, amputation, severe sequelae in the affected limb, or other complications, such as subdural collection of fat emulsion, liporrhachis, and acute abdomen after intra-abdominal extravasation. Children are at special risk, because very young infants and children are unable to communicate the pain that results from the pressure of extravasated fluid. Other individuals in this situation are comatose patients, those under general anesthesia, and patients who are being resuscitated. Other risk factors that predispose to extravasation are related to venepuncture technique, state of the patient, and medication delivery. Special care should be taken when high-osmolarity (1000–1700 mosmol/l) peripheral parenteral nutrition is administered, as fluids of this osmolarity are likely to cause severe tissue damage if extravasated. Fluids should not generally exceed 600–900 mosmol/l in order to minimize the risk of this complication. The position of the catheter needs to be regularly checked. Fat emulsions are harmless to the tissues if extravasated.

© 2006 Elsevier B.V. All rights reserved.

After a preterm infant developed parenteral nutrition ascites after infusion through a low umbilical vein catheter, a follow-up study of eight patients, all of whom developed hypotension and ascites, showed that each had an umbilical vein catheter overlying the liver on plain X-ray (156). The catheters had been in place for a mean of 8.9 days before extravasation. Ultrasound in four patients showed hepatic parenchymal damage around the umbilical vein catheter tip. Parenteral nutrition given through abnormally placed umbilical vein catheters is not without risk, and correct placing of the catheter is paramount.

Drug–Drug Interactions

Glucocorticoids

Infants of very low birth weight have reduced tolerance to intravenous fat emulsions, with consequent hyperlipidemia. Since glucocorticoids are often used to prevent or treat chronic lung disease, and since they can cause hyperlipidemia, this potential drug interaction has been investigated in a randomized double-blind trial (157). The results supported the hypothesis that dexamethasone increases triglyceride serum concentrations, and the authors recommended that low birth weight infants who are receiving both dexamethasone and fat emulsion should be monitored carefully for signs of impairment of lipid tolerance.

Propofol

Drugs with a high lipid content, when given concurrently with lipid-containing parenteral nutrition, can aggravate the problems of lipid overload (29). The anesthetic, propofol, which is used for continuous sedation in a dose of 1–3 mg/kg/hour (an equivalent of 300–500 ml of a 10% fat emulsion), may aggravate the symptoms and pathological effects of fat overload (29).

Warfarin

Warfarin resistance has been described in a patient with short bowel syndrome receiving intravenous lipid (158). Up to 20 mg of warfarin was given daily without increase in the International Normalized Ratio (INR). Although intravenous lipid has been reported anecdotally to account for warfarin resistance, this report suggests that the more likely explanation was the reduced surface area for drug absorption secondary to total surgical removal of the patient's duodenum and gastrojejunostomy. However, several other reports have refuted a correlation between warfarin resistance and short bowel syndrome. Conversely, warfarin resistance has occurred secondary to intravenous lipid administration in a patient with only 12 cm of small bowel; the patient had been given oral warfarin while he received daily fat emulsion (Intralipid) to prevent fatty acid deficiency (159).

Paroxetine

See also Selective serotonin re-uptake inhibitors (SSRIs)

General Information

Paroxetine is a phenylpiperidine derivative. Its half-life is about 17–22 hours and about 95% of it is bound to plasma proteins. Its metabolites have no more than 1/50 of the potency of the parent compound in inhibiting serotonin re-uptake. The metabolism of paroxetine is accomplished in part by CYP2D6, saturation of which at therapeutic doses appears to account for the non-linearity of paroxetine kinetics at higher doses and increasing durations of treatment. The adverse effects of paroxetine are those of the SSRIs in general. Commonly observed adverse events

© 2006 Elsevier B.V. All rights reserved.

in placebo-controlled clinical trials were weakness, sweating, nausea, reduced appetite, somnolence, dizziness, insomnia, tremor, nervousness, ejaculatory disturbance, and other male genital disorders. Paroxetine seems to have a higher incidence of withdrawal symptoms than other SSRIs.

Organs and Systems

Cardiovascular

Electrocardiographic changes, with a prolonged QT_c interval and bradycardia, have been reported with paroxetine (1).

Nervous system

Serotonin syndrome

The serotonin syndrome is a recognized complication of SSRI treatment. Usually it occurs as part of a drug interaction, when the serotonergic effects of SSRIs are augmented by medications that also have serotonin-potentiating properties (SEDA-22, 14) (SEDA-25, 16). Occasionally, however, the serotonin syndrome can occur after SSRI monotherapy.

- A 23-year-old Japanese woman with major depression took a single dose of paroxetine (20 mg) and 1 hour later had agitation, myoclonus, mild hyperthermia (37.5 °C), sweating, and diarrhea, symptoms that meet the criteria for the serotonin syndrome; she recovered with supportive treatment over 3 days (2).

Blood concentrations of paroxetine were not obtained, but the authors reported that the patient was homozygous for the 10* form of the CYP2D6 allele, which is associated with low CYP2D6 activity in vivo. While this is an interesting observation, it is unlikely by itself to explain the patient's sensitivity to paroxetine, because this genotype is not uncommon in the Japanese population, and if a lot of Japanese have this genotype, the serotonin syndrome with SSRI monotherapy would be quite common, given the widespread prescription of SSRIs. However, it reinforces clinical advice that in patients new to SSRI treatment it is advisable to start therapy with half the standard dose.

Dystonias

Acute dystonia has been described during the first days of paroxetine treatment (SEDA-17, 19).

Paroxetine-induced akathisia has been described in an 81-year-old man with bipolar depression. The akathisia began one week after paroxetine treatment (20 mg/day) and remitted within 6 days of withdrawal (3).

The authors pointed out that it is important to recognize SSRI-induced akathisia, because increasing agitation and restlessness early in treatment can be mistaken for worsening depression. In addition, case reports have suggested that akathisia can be associated with suicidal impulses.

Sensory systems

Tricyclic antidepressants can precipitate acute glaucoma through their anticholinergic effects. There are also reports that paroxetine can cause acute glaucoma, presumably by pupillary dilatation.

- An 84-year-old woman developed acute closed-angle glaucoma after taking paroxetine for 6 days (SEDA-21, 13).
- A 70-year-old woman taking paroxetine developed acute closed-angle glaucoma (4).
- A 91-year-old developed bilateral acute closed-angle glaucoma after taking paroxetine (5).

Three patients taking paroxetine for interferon-alpha-induced depression developed retinal hemorrhages, including one with irreversible loss of vision (6).

Psychological, psychiatric

In three children (two aged 9 years and one aged 10 years) who took paroxetine 10–20 mg/day for the treatment of childhood obsessive-compulsive disorder, symptoms of mania, including overactivity, pressure of speech, irritability, and antisocial behavior, occurred within 3 weeks of starting paroxetine and remitted after paroxetine withdrawal or dosage reduction (7). Symptoms of mania are rare in childhood, suggesting that the elevated mood in these cases was a direct effect of the paroxetine.

Psychomotor retardation with semistupor has been reported in one patient taking paroxetine; however, she was also taking antipsychotic drugs, which may have contributed (SEDA-18, 20).

Endocrine

Serotonin pathways are involved in the regulation of prolactin secretion. Galactorrhea has been associated with paroxetine (8).

Serotonin pathways are involved in the regulation of prolactin secretion. Amenorrhea, galactorrhea, and hyperprolactinemia have been reported in a patient taking SSRIs.

- A 32-year-old woman taking paroxetine 40 mg/day had a raised prolactin concentration (46 ng/ml) and galactorrhea, both of which resolved a few days after paroxetine withdrawal (9).

Hematologic

Clozapine and SSRIs are often used together, because depressive syndromes are common in patients with schizophrenia. Clozapine carries a relatively high risk of agranulocytosis, but this adverse effect is very rarely seen with SSRIs, although a case of possible fluoxetine-induced neutropenia has been described (SEDA-22, 15). Two cases in which the addition of paroxetine to clozapine was associated with neutropenia have been reported (10). The patients had been taking stable doses of clozapine for 6–12 months and had previously tolerated other SSRIs without adverse hematological consequences. In both cases the white cell count recovered when clozapine was withdrawn, although paroxetine was continued.

Fluoxetine has infrequently been associated with abnormal bleeding, including ecchymoses, melena, and hematuria. Spontaneous ecchymoses have been reported in a woman taking paroxetine (11).

© 2006 Elsevier B.V. All rights reserved.

- A 47-year-old woman who had had bilateral mastectomies for breast cancer became depressed and was given paroxetine 20 mg/day. After 15 days she developed widespread multiple ecchymoses over the arms, legs, and abdomen. Her platelet count, prothrombin time, partial thromboplastin time, and bleeding time were normal. Paroxetine was withdrawn, and 5 days later, the bruising had markedly abated and no new lesions were identified. She was subsequently treated with a tricyclic antidepressant without recurrence of the ecchymoses.

The authors noted two earlier reports of ecchymoses with paroxetine, with normal laboratory values. They speculated that an indirect effect on platelet function through inhibition of platelet 5-HT uptake may be involved.

Paroxetine caused neutropenia in a patient whose white cell count fell to 2.9×10^9/l (neutrophils 1.37×10^9/l) (12). The white cell count gradually recovered over 6 weeks after paroxetine withdrawal.

Liver

Hepatotoxicity associated with paroxetine has been documented in two case reports (SEDA-21, 12). Severe hepatitis has been reported in two young women who took Atrium (febarbamate + difebarbamate + phenobarbital) and paroxetine (13). Liver biopsy showed lesions compatible with drug-related injury. Both recovered completely. The authors suggested that simultaneous treatment with Atrium and paroxetine increased each drug's hepatotoxicity.

Sexual function

Delayed ejaculation associated with paroxetine has been reported (SEDA-18, 21).

Immunologic

A skin reaction consistent with a vasculitis has been reported.

- A 20-year-old woman taking paroxetine 10 mg/day for obsessive-compulsive disorder developed multiple purple lesions on the fingers of both hands after 15 weeks (14). The lesions disappeared after 1 week but returned in 2 days after rechallenge with paroxetine.

Long-Term Effects

Drug withdrawal

Sudden withdrawal of paroxetine has been associated with nausea, dizziness, tremor, insomnia, irritation, and agitation (SEDA-17, 20). In three cases, a withdrawal reaction occurred with paroxetine, despite tapering of the dose for 7–14 days before discontinuation; the symptoms were the same as in earlier reports, but also included in one case myalgia, and in another rhinorrhea and visual phenomena similar to those associated with migraine (15). The authors suggested that cholinergic mechanisms and functional changes in 5-HT may play a role in the mediation of withdrawal symptoms.

Drug Administration

Drug overdose

There were gastrointestinal symptoms and CNS disturbances in patients who took overdoses of paroxetine, the largest amount being 850 mg (16).

Drug–Drug Interactions

Beta-blockers

Paroxetine can cause clinically important increases in plasma concentrations of metoprolol (17).

Clozapine

In a prospective study, paroxetine (20 mg/day), a potent inhibitor of CYP2D6, did not increase clozapine concentrations ($n = 14$), and the authors therefore suggested that CYP2D6 is not an important pathway of metabolism of clozapine (18). However, other studies (SEDA-21, 22) have shown that paroxetine can increase clozapine concentrations, suggesting that this combination should be used with caution.

Linezolid

SSRIs can also cause pharmacodynamic drug interactions for some time after withdrawal, through residual serotonin reuptake blocking activity.

- A 56-year-old woman with a postoperative wound infection developed the serotonin syndrome when she was given the antibiotic linezolid intravenously (19). The dose of paroxetine had been tapered and it had been withdrawn 5 days before.

Linezolid inhibits monoamine oxidase activity and has been reported to cause serotonin toxicity in combination with paroxetine. While some patients have apparently taken the combination of linezolid and an SSRI safely, this report suggests that patients taking combined treatment should be monitored for serotonin toxicity.

Methadone

Methadone-maintenance treatment is now established by controlled trials as effective in managing patients with opioid dependence. SSRIs are often co-prescribed for such patients, and there have been reports that SSRIs can increase methadone concentrations, presumably by inhibition of CYP2D6 (SEDA-25, 15). The effect of adding paroxetine (20 mg/day) to the treatment regimen has been studied in 10 opiate-dependent patients taking methadone maintenance (20). Methadone concentrations increased on an average by about one-third, although there was much individual variation. There were no obvious clinical consequences, presumably because the patients were fairly tolerant to the effects of methadone. However, the authors cautioned that sudden withdrawal of an SSRI in methadone users has the potential to trigger opioid-withdrawal symptoms.

© 2006 Elsevier B.V. All rights reserved.

Tricyclic antidepressants

Paroxetine can cause clinically important increases in plasma concentrations of tricyclic antidepressants (21).

Triptans

Treatment of 12 healthy volunteers with paroxetine (20 mg/day for 14 days) did not alter the pharmacokinetics or pharmacodynamic effects of an acute dose of rizatriptan (10 mg orally) (22). These data are reassuring, but (as with sumatriptan) it is possible that sporadic cases of 5-HT neurotoxicity could still occur when rizatriptan is combined with an SSRI.

Risperidone

The addition of paroxetine 20 mg/day to risperidone 4–8 mg/day in 10 patients with schizophrenia produced a 45% increase in plasma concentrations of risperidone and its active metabolite, 9-hydroxyrisperidone (23). One of the patients developed signs of drug-induced Parkinson's disease following the addition of paroxetine.

The serotonin syndrome occurred in a patient taking paroxetine plus an atypical antipsychotic drug, risperidone (24).

- A 53-year-old man took paroxetine 40 mg/day and risperidone 6 mg/day, having previously taken lower doses of both. Within 2 hours he developed ataxia, shivering, and tremor. He had profound sweating but was apyrexial, and was confused, with involuntary jerking movements of his limbs. He recovered without specific treatment over the next 2 days.

This was the first report of the serotonin syndrome in a patient taking an SSRI and an atypical antipsychotic drug. The reaction was unexpected because risperidone, in addition to being a potent dopamine receptor antagonist, is also a 5-HT_2-receptor antagonist. Subsequent animal studies suggested that 5-HT_2-receptor antagonists increase the firing of serotonergic neurons, perhaps through a postsynaptic feedback loop. This could account for potentiation of the effects of SSRIs by 5-HT_2-receptor antagonists, such as risperidone.

Passifloraceae

See also Herbal medicines

General Information

The family of Passifloraceae contains the single genus *Passiflora*.

Passiflora incarnata

Passiflora incarnata (apricot vine, grenadille, passion flower, passion vine) is widely touted as a herbal sedative and anxiolytic (1). It contains harman alkaloids.

Adverse effects

Passion flower has reportedly caused prolongation of the QT interval (2).

- A 34-year-old woman developed nausea, vomiting, drowsiness, a prolonged QT interval, and episodes of non-sustained ventricular tachycardia after self-medication with passion flower for 1 day. She made a full recovery after withdrawal of the passion flower.

The authors suggested that the adverse event had been caused by harman alkaloids from *P. incarnata*.

Five patients developed altered consciousness after taking the herbal product Relaxir for insomnia and restlessness, produced mainly from the fruit of the passion flower (3).

Pazufloxacin

See also Fluoroquinolones

General Information

Pazufloxacin is an injectable quinolone antibiotic with bactericidal effect against cephalosporin-resistant, carbapenem-resistant, and aminoglycoside-resistant strains of bacteria.

Organs and Systems

Skin

In in vivo studies in animal models of phototoxicity, pazufloxacin was less potent than nalidixic acid, ofloxacin, ciprofloxacin, or sparfloxacin, and there was no photoallergenicity (1).

Drug–Drug Interactions

Theophylline

Co-administration of pazufloxacin and theophylline has been studied in rats (2). Pazufloxacin reduced the clearance of theophylline by about 25%. In seven healthy volunteers taking modified-release theophylline, intravenous pazufloxacin mesilate increased serum theophylline concentrations; analysis of the urinary excretion of theophylline and its metabolites suggested that CYP1A2 had been inhibited (2). Theophylline concentrations need to be monitored if pazufloxacin is co-administered.

Pedaliaceae

See also Herbal medicines

General Information

The genera in the family of Pedaliaceae (Table 1) include sesame.

Harpagophytum species

Harpagophytum procumbens (devil's claw, grapple plant, wood spider) contains the iridoids harpagoside and procumbide. It is used to treat pain in the joints and lower back, although the quality of trials demonstrating efficacy is poor and there is variability from formulation to formulation (1).

Adverse effects

It is sometimes stated that *H. procumbens* should be avoided during pregnancy because of its supposed abortifacient effect, but the oxytoxic properties of the plant remain to be verified. There may be an interaction with warfarin (2).

Table 1 The genera of Pedaliaceae

Pefloxacin

See also Fluoroquinolones

General Information

Pefloxacin is a fluoroquinolone antibiotic that inhibits *Plasmodium falciparum* in vitro. It is effective against *Plasmodium yoelii* infections in mice.

Observational studies

In humans pefloxacin was tested in a dosage of 400 mg every 12 hours for 3 days against chloroquine-resistant *P. falciparum* infections in Madagascar, and proved successful in 9 out of 22 cases; seven further cases responded at first but recrudescence followed. The investigators suggested that pefloxacin should be used as a complementary drug rather than as a primary antimalarial drug.

There was a significant reduction in proteinuria in ten children with idiopathic nephrotic syndrome after pefloxacin therapy (mean dose 2–4.6 mg/kg/day for 4–8 weeks) (1). All had received a course of cyclophosphamide at least 6 months before. One patient discontinued pefloxacin within 2 weeks because of nausea and vomiting, one complained of arthralgia, and one developed nail discoloration.

The efficacy and safety of pefloxacin, 15–20 mg/kg bd for 14–28 days in combination with ceftazidime and amikacin, have been investigated in 21 children (aged 7–16 years) with mucoviscidosis or aplastic anemia (2). Combined therapy had good clinical efficacy. Arthropathy developed frequently and children at risk were over 10 years old and had a history of allergies.

General adverse effects

The adverse effects of pefloxacin are those of the fluoroquinolones, which are generally well tolerated. Gastrointestinal complaints occur in some 3–6%, and have included (in declining order of frequency) nausea, abdominal discomfort, vomiting, and diarrhea. Colitis due to *Clostridium difficile* infection has been reported infrequently. Nervous system effects have been less common, but headache, dizziness, agitation, sleep disturbances, and more rarely seizures, delirium, and hallucinations have been reported. Allergic reactions are infrequent. Photosensitivity reactions have been reported. The quinolones cause cartilage erosion in weight-bearing joints in young growing animals, and the long-term use of pefloxacin in growing children, such as would be required for prophylaxis, should be avoided. In bacteria that have developed resistance to fluoroquinolones, cross-resistance with chemically unrelated antibiotics, such as tetracycline and chloramphenicol, is possible.

Organs and Systems

Musculoskeletal

In vitro, pefloxacin was more toxic to tendons than ofloxacin, ciprofloxacin, or levofloxacin (3). In rodents, pefloxacin (400 mg/kg for several days) caused oxidative damage to the type I collagen in the Achilles tendon; these alterations were identical to those observed in experimental tendinous ischemia and a reperfusion model (4). Oxidative damage was prevented by the co-administration of *N*-acetylcysteine (150 mg/kg). Several cases of rupture of the Achilles tendon have been reported during or shortly after the use of fluoroquinolones, including five case in which pefloxacin was used (5).

The efficacy and safety of pefloxacin, 15–20 mg/kg bd for 14–28 days in combination with ceftazidime and amikacin, have been investigated in 21 children (aged 7–16 years) with mucoviscidosis or aplastic anemia (2). Combined therapy had good clinical efficacy. Arthropathy developed frequently and children at risk were over 10 years old and had a history of allergies.

In patients with mucoviscidosis treated with pefloxacin the most common adverse event was arthropathy, and the symptoms disappeared 3 days to 3 months after drug withdrawal (6).

Immunologic

Pefloxacin in suprabactericidal concentrations (2.0 mg/ml and 0.4 mg/ml) markedly suppressed T lymphocyte proliferation in blast transformation; 0.08 mg/ml did not (7). Pefloxacin in a maximal effective dose (200 mg/kg) suppressed delayed hypersensitivity skin reactions in mice.

Susceptibility Factors

Renal disease

In moderate impairment of renal function, prolongation of the dosage interval of pefloxacin should be considered; pefloxacin should be avoided in severe renal impairment (8).

Drug–Drug Interactions

Theophylline

Pefloxacin inhibits theophylline metabolism (9).

Pemirolast

General Information

Pemirolast is a mast-cell stabilizer, like cromoglicate, used in eye-drops for the treatment of allergic disorders (1). It has also been used to prevent coronary artery restenosis after the insertion of a stent (2).

In a 7-day, double-blind, single-dose, crossover, parallel-group study, 45 adults with asymptomatic eyes were randomized to bilateral pemirolast, cromoglicate, or ketorolac at each of three visits (1). Overall discomfort was significantly less with pemirolast than with cromoglicate or ketorolac. Burning/stinging and tearing were also significantly less with pemirolast than with cromoglicate.

In a 1-day, randomized, double-blind, single-dose study in which 48 subjects received pemirolast in one eye and nedocromil in the other, overall discomfort was significantly less with pemirolast than with nedocromil (1).

The most common adverse effects of pemirolast are headache, rhinitis, and mild cold- or flu-like symptoms. After ocular administration for 2 weeks, plasma concentrations were detectable, but with no significant accumulation (SEDA-24, 534).

Pemoline

General Information

Pemoline has similar actions to dexamfetamine and is used in the management of hyperactivity disorders in children (1).

Organs and Systems

Liver

During the past two decades there have been many reports of liver failure resulting in death or transplantation in patients being treated for ADHD with pemoline. However, a descriptive meta-analysis of the existing scientific literature and drug reporting databases showed that current assumptions of the risk of acute hepatic failure posed by pemoline alone are overestimates.

- A 7-year-old boy with Duchenne muscular dystrophy and attention deficit hyperactivity disorder (ADHD) developed acute hepatic failure, with features of autoimmune hepatitis (2). The only medications he had taken were pemoline (56 mg/day) and cyproheptadine (2 mg/day). Pemoline was withdrawn after 8 months as the presumed cause of his raised transaminases. Two weeks later he developed an altered mental state, jaundice, and encephalopathy. The histological features of the liver and his autoimmune antibody panel were consistent with autoimmune hepatitis. He was treated with corticosteroids and azathioprine and recovered.
- A 9-year-old boy with ADHD taking pemoline developed signs and symptoms of liver failure requiring liver transplantation (3).

The evidence linking pemoline to life-threatening liver failure prompted the Food and Drugs Administration to require the manufacturer to add a black box warning to the package insert, whereas in the UK the Committee on Safety of Medicines withdrew marketing approval for pemoline, citing safety and a lack of adequate evidence of efficacy as the reason (4).

Drug Administration

Drug overdose

There has been a report of pemoline-induced acute movement disorders after presumed overdose (5).

- Two 3-year-old identical male twins were found playing with an empty bottle of pemoline that had originally contained 59 tablets. They had a history of attention deficit disorder previously unsuccessfully treated with methylphenidate, but no history or family history of movement disorders. Choreoathetoid movements began 45 minutes to 1 hour after ingestion. The children received gastrointestinal decontamination and high doses of intravenous benzodiazepines but continued to have choreoathetosis for about 24 hours and were discharged at 48 hours.

Five children who took excessive amounts of pemoline have been described (6). They had a relatively benign course and their symptoms appeared to be primarily accentuated pharmacological effects on the central nervous and cardiovascular systems. Sinus tachycardia, hypertension, hyperactivity, choreoathetoid movements, and hallucinations were most commonly observed, consistent with previous reports.

Possible rhabdomyolysis occurred after overdose, accompanied by raised serum creatine kinase activity in three of four patients in whom it was measured; this appears to be common in acute pemoline poisoning. After ingestion, symptoms occurred within 6 hours and lasted up to 48 hours in all cases.

Gastric lavage and activated charcoal are considered to be effective decontamination measures, whereas ipecac-induced emesis should be avoided after massive ingestion, because of the risk of seizures. Aggressive use of benzodiazepine is a reasonable first choice to treat associated involuntary movements, tremor, hyperactivity, and agitation. Chlorpromazine or haloperidol can also be used, especially for serious, life-threatening symptoms, including hypertensive crises and severe hyperthermia, and labetalol or sodium nitroprusside are reasonable choices for rapid stabilization of blood pressure.

Penicillamine

General Information

Penicillamine is dimethylcysteine or 2-amino-3-mercapto-3-methylbutyric acid, a sulfur-containing amino acid. It has three functional groups: an alpha-amine, a carboxyl, and a sulfhydryl, which largely determine its pharmacological effects. Because the levorotatory isomer, L-penicillamine, is a pyridoxine antagonist and toxic, the racemic mixture has been replaced for medicinal purposes by purified D-penicillamine. Here "penicillamine" refers to the D-isomer unless otherwise specified.

Acetylpenicillamine is a weaker chelating agent than penicillamine, has no effect on collagen cross-links, and is not effective in rheumatoid arthritis. It has been used in the treatment of mercury poisoning (1).

As its name suggests, penicillamine is a degradation product of penicillin. There have been several reviews of the chemistry, pharmacokinetics, and pharmacology of penicillamine (SED-12, 537) (2). After oral administration about two-thirds (50–70%) of a dose of penicillamine is absorbed. As much as 33% can be degraded in the gut before absorption can take place. With a half-life of less than 1 hour, penicillamine is rapidly cleared after oral administration, largely by formation of disulfides with plasma albumin and with low-molecular weight thiols, such as cysteine and glutathione. Low-molecular weight disulfides constitute the major urinary metabolites. The penicillamine-albumin disulfide, on the other hand, has a long half-life. The consequence of this is slow accumulation: in healthy volunteers pseudo-steady-state plasma concentrations of penicillamine-albumin disulfide are not reached until the second week of daily administration. Peak plasma concentrations of penicillamine occur at 1.5–4 hours after ingestion and range from 5 μmol/l after 150 mg to 28 μmol/l after 800 mg (when conventional-release oral formulations are used). About 80% of penicillamine is protein-bound; about 7% occurs as L-cysteine-D-penicillamine disulfide, 5% as penicillamine disulfide, and 6% as free penicillamine. A large proportion is rapidly excreted in the urine, mainly as the disulfide or as the disulfide metabolite conjugated with cysteine; formation and excretion of the latter can cause cysteine depletion. Some penicillamine is converted to *S*-methyl-penicillamine and is either excreted by the kidneys or metabolized in the liver. Although S-methylation is a quantitatively minor elimination pathway, *S*-methyl-penicillamine is a potential substrate for sulfoxide formation, and patients with rheumatoid arthritis who form the sulfoxide at a reduced rate are at greater risk of adverse effects (3). The concentrations of penicillamine and its metabolites within cells and at the cell surface are largely unknown, but may be relevant to variability in response in regard to cellular sites of action.

Uses

Penicillamine is mainly used in the treatment of rheumatoid arthritis, Wilson's disease, and cystinuria. Although penicillamine and gold compounds were both originally used in rheumatoid arthritis on the basis of erroneous pharmacological hypotheses, they have been strongholds in the treatment of debilitating rheumatoid arthritis for more than a quarter of a century (4). Whereas they do not have much effect on the progression of joint damage, they have unexpectedly been found to be associated with a remarkable diversity of serious adverse reactions. In hindsight, they have played central roles in improvements in the understanding of the pathology of rheumatoid arthritis and of the methods of studying the benefits and harms of therapeutic strategies in rheumatoid arthritis and other chronic progressive diseases.

General trends in the treatment of rheumatoid arthritis in the past decade have been more aggressive treatment in early disease with disease-modulating antirheumatic

© 2006 Elsevier B.V. All rights reserved.

drugs (DMARDs) (5) and the use of combinations of DMARDs (6). Strategies for improving the long-term outcome in rheumatoid arthritis include early specialist referral for DMARD treatment and the avoidance of NSAID-induced gastrointestinal and renal toxicity (7). However, a 28-year observational study in Austria of the patterns of use of DMARDs has illustrated how penicillamine has given way to other drugs, in particular methotrexate and sulfasalazine (8,9). The advent of novel drugs with different mechanisms of action, such as cytokine antagonists, has empowered rheumatologists with effective new instruments (10–12).

Some believe that early, aggressive, and continuous use of DMARDs and of combinations thereof slows joint destruction, modifies the natural course of the disease, and improves outcome (13,14). On closer inspection, however, the evidence still seems thin. Schemes for treatment and monitoring are variable and complex, and none is demonstrably superior to any other. It is in any case always important to tailor treatment to the needs of the individual patient rather than following rigid guidelines.

In other reviews, the conclusion has again been reached that the long-term use of DMARDs, including penicillamine, is limited by both frequent loss of response and serious adverse reactions, and that the advantages of combination DMARDs treatments remain controversial (15,16) (SEDA-19, 229) (SEDA-20, 219) (SEDA-25, 266). In particular, the treatment of juvenile rheumatoid arthritis is difficult, since DMARDs are often poorly active in children and some (gold compounds, sulfasalazine) cause special adverse reactions, such as the macrophage activation syndrome (which in turn can lead to severe infections) (17). There is still much to be achieved and improved. As Fries has put it (16): "Determining the most clinically useful DMARD combinations and the optimal sequence of DMARD use requires effectiveness studies, Bayesian approaches and analyses of long-term outcomes. Such approaches will allow optimization of multiple drug therapies in rheumatoid arthritis, and should substantially improve the long-term outcome for many patients." In the same paper it was emphasized that patients taking penicillamine should have blood cell counts and urine protein measurements every 2 weeks during drug titration and then about monthly for as long as treatment lasts.

Since the recognition of the superior effectiveness of methotrexate and the publications of the Pediatric Rheumatology Collaborative Study Group, penicillamine has been used infrequently in juvenile rheumatoid arthritis. The maximum daily dose is about 10 mg/kg (750 mg/day) (18). This dosage is reached in three equal steps, each of 6–8 weeks' duration. Perhaps more than gold, penicillamine acts slowly, taking 9 months to 3 years for maximum effectiveness.

In a small trial, penicillamine together with metacycline was not effective in progressive multiple sclerosis (19).

Observational studies

In an Austrian study, patients with rheumatoid arthritis were followed for a mean of 10 years (20). Of 27 courses of penicillamine, 13 were discontinued because of adverse effects, 12 because of lack of effectiveness, and two because of remission. Furthermore, an analysis of the reasons for DMARD withdrawal in patients in the Czech and Slovak Republics has underlined the fact that lack of effectiveness is, in addition to adverse effects, an important reason for stopping penicillamine (21).

General adverse effects

In clinical trials about 50% of patients experienced one or more adverse effects and withdrawal was necessary in about one-third (22–26). A mucocutaneous reaction (for example a rash or stomatitis) is the most frequent reason for discontinuing the drug (27). Long-term follow-up studies have shown that many patients (up to 80%) stop taking penicillamine, either because of adverse effects or lack of efficacy (27–31).

Adverse effects are less common when small doses are used, when increments are made only slowly, when patients are closely monitored, and when penicillamine has been tolerated for some years. However, in a meta-analysis of a large series of clinical trials, dose was not a strong determinant of the risk of adverse effects (dose range 500–1250 mg/day) (26). With regard to the safe use of penicillamine the words of Huskisson (1981) are still true (32): "Perhaps the most important aspect of the surveillance of patients receiving penicillamine is the need for the physician and patient to be able to contact each other. The physician must find the patient if his blood count changes. The patient must find the physician if he becomes ill. Disasters have occurred when patients consulted physicians who were unaware of the problems of penicillamine and instituted unwise therapy for them. Penicillamine can only be used by those who know how to use it and skilful management [of its adverse effects] is a most important aspect, perhaps the most important aspect of the treatment."

In patients with rheumatoid arthritis, delayed disease complications or serious intercurrent disorders can be mistaken for complications of treatment with penicillamine or other drugs (SEDA-21, 252). Anyone responsible for a patient taking penicillamine must bear in mind that serious adverse reactions can occur suddenly and at any time during treatment, even with very small doses (as low as 125 mg/day) and after many years. Penicillamine can be the unexpected cause of serious adverse reactions as an additive to Chinese herbs (33).

Early effects are gastrointestinal upsets and, more characteristically, loss of taste. Although a fall in the number of platelets is common, serious thrombocytopenia is less frequent. After long-term use of high doses, skin collagen and elastin are impaired, resulting in increased friability and sometimes in disorders such as perforating elastoma or cutis laxa; the latter has also been observed in neonates.

Hypersensitivity reactions are frequent early in a course of penicillamine, with urticarial or maculopapular rashes, fever, and lymphadenopathy. Cross-allergy to penicillin can occur. In addition, the use of penicillamine can be complicated by a unique variety of often serious autoimmune reactions, involving the skin, kidneys, liver, lungs, muscles, or other organs. Proteinuria is found in more than 10% of patients and sometimes develops into the nephrotic syndrome. Pemphigus, myasthenia gravis, polymyositis, or a lupus-like syndrome occur in smaller percentages.

© 2006 Elsevier B.V. All rights reserved.

Reactions such as aplastic anemia, Goodpasture's syndrome, or thrombotic thrombocytopenic purpura (Moschcowitz's syndrome) are rare but serious.

Although lymphatic malignancies have been described in a few patients using penicillamine (SEDA-11, 212) (SEDA-8, 237), a causal relation is considered unlikely.

Combinations with other drugs used in rheumatoid arthritis

Adding chloroquine or hydroxychloroquine to penicillamine in the management of rheumatoid arthritis probably offers no therapeutic advantages, produces more adverse effects, and may even be less effective (SEDA-10, 223) (34–37). A combination of penicillamine and sulfasalazine seems to be more effective, although the extent of the advantage is uncertain, and adverse effects may be more frequent (34). In one study penicillamine and intramuscular gold together produced much earlier improvement, but efficacy and adverse effects did not differ significantly compared with either drug alone. In an open, uncontrolled study, the combination of penicillamine and intramuscular gold yielded the highest proportion of remissions in patients with refractory rheumatoid arthritis (34). The possible consequences of previous intolerance to gold compounds in association with adverse reactions to penicillamine administration have been reviewed (SEDA-8, 236); at present no firm conclusions can be made. Penicillamine does not chelate gold stores in the body.

Comparisons with other drugs used in rheumatoid arthritis

In an outpatient study in New Zealand, the changing patterns were studied in the use of "slow-acting" antirheumatic drugs (38). There were increases in the use of methotrexate and of drugs in combination, whereas there was a marked reduction in the use of auranofin. Penicillamine had the highest "average toxicity" score. However, despite the increased popularity of sulfasalazine and immunosuppressive drugs, drugs such as penicillamine continue to be used worldwide. In a long-term follow-up study, the proportion of patients who continued to take their first DMARD or who were in remission at 5 years was 53% for penicillamine, compared with 34% for aurothiomalate, 31% for auranofin, and 30% for hydroxychloroquine (39). Of the 179 patients who used penicillamine, 36 stopped taking it because of adverse effects (see Table 1). In an open, randomized, follow-up study of patients with rheumatoid arthritis, 98 were allocated to penicillamine (median daily dose 750 mg, range 375–1000 mg) and 102 to sulfasalazine (40). Over follow-up for 12 years as many as 95 patients (48%) died, four from peptic ulcer disease complications, illustrating the prevalence of premature mortality in patients with rheumatoid arthritis. Only four of the 98 patients continued to take penicillamine. Major reasons for withdrawal of penicillamine, other than death, were adverse effects ($n = 47$) and lack or loss of effect ($n = 36$) (see Table 1). In neither study was any of the deaths thought to have been related to penicillamine. The picture given in Table 1 illustrates the remarkable diversity and seriousness of the adverse reactions pattern of penicillamine.

Table 1 Adverse effects leading to the withdrawal of penicillamine in two studies

Reference	(40)	(39)
Total number of patients	98	179
Patients with adverse effects	47 (48%)	37 (20%)
Proteinuria	17	8
Rash, pruritus, or mouth ulcers		16

Thrombocytopenia	4	1
Leukopenia	2	2
Mouth ulcers	4	
Malaise	1	1
Exacerbation of joint pains		1
Myasthenia gravis		1
Pemphigus		1
Lupus-like syndrome	1	

A diagnostic and monitoring database program called DIAMOND runs across a network of personal computers throughout the Staffordshire Rheumatology Centre (41). For about 10 years, drug histories, blood test results, and clinical correspondence files for about 2000 patients have been accessible, and the system is linked to the main hospital pathology database. The DIAMOND system has been used to study adverse reactions and durations of treatment for commonly prescribed DMARDs, including penicillamine (combination treatments excluded). With a median survival time of 34 months, penicillamine held an intermediate position, between methotrexate (<96 months) and azathioprine (13 months) at the extremes; 38% of the patients continued to take penicillamine after 5 years. There were strong associations between penicillamine and both proteinuria and thrombocytopenia, both well-established adverse effects of penicillamine. Myasthenia gravis occurred in eight of 582 penicillamine users (1.4%) and not in patients using other DMARDs.

Prevention

Some 15 years ago, a more aggressive "sawtooth" strategy (early continual serial use) for the treatment of rheumatoid with disease-modifying drugs (DMARDs) was advocated (SEDA-19, 229). There is now evidence that DMARDs, when carefully monitored, are both less toxic and less effective than previously thought (42). Apparently, the sawtooth strategy has not changed the balance of benefit and harm of these drugs. No single DMARD or combination of DMARDs stood out favorably with respect to efficacy, toxicity, or survival. Ineffectiveness, rather than toxicity, was the main reason for drug withdrawal. A Canadian study has added to the evidence that the long-term results of treatment with DMARDs, such as penicillamine and gold, are disappointing, as well as in patients treated early in the course of their disease (43). After 3 years, only 30% were still taking penicillamine. After 6 years only 20% of patients had not been withdrawn, and there were no substantial differences between the drugs.

The effect of a patient education program, taught by rheumatology nurse practitioners, on adherence of patients to treatment with penicillamine has been studied

© 2006 Elsevier B.V. All rights reserved.

(44). The program significantly and persistently increased adherence over a period of 6 months in 51 patients compared with 49 controls (who used penicillamine without the educational program). Most of the patients (in both groups) had adverse effects, including thrombocytopenia in two and myasthenia gravis in one. The number of patients who asked to have penicillamine withdrawn was far higher in the control group ($n = 12$) compared with the patient education group ($n = 2$). Taste disturbances, for example, led to self-withdrawal in four patients, all in the control group. On the other hand, the patients in the patient education group were much more reluctant to withdraw, even in the event of serious adverse effects.

Dose relation

In a comparison of high doses (750–1000 mg/day) and low doses (125 mg every other day) of penicillamine in the treatment of early diffuse systemic sclerosis, there were no differences in efficacy (45). However, 16 of the 20 adverse event-related withdrawals were in the high-dose group. Seven of the 34 patients in the high-dose group had proteinuria (over 1 g/day) compared with only one of the 32 patients in the low-dose group. On the other hand, and in accordance with previous experience (SED-14, 723), other recorded adverse reactions, including myasthenia gravis, flu-like illness, thrombocytopenia, stomatitis, and rash, were only slightly more common in the high-dose group.

Time-course

Certain adverse effects occur predominantly during the first few months of treatment, for example taste alterations and non-specific hypersensitivity reactions, whereas others are more frequent during the second half-year of treatment (thrombocytopenia, proteinuria) or become apparent even later (for example collagen insufficiency). However, almost the entire spectrum of possible adverse reactions can occur at any time and without warning throughout a course of treatment with penicillamine. Although different schemes may be used, the monitoring of penicillamine treatment usually includes regular testing of platelet and white cell counts, a blood smear, proteinuria, and hematuria.

Organs and Systems

Cardiovascular

Penicillamine has no direct effect on the cardiovascular system. However, penicillamine-associated polymyositis can involve cardiac muscle and cause dysrhythmias, Adams–Stokes attacks, and death. Necrotizing vasculitis can occur as an immunological reaction to penicillamine (46). The effect of penicillamine on collagen and elastin fibers, which causes characteristic skin lesions, also includes the vascular wall, but effects of vascular insufficiency have not been reported.

Respiratory

Although penicillamine has no direct effects on the lungs (47), its use is associated with a spectrum of pulmonary injury: interstitial and alveolar reactions, pulmonary fibrosis, bronchiolitis obliterans, and pulmonary/renal syndromes (48–52). However, the differentiation between drug reactions and pulmonary disorders secondary to rheumatic or other underlying diseases is often difficult. The clinical presentation of bronchiolitis obliterans is acute, with cough, shortness of breath, and other non-specific respiratory complaints. The prognosis is often poor. Two separable but overlapping groups have been described: acute and chronic cellular bronchiolitis with less conspicuous scarring, and constrictive bronchiolitis, with histology varying from fibrotic and inflammatory lesions to complete small airway obliteration (SED-12, 539) (51,53–55).

In addition, several autoimmune reactions to penicillamine can secondarily affect pulmonary function. Penicillamine-induced polymyositis (56) or myasthenia gravis can cause respiratory failure, even requiring ventilatory support (57). The diagnosis and management of lupus-induced pleurisy have been reviewed (58).

Alveolar hemorrhage can occur with penicillamine, usually as part of a life-threatening pulmonary-renal syndrome resembling Goodpasture's syndrome (59,60).

Rhinitis, bronchospasm, and asthma can occur as a manifestation of hypersensitivity to penicillamine (SEDA-5, 248) (61–63) and rarely of the Churg–Strauss syndrome (64). Rhinitis can also be a symptom of penicillamine-induced pemphigus (65). In one patient a large pulmonary cyst developed concomitantly with skin lesions characteristic of the use of large doses of penicillamine (66). Microscopic derangement of the elastic fibers predominated. Although the frequency is uncertain, penicillamine can be associated with recurrent respiratory tract infections, that is secondary to IgA deficiency (67,68) or as part of the "yellow nail syndrome" (SEDA-9, 223).

Nervous system

Penicillamine, both L-penicillamine and the racemic mixture, strongly inhibit pyridoxal-dependent enzymes, cause pyridoxine deficiency in animal experiments, and are neurotoxic. Although this effect is much weaker with D-penicillamine, a few case reports have shown that D-penicillamine can also occasionally cause a polyneuropathy, as either a toxic or an allergic reaction (69–72). Rarely, an optic neuropathy (73) or a polyradiculoneuropathy (Guillain–Barré syndrome) (74,75) can occur.

When penicillamine is started in patients with Wilson's disease, pre-existing neurological involvement can acutely worsen; convulsions, muscle spasms, and coma can occur and death can follow (76–81). Worsening of neurological symptoms after starting therapy with penicillamine can occur in up to 50% of neurologically affected patients with Wilson's disease (79,80) and penicillamine can precipitate serious neurological injury in previously asymptomatic patients (82,83). It is uncertain if this results from alterations of copper distribution at submolecular, subcellular, transcellular, or transorganic levels, or whether it results from some other property of penicillamine (for example its capacity to donate sulfhydryl groups). Since the initial damage may be caused by copper decompartmentalization, it has been suggested that pretreatment with lipid-soluble antioxidants, such as vitamin E, may be useful (77), whereas at least some of these effects may reflect secondary pyridoxine deficiency. Supplementary oral pyridoxine may be advisable (80).

© 2006 Elsevier B.V. All rights reserved.

Two patients have been described with the internuclear ophthalmoplegia syndrome, probably induced by penicillamine. In one it was secondary to serious progressive intracerebral necrotizing vasculitis (46), in the other the underlying condition was a myasthenic reaction (84). Isolated cases have been described of neuromyotonia (85) and diffuse fasciculations (86), attributed to penicillamine.

Myasthenia

Penicillamine can induce a myasthenia gravis-like reaction, indistinguishable from idiopathic myasthenia gravis (33,57,82,87–101). It develops in up to 4% of patients using penicillamine, is most often described in patients with rheumatoid arthritis, but can also occur with other indications (for example biliary cirrhosis (102) or eosinophilic fasciitis (103)). However, it reportedly does not occur in Wilson's disease (104). The reaction often starts with involvement of ocular muscles, but any striated muscle can become involved. In contrast to other drug causes, it is characteristic of penicillamine-related myasthenia that about 90% of patients have antiacetylcholine receptor antibodies (101). The antigenic properties of circulating acetylcholine receptor antibodies in penicillamine-induced and idiopathic myasthenia are similar to those in recent-onset cases of spontaneous myasthenia gravis (92,99). Antistriational and antinuclear antibodies (105) can be present, and a sensitive immunoassay for striational autoantibodies can be used to monitor patients taking penicillamine for the development of myasthenia (94). In one study, measurement of acetylcholine receptor antibodies was considered to be of little or no use in routine monitoring of patients using penicillamine, because in 20% of patients antibodies were detected at least on one occasion, although none of the patients had signs or symptoms of myasthenia, and the antibody tests returned to normal despite continuation of the drug (106). Others have advised annual monitoring of every patient taking penicillamine, to detect subclinical changes in neuromuscular transmission and by acetylcholine receptor antibody testing (107,108).

- A 68-year-old woman, with HLA type DR1+, had been taking penicillamine (dose not specified) for 9 months for erosive seropositive rheumatoid arthritis (109). T cell clones were highly specific for D-penicillamine, but not for L-penicillamine or D-cysteine, and were restricted to HLA DR1. They responded well to blood mononuclear cells prepulsed with D-penicillamine but not to autologous B cell lines pulsed with D-penicillamine.

Apparently, penicillamine can couple directly to distinctive peptides resident in surface DR1 molecules on circulating macrophages or dendritic cells. In another article, apparently concerning the same patient, the same group described the selection of T cell clones specific for the ϵ (rather than the α or γ) subunit, responding to peptide ϵ 201–219 (110). They were restricted to HLA-DR52a (a member of the strongly predisposing HLA A1-B8-DR3 haplotype). Since these T cells had a pathogenic Th1 phenotype with the potential to induce complement-activating antibodies, they could be important targets for selective immunotherapy. In another patient, penicillamine-related myasthenia gravis developed simultaneously with polymyositis and pemphigus (111).

In spite of the similarities, there are some differences between spontaneous and penicillamine-induced myasthenia in respect to genetics. Myasthenic reactions to penicillamine appear to occur in a special genetic subgroup of patients, in whom there is a higher prevalence of the HLA antigens DRI and Bw35, and a lower prevalence of the antigens DR3 (which is associated with idiopathic myasthenia) and DR4 (which is increased in rheumatoid arthritis) (112,113).

Myasthenia usually improves rapidly after withdrawal of penicillamine, but it may have a protracted course. Fatal cases have occurred. Unrecognized myasthenia can present with prolonged paralysis after general anesthesia. For this reason, for patients taking penicillamine undergoing anesthesia the same precautions are advisable as for patients known to have myasthenia gravis (114). Penicillamine unexpectedly caused myasthenia gravis when present as an unrecognized adulterant in Chinese herbs (33).

Sensory systems

Alteration or loss of taste is a characteristic adverse effect of penicillamine. Depending on the dose used, taste impairment (dysgeusia) occurs in 10–25% of patients and when daily doses in excess of 900 mg are used this increases to over 50% (SED-11, 466) (23,115). It usually develops in about the sixth week of treatment. Patients complain of requiring increasing amounts of sugar and spices. Food does not taste normal, but salty or metallic, or like cotton wool or blotting paper. Identification of certain foods becomes difficult. Absolute taste loss can ensue but the sense of smell is unaltered. Spontaneous recovery usually follows within 6–8 weeks, despite continuation of the drug. Dysgeusia can occur at any time and can be persistent (116).

In a review of drug-induced olfactory disorders, penicillamine was mentioned as a cause of abnormal smell (117). However, there may have been confusion with its effect on taste.

In patients with Wilson's disease, penicillamine is rapidly attached to copper and, although higher doses are used, taste disturbances develop in a lower frequency, about 4% (SED-8, 536). It has been suggested that dysgeusia is related to deficiency of copper or zinc, but a strong connection between taste impairment and urinary copper excretion has not been demonstrated (118). Serum copper concentrations remained within normal limits and copper supplements were not effective in prevention (119).

In another study, there was an association with reduced serum zinc concentrations, and taste recovered after zinc supplements were given, although it should be remembered that spontaneous recovery occurs in most patients (120).

Taste alterations have been reported with other sulfhydryl compounds, including pyritinol, captopril, and propylthiouracil (121), suggesting that the thiol moiety is involved. However, dysgeusia has not been observed in many studies on the use of penicillamine in children (SEDA-7, 258) (122).

© 2006 Elsevier B.V. All rights reserved.

Optic neuropathy has only rarely been reported in association with penicillamine (73). In one patient, blurred vision occurred as a result of the development of bilateral choroidal hemorrhage complicating penicillamine-induced thrombocytopenia (123).

Ocular pseudotumor has been described in one patient as part of an ANCA-positive vasculitis (124).

Endocrine

A few patients are on record with suspected penicillamine-induced thyroiditis, one case being associated with a myasthenic reaction (125,126).

Metabolism

Penicillamine had a small effect on urinary glucaric acid excretion in patients with rheumatoid arthritis (127). This effect was thought to be the result of an indirect effect on hepatic metabolism and not to be related to disease activity.

Anti-insulin antibodies and hypoglycemia

One of the remarkable autoimmune phenomena that penicillamine can cause is the induction of anti-insulin antibodies, with resultant hypoglycemia (autoimmune hypoglycemia) (128,129). In these patients, there are high concentrations of immunoreactive insulin, despite undetectable free insulin. When penicillamine is withdrawn antibody titers fall sharply. The occurrence of hypoglycemia rather than hyperglycemia is not fully understood (130).

In two previously well-controlled diabetic patients taking penicillamine who developed hypoglycaemia, no reference was made to anti-insulin antibodies (131).

In a study using a competitive radiobinding assay, as many as 43% of patients with rheumatoid arthritis using penicillamine had autoantibodies against insulin (132). These antibodies did not appear to affect pancreatic beta-cells, as the response to intravenous glucose was normal and there were no episodes of hypoglycemia. Other sulfhydryl compounds that have occasionally been reported to cause autoimmune hypoglycemia are tiopronin, pyritinol, and thiamazole (methimazole) (133).

Enzyme inhibition

In in vitro studies penicillamine inhibited angiotensin-converting enzyme (ACE) and carboxypeptidase (134). Penicillamine interferes with the functions of the copper-containing enzyme ceruloplasmin, and some of the penicillamine- and copper-containing complexes formed in vivo have a superoxide dismutase effect (2). In patients with scleroderma, penicillamine normalized collagen metabolism, by inhibiting beta-galactosidase activity (135).

Nutrition

L-penicillamine strongly inhibits pyridoxal-dependent enzymes and causes pyridoxine deficiency in animals. Although D-penicillamine is much less active in this respect, there is some reduction in pyridoxine, and in a report of penicillamine-associated polyneuropathy, pyridoxine supplements for patients receiving D-penicillamine were advised (69).

Metal metabolism

Penicillamine is a potent chelator of metals. The stability of complexes of metals with penicillamine varies in the following order (from highest to lowest): mercury, lead, nickel, copper, zinc, cadmium, cobalt, iron, manganese (136–138). Most human data refer to copper, lead, and mercury.

Because of the strong affinity of penicillamine for copper and other metals, it is used in the treatment of Wilson's disease and lead poisoning. In other patients, however, this effect may sometimes cause deficiencies (SED-8, 531), especially of copper (SEDA-10, 223). Copper deficiency has been thought to play a role in the occasionally reported alopecia and in the loss of taste that is often experienced by patients with rheumatoid arthritis taking penicillamine (but rarely in Wilson's disease), but this could not be confirmed (118).

Penicillamine-induced deficiency of both copper and iron has been held responsible for the development of anemia (139), but serum iron concentrations do not usually change in patients using penicillamine (SED-8, 535).

The influence on metals such as copper and zinc may be difficult to assess, since penicillamine not only increases the excretion but also the absorption of these metals (140). A zinc deficiency syndrome, with skin lesions, alopecia, granulocytopenia, and eye damage, has been described in association with penicillamine (141).

Hematologic

The pathogenesis of hematological reactions to penicillamine is uncertain, but the available evidence suggests that pharmacological as well as immunological processes may be involved (142–144).

In the ARAMIS PMS Program, hematological events regarded as adverse effects of penicillamine, calculated per 1000 person-years, were as follows: pancytopenia 10, low white blood cell count 8, low platelet count 18, and polycythemia 2 (145). Serious blood dyscrasias, although rare, are among the most important adverse effects of penicillamine (SED-12, 541) (146,147). The assessment of the frequency of penicillamine-related hematological reactions can be hindered by the use of other potentially hemotoxic drugs, such as analgesics or gold compounds.

Eosinophilia can occur in up to 25% of patients using penicillamine, but is of little value in predicting serious hypersensitivity reactions (148).

Thrombocytopenia occurs in about 10–16% of patients and requires withdrawal in up to 10% (22,23,115), but these percentages vary considerably, presumably reflecting the use of different doses of penicillamine and different definitions of thrombocytopenia. In a series of 309 spontaneous case reports of drug-related thrombocytopenia, penicillamine was the fifth most common cause (18 cases, 6%) (149). The fall in platelet count is usually transient, but it is occasionally a warning of impending profound and dangerous thrombocytopenia or other serious hematological reactions, such as aplastic anemia or thrombotic thrombocytopenic purpura. Thrombocytopenia mainly develops during the first 6 months of penicillamine administration and appears to be associated with certain HLA antigens (DRA4, A1, C4BQO). Platelet counts fall to some extent in about 75% of patients taking penicillamine

© 2006 Elsevier B.V. All rights reserved.

and it can be difficult to decide when to withdraw it. Platelet counts are recommended initially at 2-weekly intervals and subsequently each month, in addition to clear instructions to the patient. Weekly checks are needed when counts fall to between 100 and 70×10^9/l, and daily checks when below 70. If the platelet count falls progressively or falls below 70×10^9/l penicillamine should be immediately withdrawn (150).

In all but one of 26 children with Wilson's disease who were treated with penicillamine 20 mg/kg/day, there were fewer adverse reactions than expected: two patients developed a rash, one patient had to stop taking the drug because of a lupus-like syndrome, and another had thrombocytopenia, which resolved after treatment with prednisone (151).

Concurrent thrombocytopenia and anemia have been attributed to penicillamine (152).

- A 66-year-old woman had taken penicillamine 200 mg/day for 8 months for long-standing systemic sclerosis, together with erythromycin (800 mg/day) for prophylaxis of pulmonary infection. Her platelet count was 39×10^9/l and her hemoglobin concentration 7.3 g/dl. The leukocyte count was 3×10^9/l with a normal differential count. There was no hemolysis. A bone marrow aspirate showed mild hypoplasia and reduced megakaryopoiesis. Incubation with penicillamine produced inhibition of erythroid and megokaryocyte burst-forming units, but not of granulocyte/macrophage colony-forming units, suggesting a selective effect of penicillamine on erythropoiesis and megakaryopoiesis. The blood cell counts recovered gradually on withdrawal of both penicillamine and erythromycin, treatment with corticosteroids, and a blood transfusion.

The authors did not make reference to the effects of incubating the bone marrow with erythromycin.

There have been several cases of thrombotic thrombocytopenic purpura or Moschcowitz's syndrome, characterized by intravascular coagulation, thrombocytopenia, and hemolysis, as a rare but life-threatening complication of penicillamine (153–156). There is one case report of Evans' syndrome, thrombocytopenic purpura in combination with autoimmune hemolytic anemia, in suspected association with penicillamine (157). In this patient antiplatelet antibodies as well as antibodies against erythrocytes were detected.

Penicillamine can cause other serious hematological reactions such as agranulocytosis and aplastic anemia (27,144,146,158–167).

- Pure red-cell aplasia developed in a 40-year-old woman as a rare idiosyncratic hematological reaction to penicillamine (105). Withdrawal of the drug, which had been taken in a daily dose of 500 mg for rheumatoid arthritis, and a short course of glucocorticoids was followed by permanent recovery.

Sideroblastic anemia has been attributed to penicillamine (168).

Because of its effect on ceruloplasmin and, in turn, the utilization of stored iron, penicillamine is considered to be able to cause iron deficiency anemia (139,169,170).

Penicillamine can also cause hemolytic anemia (SEDA-8, 535) (171), although good clinical evidence of this is lacking. A positive Coomb's test can occur as part of a lupus-like syndrome (172).

Polycythemia (145), leukocytosis, and thrombocytosis have been mentioned in association with penicillamine, but data are lacking.

Mouth and teeth

Stomatitis is a troublesome adverse effect of DMARDs. Ulcers of the oral mucosa are not uncommon in patients taking penicillamine (188,173) and lead to withdrawal in 3.1% of patients (174). However, stomatitis may be a consequence of multiple factors, including hematinic deficiency, virus or Candida infection, recurrent aphthous ulceration, or Sjögren's syndrome. Moreover, aphthous stomatitis often occurs in users of non-steroidal anti-inflammatory drugs (175).

When high doses are used, stomatitis may reflect impaired collagen synthesis. In one patient, mucosal ulcers were associated with leiomyomatosis in the peripheral serosa, which in turn caused intestinal obstruction (176). In another patient taking penicillamine for Wilson's disease, the removal of an impacted maxillary third molar was followed by the development of an oroantral fistula, presumably as a result of impaired collagen synthesis and disturbed wound healing (177). Furthermore, oral ulcers may be an important warning sign of penicillamine-induced agranulocytosis.

Cheilosis has also been reported (178). Oral lesions in patients using penicillamine may be due to pemphigus, cicatricial pemphigoid, or lichen planus, even in the absence of lesions outside the oral cavity. In 56 consecutive patients taking penicillamine, oral lichen planus was found in as many as seven (179). Penicillamine-induced cicatricial pemphigoid can be associated with oral ulcers as well as lesions of the esophagus, and stenosis can develop.

Gastrointestinal

Gastrointestinal complaints, including nausea, vomiting, heartburn, abdominal distress, and diarrhea, occur in up to one-third of patients starting penicillamine and may account for up to half of the withdrawals in the first 3 months of treatment (SED-12, 541) (22,23,173). However, penicillamine is not known to be ulcerogenic (SED-8, 535) (SEDA-2, 217) (180), and the nature of gastrointestinal effects is not clear. Gastrointestinal symptoms are less frequent with initially low doses that are slowly increased. Taking penicillamine with food improves tolerance but reduces its absorption.

- A woman taking penicillamine developed dysphagia, heartburn, and weight loss; numerous large aphthoid ulcers were found in the esophagus (181).

Sulfhydryl compounds can damage the gut mucosa, but examination of the mucosa of cysteinuric patients who reported gastrointestinal upsets while taking penicillamine showed no evidence of structural damage (182).

Although less well documented than with gold, penicillamine can also occasionally cause life-threatening colitis (183).

© 2006 Elsevier B.V. All rights reserved.

Liver

Several case reports have demonstrated that penicillamine can cause liver damage (SEDA-13, 199) (184), mainly cholestatic hepatitis, often associated with other signs of hypersensitivity such as fever, rash (185), and pulmonary (159,186) or hematological reactions (162). In two children with Wilson's disease, penicillamine was thought to have caused persistence of a pre-existing increase in aminotransferase activity (187).

- A 30-year-old Japanese man with polyarthritis, in whom sodium aurothiomalate for 3 years had been ineffective, was given penicillamine 200 mg/day (188). After 10 days he became febrile and 2 days later jaundiced. A lymphocyte stimulation test against penicillamine was positive, suggesting type IV hypersensitivity. Later on he had a good response to tiopronin, without further adverse reactions.

In 29 Chinese patients, there was evidence in one that DMARDs and chronic viral hepatitis have synergistic hepatotoxic effects (189). However, the relevance of this anecdotal observation is uncertain.

Copper and iron are both capable of electron exchange and play a complex role in oxygen utilization. Copper proteins are critical in the transfer and transport of iron (190). In four patients with Wilson's disease, the fall in serum ceruloplasmin concentrations after treatment with penicillamine was associated with increased hepatic iron content; in two of these patients serum ferritin was increased (191). In another patient a liver biopsy taken after 15 years of treatment with penicillamine and zinc showed iron-laden hepatocytes, whereas histochemically detectable iron had been absent from an initial biopsy (192). The copper-containing protein ceruloplasmin and its membrane-bound homolog hephaestin are pivotal in iron metabolism. In addition there are intracellular transfer proteins ("chaperones") that deliver copper to ferroxidase proteins. Intracellular ferroxidase proteins accelerate the efflux of iron through stimulating the conversion of Fe^{2+} to Fe^{3+} and subsequent binding to transferrin. Presumably, excess loss of copper due to penicillamine or penicillamine plus zinc can reduce ferroxidase activity and cause intracellular iron deposition and paradoxical deterioration in liver function. Therefore, during treatment of Wilson's disease when the non-ceruloplasmin-bound copper falls to within the reference range (<150 ng/ml), the maintenance dose of penicillamine should be reduced to the minimum needed; temporary withdrawal of penicillamine may even be indicated (190).

Pancreas

There have been three poorly documented cases of pancreatitis attributed to penicillamine (SED-8, 385) (SEDA-2, 217).

Urinary tract

Penicillamine is often associated with renal damage. Proteinuria occurs in about 10–25% of patients taking penicillamine (SED-11, 464) (22,23,115,145,193–196) and occurs in 50% of patients with cysteinuria (SEDA-8, 236). However, microalbuminuria is common in patients with rheumatoid arthritis and may reflect either rheumatoid nephropathy or renal injury caused by penicillamine (or other drugs, such as gold compounds) (197). In about 5% of patients, proteinuria is the reason for withdrawing penicillamine. To avoid renal damage, response-dependent prescribing is recommended in rheumatoid arthritis, starting with a low dose and making increments at intervals of at least 1–2 months. Frequent urine testing is necessary, particularly during the first 18 months. Mild proteinuria (<1 g/day) occurs most frequently, is often transient, and may be coincidental. Moderate proteinuria may be penicillamine-induced but need not be progressive or clinically harmful; close monitoring is indicated in such cases, and a temporary reduction in dose is advisable, although withdrawal of penicillamine may not be needed. When proteinuria increases, nephrotic syndrome can develop, necessitating withdrawal (198). In cysteinuria it is advisable to withdraw penicillamine when proteinuria exceeds 5 g/day (199), but in rheumatoid arthritis a lower limit of 2 g/day has been proposed (200). Nephropathy mainly develops during the second 6 months of treatment with penicillamine (200). It is more frequent in patients with a low sulfoxidation capacity (3,201) and with the HLA antigens DR3 and B8 (SEDA-11, 212) (202). Although nephropathy is thought to be rare in Japanese people (SEDA-8, 235) (25), it has been encountered in Japan (203).

In a comparison of high doses (750–1000 mg/day) and low doses (125 mg every other day) of penicillamine in the treatment of early diffuse systemic sclerosis, seven of the 34 patients in the high-dose group had proteinuria (over 1 g/day) compared with only one of the 32 in the low-dose group (45). Rheumatoid arthritis is a risk factor for renal disease, and the distinction from adverse drug reactions can be difficult in these patients (SED-14, 729).

On the basis of experience in one patient and 10 published case histories, the "scleroderma-pulmonary-renal syndrome," a rare and usually fatal complication of systemic sclerosis, characterized by fulminant alveolar hemorrhage and rapidly progressive renal insufficiency, has been reviewed (204). In their patient penicillamine was continued, and the disease progressed. Five of the 11 patients in their review had been using penicillamine.

In a prospective study of renal disease in 235 patients with early rheumatoid arthritis, persistent proteinuria and a raised serum creatinine concentration were predominantly related to drugs, including penicillamine and other DMARDs, whereas isolated hematuria was more directly associated with the activity of the disease process (205). Risk factors for drug-induced proteinuria were raised C-reactive protein, raised erythrocyte sedimentation rate, and age over 50 years.

Of 44 patients with rheumatoid arthritis, 24 had proteinuria (206). Two of these had drug-related nephropathy (penicillamine and gold, respectively); both had nonselective tubuloglomerular proteinuria, type V.

The principal renal lesion associated with proteinuria is membranous glomerulopathy or minimal-change glomerulopathy (196,201,207,208), characterized by minor thickening of the basement membrane or no change on light microscopy, but striking disturbances of the glomerular

© 2006 Elsevier B.V. All rights reserved.

structures on electron microscopy (fusion of epithelial cell foot processes, subepithelial electron-dense deposits, and mesangial cell hyperactivity). Immunofluorescence microscopy shows granular deposits that contain IgG and C3 (209). These immunoglobulin deposits are not the result of precipitation of circulating immune complexes, as was previously thought. The available evidence suggests that the nephritogenic antigen, although still not identified, is expressed in the glomerulus and the immune complexes are formed in situ (207,210). Although proteinuria may be profound, serum creatinine is usually unaltered and penicillamine glomerulopathy usually has a good prognosis. Proteinuria can nevertheless continue for longer than 12 months after withdrawal and microscopic lesions can persist for longer. Although penicillamine nephropathy is more frequent when high doses are taken, it can also occur with small doses (for example 125 mg/day). On rechallenge, nephropathy does not necessarily relapse (SEDA-10, 218), and a history of previous gold nephropathy is not thought to be a risk factor (203). In one study, titers of antigalactosyl antibodies were correlated with the prior development of penicillamine (or gold) nephropathy (211).

Occasionally, penicillamine-associated renal injury is proliferative and progressive, extending beyond the basement membrane, with crescent formation in the glomeruli, and encompassing other renal structures, for example in the case of renal vasculitis, IgM nephropathy (212), or as part of a more general reaction; persistent renal insufficiency can develop and death can follow (196,213–218).

Penicillamine-induced lupus-like syndrome can be associated with proliferating glomerulonephritis with mesangial involvement and interstitial infiltrates (213,219). In such cases antibodies to native DNA can be found.

A rare but life-threatening complication of penicillamine is the development of a Goodpasture's syndrome-like reaction, characterized by alveolar hemorrhage, crescentic glomerulonephritis, and fever (59,220–224). In contrast to genuine Goodpasture's syndrome, circulating antiglomerular basement membrane antibodies are not detected (222), perhaps because the antigen concerned is not present in the test extracts used (223). Patients who have taken immunosuppressive therapy have a comparatively good outcome, but plasmapheresis and hemodialysis may be needed (220).

Serious renal injury can develop as a late complication of pre-existing benign penicillamine nephropathy (220,225). Unfortunately, microscopic hematuria has limited predictive value for imminent serious renal injury, since in most patients who take penicillamine it is a transient or coincidental finding (SEDA-7, 260). The diagnosis of penicillamine-induced renal injury is often difficult because of the frequent association of rheumatoid arthritis with renal disorders (198,204,226–228), including spontaneous membranous glomerulopathy (229), or with injury caused by concomitant analgesics (230).

In a comprehensive study of 158 Japanese patients with rheumatoid arthritis, there was an obvious relation between membranous nephropathy and exposure to disease-modifying antirheumatic drugs (DMARDs) in 40 of 49 patients (231). In this study penicillamine (15%), bucillamine (67%), and gold compounds (17%) clearly predominated.

A patient with nephrotic syndrome that developed soon after the start of treatment with penicillamine has been described in detail (232).

- A 12-year-old boy with a history of a generalized pruritic rash after penicillin took penicillamine up to 500 mg/day for Wilson's disease. He had a rash after using penicillamine for 1 week. The penicillamine was stopped for 3 days. He developed nephrotic syndrome 2 weeks after restarting penicillamine. On electron microscopy, there was the typical picture of minimal change disease with extensive foot process effacement.

In rare cases penicillamine can cause extracapillary glomerulonephritis with more extensive and serious glomerular injury leading to progressive and persistent renal insufficiency. One such patient has been described with a review of 26 similar published cases (233).

- A 51-year-old woman, who used penicillamine, maximum dose 600 mg/day, for systemic sclerosis, developed microscopic hematuria after 11 months. The penicillamine was withdrawn. Three months later she had progressive renal insufficiency. A biopsy showed extracapillary glomerulonephritis, with central fibrinoid necrosis and segmentary mesangial proliferation, and marked tubulointerstitial lesions. After treatment with glucocorticoids, cyclophosphamide, and 12 plasma exchanges her renal function improved slightly.

In half of the 26 patients renal damage was associated with alveolar hemorrhage (233). In eight patients plasma exchange treatment was performed. Seven patients died, including four with alveolar hemorrhage; 12 ended up with more or less chronic renal insufficiency. Only seven patients regained normal renal function; five of these had had plasma exchange.

- Acute renal insufficiency together with diffuse alveolar hemorrhage and bilateral pulmonary infiltrates was suspected to have been caused by penicillamine (500 mg/day for 6 months) in a 34-year-old white woman, who took penicillamine for progressive systemic sclerosis (234). Because of disseminated intravascular coagulation, a biopsy was not made and the role of penicillamine remained uncertain.

Hemolytic–uremic syndrome has been described in a patient with paradoxical rapid progression of systemic sclerosis (235).

- A 58-year-old man with a complex history of Hashimoto's thyroiditis and mixed cellularity Hodgkin's disease in complete remission developed systemic sclerosis involving the skin and the lungs but not the kidneys. He was given penicillamine 250 mg/day and prednisone 60 mg/day. After a few weeks there was rapidly progressive skin thickening, spreading from the hands to the trunk. However, his treatment was not altered, and 4 months later he developed hemolytic–uremic syndrome with microangiopathic hemolytic changes, thrombocytopenia, and acute renal insufficiency, with proteinuria, hematuria, and granular casts in the urine. The renal insufficiency persisted and he died with fulminant sepsis.

© 2006 Elsevier B.V. All rights reserved.

Three case reports from Belgium and France have illustrated the fact that rarely proliferative crescent-forming extracapillary glomerulonephritis and renal insufficiency can also occur (236,237). All three patients had taken penicillamine for systemic sclerosis. Antimyeloperoxidase antineutrophil cytoplasm antibodies were found in all three; one patient also had alveolar hemorrhage (that is Goodpasture's syndrome).

A clinical algorithm for the management of hematuria, for example in patients taking penicillamine or NSAIDs, has been published (238). It should be borne in mind that in such patients hematuria may be symptomatic of underlying pathology (for example a tumor of the urinary tract).

In one study in children with low-level lead poisoning, urinary incontinence was mentioned as a suspected adverse effect of penicillamine (239).

Skin

There is probably no other medicine that causes skin reactions with such a high frequency and of such striking diversity as penicillamine (see Table 2).

During the first few weeks of treatment, allergic reactions occur in about one patient in five (SED-11, 465) (25).

Maculopapular or urticarial rashes are frequent and can be associated with pruritus, edema, lymphadenopathy, arthralgia, fever, and eosinophilia. Patients with previous hypersensitivity to penicillin are more likely to experience a rash when taking penicillamine. Cross-allergy to penicillin can occur, but the risk of a severe allergic reaction to penicillamine in penicillin-allergic patients is thought to be low (240,241). Skin reactions may be more common in the presence of the HLA antigen DRw6 (242), and rashes and febrile reactions were more frequent in patients with anti-Ro(SSA) antibodies (243). Early allergic reactions do not usually necessitate permanent withdrawal of penicillamine, and can often be overcome by lowering the dose or by timely withdrawal of the drug and the use of a glucocorticoid. On the other hand, a non-specific eruption can be the first sign of a serious penicillamine-induced skin disorder, for example pemphigus.

Table 2 Penicillamine-associated skin disorders

Maculopapular or urticarial rashes
Seborrheic dermatitis
Lichen planus-like eruptions
Psoriasiform eruptions
Erythema annulare
Photosensitivity
Pemphigus (erythematosus, foliaceus, vulgaris)
Bullous pemphigoid
Cicatricial pemphigoid
Dermatomyositis
Graft-versus-host reactions
Systemic lupus-like syndrome
Discoid lupus; subacute cutaneous lupus
Erythema multiforme and toxic epidermal necrolysis
Tardive dermopathy (friability, miliary papules, hemorrhagic bullae)
Elastosis perforans serpiginosa
Pseudoxanthoma elasticum
Cutis laxa (hyperelastica)
Cutaneous pseudolymphoma
Acantholytic dermatosis (Grover's disease)

There were no serious adverse reactions in 55 children who received 66 courses of low-dose penicillamine (about 15 mg/kg/day for a mean period of 77 days) for mild to moderate lead poisoning (244). However, in three children penicillamine was withdrawn because of a transient rash.

Paradoxically, penicillamine is occasionally involved in the development of rare diseases for which it is also sometimes used, such as systemic sclerosis-like lesions (245) and circumscribed scleroderma (or morphea) (246,247).

A rash or photosensitivity can also occur as part of the penicillamine-induced lupus-like syndrome (248–250). Type II bullous systemic lupus erythematosus (251) and necrotizing vasculitis (46) have been attributed to penicillamine. In one report, a hypersensitivity reaction to penicillamine with a skin rash and fever was associated with low back pain (252).

Erythema multiforme and toxic epidermal necrolysis are considered to occur as adverse reactions to penicillamine (SEDA-12, 465) (167).

Various other skin lesions have been described.

- In one inconclusive case report acantholytic dermatosis (Grover's disease) was described as a suspected adverse reaction to penicillamine (253). This is a papulovesicular eruption in elderly people, characterized histologically by focal acantholytic dyskeratosis.
- In a female patient acne and hirsutism developed in association with breast enlargement, probably induced by penicillamine (254).
- In a 31-year-old Korean woman with Wilson's disease, high doses (1–2 g/day) of penicillamine led to the development of a dermopathy, with mildly itchy, matchhead-sized, cream-colored papules on top of dark reddish plaques on both knees and elbows (255).

Penicillamine can cause localized scleroderma (also known as morphea), which has been reviewed (257). Bullous lesions can occur in scleroderma (localized, generalized, or systemic), and this highlights the diagnostic problems in such patients (258). In one of the four case histories presented in this paper, the bullous eruption, in a patient taking penicillamine for systemic sclerosis, was diagnosed as penicillamine-induced pemphigus foliaceus.

- A man with a history of penicillin allergy developed a hypersensitivity reaction of the penis when his wife was taking penicillamine (259).

Effects on collagen and elastin

When penicillamine is administered for a long time and in high doses (for example for Wilson's disease) it can cause a characteristic delayed skin eruption, with increased friability, hemorrhagic bullous lesions, and miliary papules (66,260–266). The lesions develop predominantly in those parts of the skin that are often exposed to trauma. This disorder is a manifestation of the effects of penicillamine on collagen and elastin. Occasionally, these eruptions imitate other rare

© 2006 Elsevier B.V. All rights reserved.

dermatological diseases and take the shape of elastosis perforans serpiginosa, cutis hyperelastica (cutis laxa) (267), or pseudoxanthoma elasticum (268–270); however, the histological and ultrastructural characteristics of the penicillamine variants differ from those of the spontaneous disorders.

In delayed penicillamine skin disorders, abnormal elastic tissue also exists in non-lesional skin, and has occasionally been documented in other organs (lungs, blood vessels, ileum, visceral adventitia, joint tissue), but the clinical implications of these findings are uncertain. In one study, multiple lymphangiectases and bloodvessel-lymphatic anastomoses were observed (263). Clinically manifest impairment of collagen and elastin has been reported in association with much lower penicillamine doses than had previously been recognized (271–273). In five of eight patients receiving penicillamine for rheumatoid arthritis, there was elastic fiber damage in joint capsules, suggesting that penicillamine-associated collagen injury may be common (273), although in only one case there was also elastic fiber damage in a skin biopsy. The fact that the lesions in delayed penicillamine skin disorders concentrate in flexural areas (neck, axillae, antecubital fossae, and buttocks) may reflect the accelerated turnover rate of elastin in these areas, secondary to shearing stresses and stretching. Perhaps impairment of collagen interferes with wound healing.

Presumably, the mechanism underlying penicillamine dermopathy is inhibition by penicillamine of cross-linkage of collagen fibers. In addition, the enzyme lysyl oxidase, required for the cross-linking of collagen fibers, is copper-dependent and may be inhibited by copper chelation by penicillamine. Another argument for a possible role of copper deficiency is the fact that cutis laxa is common in Menke's disease, a rare genetically determined disturbance of copper metabolism. Perforating elastoma occurs when abnormal elastic fibers accumulate, cause a foreign body reaction, and are transepidermally eliminated. Although the patient was also thought to have elastolytic involvement of the lining of the upper respiratory tract, there was no objective evidence of this.

Elastosis perforans serpiginosa, cutis laxa, and pseudoxanthoma elasticum

In rare cases, penicillamine dermopathy mimics elastosis perforans serpiginosa, cutis laxa, or pseudoxanthoma elasticum.

Elastosis perforans serpiginosa

Elastosis perforans serpiginosa starts as red umbilicated papules that coalesce to form annular (serpiginous or arcuate) lesions with clear centres. There are microscopically thickened coarse elastic fibers, extruding through narrow epidermal channels.

- A 37-year-old Japanese woman, who was taking penicillamine (500 mg/day) for systemic sclerosis, developed papules distributed in characteristic arcuate patterns of the skin of her neck (274). Histologically there was transepidermal elimination of degenerative elastic particles.

Cutis laxa

Cutis laxa presents with loose redundant skin folds, reduced elasticity of the skin, and connective tissue involvement.

- An 84-year-old woman, who had been taking penicillamine 1.2 g/day for 50 years for Wilson's disease, developed generalized, rapidly progressive, acquired cutis laxa (275). Faulty production of collagen and elastin fibers lead to gross folding of the skin, giving it an appearance reminiscent of the folds of the cerebral cortex.

In one patient the characteristic features of both of elastosis perforans serpiginosa and cutis laxa developed (276).

- A 36-year-old man, who had had Wilson's disease since the age of 4 years, had used penicillamine for about 13 years in a dosage of 2–3 g/day. He developed an itching papular eruption, which initially resolved after withdrawal of the drug but recurred and progressed 6 months later. Generalized cutis laxa developed, with perforating elastolytic nodules on the neck and elastosis perforans serpiginosa over the shoulders. A biopsy showed perforating channels from the dermis through the epidermis, with a surrounding inflammatory infiltrate and horseshoe-shaped multinuclear giant cells phagocytosing abnormal elastic fibers. Van Giesen staining showed a lumpy-bumpy appearance of elastin fibers, typical of penicillamine dermopathy, as originally described by Bardach et al. (SED-14, 730).

Pseudoxanthoma elasticum

Pseudoxanthoma elasticum is characterized by coalescent yellow waxy papules with a "plucked chicken" appearance (because of the prominence of follicular orifices in the papules) and a marked laxity and wrinkling of the skin, resulting in redundant skin folds. In delayed penicillamine skin disorders gross abnormalities of elastic and collagen fibers are seen on electron microscopy. Elastic fibers have "moth-eaten," "saw-toothed," or "bramble bush thorns" appearances. Collagen fibers show large differences in thickness. Elastic tissue stains show an increase in the number of elastic fibers and irregular serrated fibers. The elastin content of lesional skin is three times greater than normal, whereas the number of elastin cross-links is only 15% of normal. In electron photomicrographs, dermal elastic fibers are studded with multiple perpendicular buds of different sizes and shapes, described as "lumpy-bumpy" and show varying degrees of fragmentation. Aggregations of granular elastinophilic material surround the central core of normal mature elastic tissue. In contrast to spontaneous pseudoxanthoma elasticum there is no calcium deposition in elastic fibers.

- A 47-year-old man had been using penicillamine 1.5 mg/day for 18 years for Wilson's disease. He developed pseudo-pseudoxanthoma combined with dysphagia and dyspnea. Biopsy specimens showed systemic involvement of elastic fibers, including skin, lung, esophageal muscle, gum, and pharyngeal and cervical connective tissue. All biopsies showed abnormal elastic fibers, consisting of a central core of uneven thickness with many lateral arborizations. There were branches at

© 2006 Elsevier B.V. All rights reserved.

right angles to the main fibers, with perpendicular lateral arborizations off these, producing a stag-horn or fractal appearance. On the other hand, the adjacent collagen fibers were normal in structure.

Pseudo-pseudoxanthoma elasticum, caused by the use of high doses of penicillamine, has also been described (277).

Wound healing

In the past, penicillamine, because of its effects on collagen synthesis, has been suspected of interfering with normal wound healing. Experience of 217 operations in 150 patients did not show such effects, and consequently, there does not seem to be a need for stopping penicillamine before surgery (278). On the other hand, a few reports have suggested that penicillamine can, at least in some patients, have deleterious effects on wound healing (177,279).

Pemphigus

Pemphigus is a bullous autoimmune disorder of the skin, characteristically associated with antidesmoglein antibodies. Although many different drugs have been described as a cause of pemphigus, there is a remarkably strong predominance of penicillamine (and other sulfhydryl compounds) (280–283). Three groups of pemphigus-inducing drugs can be distinguished (284):

1. thiol drugs (for example penicillamine);
2. "masked thiol drugs" (sulfur-containing drugs that undergo metabolic changes to form thiol groups, for example piroxicam, beta-lactam compounds);
3. drugs with an active amide group (for example dipyrone, enalapril).

Thiol-related pemphigus usually presents as the foliaceus variant, with comparatively few immunofluorescence findings and a good prognosis, whereas drugs with an active amide group can provoke pemphigus vulgaris with a less favorable prognosis on drug withdrawal. A pemphigus-like eruption (284–297) develops in 1–2% of the users of penicillamine (SEDA-11, 213). Penicillamine is by far the most frequent cause of the drug-related variant.

- A 71-year-old woman taking penicillamine (dosage not specified) developed pemphigus vulgaris rather than pemphigus foliaceus, which is the usual form of pemphigus that penicillamine causes (298). She presented with pustular bullae (due to secondary infection with *Pseudomonas aeruginosa*), and the indication for penicillamine was not rheumatoid arthritis but systemic sclerosis.
- A 64-year-old woman, who had used penicillamine 500 mg/day for 3 years for rheumatoid arthritis, developed a bullous skin eruption affecting her neck and limbs (299). After treatment with prednisolone (dose not specified) she improved, but relapsed when the dose was reduced below 10 mg. Eleven months after the onset of blistering, penicillamine was discontinued and within 2 months the prednisolone was also stopped, with no recurrence of the eruption during 12 months follow-up. Direct immunofluorescence was positive for immunoglobulin G and complement component C3, and indirect immunofluorescence was positive on the roof of the NaCl split skin preparation.

A consultation of the database of the Committee on Safety of Medicines in London showed that 41 cases of bullous pemphigoid have been reported in suspected connection with penicillamine, suggesting that this adverse reaction is less rare that the published literature suggests.

Pemphigus usually recedes when penicillamine is stopped, but can persist for many years (286,296), and recur on rechallenge (300); fatal cases have occurred (301,302). Pemphigus that continues after drug withdrawal is referred to as triggered pemphigus, whereas a reaction that clears soon after withdrawal is called induced pemphigus (285). Although it is usually rapidly reversible, penicillamine-induced pemphigus can run a protracted course (SED-14, 730). In a report from the Netherlands, penicillamine-related pemphigus foliaceus was highly resistant to treatment for 7 years (303). Eventually the intravenous administration of low doses of normal human immunoglobulin (40 mg/kg/day for 5 days in cycles of 3 weeks), together with dexamethasone pulse therapy, led to remission.

The entire clinical and pathological spectrum of pemphigus can occur in association with penicillamine, that is pemphigus erythematosus, pemphigus foliaceus, pemphigus vulgaris, and bullous pemphigoid (297). In this order of sequence the level of blister formation descends from the superficial layers to the deeper layers of the epidermis toward the basement membrane and subepidermal tissue. Penicillamine-induced pemphigus is predominantly of the foliaceus type. As in spontaneous pemphigus, antidesmoglein antibodies are present, although they may not be found in early stages. In pemphigus vulgaris antibodies react with desmoglein 3 and in pemphigus foliaceus with desmoglein 1, suggesting that different antigens are involved (304,305). The antibody reactivity of patients with idiopathic and penicillamine-related pemphigus appeared to be the same (284), which is suggestive of a similar basic molecular mechanism. Sometimes the characteristic lesions of different eruptions, for example pemphigus, bullous or cicatricial pemphigoid, lupus erythematosus, discoid lupus, or seborrheic dermatitis, can be seen in one and the same patient taking penicillamine (SEDA-11, 213) (SEDA-15, 239) (300). This suggests differences in the pathogenic process rather than the simultaneous occurrence of different reactions.

Penicillamine has epidermotropic properties and accumulates in the skin. There are several possible mechanisms involved in penicillamine-induced pemphigus (SED-12, 544):

- penicillamine may cause acantholysis by direct destruction of epidermal intercellular attachment (without pemphigus antibodies) (306–308);
- the drug may induce autoantigens through modification of epidermal differentiation or interaction with epidermal tissues;
- penicillamine may change immunological tolerance, influence T-suppressor cells, and elicit autoimmune responses (280,281).

There is still uncertainty about the precise underlying processes. Apart from a reduced frequency of the rheumatoid arthritis-associated antigen B15, penicillamine-induced

© 2006 Elsevier B.V. All rights reserved.

pemphigus does not appear to be strongly associated with a characteristic HLA antigen pattern (309,310).

Penicillamine-induced pemphigus can pose diagnostic difficulties, for example because it can present as a nonspecific rash, seborrheic dermatitis, erythema annulare (311), isolated stomatitis, or even rhinitis (65). Because of the friability of the superficial blisters, the bullous nature of pemphigus erythematosus and pemphigus foliaceus may be overlooked.

Since beta-lactam antibiotics also appear to be associated with pemphigus, especially ampicillin and amoxicillin, an earlier hypothesis (SEDA-5, 244) that this (and perhaps other reactions) to beta-lactam antibiotics may in fact be induced by the hydrolytic metabolite penicillamine has received attention (280,283).

A rare but potentially serious skin reaction to penicillamine is cicatricial pemphigoid (312,313). These patients can have symblepharon and entropion of the eyes, ulcers in the mouth, and blistering lesions on the trunk, extremities, and perineum (314). Involvement of the esophageal or vaginal epithelium can cause stenosis.

Ulcerative lesions of the vagina can occur in patients taking penicillamine, as a manifestation of pemphigus or cicatricial pemphigoid, or following impaired collagen synthesis (SED-8, 533) (315).

Graft-versus-host-like eruptions

Although rarely described, skin reactions that mimic graft-versus-host disease are an established complication of penicillamine (SED-14, 731). The similarity of the pathology of these drug-induced eruptions to those that occur after bone marrow transplantation has been reviewed (316). The drug-related eruptions may have different manifestations and can, for example, resemble smallpox, lichen planus (317), eczema, or other eruptions (318). However, their histological features are similar to those seen in cutaneous graft-versus-host disease, in particular eruptions in which liquefactive necrosis is seen at the interface between the epidermis and the cutis. One of the possible mechanisms involved in hypersensitivity reactions to sulfhydryl-containing drugs is based on the immune response of T cells to the sulfhydryl group, which arises when binding of IL-2 to the IL-2 receptor induces autoreactive T cells (319). The concentrations of IL-2 and IL-2 receptor were closely associated with the onset and severity of cutaneous graft-versus-host disease, suggesting an etiological similarity between the disease and skin eruptions induced by sulfhydryl-containing drugs. Proliferation of autoreactive T cells is induced by the binding of IL-2 to its receptor in these patients.

With seven cases in 56 consecutive patients taking penicillamine in one study, oral lichen planus may be fairly frequent (179). Most patients have erosive oral lichen planus, but bullous, plaque-like, or "classic" lichen planus can occur. Rarely a psoriasiform eruption has been reported with penicillamine (320).

Hair

Alopecia has occasionally been reported in association with penicillamine (145), but is ill-understood; hair loss can occur in association with polymyositis (321).

Nails

The peculiar yellow nail syndrome (SEDA-9, 223), characterized by dystrophy of the nails, lymphedema, pleural effusion, and bronchial involvement, has occasionally been reported in association with penicillamine and also with bucillamine (SEDA-9, 223) (SED-13, 612) (322–325). It has been suggested that penicillamine and bucillamine, because of their structural similarity to cysteine, might disturb nail growth by interfering with keratin synthesis. Although the nail changes and injury to other organs probably develop by different mechanisms, in patients with nail changes a careful search for possible systemic disorders is needed.

Monosymptomatic nail changes, with longitudinal ridging, transverse or longitudinal defects of the nail plate, absence of lunulae, and a tendency toward onychoschizia, can also occur as adverse effects of penicillamine (326).

Musculoskeletal

Joint symptoms in patients taking penicillamine vary from "creaking" and subjective discomfort and worsening of joint pain to severe arthralgia (327–329). Paradoxical acute severe exacerbation of rheumatoid arthritis has been reported in three patients, probably induced by penicillamine (330). Arthritis can also be a manifestation of penicillamine-induced systemic lupus erythematosus.

Although rare, Wilson's disease may itself be associated with a polyarthritis resembling rheumatoid arthritis and when it develops during the use of penicillamine it can be mistaken for an adverse reaction to the drug (331). Demineralization osteopathy has been reported in a study on the use of D-penicillamine in Wilson's disease (SED-8, 536).

- Progressive eosinophilic fasciitis with muscular involvement in a 35-year-old Brazil woman has been attributed to penicillamine (250 mg/day) (332).

In a prospective analysis of 74 women with systemic sclerosis, low bone mineral density and densitometric osteoporosis were related to the menopause and not to the previous use of penicillamine or other drugs (333).

Reproductive system

Gigantism of the breasts (macromastia) can occur in patients using penicillamine (SEDA-8, 238) (255,334–338). It usually develops in women and very rarely as gynecomastia in men (337,339). There is resemblance to the pubertal form of massive breast enlargement. It can be painful and has been encountered in pre- and postmenopausal women, with normal and increased prolactin concentrations. Histological examination mainly shows increased connective tissue and no changes in the glandular tissue.

- In one patient, the breasts were tender and grew progressively larger during each menstrual period.
- A 55-year-old premenopausal woman took penicillamine 1 g/day for 2 years for localized scleroderma (340). She used no other drugs. She noticed a gradual enlargement of her breasts, from a size B to size D+ bra cup. There were no palpable masses or tenderness. The only abnormal laboratory test finding was a positive test

© 2006 Elsevier B.V. All rights reserved.

for homogeneous antinuclear antibodies (titer < 1:80), which is often found in patients with scleroderma. Serum prolactin was normal. Penicillamine was withdrawn and the breast enlargement regressed over 3 months; the bra cup size reverted to B.

- In a 25-year-old woman with Wilson's disease, treatment with penicillamine (1.5 g/day) was first followed by the development of hirsutism, mainly of the face (255). After she started to use an oral contraceptive, her breasts enlarged rapidly and she experienced cyclic mastodynia; in addition, gingival hyperplasia developed. All symptoms improved on withdrawal of penicillamine, but additional mammoplasty was needed.

The sequence of events in the last patient suggested that the use of the oral contraceptive contributed to the development of macromastia.

In one case breast enlargement was accompanied by systemic lupus erythematosus (341).

- A 37-year-old woman with a 7-year history of rheumatoid arthritis had taken penicillamine for about 1–2 years (dose not specified). When she presented at the Cambridge Breast Unit she had had rapidly increasing painful enlargement of the breasts for 7 months. The breasts were symmetrically enlarged (from an A cup to DD) and had thickened and erythematous skin. There were several palpable masses; mammography showed no evidence of malignancy and an ultrasound scan showed large hypo-echoic nodules with engorged vessels. Histology of a large lump in the left breast showed a fibroadenoma. Immunohistochemistry for estrogen receptors showed 50% nuclear staining. She had stopped taking penicillamine 2 months before because of a lupus-like syndrome with thrombocytopenia, lymphopenia, and positive ANA and DNA antibodies (whether single-stranded or double-stranded was not stated).

Although breast gigantism is a rare manifestation of idiopathic SLE, in this case autoimmune substances could have stimulated mammary duct proliferation or mimicked estrogen or other growth factors in the breast.

Immunologic

Several experimental studies in humoral and cell-mediated immune systems have demonstrated numerous effects of penicillamine on the immune system; these findings are in keeping with a reduction in the overactivity of helper T lymphocyte that is found in rheumatoid arthritis (2,342). There is a fall in the numbers of immunoglobulin-secreting cells, and cultured mononuclear cells produce less IgA, IgG, and IgM. There is suppression of the autologous mixed lymphocyte reaction (343) and reduced hydroxyl radical generation from polymorphonuclear leukocytes (344). Penicillamine reduces the clearance of immune complexes and inhibits the complement cascade (345).

Penicillamine is uniquely likely among therapeutic drugs to cause autoimmune reactions (see Table 3).

Clinically and pathologically these variants of autoimmune disorders are closely similar to or indistinguishable from the spontaneous diseases. A major difference is that the patients usually recover when penicillamine is withdrawn. Differences in HLA configurations also suggest that penicillamine-induced and spontaneous autoimmune disorders occur in different populations.

Table 3 Autoimmune-like reactions reported in suspected association with penicillamine

Pemphigus (erythematosus, foliaceus, vulgaris)
Bullous pemphigoid, cicatricial pemphigoid
Graft-versus-host-like skin eruptions
Myasthenia gravis
Dermatomyositis/polymyositis
Glomerulonephritis
Lupus-like syndrome
Goodpasture's syndrome
Autoimmune hypoglycemia
Thyroiditis
Sjögren's syndrome
Aplastic anemia
Thrombocytopenia
Agranulocytosis
Thrombotic thrombocytopenic purpura (Moschcowitz's syndrome)
Evans' syndrome
Churg–Strauss syndrome
Necrotizing vasculitis
Guillain–Barré syndrome

During penicillamine treatment autoantibodies develop in a high proportion of patients without clinical disease (346). For example, penicillamine can be associated with the development of anticentromere antibodies (347,348). Although these are usually a marker of serious autoimmune diseases, in association with penicillamine, the phenomenon was not accompanied by clinical symptoms and disappeared after stopping the drug.

In the serum of three patients with acute hypersensitivity reactions to penicillamine, complement-binding antibodies against penicillamine were detected (349). Patients with Wilson's disease are not known to have an abnormal immune status. The striking variability of penicillamine-induced pathology, including autoimmune reactions such as SLE, is also seen in patients with Wilson's disease, but the proportion of these patients in whom withdrawal is necessary is smaller, about 2–8% (72,79,80,350).

An unusual case report showed that low back pain can be a manifestation of drug hypersensitivity (253).

Anaphylaxis

Although hypersensitivity reactions are frequent, systemic anaphylaxis has only been reported rarely (351).

ANCA-positive vasculitis

Various vasculitic diseases, including Wegener's granulomatosis, microscopic polyangiitis, Churg–Straus syndrome, and crescentic glomerulonephritis, are associated with antineutrophil cytoplasmic antibodies (ANCA) or leukocytoclastic vasculitis. In drug-induced ANCA-positive vasculitis antimyeloperoxidase antibodies are most often found; they produce a perinuclear pattern of staining by indirect immunofluorescence (pANCA), but antiproteinase 3 (anti-PR3) antibodies can also occur (cANCA).

The possible drug causes of ANCA-positive vasculitis with high titers of antimyeloperoxidase antibodies in

© 2006 Elsevier B.V. All rights reserved.

30 new patients have been reviewed (124). The findings illustrate that this type of vasculitis is a predominantly drug-induced disorder. Only 12 of the 30 cases were not related to a drug. The most frequently implicated drug was hydralazine (10 cases); the rest involved propylthiouracil (three cases), penicillamine (two cases), allopurinol (two cases), and sulfasalazine.

- A 49-year-old woman with systemic sclerosis, taking penicillamine 750 mg/day, developed a vasculitis, with an orbital pseudotumor and, 2 months later, fatal alveolar hemorrhage. She also had antinuclear antibodies with a homogeneous pattern.
- A 56-year-old woman with systemic sclerosis taking penicillamine 750 mg/day had homogeneous antinuclear antibodies and antibodies to native DNA. Her manifestations of vasculitis were glomerulonephritis with renal insufficiency, pulmonary hemorrhage, and bilateral hemothorax (that is similar to Goodpasture's syndrome).

As the authors pointed out, practically all drugs known to cause ANCA-positive vasculitis (including penicillamine) have also been associated with a lupus-like syndrome, suggesting the possibility of a similar underlying mechanism. However, the presence of discriminating markers (such as anti-elastase and antilactoferrin antibodies) in drug-induced ANCA-positive vasculitis, but not in idiopathic cases, is suggestive of different pathways in these conditions.

In three Japanese patients with penicillamine-associated glomerulonephritis, antimyeloperoxidase ANCA assays were strongly positive (352). These patients had been taking penicillamine for rheumatoid arthritis in daily doses of 100, 200, and 300 mg for 32, 42, and 39 months respectively. All three had proteinuria, hematuria, anemia, and rapidly progressive renal insufficiency. Histological examination showed crescentic glomerulonephritis with granular deposits of IgG, IgM, IgA, C1q, and C3 in the mesangium. Penicillamine was withdrawn and the patients were given steroid pulse therapy, warfarin, and in two cases cyclophosphamide. Renal function gradually improved and the antineutrophil cytoplasmic antibodies disappeared.

- In a 69-year-old man with penicillamine-induced crescentic glomerulonephritis ANCA tests were repeatedly negative (353). He had been taking penicillamine up to 750 mg/day for systemic sclerosis.

Churg–Strauss syndrome

The Churg–Strauss syndrome is a rare disease, with eosinophilia, vasculitis, and granulomas, involving many organ systems (skin, lungs, kidneys, gastrointestinal tract, joints, heart, and central nervous system); rhinitis and asthma are often early manifestations. In one of two patients with the syndrome, penicillamine might have triggered its development (64); however, withdrawing the drug had no effect on the course of the disease and the relation was therefore uncertain.

Dermatomyositis and polymyositis

Penicillamine can cause other serious autoimmune reactions involving the muscles: dermatomyositis, with its characteristic facial rash (354), and polymyositis (56,95,96,321,355–366). Effects vary from only biochemical abnormalities, through moderate muscular weakness, to severe polymyositis with myolysis and sometimes myocarditis. There can be dysrhythmias, heart block, and Adams–Stokes attacks (362) and deaths have occurred (96). Muscle weakness can cause secondary respiratory failure (56,321). The clinical, pathological, and electromyographic features are similar to those of idiopathic polymyositis.

Antinuclear antibodies are found in about 90% of cases of penicillamine-induced polymyositis, a finding that may be helpful in distinguishing this condition from true polymyositis (357). In one patient anti-Jo-1 antibodies were found, which was thought to be an epiphenomenon and not pathogenic (78). Myositis occurs in about 1% of patients taking penicillamine and appears to be relatively common in Japanese and Indian patients (SEDA-15, 240) (23,355,363). HLA investigations showed that the antigens DR2 and DQwl are increased in patients with penicillamine-induced myositis, suggesting that myositis occurs in a specific genetic subgroup (363). Of interest is the report of a patient with penicillamine-associated polymyositis who had a relapse after administration of ampicillin (358).

In penicillamine-induced polymyositis, weakness can be the presenting symptom and it may at first be mistaken for myasthenia (56).

The diagnostic pitfalls of penicillamine-induced polymyositis have been reviewed in the light of a report of a patient in whom postural changes were at first mistaken for possible ankylosing spondylitis (367).

IgA deficiency

IgA deficiency is a rare penicillamine-induced immune disorder, which can be accompanied by recurrent upper respiratory tract infections (67,68,368). IgA deficiency is more likely to develop when there is improved rheumatic disease activity, together with other adverse effects (for example rash, thrombocytopenia, proteinuria).

Lupus-like syndrome

Serological features of systemic lupus erythematosus develop in about 7% of patients taking penicillamine (172,227,249–251,369). A clinical lupus-like syndrome is less frequent (about 2%) and is as frequent in rheumatoid arthritis as in Wilson's disease. Characteristic phenomena are polyarthropathy, rash, pleurisy, fever, leukopenia, thrombocytopenia, antinuclear antibodies, and LE cells. The syndrome can be associated with antibodies to native DNA, renal damage, and neurological symptoms. The disorder usually improves in a few weeks or months after stopping penicillamine, but serological tests may remain abnormal for a longer period. Also, type II bullous systemic lupus erythematosus has been attributed to penicillamine (252). Penicillamine is no longer used in juvenile rheumatoid arthritis, in particular because of lack of effect and the possibility of inducing a lupus-like syndrome (370).

- A 6-year-old Taiwanese girl, who had taken penicillamine (dosage not specified) for Wilson's disease for 17 months, developed arthralgia, fever, and oral ulcers (371). She had antinuclear antibodies with a homogeneous pattern at a dilution of 1/5120, and a direct

© 2006 Elsevier B.V. All rights reserved.

Coombs' test was positive. On the other hand, anti-DNA antibodies were within the reference range and antibodies against non-histone nuclear antigens (Sm, RNP, SS-A/Ro, SS-B/La, Scl-70) were all negative. She improved with prednisolone, and penicillamine was continued in a lower dosage.

Sjögren's syndrome

There have been two reports of Sjögren's syndrome (keratoconjunctivitis sicca, xerostomia, swelling of the parotids) in suspected association with penicillamine (372,373). In one study, reference was made to a patient with a Henoch–Schönlein-like syndrome as a suspected adverse reaction to penicillamine, but no details were given (374).

Multiple autoimmune reactions

Penicillamine often elicits multiple adverse reactions in the same patient, illustrating its immunomodulatory actions. Examples are listed in Table 4.

In a long-term prospective study of 69 patients taking penicillamine (750 mg/day) for progressive systemic sclerosis, 27 had adverse effects requiring either temporary reduction or complete withdrawal of therapy. Five of these had two, or, in one case, three different reactions (115).

- A 47-year-old woman developed concurrent pemphigus and myasthenia gravis (with ptosis and diplopia), apparently induced by penicillamine (500 mg/day for rheumatoid arthritis) (376).

In another patient, pemphigus, polymyositis, and myasthenia gravis developed simultaneously (111).

- A 67-year-old patient with rheumatoid arthritis had taken penicillamine 600 mg/day for 15 months when a skin eruption developed. Although no intercellular substance or basement membrane antibodies were found, a biopsy showed characteristic intraepidermal blistering. Direct immunofluorescence showed anti-IgG and anti-C3 antibodies, and desmoglein immunolabelling (32–2B) favored drug-induced pemphigus. In addition, acetylcholine receptor antibodies were found. After the withdrawal of penicillamine there was rapid improvement of pemphigus and myasthenia. However, polymyositis was progressive, required high doses of corticosteroids for about 18 months, and improved only slowly.

Table 4 Examples of simultaneous multiple reactions reported with penicillamine

Pulmonary alveolitis, pancytopenia, cholestatic hepatitis, stomatitis, proctitis, skin rash, proteinuria, renal insufficiency (52)
Cholestatic hepatitis with allergic pneumonitis (186)
Pemphigus and nephrosis (minimal change nephropathy) (375)
Pemphigus and myasthenia gravis (376)
Thyroiditis and myasthenia gravis (125)
Polyradiculopathy and nephrosis (70)
Aplastic anemia and cholestatic hepatitis (162)
Gingival hyperplasia, acne, hirsutism, breast gigantism (255)
Agranulocytosis and toxic epidermal necrolysis (167)

Desensitization

The National Taiwan University Hospital has reported successful desensitization with prednisolone in a patient with hypersensitivity to penicillamine (377).

- A 14-year-old boy with Wilson's disease had a rash, fever, and angioedema repeatedly after the administration of penicillamine (600 mg/day). He was given prednisolone 30 mg/day for 2 days and then 20 mg/day. He was given penicillamine in an initial dose of 300 mg/day, which was increased to 600 mg/day in increments of 150 mg over 3 days and subsequently to 900 mg/day. Prednisolone was gradually discontinued over a 4-week interval, and penicillamine was increased to 1.2 g/day without further problems.

Infection risk

In a nested case-control study in Mexican patients with rheumatoid arthritis encompassing 1274 patient years, the risk factors were determined for acquiring infectious diseases (378). In addition to the cumulative doses of methotrexate and the duration of corticosteroids use, the mean daily dose of penicillamine was a risk factor. In one patient the infection was secondary to neutropenia. Tests for a possible immunoglobulin deficiency were not performed.

Long-Term Effects

Mutagenicity

In one experimental study it has been suggested that penicillamine may be mutagenic (379).

Tumorigenicity

There are a few case reports of lymphatic malignancies in patients using penicillamine, but epidemiological data in support of the association are lacking (SEDA-7, 259) (380–382).

Second-Generation Effects

Teratogenicity

Whereas the benefits of penicillamine outweigh the risk in patients with Wilson's disease and probably cysteinuria, there have been a few reports of congenital injury attributed to the use of penicillamine, notably congenital cutis hyperelastica with a fatal course in three infants. Penicillamine should be withdrawn during pregnancy in patients with rheumatoid arthritis (383–385). It should be added, however, that in Wilson's disease it is also worth considering if it is possible to control copper metabolism with less penicillamine or without it altogether.

- A baby with a bilateral cleft lip with total cleft palate was born at 41 weeks to a 22-year-old mother who had taken penicillamine (dosage not specified) throughout an uncomplicated pregnancy for Wilson's disease (386). The child did not have a lax skin.

This case was found as part of a case-control study of 24696 mothers of malformed infants. It was the only case of penicillamine exposure in the entire series.

© 2006 Elsevier B.V. All rights reserved.

However, cleft lip has not previously been observed in association with maternal use of penicillamine, and there is little reason for suspecting the drug.

Susceptibility Factors

Genetic factors

Several studies have shown an increased frequency of penicillamine adverse effects in patients with low sulfoxidation activity, especially with regard to proteinuria and probably thrombocytopenia and myasthenia gravis (SED-12, 547) (3,196,387,388). The sulfoxidation capacity is expressed as the sulfoxidation index, calculated as the percentage of administered *S*-carboxymethyl-L-cysteine (750 mg), excreted as sulfoxides in the urine in 8 hours. A sulfoxidation index above 6% is taken as indicative of relative impairment of sulfoxidation capacity.

Certain adverse reactions to penicillamine are associated with increased or decreased frequencies of HLA antigens (SEDA-8, 235) (SEDA-11, 212) (22,389–396). Most consistently reported are the associations between proteinuria and the antigens B8 and DR3 and between thrombocytopenia and DR4. These associations are not strong enough to include HLA typing into the routine of treatment with penicillamine. The relative risk of toxicity for patients possessing either HLA-DR3 or poor sulfoxidation appeared to be 25 as compared with those possessing neither; if these tests could be simplified, a valuable opportunity would become available for identifying patients at risk (202,387). Racial factors may be involved: proteinuria is less frequent in Japanese people, whereas polymyositis occurs at an increased frequency in India and Japan (202,330).

Age

Although published experience in children is limited, penicillamine has the same pattern of adverse effects as in adults. However, an interesting difference is that taste dysfunction has so far not been reported in children (SED-10, 221) (SEDA-14, 198). In two children with Wilson's disease, penicillamine was thought to have caused persistence of a pre-existing increase in amintransase activity (187).

Other features of the patient

Patients with previous hypersensitivity to penicillin are more likely to experience a rash when taking penicillamine. Cross-allergy to penicillin can occur, but the risk of a severe allergic reaction to penicillamine in penicillin-allergic patients is thought to be low. An important measure to reduce the frequency of adverse reactions of penicillamine is to start with a small dosage (for example 125 mg/day in rheumatoid arthritis), to increase the dosage only slowly, and to maintain treatment with the lowest effective dosage. Nevertheless, serious complications such as nephrosis, pemphigus, alveolitis, and polymyositis have occurred while only 250 mg/day or less was used (SEDA-8, 235) (50,182,355).

The absorption of penicillamine can be significantly altered by alimentary factors. Changing habits, for example taking penicillamine between meals instead of with food, or stopping iron supplements, can precipitate adverse reactions by increased absorption.

Early hypersensitivity reactions are usually transient, and although there is undoubtedly an increased risk, in patients with a history of previous adverse reactions to penicillamine (or gold), re-exposure may not be followed by a relapse (SEDA-10, 218). In the case of serious complications, such as agranulocytosis, profound thrombocytopenia, polymyositis, or Goodpasture's syndrome, the repeated use of penicillamine carries unacceptable risks. Commencing penicillamine in patients with Wilson's disease can aggravate or even precipitate neurological involvement.

Antibodies to the Ro(SSA) cellular antigen (244,397) and circulating cryoglobulins (244) are risk factors for adverse reactions to penicillamine. AntiRo (SSA) antibodies characterize a distinct group of patients with rheumatoid arthritis who are almost exclusively female, express more activated B cell function, have a high prevalence of Sjögren's features, and commonly develop adverse reactions to penicillamine. Rashes and febrile reactions were especially associated with anti-Ro(SSA) antibodies, and renal pathology was more frequent in men (244).

Drug–Drug Interactions

Antacids

Antacids that contain aluminium or magnesium can reduce the absorption of penicillamine by up to 45%, presumably because increased gastric pH favors oxidation to the poorly absorbed disulfide (182,398,399).

Iron compounds

Iron compounds reduce the systemic availability of penicillamine to about 35% and copper excretion to about 28%, probably as a result of catalysis of the oxidation of penicillamine to its disulfide (2,398,400). Even the iron present in certain multivitamin formulations can be sufficient to cause interference, and when a patient who has regularly taken iron stops taking it, increased absorption of penicillamine and adverse effects can ensue (401,402).

Probenecid

When probenecid is co-administered with penicillamine in cystinuria, the efficacy of the penicillamine is significantly reduced (403).

Interference with Diagnostic Tests

Alpha-1 antitrypsin

Penicillamine can cause an artificially abnormal alpha-1 antitrypsin protein pattern, which can result in diagnostic errors (404).

Diagnosis of Adverse Drug Reactions

Reporting adverse reactions

Penicillins

See also Beta-lactam antibiotics

General Information

The basic structure of the penicillins consists of a thiazolidine ring, the beta-lactam ring, and a side chain. The beta-lactam ring is essential for antibacterial activity. The side chain determines in large part the antibacterial spectrum and pharmacological properties of a particular penicillin. The rapid emergence of bacteria, particularly *Staphylococcus aureus*, that produce beta-lactamases (penicillinase) has been partly countered by the development of compounds that resist hydrolysis by beta-lactamases and compounds that are more active than penicillin G against Gram-negative species. This has led to the production of many semisynthetic penicillins, the first of which was meticillin, active against beta-lactamase-producing *S. aureus*; followed by ampicillin, active against selected Gram-negative bacilli; carbenicillin, which has activity against *Pseudomonas aeruginosa*; and subsequently many agents with different pharmacological and antimicrobial properties. Some of the more important penicillins are listed in Table 1. Another method of combating beta-lactamase-producing organisms has been the development of beta-lactamase inhibitors.

Clinical experience with penicillins, especially penicillin G and the aminopenicillins, is extensive. These substances are rarely toxic, even when they are given in an extended range of dosages, making them invaluable for use in pregnant women and children. Their major limitation is their propensity to cause allergic reactions.

Use in non-infective conditions

In spite of the fact that most trials of antibiotics in pregnancy have shown that antibiotic administration prolongs pregnancy, the mechanism is unclear. However, it is well established that several antibiotics can alter intracellular calcium concentrations (1–3) or inhibit some enzymes, including various phospholipases (4). It is also well established that bacterial products, such as phospholipases and

Table 1 Some penicillins (all rINNs except where stated)

Beta-lactamase sensitive penicillins	Broad-spectrum penicillins	Beta-lactamase resistant penicillins	Antipseudomonal penicillins
Benzylpenicillin (penicillin G)	Ampicillin	Flucloxacillin	Piperacillin
Benzylpenicillin benethamine	Amoxicillin	Meticillin (pINN)	Ticarcillin (pINN)
Penicillin G procaine	Azlocillin	Oxacillin	
Phenoxymethylpenicillin (penicillin V)	Mezlocillin	Cloxacillin	
	Piperacillin	Dicloxacillin	

endotoxins, can stimulate prostaglandin biosynthesis and release by the human amnion (5). Therefore, because prostaglandin biosynthesis depends on the action of phospholipase A2, a calcium-dependent enzyme (4), it has been hypothesized that antibiotics that interfere with phospholipase A2 might affect prostaglandin biosynthesis and release by the amnion. This hypothesis has been tested by evaluating the effect of ampicillin on the release of prostaglandin E from human amnion (6). The results were clear: ampicillin dose-dependently inhibited the release of prostaglandin E from human amnion in vitro. Moreover, ampicillin reversibly counteracted the rise in prostaglandin E induced by arachidonic acid or oxytocin. The authors concluded that inhibition of prostaglandin E release from amnion is a mechanism whereby ampicillin might prevent some cases of premature delivery, even in the absence of infection.

General adverse effects

Non-allergic reactions to penicillins occur mainly with high doses or are related to renal insufficiency. They consist of convulsions or electrolyte disturbances, with hyperkalemia or sodium retention. The penicillinase-resistant and broad-spectrum penicillins can cause specific adverse reactions. Leukopenia, agranulocytosis, liver damage, and some cases of nephropathy are considered to be due to toxic rather than to allergic mechanisms. Diarrhea is a common complication, whereas severe antibiotic-associated colitis is rare. Hypersensitivity reactions are of great importance and are dealt with in the monograph on beta-lactam antibiotics. They range from mostly harmless skin reactions to life-threatening immediate reactions, including anaphylactic shock, acute bronchial obstruction, and severe skin reactions. Tumor-inducing effects have not been described.

Organs and Systems

Respiratory

Bronchospasm may be a consequence of penicillin allergy (7–12). Acute severe dyspnea with cyanosis has also been observed without symptoms of bronchial obstruction or pulmonary edema (13). Specific mechanisms for such cases have yet to be identified.

Allergic pneumonitis and transient eosinophilic pulmonary infiltrate (Loeffler's syndrome) are rare. These syndromes have also been observed with penicillin hypersensitivity (14–16). In one case, an alveolar allergic reaction, probably due to ampicillin, showed features of an adult respiratory distress syndrome (17).

Nervous system

High doses of penicillins, in the order of several million units/day of penicillin G, can produce myoclonic jerks, hyper-reflexia, seizures, or coma. Drowsiness and hallucinations can occur occasionally (18–20). Such reactions are due to a direct toxic effect and are more likely with high concentrations, as seen with intravenous administration (21,22) and with cardiopulmonary bypass in open-heart surgery (23,24).

Myasthenia gravis can be aggravated by ampicillin (25), a reaction that is well described with aminoglycosides and some other antibiotics.

Intrathecal instillation of more than 10 000 units of penicillin and the topical application of high concentrations of penicillin to the nervous system, especially the brain, during surgery have produced comparable reactions (26). All penicillin formulations can produce this kind of reaction.

Benign intracranial hypertension is an extremely rare reaction to penicillins, possibly allergic (27).

Metabolism

Lipoatrophy can occur after the injection of some drugs, including penicillin (28).

- A 2-year-old boy developed a non-tender, hypopigmented, atrophic patch measuring about 2 × 6 cm on his right buttock. He had been well until 5 months before, when he had received an injection of penicillin into the right buttock.

The incidence of this adverse effect is unknown, as is the mechanism.

In six healthy subjects, ampicillin caused an increase in urinary uric acid excretion; this effect was attributed to competition for active renal tubular reabsorption of urate (SEDA-13, 212).

Electrolyte balance

Potassium penicillin G can significantly alter potassium balance when given in very high doses; 20 million units of potassium penicillin G contains about 30 mmol of potassium, and in patients with renal insufficiency this amount can decisively aggravate potentially lethal hyperkalemia. Similarly, large doses of sodium penicillin G, carbenicillin, or ticarcillin can cause hypernatremia (29,30).

High doses of sodium penicillin can cause urinary potassium loss, presumably by acting as a non-absorbable anion in the distal tubule (30). Apparently by analogous mechanisms a variety of semisynthetic penicillins, including carbenicillin, cloxacillin, mezlocillin, nafcillin,

© 2006 Elsevier B.V. All rights reserved.

piperacillin, and ticarcillin, caused hypokalemia, mainly in severely ill patients (30–36).

Urinary loss of potassium and interstitial nephritis are well-recognized adverse effects of piperacillin. Since patients in ICU may have increased risks of renal complications, serum electrolyte concentrations have been measured in 43 patients before and after piperacillin administration and in 40 patients who were given other antibiotics (37). The groups were comparable in regard to age and severity of disease and all had normal serum creatinine concentrations before the study. Serum concentrations of magnesium, potassium, and, to a lesser degree, calcium fell significantly 36 hours after the start of therapy in patients who were given piperacillin, but not in patients who were given other antibiotics. The fall was most pronounced in the subgroup of patients who were also given furosemide. The authors concluded that treatment with piperacillin can cause or aggravate electrolyte disorders and tubular dysfunction in ICU patients, even when serum creatinine is normal and that the mechanism is probably exacerbation of pre-existing tubular dysfunction. Serum concentrations of electrolytes, including magnesium, should be regularly monitored and, if necessary, supplements should be given to patients in ICU who are receiving piperacillin. This may hold true for all patients receiving piperacillin.

Hematologic

Since the days when chloramphenicol was more commonly used, it has been recognized that many antimicrobial drug are associated with severe blood dyscrasias, such as aplastic anemia, neutropenia, agranulocytosis, thrombocytopenia, and hemolytic anemia. Information on this association has come predominantly from case series and hospital surveys (38–40). Some evidence can be extracted from population-based studies that have focused on aplastic anemia and agranulocytosis and their association with many drugs, including antimicrobial drugs (41,42). The incidence rates of blood dyscrasias in the general population have been estimated in a cohort study with a nested case-control analysis, using data from a General Practice Research Database in Spain (43). The study population consisted of 822048 patients aged 5–69 years who received at least one prescription (in all 1 507307 prescriptions) for an antimicrobial drug during January 1994 to September 1998. The main outcome measure was a diagnosis of neutropenia, agranulocytosis, hemolytic anemia, thrombocytopenia, pancytopenia, or aplastic anemia. The incidence was 3.3 per 100000 person-years in the general population. Users of antimicrobial drugs had a relative risk (RR), adjusted for age and sex, of 4.4, and patients who took more than one class of antimicrobial drug had a relative risk of 29. Among individual antimicrobial drugs, the greatest risk was with cephalosporins (RR = 14), followed by the sulfonamides (RR = 7.6) and penicillins (RR = 3.1).

An immunologically induced hemolytic anemia due to penicillin or its congeners occurs but is rare (44–47). It typically occurs during treatment with high doses (over 10 million units/day) of penicillin for more than 2 weeks (44,45,48). The dose- and time-dependence of this reaction appear to be explained by the underlying mechanism. During penicillin treatment the erythrocytes are normally coated with penicillin, thereby forming a penicilloyl bond on their surface (49). A drug-specific IgG antibody is directed against the complete antigen, that is the penicillin–erythrocyte complex, and can be shown in direct and indirect Coombs' tests. Clinical hemolysis therefore requires both sufficient coating of erythrocytes and high anti-penicilloyl IgG titers.

Besides this "hapten" or "penicillin-type" of drug-induced hemolysis, a second less frequent mechanism, the so-called "innocent bystander" mechanism can occur (46,49,50). Penicillin–antibody complexes are only loosely bound to erythrocytes and activate complement, which can be detected on the erythrocyte surface with the complement antiglobulin test ("complement" or "non-gamma" type). This mechanism plays a part in immune hemolytic anemias due to various drugs other than penicillins. The hemolytic reaction can continue for weeks after withdrawal of penicillin, that is as long as sufficient penicillin-coated erythrocytes and specific antibodies remain in circulation.

That any penicillin derivative can cause hemolytic anemia is emphasized by the following case (51).

- A 34-year-old woman with cystic fibrosis took piperacillin 6 g tds for respiratory distress. She had no known allergies, although she had previously had pruritus while taking ceftazidime and tingling in her hands with azlocillin. She had completed courses of amoxicillin and flucloxacillin without adverse effects. After about 2 weeks she complained of headache and nausea and passed pink urine. A diagnosis of hemolytic anemia was established and piperacillin was withdrawn. She was given a blood transfusion, prednisone, and folic acid, with good effect.

Various antibiotics, including azlocillin, aztreonam, cefuroxime, ceftazidime, chloramphenicol, colistin, flucloxacillin, gentamicin, imipenem, meropenem, piperacillin, tazobactam, temocillin, and ticarcillin, were incubated with this patient's serum. Only piperacillin and piperacillin + tazobactam caused agglutination in an indirect agglutination test. The authors concluded that the hemolytic anemia had been caused by piperacillin.

Penicillin has been rarely suspected to cause hemolytic–uremic syndrome (52).

Agranulocytosis and leukopenia are discussed in the monograph on beta-lactam antibiotics. Over the years, several cases of neutropenia after treatment with piperacillin with or without tazobactam have been described, especially in children (53–55).

- A 77-year-old man with chronic obstructive lung disease and pneumonia received piperacillin 4 g + tazobactam 0.5 g every 6 hours (56). The neutrophil count gradually fell to zero after 24 days. Piperacillin + tazobactam was withdrawn and lenograstim was given. Within 4 days, the number of neutrophils started to increase. Lenograstim was withdrawn, and the number of neutrophils returned to normal within a week. He made a full recovery.

Whether the rate of hematological adverse effects is higher for piperacillin + tazobactam than for other penicillins is unclear, as is the question of whether

© 2006 Elsevier B.V. All rights reserved.

neutropenia is more frequent in children than in adults or more frequent in patients with cystic fibrosis than in patients with other conditions (51). It would anyway be wise to follow patients treated with piperacillin, either alone or in combination with tazobactam, with particular attention.

Thrombocytopenia with penicillins has very rarely been reported (57–61). In two cases with mezlocillin (62) and piperacillin + azobactam (63) antibodies became attached to the platelets in the presence of the incriminated drug. The second of these cases is of particular interest, since drug-dependent antibodies were found in the presence of piperacillin but not tazobactam.

- A young woman developed microangiopathic hemolysis and thrombocytopenia in temporal relation to three separate courses of penicillin or ampicillin (64).

Bleeding disorders with penicillins are discussed in the monograph on beta-lactam antibiotics.

Disseminated intravascular coagulation has been reported during long-term administration of piperacillin (65).

- A 51-year-old man was given piperacillin 2 g bd for osteomyelitis. After close to 4 weeks he developed acute renal insufficiency and superior mesenteric venous thrombosis. His coagulation profile showed disseminated intravascular coagulation. Withdrawal of piperacillin and anticoagulation therapy resulted in clinical improvement and normalization of the laboratory data.

Gastrointestinal

Antibiotic-induced colitis and diarrhea and non-specific gastrointestinal symptoms are discussed in the monograph on beta-lactam antibiotics.

Liver

Penicillin-induced hepatotoxicity may not be as uncommon as has been thought. There have been three reviews. The first was a comparison of the assessment of drug-induced liver injury obtained by two different methods, the Council for International Organizations of Medical Sciences (CIOMS) scale and the Maria & Victorino (M&V) clinical scale (66). Three independent experts evaluated 215 cases of hepatotoxicity reported using a structured reporting form. There was absolute agreement between the two scales in 18% of cases, but there was no agreement in cases of fulminant hepatitis or death. The authors concluded that the CIOMS instrument is more likely to lead to a conclusion compatible with the specialist's empirical approach.

In the second review some syndromes of drug-induced cholestasis were outlined, with lists of typical examples of which drugs cause what (67). The authors stated that the treatment of drug-induced cholestasis is largely supportive and that the offending drug should be withdrawn immediately.

In the third review the authors' intention was to give new insights into basic mechanism of bile secretion and cholestasis (68). Some drug-induced forms of cholestasis appear to be associated with certain HLA class II haplotypes in patients taking co-amoxiclav (SEDA-24; 276). Whether or not this holds true for hepatotoxicity due to other beta-lactam antibiotics is not known.

Co-amoxiclav

Transient rises in serum transaminases are not uncommon after the use of co-amoxiclav, and hepatic dysfunction with jaundice can also occur. Since this effect is thought to be largely due to the clavulanic acid that co-amoxiclav contains rather than the amoxicillin, it is covered in the monograph on beta-lactamase inhibitors.

Isoxazolyl penicillins

Flucloxacillin is the most important cause of antimicrobial drug-induced hepatotoxicity in various countries (69–71). The risk has been estimated in some countries to be in the range of 1 in 10000 to 1 in 30000 prescriptions (72–74). The hepatic injury is often severe and deaths have occurred (73). The course can be prolonged. Cholestasis is the most frequent and prominent feature and the so-called "vanishing bile duct syndrome" can develop. Female sex, increasing age, and duration of therapy are risk factors (75). High daily doses increase the risk (74).

Chronic hepatitis has been reported in a patient with a history of flucloxacillin-induced hepatitis (76).

- A 55-year-old woman with psoriasis was treated with oral 5-methoxypsoralen and UVA photochemotherapy. After 40 treatments over 5 months she became unwell and complained of headaches, nausea, and abdominal pain. Laboratory tests confirmed a diagnosis of hepatitis. Six years earlier she had had flucloxacillin-induced hepatitis.

Hepatitis after 5-methoxypsoralen is supposedly very rare, and the authors gave only one reference, although there have been several more reports after the use of 8-methoxypsoralen. Without discussing possible mechanisms underlying this difference, it might be wise to remember that a previous history of drug-induced hepatitis should be a reminder of the need to consider hepatotoxic reactions in any patient who develops unexplained symptoms while using another drug.

The other isoxazolyl penicillins, that is cloxacillin, dicloxacillin, and oxacillin, can cause similar hepatotoxicity (77–82). However, it is not known whether the incidence is as high as with flucloxacillin. Nor is it known whether the clearly dose-dependent "oxacillin hepatitis" (83–85) is an identical reaction.

In isolated cases, glucocorticoids (77) and ursodeoxycholic acid (86) apparently improved the outcome of hepatitis related to isoxazolyl penicillins.

Other penicillins

Other penicillins have been only very rarely associated with hepatotoxicity. There are isolated reports involving, among others, penicillin G (87), penicillin V (88), ampicillin and amoxicillin (89,90), carbenicillin (91), and nafcillin (92).

- A 28-year-old woman developed upper abdominal pain, weakness, and dark urine 5 days after a single injection

© 2006 Elsevier B.V. All rights reserved.

of benzylpenicillin 2 million units for suspected streptococcal pharyngitis (93). Liver dysfunction persisted for up to 18 months.

The authors rated the likelihood that benzylpenicillin had caused cholestasis as probable and referred to three previous reports in which penicillin was claimed to cause hepatotoxicity.

- A 20-year-old man with abdominal trauma received a single dose of piperacillin (1 g) followed by nine doses of imipenem + cilastatin (500 mg tds for 3 days) and 2 weeks later developed jaundice, fatigue, and pruritus (94). A liver biopsy showed centrilobular cholestasis, portal infiltration with eosinophils, and cholangitis. Lymphocyte transformation tests for piperacillin and imipenem/cilastatin were positive, suggesting an immunological mechanism. He made a full clinical and biochemical recovery after 3 months.

The authors concluded that short-term therapy with piperacillin, imipenem + cilastatin, or the combination could cause the same type of liver damage as described with co-amoxiclav and antistaphylococcal penicillins.

Pancreas

The list of agents associated with pancreatitis is long and diverse and is growing. Drugs such as glucocorticoids, estrogens, diuretics, and cancer chemotherapeutic agents have all been implicated, as have various antibiotics, including tetracyclines, rifampicin, and isoniazid (95). Cases of pancreatitis have been reported after the administration of ampicillin (96) and a penicillin derivative (97).

- A 7-year-old boy developed epigastric pain, nausea, and vomiting, starting 10 days after a course of oral penicillin (dose and derivative not stated). His serum amylase activity was 1260 U/l and lipase 528 U/l; electrolytes and liver functions tests were within the reference ranges. Ultrasonography showed a normal liver, spleen, and gallbladder, but his pancreas was diffusely enlarged.

Urinary tract

Acute tubulointerstitial nephritis has been reported in relation to various penicillins, including penicillin G, ampicillin, and amoxicillin (98–102), dicloxacillin (103), meticillin (104–109), nafcillin (110,111), oxacillin (107), and piperacillin (112–114). However, meticillin is the prototype that has caused this reaction more often than any other beta-lactam.

Meticillin-induced acute interstitial nephritis follows a similar pattern of dose-dependence and time-dependence to that of neutropenia (104,105). This reaction occurred in 16% of all children treated with high-dose meticillin (115). Nephritis occurred after a mean of 17 days and a mean cumulative dose of 120 g.

Fever and hematuria (macroscopic or microscopic) are the dominating symptoms. Rash, eosinophilia in the blood, possibly eosinophiluria, and signs of non-oliguric renal insufficiency can occur but are not always present (107). Acute anuric/oliguric renal insufficiency is rare.

Hemorrhagic cystitis has been observed in connection with meticillin (116) and carbenicillin (117).

A very high dose of amoxicillin (250 mg/kg/day for *Listeria monocytogenes* meningitis) combined with an aminoglycoside led to crystal-induced acute renal insufficiency after 14 days (118).

Drug-induced nephrolithiasis, often seen during the sulfonamide era, is nowadays rare, especially in patients taking beta-lactams. However, it can still occur with penicillins (119).

- A 48-year-old woman with pneumococcal meningitis developed acute oliguric renal insufficiency after taking high-dose amoxicillin (320 mg/kg/day) for 4 days. Amoxicillin crystallization was documented by infrared spectrometry. The outcome was favorable after dosage reduction, a single hemodialysis, and adequate hydration.

As was true for the sulfonamides, the risk of crystalluria due to penicillins is increased by high doses, a low urinary pH, and low urine output.

Skin

Skin reactions are the commonest adverse effects of therapeutically administered penicillins (120). Penicillin-contaminated milk or meat can cause itching or generalized skin reactions (121) or even anaphylaxis (122,123).

Incidence

The overall annual incidence of severe erythema multiforme (toxic epidermal necrolysis and Stevens–Johnson syndrome) is about one case per million, antibiotics being involved in 30–40% (124,125). The clinical differentiation between these syndromes can be difficult (126). Allergic contact dermatitis is usually caused by topical drugs, but is also seen in connection with ingestion, injection, or inhalation (127–129).

The increased frequency of contact eczema due to cloxacillin and bacampicillin may be because they are intensely irritant and lipophilic (130).

Mechanisms

Mechanisms of non-immediate reactions are unclear; but may be immunological and non-immunological. Delayed reactions of the IgE type are known (131). Aminopenicillins seem to be an important cause of non-immediate reactions (132–134). The morbilliform rash that begins 1–10 days after amoxicillin can be caused by a delayed cell-mediated immune reaction (135) as can fixed drug eruptions (136,137), toxic epidermal necrolysis (138–140), bullous erythroderma (141), and contact eczema (142). Investigation of these disorders should include delayed readings of skin tests (135). In patients with chronic urticaria, penicillin allergy was demonstrated by cutaneous tests.

Presentation

In contrast to other drugs, penicillin-induced skin reactions can occur after more than 1 week of therapy (60). The typical presentation is a maculopapular, erythematous, symmetrically disposed rash on the legs, buttocks, and trunk.

In very rare cases, certain penicillins can cause pemphigus vulgaris (143) or pemphigoid-like reactions (144,145).

© 2006 Elsevier B.V. All rights reserved.

Linear IgA disease is an acquired subepidermal bullous disease characterized by linear deposits of IgA at the cutaneous basement membrane zone and by circulating IgA anti-basement membrane antibodies. Although the cause of linear IgA disease is usually unknown, a few cases have been reported to follow ingestion of drugs, especially vancomycin and diclofenac. A patient with penicillin G-induced linear IgA disease who had circulating IgA antibodies showed specificity against type VII collagen (146).

- A previously fit, 76-year-old man developed pneumococcal pneumonia and acute confusion. He was given oxygen, digoxin, furosemide, and penicillin G 9.6 g/day. Because his symptoms of infection continued he was then given higher doses of penicillin, together with intravenous dexamethasone, and his condition slowly improved. After 10 days of treatment with penicillin (cumulative dose 125 g), he developed a maculopapular truncal eruption compatible with a drug rash. Penicillin was withdrawn and the eruption faded over several days, but 1 week later he developed a localized blistering eruption with tense clear bullae and erosions on the penis, scrotum, and inner thighs. This became generalized, affecting most of the body, and he developed large erosions over pressure-bearing sites, oral ulcers, and hemorrhagic nasal crusting. He was given oral prednisolone. His blistering abated within a month, steroid therapy was withdrawn after 3 months, and his disease remained in remission at follow-up 12 months later. Histology of the affected skin showed subepidermal bullae and a mixed inflammatory infiltrate in the dermis. Direct immunofluorescence showed linear IgA deposition along the basement membrane. Anti-basement membrane antibodies were demonstrated by indirect immunofluorescence and were identified by Western blotting to be against a 250 kDa antigen in dermal extracts. Monoclonal antibodies to collagen VII co-migrated to the same spot.

Collagen VII is the major target antigen of epidermolysis bullosa acquisita (147). Consequently, it is open for discussion whether such patients should be classified as having IgA epidermolysis bullosa acquisita or collagen VII linear IgA disease. The authors stated that their patient did not have the clinical phenotype of epidermolysis bullosa acquisita, and the diagnosis of drug-induced collagen VII linear IgA disease seems to have been well validated (95).

Allergic contact urticaria has been attributed to amoxicillin (148).

- A 40-year-old male nurse developed facial angioedema, dyspnea, rhinoconjunctivitis, dysphonia, and dysphagia immediately after opening a sachet containing amoxicillin and clavulanic acid (149). Skin prick tests were positive for both amoxicillin and ampicillin, and an open test with amoxicillin resulted in a severe immediate-type reaction with large localized wheals and erythema at 10 minutes. Six months later, when he was asymptomatic, erythema was observed during open tests with ampicillin 5%.

Consort urticaria has been attributed to penicillins and may occur more often than recognized.

- A 22-year-old woman had labial urticaria with oropharyngeal edema some minutes after kissing her boyfriend, who had taken amoxicillin some minutes before kissing her (150). A few months before, she had had generalized urticaria several minutes after taking amoxicillin. A prick test with amoxicillin was positive and a similar test with penicillin G was negative. Total serum IgE was 90 kU/l and a RAST test for amoxicillin was positive (4.74 kU/l).
- Two episodes of urticarial angioedema occurred in a 45-year-old woman (151). The first episode occurred 1 hour after she had taken a fifth dose of bacampicillin 1200 mg. In the second episode, she had mild itching and edema of the lips and moderate cutaneous itching and swelling about 30 minutes after making love with her husband, who was taking bacampicillin 1200 mg bd and had taken a tablet about 2 hours before. He had used a condom as contraception, and so the only contact between their mucosae was by kissing. Her symptoms disappeared 2 hours after she took cetirizine 10 mg. Some months later, her husband took placebo or bacampicillin 120, 360, or 520 mg on different days, and 2 hours after taking the tablets kissed his wife. She developed mild intraoral itching and itching and wheals on the face and arms 20 minutes after kissing her husband after he had taken bacampicillin 360 mg.

Kissing can cause an allergic reaction if one of the lovers is sensitized to a compound that has just been taken by the other. This holds true for both drugs and food (152,153). Whether a similar reaction can occur if the lovers have intercourse without using a condom has neither been reported nor investigated. However, allergic reactions to penicillin during in vitro fertilization and intrauterine insemination are possible, and the authors recommended that in patients who are penicillin-sensitive, penicillin should not be used during transfer of gamete and embryo for assisted reproductive procedures (154).

Pustular drug eruptions due to penicillin (155), amoxicillin (156), ampicillin (157), bacampicillin (158), or imipenem + cilastin (159) seem to form a distinct clinical entity that has to be differentiated from pustular psoriasis, which can be drug-induced as well (159). A history of drug exposure, rapid disappearance of the eruption after the drug is stopped, and eosinophils in the inflammatory infiltrate argue in favor of pustular drug eruptions.

Pseudoallergic reactions are reactions that mimic immunoallergic reactions, but in which a specific immune-mediated mechanism is not involved. The so-called "ampicillin rash," which also occurs with amoxicillin, another aminopenicillin, is an example of a pseudoallergic reaction, which looks like a typical type III allergic rash, but usually occurs at 7–12 days after the start of administration rather than 3–10 days (160). Some major mediators of pseudoallergic reactions have been reviewed (161). The roles of newer putative mechanisms, involving cytokines, kinins, and other host-derived substances, remain to be ascertained. Most important is the fact that currently there are no standardized and validated animal models for predicting pseudoallergic reactions (162). In patients with infectious mononucleosis, the aminopenicillins evoke rashes in a much higher percentage

© 2006 Elsevier B.V. All rights reserved.

than usual (163). The incidence of rashes in infectious mononucleosis without antibiotics is 3–15%, compared with 40–100% with ampicillin. The underlying mechanism is speculative.

Although several reports have described fixed rashes due to amoxicillin, palmar exfoliation has rarely been described (164).

- Five patients (one man, four women, aged 30–72 years) developed intense palmar rashes and itching during treatment with amoxicillin (doses not stated). All the episodes began after several days of treatment with amoxicillin, either alone or in combination with clavulanic acid. Three of the patients had repeated episodes, and the interval between treatment and onset was shorter each time (down to 5 hours on the third occasion). In all cases the rash was followed by exfoliation and cleared in 7–10 days without residual lesions. Skin prick tests, intradermal tests, and patch tests were performed with several beta-lactams, including amoxicillin, and all were negative. A challenge test with amoxicillin was performed in one patient, and the erythema recurred in 3–4 hours. All five patients tolerated cefuroxime and ceftazidime. Cefalexin was given to one patient only, and palmar exfoliative erythema developed a few days later.

Diagnosis

A maximum of 20% of subjects with a history of allergy-like reactions after administration of a penicillin antibiotic have positive skin or RAST tests (165–167). Tests using benzylpenicillin derivatives or semisynthetic penicillins can almost double positive test results (168,169). Patients with a positive history but negative skin tests run a 1–3% risk of an IgE-mediated reaction and 60% of test-positive patients had evidence of an immediate reaction, including urticaria and angioedema (165).

Management

Penicillins should be avoided in any patient who gives a history of a skin reaction or anaphylaxis to any penicillin derivative. To prevent mild skin reactions becoming severe when they occur, it is advisable to withdraw the culprit antibiotic not only when a type I reaction is suspected but in all kinds of common rashes, in view of a possible epidermolytic process. A diet free of dairy products was curative in 30 of 70 patients with positive tests (170).

Immunologic

Type I reactions

Anaphylactic shock can occur, even after oral administration of penicillin and skin testing. However, anaphylactic shock is less common after oral than parenteral administration (171). In one study the incidence of anaphylactic shock was 0.04% of all patients treated with penicillin (7). It is also low in patients receiving long-term benzathine penicillin (1.2 million units every 4 weeks). Four episodes of anaphylaxis occurred in 0.012% of injections (1.2 reactions to 10 000 injections) (172). Anaphylactic shock resulting in death occurred in 0.002% of all patients treated with penicillin (7) and in 0.003% of those treated with benzathine penicillin (172).

In nearly half of the cases, the course of anaphylactic shock, especially that induced by penicillin and other small molecular substances, is that of a cardiovascular reaction without any other effects suggestive of an allergic mechanism (173–175). There is an extensive list of articles on anaphylactic shock to penicillins (7–10,173,174,176,177). General anesthesia does not inhibit the development of anaphylactic shock in penicillin allergy (178).

Diagnosis

The two most important elements in the evaluation of an individual for the presence or absence of beta-lactam hypersensitivity are the drug history and skin tests. Other diagnostic tools, such as measurement of drug-specific antibodies and lymphocyte transformation tests, are investigational or restricted to specialized laboratories. Standardized and widely used protocols for skin testing only exist for the penicillins and allow assessment of IgE-mediated hypersensitivity. The most commonly used reagents are penicilloyl-polylysine (PPL, which contains multiple penicilloyl molecules coupled to a polylysine carrier) and fresh penicillin followed by minor determinant mixtures (MDM), containing penicilloate, benzylpenicilloate, and benzylpenilloate (179). A survey conducted among members of the American Academy of Allergy and Immunology reported the use of penicilloyl-polylysine and fresh penicillin by 86% and minor determinant mixtures by 40% of those responding to the questionnaire (180).

Skin tests are first applied as a prick test for safety. In the absence of a local or systemic reaction, an intradermal test is performed and interpreted as described elsewhere (181,182). Experience with skin testing in penicillin allergy has been reviewed (176,183). Properly performed sequential testing is considered a safe procedure, and only an estimated 1% or less of penicillin allergic patients will have systemic symptoms while undergoing skin tests. However, at least three deaths have been reported with both epicutaneous and intradermal testing (184).

In a collaborative study in the National Institute of Allergy and Infectious Diseases (NIAID), hospitalized patients were tested with major and minor skin test reagents in order to assess the predictive value of skin testing. Among 600 history-negative patients, 568 had negative skin tests and none had a reaction to penicillin. Among 726 history-positive patients, 566 had a negative skin test and received penicillin, seven of whom (1.2%) had a possibly IgE-mediated reaction. Nine of the 167 patients with positive skin tests were exposed to penicillin, two of whom had reactions compatible with IgE-mediated reactions. These data suggest that overall, 99% of patients with negative skin tests to penicilloyl-polylysine and minor determinant mixtures can safely receive penicillin. A history of a previous reaction slightly increases the risk of an adverse reaction, to 1.2%. Most positive skin tests were detected with penicilloyl-polylysine with or without minor determinant mixtures, and a further 16% reacted to minor determinant mixtures alone (166).

In another study in an outpatient clinic for sexually transmitted diseases, 5063 consecutive patients were

© 2006 Elsevier B.V. All rights reserved.

tested with penicilloyl-polylysine with and without minor determinant mixtures (167). The role of the history of a previous penicillin reaction was emphasized in this study: 1.7% of history-negative subjects had a positive skin test; in contrast, 7.1% of history-positive patients had a positive skin test, and a previous history of anaphylaxis or urticaria was associated with positive skin tests in 17% and 12% respectively. Penicillin was safe in more than 99% of patients with a negative history and a negative skin test. Reactions were more common (2.9%) in patients with a positive history and a negative skin test. The reactions were mild and self-limiting. Two patients with a history of severe IgE-mediated reaction had mild anaphylactic reactions.

Relatively safe doses for skin testing, provided that one begins with a prick test, are 25 nmol/ml of penicilloyl-polylysine and purified benzylpenicillin. Positive skin tests of the immediate type with penicilloyl-polylysine are usually obtained 2 weeks to 3 months after the clinical reaction (185).

The safety of such an approach has been challenged in a description of three patients who were negative in skin tests with penicilloyl-polylysine and minor determinant mixtures and who tolerated therapeutic doses of benzylpenicillin, but reacted to amoxicillin (173). In an extension of that study, 177 patients who were allergic to beta-lactams were identified using the clinical history, a skin test panel including penicilloyl-polylysine, and minor determinant mixtures, as well as ampicillin and amoxicillin and drug-specific radio-allergosorbent tests. Fifty-four patients (31%) tolerated penicillin G but reacted to amoxicillin with anaphylaxis, urticaria, or angioedema. Skin tests with penicilloyl-polylysine and minor determinant mixtures failed to detect those patients, but tests with amoxicillin were positive in 63% (168).

Canadian data have partly confirmed these findings (169). Benzylpenicillin derivatives and semisynthetic penicillins were applied to 112 patients with a history of an allergic reaction to penicillins. The tests were positive in 21 patients (19%), of whom 10 reacted against the semisynthetic penicillin reagents only. Reports of subjects allergic to flucloxacillin (186), cloxacillin (187), and cefadroxil (188), but not penicillin, lend further support to the concept of side chain-specific allergic reactions (see the monograph on beta-lactam antibiotics).

Management

Fearing penicillin anaphylaxis, many clinicians overdiagnose penicillin allergy in patients who have not had a true allergic reaction. Consequently, penicillins are withheld from many patients who could safely receive them. This was the background to a study whose objectives were to determine the likelihood of true penicillin allergy, taking into consideration the clinical history, and to evaluate the diagnostic value added by appropriate skin testing (189). The authors searched MEDLINE for relevant English-language articles dated 1966 to October 2000. Bibliographies were searched to identify additional articles. Original articles describing the precision of skin tests in the diagnosis of penicillin allergy were included, and studies that did not use both minor and major determinants were excluded; 14 studies met the inclusion criteria. At least three authors independently reviewed and abstracted the data from all the articles and reached a consensus about any discrepancies. Some of their conclusions are worth remembering:

- 80–90% of all patients who report penicillin allergy have negative skin tests, suggesting that penicillins are withheld from many patients who could safely receive them;
- patients who develop a rash while taking penicillins should not be automatically labeled as allergic without considering other possibilities, including rashes due to ampicillin distinct from allergic rashes, and rashes caused by the infection being treated or by other drugs;
- for patients with a history of immediate (type I) penicillin allergy who have a compelling need for penicillin, skin testing should be performed;
- at least 98% of patients with positive histories of penicillin allergy and negative skin test results can tolerate penicillin without any sequelae.

Desensitization

Patients with a history of penicillin allergy should undergo skin testing with both penicilloyl-polylysine and minor determinant mixtures. Patients with positive skin tests should be treated with another immunologically unrelated compound or should undergo desensitization. The management of patients with a negative skin test but a history of a severe IgE-mediated reaction has to be individualized; options include the use of an alternative compound, desensitization, or the controlled administration of a test dose.

Acute drug desensitization is commonly described as the process by which a drug-allergic individual is converted from a highly sensitive state to a state in which the drug is tolerated. The procedure involves cautious administration of incremental doses of the drug over a short period of time (hours to a few days). In the past it has mainly been considered to be of value in patients in whom IgE antibodies to a particular drug are known or assumed to exist and no alternative treatment agent is available. In clinical practice, most of the desensitization protocols have involved penicillins (190). However, the principle has been applied successfully to other agents as well (191,192), including other antibiotics, insulin, chemotherapeutic agents, vaccines, heterologous sera, and other proteins.

Mechanism It has been stated that in patients with penicillin-specific IgE antibodies who underwent successful penicillin desensitization, the data suggest that anti-specific, mast cell desensitization is responsible for the tolerant state and that mediator depletion plays no role (190). Additionally, the clinical observation that wheal-and-flare skin responses to penicillin often become negative with successful desensitization, while IgE responses to other antigens remain unchanged, also supports an involvement of an antigen-specific mechanism. Furthermore, both clinical reactivity and skin-test reactivity return within a few days, unless a tolerant state is maintained by continued drug administration. The author stressed that these findings show that the desensitized state depends on the

© 2006 Elsevier B.V. All rights reserved.

continuous presence of antigen and that clinical sensitivity returns rapidly in the absence of antigen.

However, the underlying mechanisms responsible for the antigen-specific desensitized state are still unclear. It has been hypothesized that IgE receptor aggregation may generate counter-regulatory forces that, instead of causing cell activation, actually extinguish activating signals (191). The key point is that during desensitization, the drug is introduced very slowly and the drug concentration rises gradually. The slow rate of possible receptor aggregation caused by the gradual increase in drug concentration, along with suppression of cellular activation signals, may lead to antigen-specific desensitization and clinical tolerance. It has also been long thought that during desensitization, univalent drug-hapten protein conjugates are formed and may act by inhibiting the cross-linking of drug-specific IgE molecules on mast cells. It is slightly surprising that this prospect has not come into routine therapy.

Procedure Beta-lactam desensitization should be done in an intensive care unit and any concomitant risk factors for anaphylaxis, such as use of beta-blockers should be corrected. Protocols based on incremental use of the drug orally or parenterally have been described (190,193). The oral route is preferable and is associated with a lower incidence of adverse events, but mild transient reactions are frequent (171,194,195). Pregnant women with limited antibiotic choices have been treated with immunotherapy (196). Repeated administration will maintain a state of anergy, which is often lost after withdrawal (197). At the conclusion of therapy, patients must be informed that after withdrawal, they may once again become allergic to penicillin, with a new reaction to the first subsequent application (197).

Desensitization is not effective in non-IgE-mediated reactions and should therefore not be attempted, for example in cases of serum sickness-like syndromes or Stevens–Johnson syndrome.

Treatment of acute anaphylaxis
For acute anaphylaxis, immediate treatment is essential, with adrenaline followed by intravenous histamine H_1 receptor antagonists, glucocorticoids, fluids, and electrolytes. In view of the frequency of cardiac dysrhythmias and conduction disturbances in patients with anaphylactic shock, they should immediately be monitored (198,199).

Type III reactions
Serum sickness was first described by von Pirquet and Schick in 1905 and was regarded as a syndrome resulting from the administration of heterologous serum or other foreign proteins. The immunopathology of classic serum sickness results from antigen–antibody complex formation with a foreign protein as the antigen. Characteristic symptoms include fever, cutaneous eruptions, edema, arthralgia, and lymphadenopathy. The incidence of classical serum sickness has fallen secondary to the refinement of foreign proteins. However, a serum sickness-like reaction that is clinically similar to classical serum sickness can result from the administration of a number of non-protein drugs, such as tetracyclines, penicillins, and cephalosporins (200). The reaction typically occurs within 1 month of the start of therapy and resolves after withdrawal.

Serum sickness has been associated with penicillins (201).

- A 39-year-old woman developed the characteristic symptoms for serum sickness, having completed a 5-day course of amoxicillin for a perilingual infection 1 week before. She was treated with prednisone 60 mg/day and diphenhydramine 25–50 mg tds. Her symptoms gradually resolved and the prednisolone dose was tapered over 2 weeks.
- A 29-year-old woman complained of fever, rash, throat and facial swelling, abdominal pain, and increasing joint pain, leaving her wheelchair-bound. Her symptoms started a week after she had completed a 10-day course of penicillin V for a dental abscess. She was given oral methylprednisolone, 40 mg every 6 hours, and over the next few days her symptoms gradually resolved.
- A 29-year-old woman developed symptoms of serum-sickness 2 weeks after completing a 21-day course of co-amoxiclav for sinusitis. She responded to prednisone 40 mg/day.

The authors suggested that serum sickness may be more common than has previously been described and that the reaction may be under-reported or unrecognized.

Second-Generation Effects

Teratogenicity

Early animal studies suggested that malformations could be caused by penicillins. However, this was not confirmed in later, more extensive evaluations (202). Penicillin G, ampicillin, and probably most other penicillins can be safely used in pregnant women and children. Experience with the newer semisynthetic penicillins is not extensive enough to allow definite conclusions regarding their safety for mother and fetus during pregnancy.

Fetotoxicity

Increased antenatal administration of ampicillin for the prevention of neonatal group B streptococcal disease may be responsible for the higher incidence of more severe neonatal sepsis with ampicillin-resistant non-group B streptococci, without a change in the overall infection rate (203,204).

Lactation

The transfer of penicillins (ampicillin, pivampicillin, phenoxymethylpenicillin) into the breast milk of nursing mothers with puerperal mastitis to the breastfed infant is minimal (205). The risk of adverse drug reactions due to penicillins is therefore negligible, unless the infant has penicillin allergy (SEDA-14, 215).

© 2006 Elsevier B.V. All rights reserved.

Susceptibility Factors

Renal disease

Toxic effects of penicillins can occur in patients with renal insufficiency if the dosage is not altered (206).

Other features of the patient

Toxic reactions can occur in patients with pre-existing cerebral damage or during cardiopulmonary bypass. Embolic reactions can have severe consequences in patients with pre-existing cardiac or pulmonary disease.

Drug Administration

Drug formulations

Embolic-toxic reactions to penicillin depot formulations were first described in patients with syphilis (207). The symptoms include fear of death, confusion, acoustic and visual hallucinations, and possibly palpitation, tachycardia, and cyanosis (SEDA-8, 559) (175,207–211). Generalized seizures or twitching of the limbs have been observed in children and adults (210,212–216). As a rule, the symptoms abate and disappear within several minutes to an hour. They rarely persist for up to 24 hours. If a cardiovascular reaction with a fall in blood pressure occurs simultaneously with typical symptoms, a combination with anaphylactic shock must be considered (217,218).

Such reactions have been called "pseudo-anaphylactic reactions" or "acute non-allergic reactions" (174,208–210,219–223), "panic attack syndrome," and "acute psychotic reactions" (212,224). In several countries, the term "Hoigné syndrome" is used.

The frequency of such reactions is about 1–3 reactions per 1000 intramuscular injections of penicillin G procaine, the usual dose being about 0.6–1.2 million units (175,213,225–227). Eight of 920 patients with venereal diseases had a definite toxic-like reaction with a dose of 4.8 million units of penicillin G procaine, corresponding to about one in 120 patients (228). In a series of 7700 intramuscular injections with only 400 000 units of penicillin G procaine, there was not one episode (221).

The mechanism is probably embolic (172,207,219,222,225), as has been shown in one case at autopsy, in which emboli of benzathine penicillin crystals were found in the lungs (219).

Some reports suggest that the procaine component may be especially important (213,222). Plasma procaine esterase activity was low in patients with systemic toxic reactions (213). The same symptoms occurred in three patients after erroneous administration of penicillin G procaine by intravenous infusion (222), but also in two after procaine-free antihistamine penicillin was injected intramuscularly (172,225). However, observations of similar symptoms with a procaine-free antihistamine penicillin argue against a central role of the procaine component (SED-8, 560) (175,217,220,221,225).

Drug administration route

Intramuscular injection of high doses of depot formulations of penicillins can lead to painful swelling, especially when over 600 000–1 000 000 units are given at a single site (229,230). Such reactions occurred in two of 878 patients (0.2%) with intramuscular penicillin G procaine (231). Arthus phenomenon seems to be rare (127,232).

Nicolau syndrome (embolia cutis medicamentosa) is a very rare complication of intramuscular injections, in which there is extensive necrosis of the injected skin area, perhaps due to accidental intra-arterial and/or para-arterial injection (233). It usually occurs in children: in a review of 102 patients, 80 were under 12 years of age (234). Complications can include everything from an ischemic syndrome with local necrosis of the skin, subcutaneous tissue, and muscle, often combined with vascular and nervous system involvement, intestinal and renal hemorrhage, necrosis of the entire leg, and even paraplegia from spinal cord damage (235–241). Necrosis of the forearm has been described in two patients after inadvertent intra-arterial administration of dicloxacillin (242).

Special emphasis should be put on the precautionary measures to be taken when injecting long-acting penicillins or other drugs in crystalline suspensions intramuscularly.

Repeated intramuscular injections into the thighs of newborns and infants can cause severe and widespread muscular contractures of the quadriceps femoris (SEDA-8, 560). In some cases, penicillin was implicated.

Drug–Drug Interactions

Allopurinol

The risk of rashes caused by aminopenicillins does not seem to be increased by parallel treatment with allopurinol (243), as had been suggested before (244).

Aminoglycosides

High doses of parenteral penicillin can inactivate aminoglycosides (245). In patients receiving low doses of aminoglycosides because of reduced renal function this can be clinically important (246,247). Parenteral administration of these drugs in neonatal dosages does not seem to produce relevant inactivation, and so temporal separation of the infusions is not required (248).

Piperacillin protected against aminoglycoside nephrotoxicity without reducing its blood concentration; this was possibly a protective effect of co-administered mineral salts (249).

Ciclosporin

In a study in lung transplant recipients, ciclosporin nephrotoxicity was potentiated by nafcillin (111).

Methotrexate

Beta-lactams are weak organic acids that compete with the renal tubular secretion of methotrexate and its metabolites and reduce their clearance, leading to methotrexate toxicity (250,251). Consecutive aplastic crises have been described, particularly in patients with impaired

© 2006 Elsevier B.V. All rights reserved.

renal clearance (250,252,253). In contrast, co-administration of flucloxacillin in another study produced a significant but not clinically important reduction in methotrexate AUC (254).

The more basic interactions between piperacillin and methotrexate and its major metabolite 7-hydroxymethotrexate have been studied in rabbits (255). The interaction was mainly caused by reduced renal clearance of both methotrexate and its metabolite. The authors concluded that renal function in patients taking this combination should be monitored, with adequate fluid intake, especially in elderly patients, because dehydration may accelerate the occurrence of toxicity.

Phenytoin

Competitive albumin binding of drugs with high serum protein affinity can increase pharmacologically active unbound concentrations and enhance the metabolism of low clearance drugs. In vitro data suggest a significant increase in unbound phenytoin concentration by high doses of oxacillin, especially with hypoalbuminemia or uremia (256).

Interference with Diagnostic Tests

Pseudoproteinuria

Patients who take penicillin G or ureidopenicillin derivatives in doses over 5 g/day develop pseudoproteinuria. Proteinuria should be evaluated by a bromphenol blue test (Albustix) or after urine dialysis (SEDA-3, 219).

17-ketosteroids

High-dosage penicillin produces abnormally high concentrations of 17-ketogenic steroids in the blood and high concentrations of 17-ketosteroid in the urine (257).

Pentagastrin

General Information

Pentagastrin is a short peptide that stimulates the production of gastric acid from the stomach by a direct action on gastrin receptors and of calcitonin from thyroid C cells (1). It also acts on cholecystokinin receptors centrally and stimulates the release of adrenocorticotropin (ACTH) and hence the production of glucocorticoids (2).

Pentagastrin was originally used to test for suppression of gastric acid in patients who had had a vagotomy, and has been used to study gastric physiology and to test the effects of drugs that inhibit gastric acid secretion. It has also been used in the diagnosis of medullary carcinoma of the thyroid because it stimulates the production of calcitonin.

General adverse effects

Pentagastrin often causes adverse effects, which limit its use. Nausea, abdominal cramps, headache, drowsiness, and giddiness can occur. The effect on the stomach is largely dissociated from these unwanted effects. In one series 38 of 40 patients had a feeling of chest tightness (3). In 50 patients parenteral pentagastrin 6 micrograms/kg caused nausea in 14, tremor in 12, and a hot sensation in 11 (4). These effects occurred immediately after injection and continued for several minutes. In four subjects the test had to be stopped because of collapse.

Organs and Systems

Cardiovascular

Pentagastrin causes small transient increases in blood pressure and pulse (5), autonomic effects that are prevented by inhibiting cholecystokinin receptors (6). Atrial fibrillation has been observed (7).

Psychological, psychiatric

In a double-blind placebo-controlled study intravenous pentagastrin led to panic attacks in nine of 19 patients with social phobia, seven of 11 with panic disorder, and two of 19 healthy controls (8). Anxiety, blood pressure, and pulse increased in all three groups.

© 2006 Elsevier B.V. All rights reserved.

In a double-blind, placebo-controlled study in seven patients with obsessive-compulsive disorder and seven healthy controls, intravenous pentagastrin 0.6 microgram/kg produced panic-like reactions in six (86%) of the seven patients and only two (29%) of the controls (9).

The anxiety caused by pentagastrin is prevented by inhibiting cholecystokinin receptors (6).

Hematologic

In one case thrombocytopenia was attributed to pentagastrin (10).

Pancreas

- Acute severe abdominal pain occurred in a 25-year-old patient with recurrent duodenal ulcers after subcutaneous injection of pentagastrin (11). Laparotomy showed acute hemorrhagic pancreatitis. Healing and freedom from complaint occurred rapidly with drug therapy.

The authors postulated the following mechanisms: acute exacerbation of chronic pancreatitis, a direct effect of pentagastrin on the pancreas, increased pancreatic secretion due to stimulation by gastric acid, reflux of duodenal contents or bile, arterial hypotension with local acidosis in the pancreas.

Drug–Drug Interactions

Cimetidine

In 150 subjects some, but not all, of the somatic symptoms caused by pentagastrin were abolished by cimetidine; however, the combination of pentagastrin and cimetidine produced a significant incidence of dizziness (12).

Pentamidine

General Information

Pentamidine, an aromatic diamine, has been known since the late 1930s as a treatment for trypanosomiasis and some forms of leishmaniasis. In recent times it has been extensively used in the treatment of *Pneumocystis jiroveci* pneumonia. Its mechanism of action is probably related to inhibition of dihydrofolate reductase and inhibition of oxidative phosphorylation and nucleic acid synthesis, as well as an effect on aerobic glycolysis.

Pharmacokinetics

The pharmacokinetics of pentamidine are incompletely known. It is not absorbed after oral administration and needs to be given parenterally or by aerosol. After intramuscular injection peak concentrations are seen after about 1 hour, and the serum concentration stays about the same for 24 hours. A study of multiple dosing over 2 weeks showed progressive accumulation in the plasma during that time. After multiple intravenous doses the half-life was 12.5 days. After a course of treatment decreasing amounts of pentamidine can be found in the urine for as long as 8 weeks. It seems that pentamidine is stored or bound in the tissues and excreted slowly in the urine and the amount excreted changes only marginally with repeated doses. The highest tissue concentrations have been found in the kidney, followed by the liver and then other tissues, but pentamidine was not found in the brain. Serum concentrations after aerosol therapy are markedly lower than after intravenous therapy. Uptake via the lungs is limited, which explains the lack of serious systemic toxicity seen with aerosol treatment, but also explains the reported occurrence of extrapulmonary *Pneumocystis* infections.

These pharmacokinetic data merit attention, because they may be helpful in preventing toxicity, which seems to be dictated by tissue accumulation rather than serum concentrations; major toxic reactions usually occur only

© 2006 Elsevier B.V. All rights reserved.

after the first week of parenteral treatment. The pharmacokinetics may also explain the varied response to treatment with aerosolized pentamidine and the more satisfactory results of prophylaxis with the aerosol after initial parenteral treatment (SEDA-13, 824) (SEDA-16, 312). A retrospective study showed efficacy of intravenous pentamidine in AIDS patients with *Pneumocystis jiroveci* pneumonia, the most frequent toxic effects being gastrointestinal, especially nausea (SEDA-21, 299).

Observational studies

In an uncontrolled study in French Guiana, intramuscular pentamidine isethionate (two 4 mg/kg injections 48 hours apart) in 198 patients with cutaneous leishmaniasis produced a cure rate of 87%; 80% of treatment failures responded to an identical second course (1). Compared with published studies, adverse events were relatively mild: pain on injection (54%), gastrointestinal effects (53%), and hypotension (8%). There were no dysrhythmias or glucose abnormalities. This may reflect the brief course of pentamidine used.

Pentamidine is the drug of choice for the treatment of cutaneous leishmaniasis in Surinam. Pentamidine mesylate in 235 patients and pentamidine isethionate in 80 patients have been compared in a retrospective study; the cure rate (healing without relapse) was nearly 90% in both groups (2). Relapses occurred in about 10% of patients in both groups. Minor adverse effects, such as pain at the injection site, bitter taste, and nausea, occurred with both drugs in about 65% of patients. Respiratory tract problems occurred in under 10% of patients who took pentamidine isethionate but were uncommon in those who took pentamidine mesylate.

General adverse effects

Pentamidine in therapeutic doses has a high rate of adverse effects (over 50%). Toxicity seems to occur more often in patients with AIDS. Hypotension subsequent to injection or infusion, hypoglycemia, and nephrotoxicity are the major adverse effects. Hepatotoxicity and neutropenia are not uncommon. Compared with the general population there is a high incidence of pancreatitis in patients with AIDS, particularly during aerosol treatment. Hypoglycemia has also been seen after aerosol treatment. Intermittent prophylactic aerosol use causes few adverse effects, apart from cough and bronchial irritation after inhalation. There is a higher incidence of spontaneous pneumothorax with aerosol prophylaxis. There is also a higher incidence of extrapulmonary infections with *P. jiroveci* in patients treated with aerosolized pentamidine. Another disturbing finding was the higher incidence of other opportunistic infections with pentamidine aerosol versus placebo, while pentamidine aerosol was associated with a markedly lower recurrence rate of *P. jiroveci* pneumonitis in a placebo-controlled pentamidine aerosol study of prophylaxis after initial treatment (SEDA-13, 824). Intramuscular administration of pentamidine brings its own adverse effects: localized pain, erythema, and sterile abscesses are frequent and troublesome (SEDA-13, 824) (3). The use of the Z-track technique for injection mitigates the local effects. Allergic reactions have been reported. There is no information about tumor-inducing effects.

Organs and Systems

Cardiovascular

Severe hypotension can occur after a single intramuscular injection of pentamidine or with rapid intravenous administration, but has been seen with slow infusion as well. Infusing the drug over 60 minutes or more may reduce this risk. Facial flushing, breathlessness, dizziness, and nausea and vomiting can occur at the same time.

Cardiac dysrhythmias, including ventricular tachycardia, have been reported during treatment (SEDA-13, 824) (SEDA-16, 331) (4,5). Prolongation of the QT interval, which usually precedes the development of ventricular dysrhythmias with pentamidine, occurs in one-third of patients, usually within 2 weeks of starting therapy. Torsade de pointes has been described. Any dysrhythmia can recur many days after the pentamidine has been discontinued, which is not surprising, in view of the long half-life and tissue accumulation. Electrolyte abnormalities, including low serum magnesium concentrations, have been noticed at times of dysrhythmias (SEDA-16, 315) (SEDA-17, 331) (4–6).

- Torsade de pointes has been reported in a 48-year-old HIV-positive woman treated with intravenous pentamidine (7).

Local thrombophlebitis can occur after injection of pentamidine, but problems are more often seen at the injection site after intramuscular injection.

Respiratory

Inhalation of pentamidine can cause intolerable coughing. Bronchospasm can occur, especially in cases of asthma; tolerance of inhaled pentamidine is increased in nearly all patients by pretreatment with inhaled $beta_2$-adrenoceptor agonists (SEDA-16, 313) (SEDA-17, 330) (SEDA-18, 290) (4).

In lung function tests, high-dose aerosolized pentamidine (600 mg/month) was associated with an increased pulmonary residual volume, reduced flow rates, and increased airway reactivity (SEDA-18, 291).

There is an increased incidence of spontaneous pneumothorax after the administration of pentamidine by aerosol, which may be connected with the effect on airway resistance. There was a particularly high frequency of spontaneous pneumothorax in people with hemophilia; the authors suggested that *P. jiroveci* infection and treatment resistance had played a role (SEDA-16, 313).

Acute eosinophilic pneumonia after one dose of inhaled pentamidine of 300 mg has been reported; the reaction subsided within 2 weeks but recurred on rechallenge (SEDA-18, 292).

Dissemination of lung infection is a potentially serious matter, especially when using pentamidine by the aerosol route. While high alveolar drug concentrations can be reached in the most accessible parts of the lung, systemic absorption is minimal and the organism can spread through the lung and beyond, despite containment of the initial pulmonary infection; in some cases there has been extensive spread of *P. jiroveci* into major organs and the bone marrow (SEDA-16, 313) (SEDA-17, 332). Patients who have been treated with parenteral

© 2006 Elsevier B.V. All rights reserved.

pentamidine are at a lower risk of disseminated *P. jiroveci* infection than those given aerosol prophylaxis only (SEDA-16, 313) (SEDA-17, 322).

Nervous system

Mild dizziness can occur with pentamidine, but nervous system adverse effects are uncommon.

Psychological, psychiatric

Confusion and hallucinations have occasionally been reported with pentamidine. Magnesium deficiency may affect mental function; a flat affect, slow speech, and mental withdrawal are some of the typical effects (SEDA-13, 825) (6). The symptoms of hypomagnesemia can be ill defined; unexplained symptoms, despite improvement of the *P. jiroveci* infection, demand measurement of the serum magnesium concentration.

Metabolism

Hypoglycemia can be a serious and life-threatening effect of pentamidine and is seen in 10–30% of cases, mainly with parenteral use, although it can also occur with inhalation. In one 21-day study it was equally common with either form of therapy. Higher doses and longer durations of treatment increase the likelihood, as does prior treatment with pentamidine (SEDA-16, 314); uremia also increases the risk. In one study there was nephrotoxicity in all cases with hypoglycemia. The hypoglycemia is the result of a direct toxic effect on the pancreatic beta cells, resulting in insulin release and transient hypoglycemia, which is followed by beta cell destruction and insulin deficiency, which in turn can eventually lead to an irreversible state of diabetes mellitus (SEDA-13, 825) (SEDA-16, 315) (SEDA-17, 331) (4).

Mineral balance

Hypocalcemia has been attributed to pentamidine but not explained (8).

Hypomagnesemia (related to excess urinary excretion of magnesium due to pentamidine) and clinical signs of magnesium deficiency can have psychiatric consequences. Magnesium deficiency itself can affect mental function; a flat affect, slow speech, and mental withdrawal are some of the typical effects (SEDA-13, 825) (6). In one case (6) hypomagnesemia was still present 2 months after intravenous pentamidine treatment, although aerosolized pentamidine was being continued and could have caused hypomagnesemia. Some patients are particularly sensitive to this effect, and previous renal damage (for example by other drugs) can be a risk factor (SEDA-13, 825).

Hematologic

Anemia, leukopenia, or thrombocytopenia occur in less than 5% of cases (SEDA-13, 825). Thrombocytopenia is more likely to occur during prolonged therapy than initially.

Megaloblastic bone marrow changes can occur with prolonged therapy (SEDA-11, 598). Low blood cell counts have been reported even after aerosolized pentamidine.

- Intravenous pentamidine caused megaloblastic anemia in a 38-year-old woman with *Pneumocystis jiroveci* pneumonia (9).

In one patient with AIDS with severe but reversible thrombocytopenia after intravenous pentamidine, the serum during the acute phase contained antiplatelet antibodies that reacted with glycoprotein IIb/IIIa, similar to the reactions observed with quinine-induced thrombocytopenia (SEDA-18, 292). This suggests that even aerosol treatment or environmental exposure will need to be avoided in such patients.

Gastrointestinal

Gastrointestinal complaints due to pentamidine are usually minor. Nausea and vomiting can occur. Dysgeusia has been reported in a few cases with intravenous therapy, but one study of aerosol administration specifically noted its absence (SEDA-13, 825).

Liver

Occasionally, abnormal liver function tests have been seen in patients receiving pentamidine (10).

Pancreas

Episodes of acute pancreatitis and of hemorrhagic pancreatitis have been reported. This may or may not be combined with evidence of damage to pancreatic beta cells (SEDA-13, 825) (SEDA-16, 315) (SEDA-17, 331) (4). However, pancreatitis has also been seen in patients with AIDS who did not receive pentamidine. The risk of pancreatitis seems to be greater in children with CD4 counts under 100×10^6/l. In a case-control study 12 of 44 patients with AIDS and pancreatitis had used pentamidine (SEDA-20, 264).

Urinary tract

Nephrotoxicity is common with pentamidine. In one study, serum creatinine concentrations increased in nine of 10 patients with *P. jiroveci* infection during 2–3 weeks of treatment. The incidence is 20–35% (SEDA-13, 825), and in AIDS higher still, for example 50–65% (SEDA-17, 331) (4). Renal toxicity is more pronounced in patients with diarrhea and probably more severe with intramuscular use, perhaps because of dehydration, which is more readily corrected if the drug is given by infusion. In one study there was evidence of renal toxicity in all patients with pentamidine-induced hypoglycemia, in contrast to an incidence of 38% in the group who remained euglycemic. Because of the marked accumulation of pentamidine, it is conceivable that after an initial period of daily administration a modified treatment regimen, every other day or even twice a week, may prevent renal and pancreatic permanent damage (SEDA-13, 825).

Skin

Rashes can occur with pentamidine but are not common (11).

Local pain at the injection site, local infiltration, and sterile abscesses have been reported after intramuscular pentamidine (2,3).

© 2006 Elsevier B.V. All rights reserved.

There have been reports of a Herxheimer reaction and of skin lesions resembling toxic epidermal necrolysis, both in children (SEDA-13, 825).

Musculoskeletal

- Two patients (aged 31 and 38 years) with cutaneous leishmaniasis given intramuscular pentamidine 600 mg twice in 48 hours developed rhabdomyolysis (12). They recovered with fluid replacement and alkaline diuresis.

Drug Administration

Drug formulations

The administration of nebulized pentamidine has an environmental impact; handling the nebulizer, cleaning and preparing it for use, and assisting the patient exposes health-care workers to pentamidine (13). Adverse reactions, such as ocular and pulmonary irritation and irritation of exposed skin, have been reported in health care workers (14).

Drug–Drug Interactions

Potassium-sparing diuretics

Pentamidine is structurally similar to amiloride and can cause severe hyperkalemia if co-prescribed with potassium-sparing diuretic (15). This is a particularly important interaction in patients with AIDS.

Pentamorphone

See also Opioid analgesics

General Information

Pentamorphone is a potent opiate with a rapid onset and short duration of action, similar to that of fentanyl, which has been reported to produce analgesia with limited depression of ventilation (1).

Subjective symptoms in 23 male volunteers who received pentamorphone were pain on injection, headache, tiredness, euphoria, dizziness, visual disturbances, and nausea (2).

Organs and Systems

Cardiovascular

There was no effect on blood pressure or heart rate with pentamorphone doses of 0.015–0.48 micrograms/kg (2).

Pentaquine

General Information

Pentaquine is an 8-aminoquinoline that has been used to treat malaria (1,2) and trypanosomiasis (3,4). It has adverse effects very similar to those of primaquine.

Pentazocine

General Information

The adverse effects of pentazocine in effective doses are largely typical of its class (1,2), with some quantitative exceptions.

Pentazocine 30 mg had no effect on motor skills but impaired sensory processing and extraocular muscle imbalance (3). Other effects reported in this study were slight respiratory depression (enhanced by concurrent amitriptyline) and feelings of clumsiness, drowsiness, friendliness, and contentedness, and a muzzy head.

The effects of pentazocine were studied in 16 non-abusing volunteers recruited via posters and local newspaper advertisements and were compared with the effects of morphine (4). Pentazocine had dose-related effects on subjective, psychomotor, and physiological variables, and the clinically relevant dose of 30 mg produced a greater magnitude of dysphoric subjective effects than morphine 10 mg and, unlike morphine, impaired psychomotor performance. With pentazocine, peak ratings from the adjective checklist were significantly increased for "dry mouth," "sweating," and "turning of stomach." Compared with morphine, pentazocine led to higher ratings for "drunk," "feel bad," "having pleasant bodily sensations," and "having unpleasant bodily sensations."

Organs and Systems

Psychological, psychiatric

Perceptual disturbances are generally thought to occur more often with pentazocine than with other opioids. Objective definition of such phenomena is difficult, but in a study of postoperative dreaming after the use of pentazocine and morphine as premedicants there was no statistically significant difference between the two drugs (SED-11, 148) (5).

Hematologic

There have been reports of pentazocine-induced agranulocytosis in the absence of other predisposing factors (SED-11, 148) (6).

Skin

Two distinct types of skin lesions have been described in patients taking pentazocine: scleroderma-like changes, subcutaneous abscesses, cellulitis, ulceration, muscle atrophy and granulomas (all of which are well-recognized consequences of pentazocine abuse), and a generalized erythematous desquamative rash.

Severe renal insufficiency associated with toxic epidermal necrolysis has been reported (7).

Long-Term Effects

Drug abuse

Abusers sometimes adulterate the pentazocine with tripelennamine (T's and blues). Medical and psychiatric complications can include seizures, abscesses, depression, psychosis, dysphoria, confusion, and hallucinations (8,9).

Drug dependence

Pentazocine dependence is associated with a mild opioid–like withdrawal syndrome (8,9).

Drug withdrawal

A neonatal withdrawal syndrome has been described, with verification by the detection of pentazocine and its metabolites in the urine of both mother and baby. Within 4 hours of birth the child was irritable, jittery, and hypertonic, with a high-pitched cry, a voracious appetite, and frequent bowel movements. The symptoms improved over 3 days. The mother had abused parenteral pentazocine (23–46 mg) for the previous 10 years and injected the last dose of 46 mg some 10 hours before delivery (10).

Susceptibility Factors

Renal disease

A fatal nephrotic syndrome occurred in a 33-year-old man with renal glomerular disease dependent on pentazocine (SEDA-17, 88).

© 2006 Elsevier B.V. All rights reserved.

Other features of the patient

There is evidence that heavy smoking can increase the elimination of pentazocine; thus heavy smokers may require larger doses than non-smokers.

Drug Administration

Drug administration route

Fibrous myopathy and necrotic ulceration can occur at the injection site after repeated parenteral administration (1). Myocutaneous sclerosis and extensive calcinosis at the injection site have also been reported (SEDA-17, 88).

- A 58-year-old nurse who was given parenteral pentazocine developed large sclerotic and infected areas with multiple depressed atrophic scars at sites of prior ulceration; unsterile injection technique could not be excluded as a cause (11).
- A 47-year old woman with a 4-year history of injections of pentazocine into the legs developed very hard thigh and buttock muscles with hard, shiny, hairless overlying skin (12). Imaging showed fibrosis and calcification of the muscles and biopsy showed fibromyopathy. There were associated clinical and electrophysiological polyradiculopathy and multiple mononeuropathy of the lower extremities.
- A 26-year-old woman presented with progressive thickening and tightening of the skin over both her shoulders and buttocks, with resulting movement restrictions (13). She had a 5-year history of multiple intramuscular pentazocine injections for abdominal pain. The site of skin tightening was initially localized to the injection site. The affected areas increased progressively. There was an ill-defined area of hyperpigmented, indurated, "woody hard" skin bound to underlying structures and over her shoulders and buttocks. The diagnosis was pentazocine-induced widespread cutaneous fibrosis and myofibrosis. There was no evidence of scleroderma or dermatomyositis.
- A 38-year-old man, with a painless progressive restriction of flexion around both knee joints for 4 years, had been injecting pentazocine 1–2 ml intramuscularly for 18–20 years (14). The diagnosis was pentazocine-induced fibromyositis and contracture.

Drug overdose

Pentazocine in overdose can cause generalized tonic-clonic seizures, hypertension, hypotonia, dysphoria, hallucinations, delusions, and agitation, with a poor response to naloxone (15). Others have reported status epilepticus, coma, respiratory depression, acidosis, severe hypotension, and ventricular dysrhythmias.

Drug–Drug Interactions

Alcohol

There is increased toxicity in patients who take pentazocine with alcohol, antihistamines, or CNS depressants; one patient developed opioid pulmonary edema and one died (15).

Rhabdomyolysis and acute renal necrosis occurred in a 26-year-old man after concomitant use of pentazocine and alcohol (16).

Methylphenidate

Intravenous injection of a mixture of methylphenidate and pentazocine intended for oral use resulted in death due to granulomatosis associated with pulmonary hypertension (17).

Monoamine oxidase inhibitors

Opioids interact with monoamine oxidase inhibitors, causing CNS excitation and hypertension (18).

Serotonin re-uptake inhibitors

A serious excitatory interaction between fluoxetine and pentazocine has been reported (SEDA-16, 89). The authors commented on the similarity of this syndrome to the reported dangerous interactions between monoamine oxidase inhibitors and narcotic analgesics, and suggested that increased central 5-HT activity may be the basis of the observed interaction.
