In a randomized, double-blind, placebo-controlled study in 25 patients, fluconazole 200 mg/day increased methadone concentrations, but patients treated with fluconazole did not have signs or symptoms of significant narcotic overdose (99).

Omeprazole

Fluconazole absorption after oral administration is not influenced by gastric pH; thus there is no effect of omeprazole (100). Omeprazole is extensively metabolized in the liver by 5-hydroxylation and sulfoxidation reactions, catalysed predominantly by CYP2C19 and CYP3A4 respectively. Fluconazole is a potent competitive inhibitor of CYP2C19 and a weak inhibitor of CYP3A4. The effect of fluconazole on the pharmacokinetics of a single oral dose of omeprazole 20 mg has been evaluated after a single oral dose of fluconazole 100 mg and after 4 days of oral administration of 100 mg/day in 18 healthy male volunteers (101). Fluconazole increased the C_{max} and the mean AUC of omeprazole and prolonged its half-life (2.59 versus 0.85 hours).

Oral contraceptives

Fluconazole did not significantly alter the pharmacokinetics of ethinylestradiol or norgestrel, and this finding was interpreted by the investigators as suggesting that treatment with fluconazole in a user of oral contraceptives would not increase the risk of pregnancy (102). However, the study was carried out using a 50 mg dose of fluconazole, and experience with higher dosages has shown different results (SED-12, 682).

In another study, fluconazole reduced the systemic availability of ethinylestradiol in an oral contraceptive, but there was no information about the doses used (75).

In an open, crossover study in 10 young healthy subjects, fluconazole 150 mg increased the serum concentrations of ethinylestradiol 30–35 μg/day (103).

The potential pharmacokinetic interaction between fluconazole 300 mg once weekly and an oral contraceptive containing ethinylestradiol and norethindrone (Ortho Novum 7/7/7; Ortho-McNeil Pharmaceutical Inc, Raritan, NJ) has been studied in a placebo-controlled, double-blind, randomized, two-way, crossover study in 26 healthy women aged 18–36 years (104). During the first cycle they took the oral contraceptive only. During the second cycle they were assigned randomly to oral contraceptive + fluconazole or oral contraceptive + placebo. In the third cycle they

© 2006 Elsevier B.V. All rights reserved.

were given the other treatment. Fluconazole caused small but statistically significant increases in the $AUC_{0–24}$ of both ethinylestradiol and norethindrone. There were no adverse events related to treatment in those given fluconazole.

It therefore appears that there is no threat of contraceptive failure because of concomitant fluconazole administration.

Phenytoin

Co-administration of fluconazole and phenytoin resulted in markedly higher phenytoin concentrations (SED-12, 682) (21,84,87,105).

Rifamycins

The combination of rifampicin with fluconazole has insignificant effects (SED-12, 682) (21,87,106).

Statins

The effects of fluconazole on plasma fluvastatin and pravastatin concentrations have been studied in two separate, randomized, double-blind, two-phase, crossover studies (107). Healthy volunteers were given oral fluconazole (400 mg on day 1 and 200 mg on days 2–4) or placebo. On day 4, they took a single oral dose of fluvastatin 40 mg or pravastatin 40 mg. Fluconazole increased the plasma AUC and the half-life of fluvastatin by 80% but had no significant effects on the pharmacokinetics of pravastatin. The mechanism of the prolonged elimination of fluvastatin was probably inhibition of CYP2C9. Pravastatin, in contrast, appears not to be susceptible to interactions with fluconazole and other CYP2C9 inhibitors.

The effect of fluconazole on the pharmacokinetics of rosuvastatin has been investigated in a randomized, double-blind, two-way, crossover, placebo-controlled study (108). Healthy male volunteers ($n = 14$) were given fluconazole 200 mg/day or matching placebo for 11 days; rosuvastatin 80 mg was co-administered on day 8. Plasma concentrations of rosuvastatin, *N*-desmethylrosuvastatin, and active and total HMG-CoA reductase inhibitors were measured up to 96 hours after the dose. Fluconazole increased the AUC and C_{max} of rosuvastatin by 14% and 9% respectively. Limited data available for the *N*-desmethylated metabolite showed that the C_{max} fell by about 25%. Fluconazole did not affect the proportion of circulating active or total HMG-CoA reductase inhibitors accounted for by circulating rosuvastatin. Thus, fluconazole produced only small changes in rosuvastatin kinetics, which were not considered to be of clinical relevance.

Sulfonylureas

The concurrent administration of fluconazole with tolbutamide resulted in increased tolbutamide concentrations (SED-12, 682) (71).

- A 56-year-old HIV-positive patient with diabetes mellitus taking gliclazide 160 mg/day developed severe hypoglycemia when treated with co-trimoxazole 480 mg/day and fluconazole 200 mg/day (109). The authors speculated that fluconazole might have inhibited gliclazide metabolism by inhibiting CYP2C9.

The effects of fluconazole and fluvoxamine on the pharmacokinetics and pharmacodynamics of glimepiride have been studied in a randomized, double-blind, crossover study in 12 healthy volunteers who took fluconazole 200 mg/day (400 mg on day 1), fluvoxamine 100 mg/day, or placebo once daily for 4 days (110). On day 4 they took a single oral dose of glimepiride 0.5 mg. Fluconazole increased the mean total AUC of glimepiride to 238% and the peak plasma concentration to 151% of control values, and the half-life of glimepiride was prolonged from 2.0 to 3.3 hours. This was probably due to inhibition of CYP2C9-mediated biotransformation of glimepiride by fluconazole. However, fluconazole did not cause statistically significant changes in the effects of glimepiride on blood glucose concentrations.

Tacrolimus

Since tacrolimus (FK506) is metabolized by intestinal and hepatic CYP3A4, drugs that inhibit CYP3A4 can reduce the metabolism of tacrolimus and increase tacrolimus blood concentrations (111). The effect of fluconazole on the blood concentrations of tacrolimus have been investigated in eight liver transplant patients in whom prophylactic fluconazole (200 mg/day) was withdrawn because of rises in hepatic transaminases ($n = 6$), renal dysfunction, or eosinophilia ($n = 1$ each) (112). Calculated tacrolimus concentrations fell by 13–81% (median 41%) between the fourth and ninth days after withdrawal of fluconazole. Tacrolimus blood concentrations should be carefully monitored and dosages increased as necessary after withdrawal of fluconazole.

The interaction of tacrolimus with fluconazole has been retrospectively evaluated in 19 kidney and pancreas/kidney transplant recipients (90). Both intravenous and oral fluconazole altered the blood concentration of tacrolimus. Five subjects did not have a significant interaction and 15 did. No patient had nephrotoxicity or transplant rejection related to antifungal therapy.

- A 17-year-old man with cystic fibrosis who took itraconazole after a lung-liver transplant had high trough concentrations of tacrolimus, despite the relatively low dosage (0.1–0.3 mg/kg/day) (113).
- A patient taking tacrolimus 0.085 mg/kg bd with itraconazole 200–400 mg/day developed ketoacidosis, neutropenia, and thrombocytopenia, requiring the withdrawal of both drugs (114).
- A 34-year-old renal transplant recipient taking a stable regimen of tacrolimus and methylprednisolone was given itraconazole 100 mg bd for a yeast infection of the urinary tract (115). Concomitant therapy with itraconazole led to a marked increase in tacrolimus trough concentrations on the second day of therapy (from 13 to 21 ng/ml) and an increase in serum creatinine concentrations, necessitating dosage reduction of tacrolimus by 50%.

When itraconazole was withdrawn the effect of itraconazole on the kinetics of tacrolimus took 12 days to reverse.

The inhibitory effect of itraconazole occurred quickly, while the time of disappearance was much longer, which is important for clinical management. Thus, during co-administration of itraconazole with tacrolimus, close

© 2006 Elsevier B.V. All rights reserved.

monitoring of tacrolimus blood concentrations and careful dosage adjustments are essential to avoid toxicity.

Warfarin

Co-administration of fluconazole and warfarin has led in some cases to prolongation of the prothrombin time (21,87,106,116).

Zidovudine

Zidovudine glucuronidation in human hepatic microsomes in vitro was inhibited more by the combination of fluconazole with valproic acid than with other drugs, such as atovaquone and methadone (117).

Flucytosine

General Information

Flucytosine is an antimetabolite of the fluoropyrimidine type. The principle of selectivity of flucytosine for the fungal cell is dual: it depends on an enzyme in order to penetrate the cell (fungal cytosine permease) and a fungal enzyme that deaminates flucytosine to the active antimetabolite 5-fluorouracil, which is metabolized to 5-fluorouridine. Replacement of 5-fluorouracil in RNA results in the disruption of protein synthesis in the fungus. Flucytosine has selective activity against pathogenic yeasts such as Candida, but only moderate activity against Aspergillus and chromoblastomycosis. There is synergy between flucytosine and amphotericin, and the combination is effective against meningeal cryptococcosis and pheohyphomycosis of the central nervous system, specifically disease caused by *Xylohypha bantiana* (1–3). Flucytosine can be given orally as well as parenterally. For most fungal infections it should not be given as a single agent, because of the development of secondary drug resistance (4), with the possible exception of urinary tract infection (5), in which secondary resistance does however also occur.

The mechanism of toxicity of flucytosine is not fully understood. Conversion of flucytosine to certain metabolites, in particular 5-fluorouracil, in the liver or by the intestinal microflora after oral administration has been proposed. Toxicity may also occur through impurities in the raw material and the formation of fluorouracil from flucytosine after sterilization and storage.

Pharmacokinetics

Flucytosine can be given orally, and peak serum concentrations occur within 1–2 hours in patients with normal renal function. The absorption of flucytosine can be delayed by food or antacids. Flucytosine is minimally bound to plasma proteins. It penetrates into the CSF, vitreous humor, peritoneal fluid, inflamed joints, and other fluid compartments. There are several methods for determining serum concentrations, particularly the creatinine iminohydrolase assay, which makes use of the spurious creatinine increase in serum, as measured by the Kodak Ektachem analyser, an apparatus widely available and providing a low cost method compared with HPLC (6). Flucytosine accumulates in patients with renal insufficiency, resulting in potentially toxic serum concentrations. About 90% of the dose is excreted unchanged in the urine. Dose adjustments in renal insufficiency can be made in proportion to the reduction in creatinine clearance (7). Metabolism occurs to a limited extent (8). There is evidence that some flucytosine (5-fluorocytosine) is converted into 5-fluorouracil by the intestinal flora (9,10); 5-fluorouracil may also be present as an impurity in the original formulation or after prolonged storage (11).

Observational studies

Experience with flucytosine monotherapy of cryptococcosis has been reviewed in 27 patients treated between 1968 and 1973 who were selected for this form of therapy on the basis of criteria associated with good prognosis (4). Flucytosine was given as primary therapy to 18 patients and as secondary therapy (following failure of amphotericin deoxycholate) to nine patients in dosages of 4–10 g/day in four divided doses for 8 weeks. Toxicity associated with flucytosine was uncommon and mild. Mild leukopenia (nadir 3–4 $\times 10^9$/l) developed in three patients, and mild thrombocytopenia (101×10^9/l) and worsening anemia occurred in one patient each. Therapy was stopped early or changed in two patients. In the first, therapy was stopped after 31 days because of a white cell count of 4.1×10^9/l; despite the shortened course of therapy, the patient achieved a long-term cure, and the leukopenia was ultimately believed to be secondary to sarcoidosis.

© 2006 Elsevier B.V. All rights reserved.

There was bone marrow suppression in the second patient shortly after the withdrawal of flucytosine (because of failure to respond); later resumption of flucytosine during amphotericin therapy for this critically ill patient was associated with severe bone marrow suppression and death.

Comparative studies

Combination therapy with fluconazole (200 mg/day for 2 months) and flucytosine (150 mg/kg/day for the first 2 weeks; $n = 30$) has been compared with fluconazole monotherapy (200 mg/day for 2 months; $n = 28$) in a randomized open trial in Ugandan patients with AIDS-associated cryptococcal meningitis (12). Patients in both groups who survived for 2 months received maintenance therapy with fluconazole (200 mg three times per week for 4 months). There were no serious adverse events in any of the patients. The combination therapy prevented death within 2 weeks and significantly increased the survival rate at 6 months (32 versus 12%). However, the rate of positive cryptococcal antigen titers remained high at 2 months after treatment in both groups.

General adverse effects

The toxicity and drug interactions of flucytosine have been reviewed (13). Nausea, vomiting, and diarrhea are common. Enterocolitis is infrequent. Hepatic dysfunction, hepatitis, and even hepatic necrosis and blood disorders, including fatal aplastic anemia, can occur (14). Severe reactions mainly occurred at a time when the importance of high serum concentrations (in excess of 100 μg/ml) of flucytosine in causing these adverse effects was not recognized. The importance of parenteral versus intravenous administration in the development of enterocolitis is unclear. Patients have been described who suffered adverse effects, such as hepatotoxicity or eosinophilia, that were idiosyncratic and not related to flucytosine concentrations. Hypersensitivity reactions can occur. Neither teratogenic nor tumor-inducing effects have been recorded.

Organs and Systems

Cardiovascular

Life-threatening fluorouracil-like cardiotoxicity has been attributed to flucytosine (15).

- A 34-year-old woman took flucytosine, 500 mg 12 times a day for 2 days, for vaginal candidiasis. After the last dose she complained of chest pain, which persisted for a week and was associated with ST segment elevation during exercise. Coronary angiography showed normal coronary arteries. One month later she was rechallenged with 500 mg 12 times a day for 2 days. The day after completion of this regimen, she developed severe chest pain. Electrocardiography showed widespread ST segment elevation and echocardiography showed apicolateral septal hypokinesia with a left ventricular ejection fraction of less than 15%. Her flucytosine plasma concentration 48 hours after the last dose was not high, but the fluorouracil concentration was similar to that found during a 5-day continuous infusion of 5-fluorouracil. Her lymphocytes showed no abnormalities of intracellular flucytosine clearance, and cytosine deaminase, the enzyme that converts flucytosine to fluorouracil, was not detectable.

Similar cardiotoxicity has been reported with 5-fluorouracil. The reported events were generally consistent with a drug- or metabolite-induced increase in coronary vasomotor tone and spasm, leading to myocardial ischemia. The authors concluded that more attention should be given to the conversion of flucytosine to fluorouracil; however, it is not clear whether flucytosine should be contraindicated in patients with vasospastic or exertional angina.

Nervous system

Headaches, confusion, hallucinations, somnolence, and vertigo can occur. There have also been a few reports of peripheral neuropathy. However, it is difficult to establish the role of flucytosine in these adverse reactions (SED-12, 674). An acute cerebellopathy has been attributed to flucytosine (16).

Hematologic

Bone marrow suppression is a recognized toxic effect of flucytosine; anemia, leukopenia, and thrombocytopenia occur in about 5% of cases. The hematological effects are dose-related and occur after prolonged high blood concentrations of flucytosine (over 100 μg/ml). Hematotoxicity is seen more often in the presence of renal insufficiency and hence during the use of flucytosine in combination with amphotericin. If bone marrow reserve has already been depleted by underlying disease or by medications, the risk of hematotoxicity increases.

The relation between the toxicity and pharmacokinetics of flucytosine has been investigated in a retrospective study in 53 patients in an intensive care unit (17). Thrombocytopenia, as a marker of bone marrow depression, was associated with a reduced clearance of flucytosine; the lowest thrombocyte count was linearly related to the clearance of flucytosine. Patients with flucytosine concentrations over 100 μg/ml were at higher risk of thrombocytopenia and raised hepatic transaminases than those who did not exceed this threshold. In a second study, the authors corroborated their earlier findings and showed a significant relation between the lowest thrombocyte counts and thrombocyte counts predicted on the basis of the creatinine clearance in a new set of patients admitted to the intensive care unit (18).

In a pilot study in six patients receiving intravenous flucytosine, hematotoxicity was monitored by measuring platelet and leukocyte counts; flucytosine and 5-fluorouracil serum concentrations were measured using HPLC (19). The concentrations of 5-fluorouracil in the 34 available serum samples were below the limit of quantification (0.05 μg/ml), but flucytosine was detectable in all samples and the 5-fluorouracil metabolite, α-fluoro-β-alanine (FBAL), was detected at low concentrations in several samples. One patient developed thrombocytopenia (50×10^9/l) during therapy, and one developed leukopenia (2.6×10^9/l). The fact that 5-fluorouracil was not detected

© 2006 Elsevier B.V. All rights reserved.

in the serum made it unlikely that the toxic effects of intravenous flucytosine resulted from exposure to 5-fluorouracil.

Patients with AIDS, treated for antifungal disease with flucytosine and amphotericin, are particularly susceptible to develop bone marrow depression (1,3). On the other hand, flucytosine can be safely administered to patients with cancer (6) or AIDS (12,20), if toxic concentrations are avoided and blood counts monitored.

Gastrointestinal

Nausea, vomiting, and diarrhea are the most common adverse effects of flucytosine.

Enterocolitis, usually sparing the rectosigmoid, has been described in some cases (21). This type of flucytosine toxicity may be associated with deamination of flucytosine to 5-fluorouracil in the gut (1). Potentially fatal ulcerative colitis has been suspected in a few patients; however, in most cases there were no diagnostic data to back up the diagnosis.

Liver

Abnormal liver function tests (above normal serum alkaline phosphatase and transaminases and, less often, raised serum bilirubin concentrations) have all been reported. Hepatic involvement is rarely serious (SED-12, 675) (22).

Liver cell necrosis, detected by means of liver biopsy, has been rarely described (SED-9, 477) (23).

The reason for antifungal treatment and the concurrent use of other medication may contribute to hepatotoxicity (SED-12, 675) (1,6).

Urinary tract

Crystalluria has been reported, with urinary gravel, consisting of a co-precipitate of flucytosine and uric acid (24).

Skin

Maculopapular and urticarial rashes severe enough to require drug withdrawal have been reported (SEDA-2, 242). The incidence is low.

Acquired photosensitivity has been described in two cases (25).

Immunologic

Anaphylaxis has been reported in a patient with AIDS (26).

Second-Generation Effects

Teratogenicity

Flucytosine is teratogenic in rats, and its close chemical relation to antimetabolites plus the fact that 5-fluorouracil is a metabolite make it inadvisable to administer flucytosine during pregnancy or to fertile women taking no contraceptive precautions.

Drug–Drug Interactions

Amphotericin

Amphotericin in combination with flucytosine results in an increased risk of hematological complications, because amphotericin often impairs renal function, causing retention of flucytosine (7). This combination also delays hematopoietic recovery after cytotoxic chemotherapy; it should not be used as empirical antifungal therapy in febrile patients with neutropenia (27).

Antifungal azoles

Flucytosine has been successfully used in combination with ketoconazole, fluconazole, and itraconazole. Flucytosine and ketoconazole were synergistic in about 40% of yeast isolates resistant to flucytosine alone. The synergistic action of flucytosine with the triazoles against *Candida* species was seen both in vitro and in vivo (3–6).

Cytarabine

The suggested interaction of cytarabine with flucytosine, in which there is competitive inhibition of antifungal activity, has not been confirmed (28).

Monitoring Therapy

Monitoring blood concentrations of flucytosine is essential, so that the dosage can be altered according to changing renal function and to avoid toxicity. Peak plasma concentrations should be 40–60 μg/ml after an oral dose, and under 100 μg/ml after intravenous infusion. To avoid fungal resistance, trough concentrations below 20 μg/ml are recommended (7).

Fludarabine

See also Cytostatic and immunosuppressant drugs

General Information

Fludarabine phosphate is a purine nucleoside antitumor agent, which inhibits adenosine deaminase. It is mainly used to treat chronic lymphocytic leukemia. Dose-limiting myelotoxicity, nausea and vomiting, and raised liver enzymes were observed during early clinical studies. The most common adverse effect is myelosuppression (WHO grade 3 or 4), and other common adverse effects include infections and gastrointestinal disturbances, although these are usually of mild to moderate intensity (WHO grade 1 or 2) (1).

Organs and Systems

Respiratory

Fludarabine can cause interstitial pneumonitis (2,3).

- A 73-year-old woman developed fever and cough 2 weeks after completing a third cycle of fludarabine for chronic lymphocytic leukemia. A chest X-ray showed multiple pulmonary nodules and a biopsy showed a mononuclear interstitial infiltrate without evidence of malignant, infectious, granulomatous, or vascular causes. Her symptoms and pulmonary nodules resolved after treatment with glucocorticoids (4).

There has also been a report of an acute eosinophilic pneumonia associated with peripheral blood eosinophilia in a patient with follicular lymphoma (5).

Nervous system

Dose-intensified fludarabine causes severe central nervous system toxicity. In 70 patients with acute leukemia who received 95 courses of fludarabine 20–220 mg/m^2 for 5–7 days there was neurotoxicity in 36% of those who received doses over 96 mg/m^2/day, but in only 0.2% of those who received lower doses (6). The onset of neurological symptoms was at 21–60 days after the last course of fludarabine. Visual symptoms were the most common. There was progressive deterioration of mental state or encephalopathy leading to a vegetative state in 11 patients. Progressive demyelination in the central nervous system was the main factor causing the neurotoxic symptoms; this can occur as a result of viral complications during drug-related immunosuppression.

Hematologic

Fludarabine can cause or exacerbate autoimmune thrombocytopenia in chronic lymphocytic leukemia. Two patients with chronic lymphatic leukemia who developed thrombocytopenia while taking fludarabine were treated

© 2006 Elsevier B.V. All rights reserved.

with high-dose glucocorticoids and initially responded with recovery of platelet counts (7). One developed recurrent thrombocytopenia on two occasions after re-exposure to fludarabine when his disease had become refractory to all other treatments. Of 45 patients with lymphoproliferative disorders treated with fludarabine over the previous 6 years, retrospectively reviewed, 2 had developed autoimmune thrombocytopenia and 3 had developed autoimmune hemolytic anemia.

In three patients with chronic lymphatic leukemia, fludarabine-associated thrombocytopenia responded to rituximab 375 mg/m^2/week for 4 weeks (8). Other similar cases have been reported (9). However, when rituximab was added to a regimen of fludarabine plus cyclophosphamide in patients with relapsed follicular lymphoma, there was unexpected severe hematological toxicity, with significant, prolonged thrombocytopenia WHO grade 3/4 in six of 17 patients (10). Older patients (mean age 65 versus 57 years) were significantly more likely to have this adverse effect, and no other clinical or hematological parameters differed between the patients with thrombocytopenia and those without.

Peripheral blood eosinophilia, in one case up to 7.9×10^9/l, has been attributed to fludarabine (11).

- A 58-year-old man who took fludarabine for 5 months developed a peripheral eosinophilia with a peak value of 1.7×10^9/l; thorough investigation for other causes of eosinophilia was negative (12).

A patient with a high-grade B cell non-Hodgkin's lymphoma treated with fludarabine developed a high-titer antibody to factor VIII while the lymphoma was in remission; the authors speculated that the occurrence of the inhibitor was an autoimmune adverse effect of fludarabine (13).

Gastrointestinal

Intestinal pseudo-obstruction has been attributed to fludarabine in a 66-year-old man with non-Hodgkin's lymphoma; it was successfully managed with a combination of parasympathomimetic drugs and mechanical decompression (14).

Immunologic

Treatment with fludarabine results in prolonged immunosuppression lasting over 6 months (15). Patients who are immunocompromised are at risk of infection with chemotherapy. Infection with JC virus, a human polyoma virus, occurred in two patients after fludarabine treatment of a low-grade lymphoma, which led to a progressive multifocal leukoencephalopathy (16). In one series of 27 patients who received fludarabine, serious infections developed in 24 (17).

Drug–Drug Interactions

Melphalan

Cardiotoxicity has rarely been reported with melphalan or fludarabine alone, but severe left ventricular failure developed in three of 21 patients treated with a combination of these two drugs (18).

Flufenamic acid and meclofenamic acid

See also Non-steroidal anti-inflammatory drugs

General Information

Flufenamic acid and meclofenamic acid are anthranilic acid derivatives similar to mefenamic acid. The withdrawal rate because of adverse effects is 7–31% and is higher in long-term studies. Flufenamic acid and meclofenamic acid are not widely prescribed and so there is little evidence to show whether they have any advantages over other NSAIDs. Both have a high incidence of gastrointestinal adverse effects (30–60% of patients at recommended doses). Diarrhea affects 11–46% of patients (SEDA-4, 68) (SEDA-6, 99) (SEDA-7, 116) (SEDA-14, 95). Thrombocytopenia with positive rechallenge has been described (1). Rashes occur in under 10% of patients. Meclofenamic acid exacerbates psoriasis in psoriatic arthropathy (2).

Flumazenil

General Information

Flumazenil is used as a benzodiazepine antagonist in the treatment of poisoning or the reversal of benzodiazepine effects in anesthesia (1,2) or in neonates (3). Guidelines for its use have been summarized (4). The problems in its use are those of dose adjustment, the risks of panic anxiety, seizures, or other signs of excessively rapid benzodiazepine withdrawal, and pharmacokinetic problems due to the short half-life of flumazenil (about 1 hour) compared with the longer half-lives of most benzodiazepines (5). Its use is also commonly associated with vomiting and headache, and rarely with psychosis or sudden cardiac death (SEDA-17, 46), especially in mixed overdoses. Flumazenil was not effective in reversing the amnesic effects of midazolam (6), but it may be useful in hepatic coma, regardless of cause (7). In patients with a history of seizures or chronic benzodiazepine dependence, or after mixed drug overdose, flumazenil can trigger convulsions, which are occasionally fatal. It is not generally helpful to measure benzodiazepine plasma concentrations, but they can assist in the diagnosis of overdose and thus guide the use of antagonists (8).

Midazolam can cause paradoxical reactions, including increased agitation and poor cooperation (9,10). Often other drugs are required to continue the procedure successfully. Reversal of these reactions by flumazenil has been reported. In 58 patients undergoing surgery under spinal or epidural anesthesia, flumazenil 0.1 mg over 10 seconds abolished the agitation without reversing sedation (total dose range 0.1–0.5 mg) (11). In 30 patients who had been given midazolam, flumazenil 0.15–0.5 mg resulted in cessation of the agitation without reversal of sedation (9). Adverse effects of flumazenil were not reported in these studies.

The usefulness and relative safety of midazolam in children have been reviewed (12). Myoclonic-like movements associated with midazolam in three full-term newborns were reversed by flumazenil (13). However, care must be taken when considering the use of flumazenil for reversal of midazolam-induced agitation, as no controlled trials have been published.

Organs and Systems

Nervous system

A case of opisthotonos after flumazenil has been reported (14).

- A healthy 17-year-old man received an interscalene brachial plexus block using mepivacaine 600 mg and bupivacaine 150 mg. He became disorientated and showed signs of local anesthetic toxicity, for which he was given midazolam 5 mg. Flumazenil 0.5 mg was given 23 minutes after the end of the procedure, causing opisthotonos.

Similar reports have appeared in the past in patients with seizure disorders. It is recommended that flumazenil not be used in patients predisposed to seizures.

Endocrine

The effects of flumazenil and midazolam on adrenocorticotrophic hormone and cortisol responses to a corticotrophin-releasing hormone challenge have been assessed in eight healthy men (15). Flumazenil significantly reduced adrenocorticotrophic responses compared with midazolam or placebo, but had no effects on cortisol secretion. The authors suggested that this agonist effect of flumazenil on the pituitary–adrenal axis might account for the anxiolytic activity of flumazenil, which has been observed during simulated stress.

Long-Term Effects

Drug withdrawal

Flumazenil can provoke acute withdrawal reactions and extreme anxiety (16). Its duration of action (less than 1 hour) is generally shorter than that of the original benzodiazepine, whose effects can therefore return while the patient is unobserved.

Flunitrazepam

See also Benzodiazepines

General Information

Flunitrazepam has acquired a reputation for toxicity, abuse potential (1) and associated forensic problems (2), including being implicated in sexual assault ("date rape") (3). It has been withdrawn from general availability in various countries, including the USA, Australia, and New Zealand, and it is considered to be a narcotic in various European countries. It has a rapid onset of action but a long half-life. The earlier recommended hypnotic dose (1–2 mg) is excessive, and like some other benzodiazepines, such as triazolam, flunitrazepam is safer in a smaller dose (4). Like triazolam, it has been associated with nocturnal binge eating (5). Although its outpatient use in individuals who are susceptible to abuse is hazardous, intravenous flunitrazepam is useful for alcohol withdrawal delirium, but assisted ventilation should be available.

Long-Term Effects

Drug withdrawal

Withdrawal syndrome and delirium has been attributed to flunitrazepam (6).

- A 69-year-old man developed acute benzodiazepine withdrawal delirium following a short course of flunitrazepam after an acute exacerbation of chronic obstructive pulmonary disease. He was not an alcohol- or drug-abuser and he had not previously taken benzodiazepines. Six days after withdrawal of flunitrazepam he became agitated and confused, and had visual hallucinations, disorganized thinking, insomnia, increased psychomotor activity, disorientation in time and place, and memory impairment. Tachycardia and significant anxiety were also noted. He fulfilled the DSM IV criteria for withdrawal syndrome and delirium, and had spontaneous remission of symptoms within 48 hours.

The authors commented that physicians should be more aware of drug withdrawal syndromes, even after limited periods of administration of sedative drugs.

Fluoride salts and derivatives

General Information

Fluoride is the single most potent bone-forming agent currently available for therapeutic use (1). The active moiety is the fluoride ion itself, and its main pharmacological effect is on dental enamel and bone. Fluoride ions bind to calcium ions, stimulating trabecular bone formation. Different fluoride products have been used for the therapy of osteoporosis. The first was sodium fluoride (NaF), but that had several adverse effects, such as epigastric pain, gastric hemorrhage, leg pain, and so-called stress fractures (2).

In a study of the adverse effects of fluorinated drinking water (3), a few patients had non-specific ailments of varying duration, involving different systems. Severe headache, loss of strength, and abdominal cramps were noted, sometimes with polydipsia and polyuria. The symptoms disappeared promptly when fluorinated water was withdrawn, and reappeared immediately after rechallenge.

Therapeutic studies

There are currently no trial-based recommendations for the treatment of idiopathic osteoporosis in men. The effects of intermittent low-dose fluoride combined with continuous calcium supplementation on bone mass and future fracture events have been evaluated in 64 men with idiopathic osteoporosis (4). They were randomized to intermittent treatment with monofluorophosphate plus calcium or calcium supplementation alone for 3 years. Seven of the patients given fluoride had leg pain. In most cases the pain, which was generally confined to the ankle, disappeared during the fluoride-free month. In a few cases, the fluoride-free month had to be prolonged to 7 or 8 weeks before the symptoms subsided. During fluoride therapy, two patients had mild epigastric symptoms and one had diarrhea, but these appeared to be related to calcium; seven of the patients who were given calcium alone complained of epigastric discomfort and two had diarrhea. All the adverse events were mild to moderate and transient, and none led to discontinuation of treatment.

A 3-year, open study (5) has been performed with monofluorophosphate in 60 patients under 75 years old (average age 62 years, body weight 42–84 kg, height 148–174 cm) with established postmenopausal vertebral osteoporosis and a lumbar t-score lower than –2.5 BDM (measured by dual-energy X-ray absorptiometry) and at least one vertebral fracture diagnosed according to WHO criteria (6). The patients had taken hormone replacement therapy for an average of 2 years. Patients with inflammatory rheumatic diseases and those who were taking other medications that can modify bone metabolism, such as calcitonins, bisphosphonates, vitamin D, or anabolic agents, were excluded. There were adverse events in 19 patients, 10 of which were probably due to the monofluorophosphate or calcium components, three with gastrointestinal symptoms and seven with leg pain. The other nine adverse events were probably due to the hormone replacement therapy component: three with vaginal bleeding, four with breast tenderness, one with "heavy legs," and one with increased body weight. All the adverse events were of mild or moderate intensity and resolved spontaneously; none required withdrawal of treatment.

Organs and Systems

Nervous system

In a child, there were tetanic spasms and a convulsion more than 12 hours after fluoride ingestion, with a normal serum calcium. It is advisable that patients with intoxication should remain under surveillance for at least 24 hours, after the usual acute symptoms such as vomiting and diarrhea have settled (SEDA-10, 439).

Mouth and teeth

Fluoride poisoning can occur: after chronic ingestion of excessive amounts of fluoride, causing osteosclerosis and dental fluorosis (mottled enamel), due to accidental ingestion of fluoride mixtures during dental treatment (7,8), or after ingestion of insecticides or rodenticides containing fluoride salts.

Gastrointestinal

Fluoride can cause gastrointestinal damage (9). In 10 subjects, 3 g of a 0.42% fluoride gel caused mucosal petechiae and erosions in 7 cases; there were histopathological changes in nine cases, mostly affecting the surface epithelium (8). The authors advocated the use of a low concentration of fluoride gel instead of a 1.23% gel in small children, in order to avoid adverse gastric effects.

Skin

Fluoride in therapeutic doses can cause atopic dermatitis (9). Two patients who used fluoride gel preparations applied to the teeth developed papulonodular eruptions similar to halogenodermas (10).

Musculoskeletal

Although sodium fluoride can be used to treat osteoporosis, there is a risk of stress fractures (11–14). Fluoride has a dual effect on osteoblasts: it increases the rate of production of osteoblasts by a mitogenic effect on their precursors but also has a toxic effect on individual cells, causing impairment of mineralization and a reduced rate of apposition resembling osteomalacia (15). Fluoride increases axial bone density, but without matching changes in cortical bone. The effect on fracture rates of adding fluoride to the drinking water is not clear, but it probably only has a small impact. In two controlled studies the incidence of vertebral fractures fell, while in two other studies it increased.

Chronic ingestion of excessive amounts of fluoride can cause osteosclerosis (15). Severe dental fluorosis, hypersensitivity of teeth, and skeletal fluorosis have been reported in rural communities exposed over a long period of time to high concentrations of fluoride in the water (10 ppm) (16). There were deformities of the arms and legs with resultant genu valgum. There was osteosclerosis of the axial bones and osteoporosis in the

© 2006 Elsevier B.V. All rights reserved.

appendicular bones. Serum calcium and inorganic phosphate were normal, but serum alkaline phosphatase was increased.

Perimalleolar pain with swelling (SED-12, 1243) and extremity pain after fluoride treatment in postmenopausal osteoporosis (17) have been reported.

Second-Generation Effects

Fertility

In a US study designed to determine whether fluoride affects human birth rate (18) the annual total fertility rate in women aged 10–49 years was calculated for 1970–88 in counties with water fluoride concentrations of at least 3 parts per million (ppm). For each region separately, the annual total fertility rate was tested by regression against the water fluoride content and sociodemographic co-variables. In most regions there was an association between increasing fluoride concentrations in drinking water and a falling total fertility rate. The study was based on population means rather than individual data, but there was no indication that the result was influenced by selection bias, inaccurate data, or inappropriate analytical methods. It does not necessarily follow that the effect of fluoride on fertility rate also applies to individual women, and that is a matter for further research.

Drug Administration

Drug overdose

Although 5–10 g of fluoride is considered to be the acute lethal dose, a fatality has been reported in a patient who took less than 50 mg, suggesting a wide variation in the lethal dose.

Fluoroquinolones

See also Individual agents

General Information

Following the introduction of the first quinolone antibiotic (nalidixic acid, see separate monograph), structural modifications to the basic quinolone and naphthyridone nucleus and to the side-chains produced fluoroquinolones with improved coverage of bacterial pathogens, with high activity against Gram-negative species and a number of atypical pathogens, and good-to-moderate activity against Gram-positive species. However, despite their broad spectrum and clinical success, defects became evident, and compounds developed in recent years have targeted improvements in pharmacokinetic properties (improved systemic availability, once-daily dosing), greater activity against Gram-positive cocci and anerobes, activity against fluoroquinolone-resistant strains, and better coverage of non-fermenting Gram-negative species (1–4).

The following fluoroquinolones are covered in separate monographs: alatrofloxacin and trovafloxacin, ciprofloxacin, garenoxacin, gatifloxacin, gemifloxacin, grepafloxacin, levofloxacin, lomefloxacin, moxifloxacin, norfloxacin, ofloxacin, pazufloxacin, pefloxacin, sitafloxacin, sparfloxacin, and tosufloxacin (all rINNs).

Fluoroquinolones are administered by several routes (5). The duration of therapy can vary from a single dose to

© 2006 Elsevier B.V. All rights reserved.

several weeks or months. Owing to their adverse effects (including severe anaphylaxis, QT interval prolongation, and potential cardiotoxicity), several fluoroquinolones have had to be withdrawn (for example temafloxacin and grepafloxacin) or strictly limited in their use (for example trovafloxacin) after marketing (6). A serious idiosyncratic reaction profile may be related to the immunologically reactive 1-difluorophenyl substituent that characterizes temafloxacin, trovafloxacin, and tosufloxacin (1).

Withdrawal of fluoroquinolones

Owing to adverse effects (including severe anaphylaxis, QT interval prolongation, and potential cardiotoxicity), several fluoroquinolones have had to be withdrawn (for example temafloxacin and grepafloxacin) or strictly limited in their uses (for example trovafloxacin) after marketing. A serious idiosyncratic reaction profile is possibly related to the immunologically reactive 1-difluorophenyl substituent that characterizes temafloxacin, tosufloxacin, and trovafloxacin (7).

The withdrawal of temafloxacin in 1992, only 6 months after its introduction, followed the observation of serious adverse events that were labeled the "temafloxacin syndrome" (8). Adverse effects, including hemolysis, renal dysfunction, coagulopathy, and hepatic dysfunction, were estimated to occur in one in 3500 patients. For comparison, incidence rates for these adverse events were about one in 17 000 patients treated with ciprofloxacin and one in 33 000 patients treated with ofloxacin.

In 1999 trovafloxacin was withdrawn after reports of lethal hepatic damage. Before this development, several studies had been published describing impressive clinical efficacy coupled with an almost flawless safety profile (9,10).

Grepafloxacin was withdrawn from the market in 1999 because of its adverse cardiovascular events, which included dysrhythmias (11).

Clinafloxacin has been withdrawn because of phototoxicity and hypoglycemia and sparfloxacin because of phototoxicity (12).

These experiences demonstrate the need to be vigilant about any untoward events associated with large-scale use of new fluoroquinolones.

Comparative studies

In a crossover, randomized study, 16 fasted volunteers (8 men, 8 women) took single oral doses of gemifloxacin 320 mg and ofloxacin 400 mg on two separate occasions, in order to assess urinary excretion (13). Urine concentrations of ofloxacin were higher than those of gemifloxacin. There were no adverse effects.

General adverse effects

In spite of widely publicized negative experiences, most fluoroquinolones are safe, and adverse events are, compared with other groups of antimicrobial agents, relatively rare (14). The rates of overall adverse events were similar in several comparisons of individual quinolones among themselves or with other antimicrobial agents. In one multicenter, double-blind, randomized study drug-related adverse events were reported by 8.9% of those taking levofloxacin and 8.2% of those taking ciprofloxacin for 7–10 days (15). A meta-analysis of data from 20 phase II and III studies in 4926 patients treated with moxifloxacin showed that adverse events led to withdrawal of treatment in 3.8% of patients (16). In a comparison of grepafloxacin and ciprofloxacin for exacerbations of chronic bronchitis withdrawal was precipitated by adverse events in 3% of 624 patients; there was no difference between ciprofloxacin and grepafloxacin (17). The most frequent causes of withdrawal were nausea, vomiting, dysgeusia, dizziness, and diarrhea. In smaller studies, adverse events are occasionally observed more often. In a prospective, double-blind comparison of ciprofloxacin, ofloxacin, and co-trimoxazole for short-course treatment of acute urinary tract infections, there were drug-related adverse events in 26% of patients treated with ciprofloxacin and 34% of patients treated with ofloxacin (18).

If analysis of the frequency of adverse events is based on prescription event monitoring (PEM), the rates of adverse events are usually substantially lower. In one study, over 11 000 patients taking each antibiotic were monitored (19). Among the fluoroquinolones, ciprofloxacin, norfloxacin, and ofloxacin were used. Adverse events resulted in withdrawal of norfloxacin or ofloxacin in under 1% of patients (19).

The main systems affected by adverse effects of the quinolones are the skin, liver, and nervous system. The best-known adverse effect is phototoxicity, the risk of which varies markedly among the quinolones; lomefloxacin and sparfloxacin carry a particularly high risk. The development of phototoxicity is based on an interaction between light and the drug. Neurotoxicity also occurs, with marked variation of incidence between the various compounds. Hypersensitivity reactions to quinolones are rare, and include anaphylactic shock and anaphylactoid reactions. Organ-specific reactions attributed to hypersensitivity involve the liver and kidneys. If hypersensitivity reactions occur, switching from one quinolone compound to another is probably not advisable, since there is cross-reactivity.

The risk of neoplastic disease is minimal, even during long-term use, but may be increased by exposure to UVA light.

Using electron spin resonance spectroscopy and spin trapping, ciprofloxacin has been shown to cause free radical production in a dose- and time-dependent manner; the authors suggested that this effect may contribute to drug-related adverse effects, including phototoxicity and cartilage defects (20).

The most common drug interactions include malabsorption interactions associated with multivalent cations and CYP450 interactions (21).

Pharmacoeconomics

The pharmacoeconomic impact of adverse effects of antimicrobial drugs is enormous. Antibacterial drug reactions account for about 25% of adverse drug reactions. The adverse effects profile of an antimicrobial agent can contribute significantly to its overall direct costs (monitoring costs, prolonged hospitalization due to complications or treatment failures) and indirect costs (quality of life, loss of productivity, time spent by families and patients receiving medical care). In one study an adverse event in a hospitalized patient was associated on average with an excess of 1.9 days in the length of stay, extra costs of $US2262 (1990–93 values), and an almost two-fold increase in the risk of death. In the outpatient setting, adverse drug

© 2006 Elsevier B.V. All rights reserved.

reactions result in 2–6% of hospitalizations, and most of them were thought to be avoidable if appropriate interventions had been taken. In a review, economic aspects of antibacterial therapy with fluoroquinolones have been summarized and critically evaluated (22).

Organs and Systems

Cardiovascular

Some quinolones can prolong the QT interval, with a risk of cardiac dysrhythmias. In an in vitro study in isolated canine cardiac Purkinje fibers the rank order of potency in prolonging action potential duration was sparfloxacin > grepafloxacin = moxifloxacin > ciprofloxacin (23). In guinea-pig ventricular myocardium sparfloxacin prolonged the action potential duration by about 8% at 10 μmol/l and 41% at 100 μmol/l (24). Gatifloxacin, grepafloxacin, and moxifloxacin were less potent, but prolonged the action potential duration at 100 μmol/l by about 13%, 24%, and 25% respectively. In contrast, ciprofloxacin, gemifloxacin, levofloxacin, sitafloxacin, tosufloxacin, and trovafloxacin had little or no effect on the action potential at concentrations as high as 100 μmol/l.

Preclinical and clinical trial data and data from phase IV studies have shown that levofloxacin, moxifloxacin, and gatifloxacin cause prolongation of the QT interval, but that the potential for torsade de pointes is rare and is influenced by several independent variables (for example concurrent administration of class Ia and III antidysrhythmic agents) (25). There is a moderate increase in the QT interval associated with sparfloxacin, averaging 3%, and the few serious adverse cardiovascular events that have been reported during postmarketing surveillance all occurred in patients with underlying heart disease (26).

In patients taking quinolones (ciprofloxacin 11 477, enoxacin 2790, ofloxacin 11 033, and norfloxacin 11 110; mean ages 49–57 years) there was no evidence of drug-induced dysrhythmias associated with enoxacin within 42 days of drug administration (27). Of the other quinolones, atrial fibrillation was reported most often within 42 days of ciprofloxacin administration, with no change in event rate over that time. The crude rate of palpitation did not change significantly with ciprofloxacin, norfloxacin, or ofloxacin. Syncope and tachycardia were also reported with ciprofloxacin and ofloxacin. There was no evidence of drug-induced hepatic dysfunction within 42 days of drug administration with any of the quinolones used.

In a retrospective database analysis 25 cases of torsade de pointes associated with ciprofloxacin ($n = 2$), ofloxacin ($n = 2$), levofloxacin ($n = 13$), and gatifloxacin ($n = 8$) were identified in the USA (28). Ciprofloxacin was associated with a significantly lower rate of torsade de pointes (0.3 cases/10 million prescriptions) than levofloxacin (5.4/10 million) or gatifloxacin (27/10 million). When the analysis was limited to the first 16 months after initial approval of the drug, the rates for levofloxacin (16/10 million) and gatifloxacin (27/10 million) were similar.

Nervous system

The main central nervous system adverse effects of the fluoroquinolones include dizziness, convulsions, psychosis, and insomnia; levofloxacin, moxifloxacin, and ofloxacin are reportedly least likely to cause these effects, based on a study of European and international data from about 130 million prescriptions (29).

A review has suggested that fluoroquinolone-associated peripheral nervous system events are mild and short-term (30). Among 60 courses of quinolones in 45 patients (levofloxacin 33 courses, ciprofloxacin 11 courses, ofloxacin 6 courses, lomefloxacin 1 course, trovafloxacin 1 course; in eight cases the same antibiotic was prescribed twice) there were 36 severe events that typically involved multiple organ systems. The symptoms lasted more than 3 months in 71% of cases and more than 1 year in 58%. The onset of the adverse events in the 45 patients was usually rapid: 15 events began within 24 hours of the start of treatment, 26 within 72 hours, and 38 within 1 week.

Dizziness is not rare in patients taking fluoroquinolones, and was observed in 2.8% of patients taking moxifloxacin (16), in 8 and 9% of patients taking grepafloxacin 400 mg/day and 600 mg/day, and in 6% of patients taking ciprofloxacin (17). Prescription event monitoring found markedly lower rates of this adverse event during treatment with ciprofloxacin, norfloxacin, or ofloxacin (19).

Headache was recorded in 8% of patients taking ciprofloxacin and 9% taking ofloxacin during short-course treatment of urinary tract infections (18). Similar rates are reported for grepafloxacin (17).

In two patients with myasthenia gravis, ciprofloxacin and norfloxacin exacerbated the symptoms (31).

Encephalopathy with unconsciousness has been reported in a 48-year-old woman with Machado–Joseph disease after the administration of fleroxacin (200 mg/day) for 3 days (32). She recovered after withdrawal. The serum and cerebrospinal fluid concentrations of fleroxacin were within normal limits.

Seizures

Quinolone antibiotics vary in their ability to cause seizures. Trovafloxacin has the greatest potential and levofloxacin possibly the least. Ciprofloxacin can cause confusion and general seizures (33,34). Seizures also occurred in patients taking ofloxacin (35) and levofloxacin (34). However, this must be rare, since there have only been isolated case reports.

Among over 30 000 patients treated with ciprofloxacin, norfloxacin, or ofloxacin, no seizures were detected during prescription event monitoring (19). The risk of seizures during treatment with individual quinolones is currently unknown. Electrophysiological field potentials in animals are affected to varying degrees by different quinolones; the smallest effect was observed with ofloxacin, followed by ciprofloxacin and nalidixic acid, whereas there was an increasing excitatory effect with clinafloxacin, enoxacin, fleroxacin, lomefloxacin, moxifloxacin, and trovafloxacin (36). The pathophysiological basis for the triggering of seizures probably lies in the binding of fluoroquinolones to $GABA_A$ receptors in the brain, blocking the natural ligand GABA; this results in nervous system stimulation (37). Binding to this receptor is strongly influenced by the side chain in the 7-position; quinolones with bulky moieties, such as temafloxacin and sparfloxacin, bind less efficiently to GABA receptors.

© 2006 Elsevier B.V. All rights reserved.

Sensory systems

Taste

Dysgeusia is reported with many quinolones. This was observed more often with higher doses of grepafloxacin (600 mg/day; 17%) than with lower doses (400 mg/day; 9%) (38). In another study there was a similar dose–response relation: 13% of patients taking 400 mg/day and 27% of those taking 600 mg/day (17).

In 135 unmedicated young volunteers, 13 elderly volunteers and 14 unmedicated HIV-infected patients, enoxacin applied to the tongue was described as metallic by young subjects, but bitter by elderly subjects; lefloxacin and ofloxacin were described as bitter (39).

Psychological, psychiatric

Isolated cases of depression (18) and psychosis have been described in temporal association with fluoroquinolones (40).

Hematologic

In over 33 000 patients treated with ciprofloxacin, norfloxacin, or ofloxacin, no case of hemolytic anemia was discovered by prescription event monitoring (19). However, ciprofloxacin has been associated with hemolysis in combination with a severe skin reaction in a young adult (41).

Leukopenia has been observed in 0.1–0.7% of patients given fluoroquinolones in Japan and eosinophilia was observed in 0.5–2.2% of these patients (42). Leukopenia was generally mild and reversible after dosage reduction or withdrawal (43,44).

Anemia, thrombocytopenia, and thrombocytosis have only rarely been reported (45–48).

Gastrointestinal

Adverse gastrointestinal events are not uncommon during treatment with fluoroquinolones. There may be some dose-dependency, since with grepafloxacin 600 mg/day the rates of the following adverse events were noticeably higher than with 400 mg/day: nausea (15 versus 11%), vomiting (6 versus 1%), and diarrhea (4 versus 3%) (38). In a randomized, double-blind comparison of prulifloxacin 600 mg/day and ciprofloxacin 500 mg bd in 235 patients with acute exacerbations of chronic bronchitis, the most common treatment-related adverse event was gastric pain of mild or moderate intensity, reported in 8.5% of the patients taking prulifloxacin and 6.8% of those taking ciprofloxacin (49).

Liver

Transient rises in serum transaminase and serum alkaline phosphatase activities have been observed with all fluoroquinolones. This occurred in 0.9–4.3% of patients in Japan. In the vast majority of the cases this alteration was self-limited and reversible without withdrawal of the drug (42).

Urinary tract

In a Medline search to investigate the incidence and features of fluoroquinolone nephrotoxicity only primarily case reports and temporally related events could be identified (50). Ciprofloxacin was associated with an increased risk of renal insufficiency, probably because it has been in use longer and more widely than the newer agents. Raised serum creatinine or blood urea nitrogen concentrations have been observed in 0.1–0.7% of patients (42).

Single cases of reversible, acute non-oliguric or oliguric renal insufficiency, probably due to tubulointerstitial nephritis, have been reported (51,52), as well as isolated cases of hematuria (53). The newer fluoroquinolones have only rarely been associated with nephrotoxicity, with an estimated incidence of 0.4–0.8%.

Rare cases of possibly drug-related crystalluria have been described in patients taking fluoroquinolones (54–56).

Skin

Skin rashes are relatively common with fluoroquinolones. A retrospective cohort study in patients in general practice in the Netherlands focused on the use of antibacterial agents and the occurrence of adverse cutaneous events covered 469 505 consultations with 87 475 patients, of whom 13 679 received prescriptions for antibiotics (57). After adjustment for age, sex, and co-medications, the incidence density ratio (incidence density per 1000 exposed days) for various groups of antibacterial agents was as follows: tetracyclines 1.0, macrolides 1.1, fluoroquinolones 2.8, penicillins 2.9, and cotrimoxazole 4.4 (57). No details of the types of skin reactions were given, and it is therefore possible that phototoxic events were included. Compared with other studies, the reported rate of antibiotic-associated adverse cutaneous events in this outpatient population was rather low.

Exposure to light causes photosensitivity reactions in patients taking quinolones and fluoroquinolones. In guinea-pigs the phototoxic potencies were: enoxacin, lomefloxacin > ofloxacin > nalidixic acid, tosufloxacin > norfloxacin, ciprofloxacin (58). Photosensitivity reactions to ofloxacin may be initiated by oxygen radicals and/or by ofloxacin radicals acting as haptens (59). In a mouse model pefloxacin and ciprofloxacin augmented the effect of ultraviolet A by increasing sunburn and apoptosis, depleting Langerhans cells, and suppressing local immune responses (60).

A combination of primary ear swelling analysis and cell counting of ear-draining lymph nodes after UV irradiation in mice was fast and highly predictive of the risks of photosensitization and photoirritancy of fluoroquinolones, depending on the route of exposure (oral or dermal) and may therefore be good tools for preclinical risk assessment in terms of discriminating photoreactions (61).

Tosufloxacin has been associated with a fixed drug eruption (62).

In a phase III, randomized, investigator-blinded comparison of the safety and efficacy of clinafloxacin with those of piperacillin/tazobactam in the treatment of adults with severe skin and soft-tissue infections, four of 84 patients randomized to clinafloxacin developed phototoxicity (63).

Photosensitivity

Photosensitivity is a common adverse effect of the fluoroquinolones. It results from an abnormal reaction of the skin to natural or artificial light sources, usually associated with the UVA part of the electromagnetic spectrum (315–400 nm), mediated by the absorption of light energy into fluoroquinolones, followed by degradation of the molecule and formation of cytotoxic photoproducts (64).

© 2006 Elsevier B.V. All rights reserved.

The chemical structure at position 8 in the quinolone ring probably determines the phototoxic potential, since the introduction of a methoxy group at this position markedly reduces the phototoxicity of individual drugs (65).

The early fluoroquinolones, that is ciprofloxacin, norfloxacin, and ofloxacin, are mild photosensitizers (66–70). Clinically relevant photosensitivity was generally only observed when high dosages were used and the patient was exposed to large amounts of sunlight. The phototoxic potential of lomefloxacin, sparfloxacin, and fleroxacin is far greater than that of earlier compounds (71–76). However, even with fluoroquinolones that are reported to have a relatively high rate of phototoxicity, the incidence is low. In a Japanese study of 4276 patients, photosensitivity was found in 44 (1.03%) and was typically not severe (77). Patients with co-morbidity or those over 60 years were at higher risk. The risk may be further increased by a long duration of treatment.

The photosensitizing effect of grepafloxacin is relatively weak and similar to that of ciprofloxacin (38). In one study, one of 207 patients taking grepafloxacin 400 mg/day and six of 204 taking 600 mg/day developed phototoxicity (17). Moxifloxacin is not phototoxic (78). Data obtained in albino mice have suggested that the phototoxic potential of sitafloxacin is milder than that of lomefloxacin or sparfloxacin (79).

Musculoskeletal

Tendinopathy

Tendinopathy and partial or complete tendon rupture as adverse events of fluoroquinolones have been reported during or shortly after the use of fluoroquinolones (80–84). Pefloxacin and ofloxacin have been implicated, as has ciprofloxacin (85,86). In six patients taking fluoroquinolones risk factors included renal insufficiency, glucocorticoid therapy, secondary hyperparathyroidism, advanced age, and diabetes mellitus (87). Cases have also been reported among immunocompromised renal transplant recipients (88).

In 42 spontaneous reports of fluoroquinolone-associated tendon disorders, 32 patients had tendinitis, 24 bilaterally, and 10 had a tendon rupture; most affected the Achilles tendon (89). The median age was 68 years and there was a male predominance. In 16 cases ofloxacin was implicated, in 13 ciprofloxacin, in eight norfloxacin, and in five pefloxacin. The delay between the start of treatment and the appearance of the first symptoms was 1–510 (median 6) days. Most patients recovered within 2 months after withdrawal, but 26% had not yet recovered at follow-up.

In a retrospective analysis, quinolone arthropathy developed during the first 3 weeks, and depended on the patient's age and history (90). It resolved fully within 7 days to 3 months after drug withdrawal.

In a study of fibroblast metabolism in vitro, ciprofloxacin stimulated matrix-degrading protease activity and inhibited fibroblast metabolism; these effects may both contribute to the tendinopathy that is associated with fluoroquinolones (91).

Animal studies show that the propensity to induce tendon lesions varies among fluoroquinolones. Fleroxacin, pefloxacin, levofloxacin, and ofloxacin were the most toxic, while enoxacin, norfloxacin, and ciprofloxacin had little or no effect (92). The structure of the substituent at position 7 seems to be a determining factor. Quinolones with toxic effects in animals share a methylpiperadinyl substituent at the position 7 of the fluoroquinolone core structure, while this position is occupied by a piperadinyl substituent in ciprofloxacin, norfloxacin, and enoxacin (92). It is recommended that quinolones be discontinued at the first sign of tendon pain or inflammation and that the patient should not exercise until the diagnosis of tendonitis can be confidently excluded.

In rodents, pefloxacin (400 mg/kg for several days) caused oxidative damage to the type I collagen in the Achilles tendon; these alterations were identical to those observed in experimental tendinous ischemia and a reperfusion model (93). Oxidative damage was prevented by the co-administration of *N*-acetylcysteine (150 mg/kg).

Arthropathy

Arthropathy has been reported with various fluoroquinolones, particularly in children. In a Russian study in children with cystic fibrosis five were withdrawn (four taking ciprofloxacin and one taking pefloxacin) (94). Two had an arthropathy that was drug- and age-dependent. Quinolone-induced arthropathy was more common with pefloxacin and occurred only in children over 10 years old with a history of joint problems. The arthropathy fully recovered within 7 days to 3 months and there was no cartilage damage.

In Wistar rats treated with ciprofloxacin, there was poor healing of experimental fractures during the early stages of repair, suggesting that fluoroquinolones may compromise the clinical course of fracture healing (95).

Sexual function

In a large study vaginitis and vulvitis were detected by prescription event monitoring in a significantly higher proportion of women taking fluoroquinolones than women taking azithromycin or cefixime (19).

Immunologic

Fluoroquinolones have immunomodulatory effects, at least partly at the gene transcription level, demonstrated by inhibition of cytokine (IL-1α, TNF-α, IL-6, and IL-8) mRNA and cytokine (IL-1α and IL-1β) concentrations by grepafloxacin (1–30 mg/l) in vitro (96).

Anaphylactic shock associated with cinoxacin was reported in three patients by the Netherlands Center for Monitoring of Adverse Reactions to Drugs (97). Another 17 cases were reported to the WHO Collaborating Center for International Drug Monitoring. In some cases the reaction was observed immediately after the first dose of a repeat cycle of treatment. Anaphylactoid reactions to ciprofloxacin have been reported in patients with cystic fibrosis (98–100).

Organ-specific reactions attributed to hypersensitivity involve the liver and kidneys. In one instance centrilobular hepatic necrosis developed during treatment of a urinary tract infection with ciprofloxacin (101). Among 14 cases of drug-induced allergic nephritis, two were associated with quinolones (102). Isolated case reports of allergic nephropathy associated with norfloxacin and ciprofloxacin therapy suggest that this type of reaction is probably very rare (103), since the authors were able to find only 28 other reported cases. If hypersensitivity reactions occur, switching from one quinolone compound to

© 2006 Elsevier B.V. All rights reserved.

another is probably not advisable, since oral provocation using different agents reproduced the initially observed hypersensitivity reaction (104). This clinical observation is supported by the results of in vitro lymphocyte transformation tests, which were positive with ofloxacin in two patients with allergy to ciprofloxacin (105).

Infection risk

Ciprofloxacin, norfloxacin, and ofloxacin increased gastrointestinal colonization by *Candida albicans* in 17 patients (106). Ciprofloxacin caused the largest increase, but the difference was not statistically significant.

In a retrospective cohort study of patients hospitalized in a Canadian teaching hospital during January 2003 to June 2004 there were 7421 episodes of care in 5619 patients, who were observed until they developed *Clostridium difficile*-associated diarrhea, or died, or for 60 days after discharge (107). Fluoroquinolones were the antibiotics that were most strongly associated with *Clostridium difficile*-associated diarrhea (adjusted hazard ratio = 3.44; 95% CI = 2.65, 4.47). Almost one-quarter of all in-patients received quinolones, for which the population-attributable fraction of *Clostridium difficile*-associated diarrhea was 36%. All three generations of cephalosporins, macrolides, clindamycin, and intravenous beta-lactam/beta-lactamase inhibitors were intermediate-risk antibiotics, with similar hazard ratios (1.56–1.89).

Long-Term Effects

Drug tolerance

To study the impact on the normal intestinal microflora, gatifloxacin was given to 18 healthy volunteers (400 mg/day orally). In the aerobic intestinal microflora *E. coli* strains were eliminated or strongly suppressed and the number of enterococci fell significantly, while the number of staphylococci increased. In the anerobic microflora the numbers of *Clostridia* and fusobacteria fell significantly. The microflora normalized 40 days after the gatifloxacin withdrawal. No selection or overgrowth of resistant bacterial strains or yeasts occurred (108).

Salmonella typhimurium DT104 is usually resistant to ampicillin, chloramphenicol, streptomycin, sulfonamides, and tetracycline. An outbreak of 25 culture-confirmed cases of multidrug-resistant *Salmonella typhimurium* DT104 has been identified in Denmark. The strain was resistant to the abovementioned antibiotics and nalidixic acid and had reduced susceptibility to fluoroquinolones. A swineherd was identified as the primary source (109). The DT104 strain was also found in cases of salmonellosis in Washington State, and soft cheese made with unpasteurized milk was identified as an important vehicle of its transmission (110).

From 8419 worldwide clinical isolates of *Streptococcus pneumoniae* associated with lower respiratory tract or blood infections obtained from 519 geographically distinct hospital laboratories during 1997–98, 69 had reduced susceptibility or resistance to fluoroquinolones. Only mutations in parC and gyrA (especially in combination), but not in gyrB or parE, contributed significantly to resistance. Efflux is probably crucial in reduced susceptibility for new hydrophilic fluoroquinolones (111).

In an in vitro study, ciprofloxacin, grepafloxacin, levofloxacin, moxifloxacin, ofloxacin, and sparfloxacin had similar good activity against *Haemophilus influenzae* and *Moraxella catarrhalis* (112). Against *S. pneumoniae* (irrespective of the strain's susceptibility to penicillin), grepafloxacin, levofloxacin, moxifloxacin, and sparfloxacin had better activity than ciprofloxacin and ofloxacin.

Clinafloxacin, moxifloxacin, sparfloxacin, and trovafloxacin were significantly more active in vitro than ciprofloxacin and levofloxacin against *Stenotrophomonas maltophilia*, a microorganism with inherent resistance to many antibiotics; new-generation quinolones may become very useful in the treatment of certain severe or life-threatening infectious conditions due to this bacterium (113).

In over 90 000 routine samples of *Escherichia coli* in five Dutch laboratories during 1989–98 resistance to norfloxacin increased from 1.3% to 5.8% (114). In addition, multiresistance, defined as resistance to norfloxacin and at least two other antibiotics (from a group consisting of amoxicillin, trimethoprim, and nitrofurantoin), increased from 0.5% to 4.0%.

Mutagenicity

In vitro lomefloxacin photochemically produced oxidative DNA damage, an effect known to be of mutagenic potential (115). This may be the basis of the photochemical mutagenicity and photochemical carcinogenicity of quinolones.

Tumorigenicity

Results of carcinogenicity studies have suggested that the risk of neoplastic disease is minimal, even during long-term use (116). However, the risk may be increased by exposure to UVA light. Skin tumors, only a minority of them malignant, developed in mice after treatment with various quinolones for up to 78 weeks and exposure to UV light. It therefore appears that fluoroquinolones have the potential to enhance the UVA-induced phototumorigenic effect (117).

Second-Generation Effects

Teratogenicity

Possible adverse outcomes were investigated in the newborns of 38 mothers who had received quinolones during pregnancy between 1989 and 1992. The majority (35 women) took norfloxacin or ciprofloxacin for urinary tract infections during the first trimester of pregnancy. There were no malformations in the quinolone group, whereas one child in the control group had a ventricular septal defect. There were no differences between the groups in the achievement of developmental milestones or in the musculoskeletal system (118). However, the authors of the study pointed out that the duration of follow-up may have been too short to draw firm conclusions regarding the safety of quinolones during pregnancy. In addition, the size of the study population was probably inadequate for statistically meaningful comparisons.

Treatment with fluoroquinolones during embryogenesis was not associated with an increased risk of major

© 2006 Elsevier B.V. All rights reserved.

malformations in a multicenter, prospective, controlled trial in 400 women (119). There was a higher rate of therapeutic abortions in quinolone-exposed women. This may have been explained by the misperception of a major risk related to quinolones during pregnancy.

In pregnant rats fed with norfloxacin, there was DNA fragmentation in fetal tissues (14). Even though this effect was attributed to general toxicity rather than genotoxicity, quinolones should be avoided during pregnancy (120).

Lactation

Given the potential for untoward effects on the cartilage of breast-feeding infants, fluoroquinolones should be avoided by nursing mothers.

Susceptibility Factors

Genetic factors

The pharmacokinetics of fleroxacin (200 mg intravenously or 200 mg orally) have been studied in 19 Nigerian men. C_{max} and AUC were 3–4 fold lower than previously reported after identical doses, but systemic availability profile was as previously reported (121).

Age

Children

The use of fluoroquinolones in children is controversial. Fluoroquinolones have greatly facilitated the management of exacerbations of pulmonary infections in cystic fibrosis. Apart from this indication, they have rarely been used in children for other indications, such as urinary tract infection, prophylaxis in neutropenia, gastrointestinal infections, and nervous system infections (122). Thorough reviews of published experience suggest that fluoroquinolones can be used without increased risks of short-term or long-term adverse events. A study of adverse events within 45 days of receiving a prescription for ciprofloxacin was remarkable for the fact that among over 1700 children, no cases of newly diagnosed acute arthritis or other serious disturbances of liver or kidney function were recorded (123). One patient with hemolytic–uremic syndrome had an exacerbation that was possibly caused by ciprofloxacin.

Renal disease

Based on their predominant renal elimination, dosage adjustment is necessary in the presence of renal disease for ciprofloxacin, gatifloxacin, levofloxacin, and sitafloxacin (124).

Hepatic disease

The penetration of routinely used fluoroquinolones into ascitic fluid after intravenous administration has been studied in patients with uncompensated hepatic cirrhosis (125). Three patients received three doses of ciprofloxacin 200 mg, six received three doses of ciprofloxacin 300 mg, seven received three doses of pefloxacin 400 mg, and six received three doses of ofloxacin 400 mg. Pefloxacin and ofloxacin produced serum and ascitic fluid concentrations above the MICs of the common pathogens that cause spontaneous bacterial peritonitis, and the authors concluded that they could be given to cirrhotic patients in dosage regimens similar to those in patients with normal hepatic function.

Other features of the patient

Given the well-described risk of phototoxicity associated with fluoroquinolones, sunlight and direct exposure to the sun are risk factors. Patients therefore need to be instructed about protective measures.

In patients with leg ischemia fleroxacin diffused into both ischemic and non-ischemic tissues (bone, subcutaneous fat, muscle, and tendons) after a 400 mg intravenous dose (126). Since the maximum antibiotic concentrations were lower than the MICs of various relevant pathogens, the dose used for perioperative prophylaxis in these patients should be increased to 800 mg.

Drug–Drug Interactions

Antacids

Concurrent treatment with antacids reduces the oral absorption of many quinolones, such as ciprofloxacin and enoxacin (127), moxifloxacin (16), norfloxacin (128), ofloxacin (129), and sparfloxacin (130).

Caffeine

CYP1A2 participates in the metabolism of both enoxacin and caffeine, and inhibition of caffeine metabolism by enoxacin can cause adverse effects (131).

In 24 healthy volunteers, 12 men and 12 women, the women had significantly different caffeine pharmacokinetics in the presence of ciprofloxacin and fleroxacin compared with the men (132). There were also significant differences between the sexes in the pharmacokinetics of ciprofloxacin and fleroxacin in the presence of caffeine. The differences were in part due to different body weights.

Clinafloxacin 200 or 400 mg reduced the mean clearance of caffeine by 84% (133).

Cimetidine

Cimetidine reduces the metabolic clearance of both enoxacin and pefloxacin by about 20% (134,135).

Digoxin

The pharmacokinetics of digoxin were not altered by sparfloxacin (136).

Drugs that prolong the QT interval

In order to prevent any untoward effect on cardiac repolarization, agents that prolong the QT interval, such as terfenadine, astemizole, erythromycin, and agents with Class Ia and Class III antidysrhythmic activity, should not be used together with sparfloxacin (137).

Furosemide

The renal excretion of lomefloxacin and ofloxacin was reduced and plasma concentrations increased by furosemide, resulting in higher concentrations (138).

© 2006 Elsevier B.V. All rights reserved.

Iron

All of the fluoroquinolones interact with polyvalent cations, and their systematic availability is reduced by 50% when they are co-administered with iron compounds; ciprofloxacin and moxifloxacin (16) are more affected than gemifloxacin or levofloxacin (139).

Ferrous salts reduce the systemic availability of fluoroquinolones (127), including sparfloxacin (140).

NSAIDs

Co-administration of fenbufen and fluoroquinolones has been associated with seizures (141). The structure at the 7-position greatly affects the risk of NSAID-potentiated nervous system effects. Fluoroquinolones with unsubstituted piperazinyl rings (ciprofloxacin, enoxacin, and norfloxacin) have a strong interaction with NSAIDs (142). The increased risk of seizures is not caused by increased serum concentrations of fluoroquinolones, since their pharmacokinetics are not altered by NSAIDs (143). The mechanism has been suggested to be facilitation by fenbufen of the fluoroquinolone-induced inhibition of $GABA_A$ receptor function in the hippocampus and frontal cortex (144).

Probenecid

Probenecid increases the serum concentrations of cinoxacin (145), enoxacin (146), and nalidixic acid (147) probably by inhibiting their renal tubular secretion.

Sucralfate

Sucralfate markedly reduces the systemic availability of fluoroquinolones (127,148,149).

Theophylline

Fluoroquinolones are potent inhibitors of hepatic cytochrome P450 isozymes (150). They inhibit theophylline metabolism, and accumulation of theophylline has led to seizures (151). Theophylline clearance is reduced by about 10% by norfloxacin, 30% by ciprofloxacin, and 70% by enoxacin (152–162). In a comparison of grepafloxacin (400 and 600 mg/day) and ciprofloxacin, increased theophylline concentrations associated with clinical symptoms were found with both doses of grepafloxacin but not in patients taking ciprofloxacin (17). The dosage of theophylline should be reduced when a quinolone is given.

No interaction has been reported with levofloxacin (139) or sparfloxacin (137,161).

Warfarin

The anticoagulant effect of warfarin was altered by ciprofloxacin (162) but not by sparfloxacin (149) or moxifloxacin (16).

Interference with Diagnostic Tests

Opioid immunoassays

The reactivity of 13 quinolones and fluoroquinolones (ciprofloxacin, clinafloxacin, enoxacin, gatifloxacin, levofloxacin, lomefloxacin, moxifloxacin, nalidixic acid, norfloxacin, ofloxacin, pefloxacin, sparfloxacin, and trovafloxacin) with five commercial opiate immunoassays has been tested in vitro and in three healthy volunteers (163). In vitro, levofloxacin and ofloxacin (using Abbott AxSYM, CEDIA, EMIT II, and Roche OnLine assays), pefloxacin (using CEDIA, EMIT II, and Roche OnLine assays), enoxacin (using CEDIA and EMIT II assays), gatifloxacin (using EMIT II assay), and ciprofloxacin, lomefloxacin, moxifloxacin, and norfloxacin (using Roche OnLine assay) cross-reacted and cause a positive test result for opiates. Clinafloxacin, nalidixic acid, sparfloxacin, and trovafloxacin did not cross-react in any of the assays. A single dose of levofloxacin 500 mg caused a false-positive test result using the EMIT II assay within 2 hours for as long as 22 hours in all three volunteers. Ofloxacin (a single dose of 400 mg) produced a similar pattern. Detectable opiate activity in the urine was seen for more than 30 hours with both levofloxacin and ofloxacin.

Fluorouracil

See also Cytostatic and immunosuppressant drugs

General Information

Fluorouracil is a fluorinated pyrimidine, which is converted intracellularly to the active form, fluorodeoxyuridine monophosphate, which inhibits thymidylate synthetase and hence reduces the production of thymidylic acid, the deoxyribonucleotide of thymine (5-methyluracil), a DNA pyrimidine base, blocking DNA synthesis. In addition, intracellular conversion to 5-fluorouridine monophosphate results in incorporation of the activated antimetabolite into RNA and consequent RNA dysfunction.

Fluorouracil is specific to the S phase of the cell cycle. It is primarily used intravenously to treat carcinoma of the breast and adenocarcinomas of the gastrointestinal tract (1). In addition, topical fluorouracil is used to treat actinic keratoses.

© 2006 Elsevier B.V. All rights reserved.

General adverse effects

The dose-limiting toxic effects of fluorouracil vary with the dose and mode of administration.

- With five consecutive daily bolus injections of 450–600 mg/m^2, the dose-limiting effects are myelosuppression, mucositis, and diarrhea.
- With weekly injections of 450–600 mg/m^2, myelosuppression is dose-limiting.
- With continuous five-day infusion of 1000 mg/m^2/day, mucositis and diarrhea are dose-limiting.
- With protracted continuous infusion of 200–400 mg/m^2/day, mucositis and palmar–plantar erythrodysesthesia syndrome are the most common dose-limiting adverse effects (2).

Some very high-dose, short-exposure studies have been reported, including 14 g over 24 hours (3) and 2.6 g/m^2 weekly (4); in the latter study, neurotoxicity was dose-limiting; with 24-hour infusion of 2.6 g/m^2 weekly, palmar–plantar erythrodysesthesia syndrome is a major adverse effect.

Relation of toxicity to pharmacokinetics

The pharmacokinetics of fluorouracil have been determined in 19 patients receiving fluorouracil by protracted intravenous infusion of 190–600 mg/m^2/day (5). The steady-state fluorouracil plasma concentration and AUC were significantly lower in the nine patients who had WHO grade 2 toxicity or less compared with the nine patients who had greater than grade 2 toxicity. In contrast, there was no difference in fluorouracil plasma concentrations between the 10 responders and the nine patients who had no evidence of a clinical response. These investigations confirm previous observations that correlations can be drawn between fluorouracil pharmacokinetics and clinical toxicity (6). Furthermore, the data suggest that pharmacokinetic monitoring might permit identification of patients at increased risk of toxicity.

Organs and Systems

Cardiovascular

Fluorouracil can cause anginal chest pain, with non-specific ST–T electrocardiographic changes, during infusion (7). The outcome is favourable if the drug is withdrawn. Re-introduction of the drug has been associated with occasional fatal outcomes and is not recommended (8). The cardiotoxicity of 5-fluorouracil in 135 reported cases has been reviewed (9).

Presentation

More frequent use of fluorouracil by continuous infusion, increased awareness of the problems, and more sophisticated monitoring have increased the reported incidence. By 1990, more than 67 clinical cases had been described (10) and an incidence ranging up to 68% of silent ischemic electrocardiographic changes was identified in patients monitored by continuous 24-hour ambulatory electrocardiography during fluorouracil infusion (11). The clinical features include the following:

- Precordial pain (both non-specific and anginal) (10).
- Electrocardiographic ST–T wave changes (non-specific and ischemic) (10,11).
- Acute myocardial infarction (rare) (12,13).
- Atrial dysrhythmias (including atrial fibrillation) and less often, ventricular extra beats (including refractory ventricular tachycardia and fibrillation) (11–13).
- Ventricular dysfunction (usually global, less frequently segmental).
- Cardiac failure, pulmonary edema, and cardiogenic shock (with and without ischemic symptoms) (13–16).
- Sudden death, presumed to be caused by ventricular fibrillation (13,17,18).

In most patients with chest pain, with or without electrocardiographic changes, the creatinine kinase MB fraction remained normal (10,13,15).

Acute dilated cardiomyopathy with left ventricular dysfunction related temporally to fluorouracil and cisplatin infusion, with subsequent complete recovery, has been tentatively linked to fluorouracil (19). Other similar events have been reported (20,21). The association is more striking in patients who receive a continuous infusion of fluorouracil and in patients who receive concomitant cisplatin (22,23). For example, myocardial ischemia and infarction occur in about 10% of patients who receive fluorouracil by infusion and sudden death has occurred (24).

Five cases of paroxysmal atrial fibrillation and sinus bradycardia attributed to fluorouracil have been reported (25).

Acute pulmonary edema leading to lethal cardiogenic shock has been reported with fluorouracil. This occurred despite the fact that the patient had received eight infusions of leucovorin 100 mg/m^2 at weekly intervals (26).

Most often, cardiotoxicity develops during the second or later course of treatment, but some patients have problems during the first course (10). Those who develop cardiac toxicity and recover usually have symptoms again when re-challenged with another infusion (10,13).

Fluorouracil has also been associated with a number of vascular effects, particularly thromboembolic or circulatory in nature (27). Although Raynaud's phenomenon has been reported after cisplatin-based chemotherapy, the first case of digital ischemia and Raynaud's phenomenon has been reported with fluorouracil given in a De Gramond type schedule (28).

Mechanisms and pathophysiology

The mechanisms of fluorouracil cardiotoxicity are not known. Those that have been suggested include:

- direct uncoupling of electromechanical myocardial function at the level of ATP generation (20);
- an immunoallergic reaction following sensitization by a complex of fluorouracil and cardiac cells;
- vasospasm secondary either to fluorouracil or to released products;
- a direct toxic effect of the drug on the myocardium.

Most reports have attributed chest pain to vasospasm (29). Certainly, the ischemic-like pains and electrocardiographic findings, lack of changes in creatine kinase, and frequent responses to nitrates and at times to calcium antagonists in the setting of anatomically normal coronary angiography, plus reversible contractility defects suggest

© 2006 Elsevier B.V. All rights reserved.

coronary vasospasm as a mechanism of fluorouracil cardiotoxicity. However, global dysfunction possibly due to stunned myocardium and the lack of universal response to coronary vasodilators leaves some questions about this hypothesis. Some investigators have postulated myocarditis or myocardiopathy (30–32). In 43 patients it did not interfere with the electrical properties of myocardial fibers (33).

Findings on autopsy and endomyocardial biopsy have shown diffuse, interstitial edema, intracytoplasmic vacuolization of myocytes, and no inflammatory infiltrate (34). Acute myocardial infarction has been demonstrated pathologically in some, but not all, patients with clinical infarction (10).

In patients with fluorouracil cardiotoxicity endothelin plasma concentrations were raised (35).

Susceptibility factors

With regard to susceptibility factors for cardiotoxicity with fluorouracil, there was no effect of age or sex on incidence (10). Symptoms have been reported in a 38-year-old man (16) and in several women in their forties (10,14) with no prior cardiac history. Cardiac findings have occurred when fluorouracil was given by infusion or bolus as a single agent or with cisplatin and other drugs (10,21). Although some felt that cardiac irradiation and pre-existing heart disease were susceptibility factors (11,36), others did not (10,37). Several investigators have documented normal coronary arteries in patients with severe symptoms (13,14).

Frequency

The cardiotoxicity of fluorouracil was first identified in 1975 (38). Of 140 patients treated with intravenous 5-fluorouracil, 4 developed ischemic chest pain within 18 hours of either the second or third dose. In three of these patients the pain recurred after subsequent doses. Predose electrocardiograms in two cases were normal. None of the four patients had a history of ischemic heart disease, although all had received left ventricular irradiation (39).

A 5% incidence of cardiotoxicity-complicating high-dose infusion of fluorouracil 1000 mg/m^2/day for 4 days has been reported and correlated with plasma fluorouracil concentrations in excess of 450 mg/ml (40).

In 910 patients toxicity was life-threatening in 0.55% (41). A combination of cisplatin, fluorouracil, and etoposide given for advanced non-small cell cancer of the lung caused only the expected amount of hematological toxicity, but was associated with a higher than expected incidence of cardiac, pulmonary, and cerebrovascular toxicity, including two myocardial infarctions, two cases of congestive heart failure, one pulmonary embolus, and one cerebrovascular accident in a study of 35 patients (42).

In 1083 patients there was cardiotoxicity in 1.1% of all patients and in 4.6% of patients with prior evidence of heart disease (36).

Management

Some investigators have reported success in preventing cardiotoxicity with calcium antagonists, such as nifedipine and diltiazem (29), while others had less success (15,43). Two patients with proven fluorouracil cardiotoxicity did not have cardiotoxicity when treated with the specific thymidylate synthase inhibitor raltitrexed 3 mg/m^2 every 3 weeks (44). The authors commented that fluorouracil cardiotoxicity is therefore not mediated via thymidylate synthase.

In most cases, fluorouracil-induced dysrhythmias were treatable and the ischemic-like symptoms and electrocardiographic changes disappeared if the infusion was discontinued or responded to nitrates, allowing the infusion to continue. The abnormalities of segmental and global ventricular function reverted to normal within days to weeks of withdrawal. In some patients intravenous inotropic and vasodilator support was needed during the initial period (14–16,19).

However, in one case, both oral nitrates and calcium antagonists failed to prevent chest pain associated with 5-fluorouracil (45).

- About 48 hours after starting her first course of 5-fluorouracil (1000 mg/m^2/day) a woman developed anginal chest pain and electrocardiographic changes that eventually normalized. She was readmitted for her second cycle whilst taking amlodipine 10 mg/day and isosorbide dinitrate 40 mg/day, and after 42 hours into the second cycle had the same chest pain and electrocardiographic changes. These were only controlled by withdrawal of the 5-fluorouracil and the intravenous administration of glyceryl trinitrate.

Respiratory

Pulmonary toxicity in the form of fibrosing alveolitis has been attributed to fluorouracil.

- A 55-year-old man with gastric adenocarcinoma received fluorouracil 1 g intravenously each week for 9 weeks and mitomycin 10 mg intravenously every 3 weeks (46). After 12 treatments he developed severe dyspnea.

Although mitomycin C was most likely the agent responsible for pulmonary toxicity in this patient, combined use with fluorouracil as a contributing factor cannot be ruled out. Necropsy confirmed that the patient had interstitial fibrosis (47).

Nervous system

Fluorouracil can cause neurotoxicity (48), with an incidence of 5–15% and with all schedules of administration in common use (49,50). The toxicity is acute in onset and cumulative dose-dependency has not been observed.

Acute cerebellar dysfunction, with gait ataxia, nystagmus, dysmetria, and dysarthria, is the most common form of neurotoxicity (48,49). A rare problem is optic neuropathy and impaired vision (51).

The acute cerebellar syndrome is considered to be associated with peak concentrations of fluorouracil (48,52). Continuous 5-day infusions appear not to cause neurological toxicity, even when the total dose is higher, although high-dose infusions can cause encephalopathy, with symptoms varying from lethargy to coma (53).

© 2006 Elsevier B.V. All rights reserved.

Cerebral demyelination has been reported in a patient receiving fluorouracil and levamisole (54).

Two patients with some of the classic neurological complications of fluorouracil have been reported. One had a cerebellar syndrome in association with global motor weakness and bulbar palsy and the other a bilateral third cranial nerve palsy (55).

Peripheral neuropathy, possibly caused by fluorouracil, has been reported (56).

Five patients developed ischemic stroke within 2–5 days of finishing a 4-day course of fluorouracil plus low-dose cisplatin by continuous infusion (57). Whilst cisplatin has been implicated as having produced central ischemic events, most commonly in combination with vindesine and bleomycin, there has only been one other report involving fluorouracil. Although the causal link was not conclusive, the circumstantial evidence was strong.

The cause of neurotoxicity is not well understood. Acute neurological symptoms, including somnolence, cerebellar ataxia, and upper motor neuron signs, are primarily seen in patients receiving intracarotid infusions for head and neck tumors and also in patients receiving fluorouracil monotherapy in high doses. This syndrome has been reproduced in animals by a neurotoxic metabolite of fluorouracil, fluorocitrate, which has been believed to cause neurotoxicity (52,58). However, several patients have developed severe toxic symptoms due to deficiency of dihydropyrimidine dehydrogenase, the enzyme that is mainly responsible for metabolizing fluorouracil (59). This toxicity appears to be due to the parent compound and not metabolites. Patients with complete or partial deficiency of the enzyme are particularly subject to fluorouracil neurotoxicity.

The neurotoxicity is usually reversible by withdrawing fluorouracil. Since there is no cumulative effect, therapy can be resumed later if desired, usually with either a lower dose or a less frequent dosing schedule to prevent recurrence.

Sensory systems

Fluorouracil-containing regimens have been linked with several ocular adverse effects, including marked lacrimation, ocular pruritus, and a burning sensation in the eyes (60).

Striate melanokeratosis of the retina has been associated with 5-fluorouracil in reports from a number of centers; there has been no consistent explanation of the pathogenesis of this adverse effect (61–63).

Excessive lacrimation and other ocular disturbances have been reported secondary to intravenous fluorouracil (64–66). In a review of this subject, blurred vision, excessive lacrimation, excessive nasal discharge, and conjunctivitis were the most commonly reported ocular effects of fluorouracil (67). The symptoms, eye irritation and excessive tear production, can be aggravated by cold weather. The onset of symptoms varies from 15 minutes to 14 months after the start of treatment (64). The symptoms usually resolve 2–3 weeks after withdrawal of therapy, with or without the use of topical antibiotic-glucocorticoid combinations (64,67).

More severe toxic effects, including tear duct fibrosis and eversion of the lower eye lid, have been reported (64). Tear duct fibrosis develops in one of six patients with excessive lacrimation from fluorouracil (66). The eversion of the lower eyelid is reversible with conservative management (68) while the tear duct fibrosis may not be (69). Persistent lacrimation has been described in six patients receiving intravenous fluorouracil weekly for 6–10 months (69). Lacrimation persisted in five patients after the withdrawal of fluorouracil, suggesting an irreversible dacryostenosis. Lacrimal duct stenosis has also been reported (70). Bilateral cicatricial ectropion was also reported in a patient after topical administration of fluorouracil for the treatment of multiple facial actinic keratoses (71). If ectropion and tear duct stenosis progress, surgical correction may be required.

Three women developed lacrimal outflow obstruction while receiving fluorouracil, cyclophosphamide, and methotrexate for breast cancer (72). The authors commented on both the high incidence of excessive tearing in patients given fluorouracil, a probable precondition, and the rarity of permanent damage (12 patients reported worldwide), but counselled on the need for vigilance and early referral to an ophthalmologist. Others have suggested that the prevalence of tearing and canalicular fibrosis in patients receiving fluorouracil is related to total dose and duration of treatment, and that the risks become significant at 20–60 weeks of therapy and a total fluorouracil dose of 20–50 g (73).

- Ankyloblepharon (adherence of the eyelids resulting in narrowing of palpebral apertures) was reported in a 59-year-old man during fluorouracil therapy for metastatic adenocarcinoma of the stomach (74). It appeared that bilateral conjunctival ulcers, secondary to fluorouracil and ulcerative blepharitis, resulted in ankyloblepharon. Withdrawal of chemotherapy resulted in improvement and re-initiation of therapy resulted in recurrence of ocular lesions.

Transient, non-infectious, crystalline, intrastromal corneal deposits have been reported after subconjunctival administration of 5-fluorouracil (75). The deposits were treated with glucocorticoids and completely resolved in 4 days.

Psychological, psychiatric

Confusion and cerebral cognitive defects have been attributed to fluorouracil (49,76).

Metabolism

Patients with poorly controlled diabetes are at risk of greater or more severe fluorouracil toxicity, causing hyperglycemia, which has been fatal. This effect seems to be independent of previous diabetic control and or fluorouracil dosage schedules (77)

There have been attempts to unravel the mechanism of fluorouracil-induced hyperammonemia, lactic acidosis, and encephalopathy, a rare adverse effect associated with high-dose therapy. The cause is not known, although Krebs cycle metabolism is almost certainly involved (78,79).

Hematologic

The hematological toxicity of fluorouracil is dose- and schedule-related (80). Leukocytes and platelets are affected, although the latter less so. Myelosuppression begins 4–7 days after the first dose, with recovery usually 14 days after the last dose (2). With continued treatment, anemia can develop in 3–4 months (81). Severe bone marrow depression causing death has been reported (82).

Leukopenia is the most common blood dyscrasia secondary to fluorouracil and usually occurs after every course. The lowest white cell counts are usually seen at 9–14 days after the first course of treatment, but can be delayed for up to 20 days (83,84). Leukopenia usually resolves after drug withdrawal. Leukopenia is often followed by megaloblastic anemia (85). Agranulocytosis has been reported during fluorouracil therapy (84).

Thrombocytopenia has occurred during fluorouracil therapy but is much less frequent than leukopenia (59).

The following summarizes the dose-relatedness of the hematological effects of fluorouracil (86,87):

- With a daily bolus of 12 mg/kg for 5 days, leukopenia (under 4×10^9/l) occurred in all of 70 patients; 31% had marked leukopenia (under 2×10^9/l).
- With a continuous infusion of 30 mg/kg/day for 5 days, the leukopenia was mild and occurred in only 12% of patients.
- A protracted continuous infusion of 300 mg/m^2/day caused one case of moderate leukopenia and four cases of mild/moderate thrombocytopenia.
- With a daily bolus of 500 mg/m^2 for 5 days there was a 38% incidence of leukopenia (with 20% below 2×10^9/l and an 8% incidence of thrombocytopenia (1% severe).

Gastrointestinal

The gastrointestinal toxicity of 5-fluorouracil is well documented and often dose-limiting. However, in a retrospective 10-year survey of gastrointestinal function in 19 patients who also had inflammatory bowel disease, although it did appear to increase the risk of exacerbation of diarrhea, it was not totally conclusive, as it was difficult to evaluate the contribution of other potentially causative factors, such as radiation (88).

Any site along the gastrointestinal tract can be affected, resulting in symptoms such as nausea and vomiting, stomatitis, dysphagia, retrosternal burning, abdominal pain, diarrhea, and proctitis.

Stomatitis is common and can be severe and life-threatening (84). Stomatitis may be preceded by a dry mouth and erythema of the mucosa followed by a white patchy membrane. In severe cases this is followed by ulceration and necrosis. Breakdown of the mucosa is very painful and can act as a focus for infection (2). Xerostomia at the start of therapy and a baseline neutrophil count of under 4×10^9/l are significantly associated with dose-limiting oral mucositis later in chemotherapy, according to the results of a logistic regression analysis of 63 patients (89). Mouth-cooling with oral ice chips for 30 minutes starting immediately before fluorouracil substantially reduced the severity of mucositis.

Nausea and vomiting are common but generally mild (84).

Gastric ulceration has been reported in patients receiving fluorouracil by intrahepatic infusion via percutaneous catheterization in doses of 20–30 mg/kg for 4 days followed by 15 mg/kg over 17 days. Symptoms were observed from 4 to 20 days after starting therapy (90). Gastrointestinal bleeding in three patients and death in one patient were also reported following intra-arterial fluorouracil (91).

Diarrhea is common, particularly in patients who receive a 5-day regimen. The diarrhea can be watery or bloody and life-threatening in severe cases. Repeated episodes of watery diarrhea (more than three movements per day) for several days should alert the oncologist to the potential dangers of dehydration and sepsis, which are potentially fatal adverse effects. Life-threatening diarrhea, with hematemesis, high intestinal obstruction, melena, septicemia, and shock, have been reported after total doses of 4–4.5 g of fluorouracil (92). Similarly, diarrhea followed by neutropenia and life-threatening or fatal sepsis occurred in two of 55 patients with advanced colorectal carcinoma in a pilot study of continuous infusion of fluorouracil (750 mg/m^2/day for 5 days) plus subcutaneous recombinant interferon alfa-2a (6–18 million units/day) (93). Severe diarrhea and mucosal ulceration of the colon with necrosis has also been reported (94).

- A 53-year-old man had a side-to-side ileo-descending colostomy for disseminated carcinoma. Fluorouracil was given in doses of 15 mg/kg for 4 days, then 7.5 mg/kg intravenously on days 6 and 8. He developed severe diarrhea and severe ulceration of the bypassed portion of the colon, resulting in necrosis, and death occurred as the result of bronchopneumonia. Autopsy showed ulcers from the ileocecal valve to the ileo-colostomy site. The mucosa of the stomach, small intestine, and colon distal to the colostomy were not involved.

In two cases the diarrhea and colitis associated with fluorouracil therapy were caused by toxigenic *Clostridium difficile*. Both patients responded to oral vancomycin (95).

Colitis has been reported as a rare complication of fluorouracil treatment. Two cases have been reported after intra-arterial chemotherapy (96). A further case has been reported, described by the authors as neutropenic enterocolitis, presenting as abdominal pain, diarrhea, and neutropenia (97). Proven pseudomembranous colitis followed 36 weekly doses of fluorouracil (700 mg) and folinic acid (150 mg); the authors believed that this was only the second reported case (98).

Liver

It has been suggested that handling cytostatic agents can insidiously cause hepatic damage and possibly irreversible fibrosis. Three case reports of hepatic injury in nurses after years of handling cytotoxic drugs (bleomycin, vincristine, cyclophosphamide, doxorubicin, dacarbazine, fluorouracil, and methotrexate) have been described (99). All had neurological symptoms associated with raised serum alanine transaminase and alkaline phosphatase

© 2006 Elsevier B.V. All rights reserved.

activities. Liver biopsy showed portal hepatitis, with piecemeal necrosis in one and hepatic fibrosis and fat accumulation in the others.

- Diffuse hepatic necrosis has been described in a 29-year-old man receiving 500 mg/day fluorouracil for 4 days (route of administration unspecified) for adenocarcinoma (100). He developed nausea, vomiting, diarrhea, and massive and diffuse hepatic necrosis. The drug was withdrawn and he died 2 days later (6 days after starting medication).

However, the role of fluorouracil in inducing hepatic disease in this patient is unclear.

In a retrospective analysis of a study of *N*-phosphonoacetyl-L-aspartate (250 mg/m^2) followed by weekly boluses of fluorouracil (600–800 mg/m^2) in 44 patients with metastatic colorectal cancer, five of 17 patients with complete or partial responses to therapy developed transient ascites (with or without associated hypoalbuminemia) compared with one of 27 without such a response (101). Other significant findings in some of the responders included raised bilirubin concentrations and transaminase activities from metastasis. The authors cautioned that the adverse effects observed do not necessarily represent disease progression.

Biliary tract

Intrahepatic infusion of fluorouracil can cause biliary sclerosis (102), believed to result from perfusion of the blood supply to the gall bladder and upper bile duct with high local concentrations of the drug. The median time to onset of biliary sclerosis is three treatment cycles, and although fluorouracil may be restarted at a lower dose after normalization of serum hepatic enzyme activities, most patients become progressively less tolerant.

Of 57 consecutive patients treated with implanted hepatic arterial infusion pumps with a regimen of alternating floxuridine (0.1 mg/kg/day for 7 days) followed by a weekly pump bolus of 5-fluorouracil (15 mg/kg for 3 weeks), two developed biliary sclerosis and 12 had mild transient liver function abnormalities (103). The liver alone or in combination with another area was the site of first progression of disease in 40 patients.

Skin

Two types of skin rashes occur with fluorouracil. The more common form involves erythema of exposed skin areas. With continued fluorouracil therapy the skin becomes hyperpigmented, thin, and atrophic (82). Patients treated with fluorouracil also have an increased susceptibility to sunburn (104). Less commonly (about 1.5%), a severe seborrheic pruritic dermatitis occurs (82). These rashes are usually reversible on withdrawal of fluorouracil. Acute, painful, swollen, and self-limiting erythema of the hands and soles has been reported in association with protracted infusion of fluorouracil (105).

Fluorouracil commonly causes hyperpigmentation and multiple pigmented macules (106). Serpentine supravenous hyperpigmentation is a peculiar dermatological effect seen with continuous infusions of fluorouracil (82,107). Residual macular pigmentation can persist for 3 months after withdrawal. Hyperpigmentation occurs only in the tissues overlying the veins proximal to the infusion site in the limb used. The veins are not sclerosed and usually remain patent (108). This has also been reported in a 56-year-old black man after intravenous fluorouracil 750 mg/m^2/week over 24 weeks for stage-D prostatic carcinoma (109). The patient developed nasal mucosal friability, diffuse pigmentation of the face and hands, and markedly increased pigmentation of the skin immediately overlying the veins that had been used for multiple fluorouracil infusions. Many irregular dark streaks were noted, extending from the hand to the shoulder. These streaks were 1–1.5 cm wide and serpiginous in their course.

Fluorouracil, alone or in combination regimens, via continuous or intermittent infusions or bolus doses, has been associated with hand–foot syndrome or palmar–plantar erythrodysesthesia, a rare syndrome of unknown cause, characterized by varying degrees of painful, erythematous, swollen palms of the hand and soles of the feet (110). Tingling, tenderness, and desquamation can also occur. The pain can be so severe as to inhibit walking and hand grasping (110). The onset of the reaction has ranged from 3 days to 10 months (110,111). Severity appeared to be dose-related in one case (112). The condition gradually subsides over 5–7 days when the drug is withdrawn (112). However, it may recur on rechallenge (111). Pyridoxine 100–150 mg/day has been used to manage this syndrome, allowing continued treatment in a small number of patients (113,114). Topical 5-fluorouracil often causes skin irritation. However, allergic contact dermatitis is only infrequently reported, although it may be underdiagnosed.

- A 64-year-old man was treated with Efudix ointment (containing 5% fluorouracil) for actinic keratosis (115). Patch-testing with the constituents of the cream showed a doubtful reaction to fluorouracil 5% in petroleum jelly; however, intradermal injection of fluorouracil 10 mg/ml gave a positive reaction.

Topical fluorouracil has been associated with allergic contact dermatitis in patients with actinic keratosis and basal cell epitheliomas (116). Topical fluorouracil ointment (5%) was reported to exacerbate dermatitis when it was mistakenly given instead of fluocinonide ointment (117).

Telangiectasia and herpes labialis have been reported in four patients receiving topical 1% fluorouracil in propylene glycol applied three times a day for 7–28 days. Two patients developed herpes labialis 7–10 days after the start of therapy and two developed persistent telangiectasia at the application site (118).

- Bullous pemphigoid has been reported in an 84-year-old man after topical therapy with fluorouracil 1% solution daily over several days for actinic keratosis. All treated lesions became bullous, with the development of a few bullae on untreated areas of normal skin. Bullous lesions were pruritic and sore and some contained hemorrhagic fluid. There was a leukocytosis (11.7×10^9/l). The blister fluid contained predominantly eosinophils, and immunofluorescent studies of the serum and blister fluid showed anti-basement membrane antibody titers of 1:640 and 1:160 respectively. Fluorouracil was discontinued and the patient was treated with steroids and saline compresses, with abatement of symptoms (119).

Fluorouracil not only augments the therapeutic effect of ionizing radiation on tumors, but also increases its mucocutaneous toxicity. The likelihood of severe toxicity within the radiation field is increased significantly and relates to the area irradiated (for example oral stomatitis, esophagitis, enteritis, and skin desquamation). The onset of these effects is within 7 days of the start of radiation.

Hair

Partial reversible alopecia is common after systemic fluorouracil therapy (84).

Nails

Diffuse blue superficial pigmentation, onycholysis, dystrophy, pain and thickening of the nail bed, transverse striations, paronychial inflammation, hyperpigmentation, and nail loss have all been reported with fluorouracil therapy (120–122). It has further been reported that the blue pigment may be scraped off (120).

Sexual function

Vaginitis (shedding of the vaginal epithelium) may be nearly as common as mucositis in women receiving systemic fluorouracil-based chemotherapy regimens (123).

Immunologic

- An anaphylactic reaction with shock after a 10th dose of fluorouracil 900 mg intravenously was reported in a 60-year-old man with colorectal adenocarcinoma (124). Two minutes after his 10th dose of fluorouracil, he became cyanotic and collapsed, with a rapid thready pulse of 120. His blood pressure was 30/0 mmHg. Adrenaline 1:1000, 1 ml, was given, with immediate and prompt signs of recovery. Within 25 minutes, his blood pressure, pulse, and skin color had returned to normal.

Second-Generation Effects

Pregnancy

Fluorouracil is contraindicated throughout pregnancy. The literature on pregnancy and cytotoxic drugs is necessarily limited, but it appears in general that risk of teratogenesis diminishes with the advancement of pregnancy. Therefore, most cytotoxic drugs are absolutely contraindicated in the first trimester, and when fluorouracil has been used in the first trimester it has been reported to cause multiple congenital abnormalities (125).

Administration of fluorouracil to pregnant rats on day 14 of gestation resulted in dose-dependent growth retardation and numerous malformations in near-term fetuses, including hind limb defects and cleft palate (126). After treatment, a number of rapid biochemical and cellular alterations were detectable in embryonic hind limbs and in craniofacial and other tissues, including inhibition of thymidylate synthetase and altered cell cycle progression. In order to assess the importance of these early events in fluorouracil-induced dysmorphogenesis, embryonic mid-facial tissues and hind limbs were dissected 3 or 6 hours after administration of fluorouracil to the dam and placed in explant culture. After 5 days in culture, craniofacial explants were evaluated morphologically for palatal closure, and growth was assessed by measuring total protein and DNA contents. Hind-limb explants were stained for cartilage using Alcian blue to evaluate development of digits. Craniofacial explants cultured at either 3 or 6 hours after exposure showed dose-dependent growth retardation and defects of palatal fusion at the end of the culture period. Deficits in protein and DNA content were similar to those in craniofacial tissues that continued to develop in utero after treatment, although morphological defects in cultured explants did not correlate well with the incidence of cleft palate in vivo. Dose-dependent deficits in metatarsal and phalanx development were observed in hind-limb explants dissected either 3 or 6 hours after maternal treatment.

Susceptibility Factors

Genetic factors

Anabolism of fluorouracil to pyrimidine nucleotide analogues is required for its cytotoxic effects and pyrimidine catabolism is important in the regulation of fluorouracil availability and its subsequent anabolism. Dihydropyrimidine dehydrogenase is the initial enzyme of pyrimidine catabolism, accounting for degradation of greater than 80% of a dose of fluorouracil. The importance of catabolism and particularly dihydropyrimidine dehydrogenase in fluorouracil chemotherapy has previously been demonstrated in studies with competitive inhibitors of dihydropyrimidine dehydrogenase and in patients with suspected or proven dihydropyrimidine dehydrogenase deficiency. Before 1991, only two cases of dihydropyrimidine dehydrogenase deficiency associated with fluorouracil toxicity in adults were reported, and in both cases it was the fluorouracil toxicity that focused attention on pyrimidine catabolism. In 1991 a third case of dihydropyrimidine dehydrogenase deficiency was reported (127), suggesting that it may be more frequent than initially thought. There was complete deficiency of dihydropyrimidine dehydrogenase in the affected patient, with evidence of partial deficiency in the patient's parents, daughter, brother, and the brother's children. This pattern of dihydropyrimidine dehydrogenase activity was consistent with the previous two reports, suggesting an autosomal recessive pattern of inheritance.

- A 35-year-old woman with breast carcinoma treated with doses of fluorouracil that were not unusually high. Chemotherapy with cyclophosphamide, fluorouracil, and methotrexate started 3 weeks after surgery. Following day 8 of the protocol, the patient had severe gastrointestinal adverse effects (nausea, prolonged vomiting, diarrhea, stomatitis), hematological toxicity (neutropenia), and fever. She also had mild neurological toxicity causing unsteadiness and difficulty in spelling simple words, which persisted for about 2 weeks.

The neurotoxicity of fluorouracil seems to be more prolonged and severe in patients with dihydropyrimidine dehydrogenase deficiency (128).

Only a few cases of dihydropyrimidine dehydrogenase deficiency have been identified: however, all cases exhibited remarkable toxicity. Enhanced toxicity occurring at normal doses is what usually sets these patients

© 2006 Elsevier B.V. All rights reserved.

apart. The authors suggested that monitoring dihydropyrimidine dehydrogenase activity may be appropriate in the management of those who have severe toxicity from fluorouracil (127).

Additional studies are needed to characterize this genetic defect, in order to answer the following questions:

- What is the frequency of this gene defect in the general population?
- Does dihydropyrimidine dehydrogenase deficiency correlate with the occurrence of severe fluorouracil toxicity?
- Do individuals with partial dihydropyrimidine dehydrogenase deficiency (that is heterozygotes) have altered metabolism of fluorouracil?
- Is monitoring dihydropyrimidine dehydrogenase activity helpful in the management of patients experiencing severe toxicity to fluorouracil chemotherapy?

Age

Cancer is most common in older people, but little information is available with regard to the impact of age on the toxicity of chemotherapy. A study has been undertaken to determine if age is an independent risk factor for fluorouracil toxicity (129). Toxicity data from a prospective, randomized, multi-institution trial of fluorouracil-based treatment for advanced colorectal carcinoma were analysed. Toxicity for each organ system was graded. The results showed that advanced age was significantly associated with the occurrence of any severe toxicity (58 versus 36%), leukopenia (24 versus 10%), diarrhea (24 versus 14%), vomiting (15 versus 5%), severe toxicity in more than two organ systems (10 versus 3%), and treatment mortality (9 versus 2%). Age and sex were independent predictors of severe toxicity. Advanced age does not contraindicate the use of this type of chemotherapy, but monitoring for multiple organ toxicity and vigorous supportive care of those with toxicity are required.

Dosing decisions in older patients are difficult and must integrate assessments of organ function, co-morbidity, overall physical status, and goals of treatment, in an effort to ensure the best possible outcome for these patients.

Other features of the patient

Circadian variation in toxicity

If the rhythm in fluorouracil toxicity is linked to the asleep–awake circadian cycle across species, the least toxic time in man would correspond to 0400 hours. This hypothesis has been tested using a single-reservoir, programmable-in-time, external ambulatory pump (Chronopump, Autosyringe, Hooksett, USA) in 35 patients with metastatic colorectal cancer (130). Fluorouracil was infused for 5 days via an implanted venous access port, with peak drug delivery at 0400 hours and no infusion from 1800 to 2200 hours. Each course was repeated after a drug-free interval of 16 days. Intrapatient dose escalation was planned from 4 to 9 g/m^2/course (800–1800 mg/m^2/day for 5 days) if toxicity was less than grade 2 according to the World Health Organization (WHO). There was grade 2 or greater toxicity in under 5% of the courses, indicating adequate control of toxicity via dose escalation, and their incidence was dose-dependent. The median maximal tolerated dose was 7.5 mg/m^2/course in 30 patients assessed for this end point.

Cellular glutathione concentrations and fluorouracil toxicity

Little is known about whether components of the diet can modulate the efficacy of fluorouracil in patients with colon carcinoma. Glutathione, an important antioxidant and anticarcinogen, is present in many foods in varying amounts.

The effect of cellular glutathione concentration on the growth of human colon adenocarcinoma cells HT-29 and on the cytotoxic activity of fluorouracil in these cells has been studied (131). Glutathione and buthionine sulfoximine were used respectively to enhance or reduce the glutathione concentration in these cells. A 34% increase in cellular glutathione concentration had no effect on the growth of HT-29 cells, nor on the cytotoxic activity of fluorouracil. A 50% reduction in the cellular glutathione concentration enhanced fluorouracil cytotoxicity by 20–31%, depending on the fluorouracil concentration.

Drug Administration

Drug dosage regimens

Stomatitis and diarrhea are particularly frequent in patients who received a 5-day regimen. An alternative regimen using continuous intravenous infusion of fluorouracil at doses of 30 mg/kg/day for 5 days gives equivalent therapeutic results but a different pattern of toxicity (132). Gastrointestinal symptoms, such as stomatitis and diarrhea, are the principal dose-limiting toxic effects, but myelosuppression is less intense. When fluorouracil is given in combination with leucovorin in patients with metastatic colon cancer, there is enhanced gastrointestinal toxicity, irrespective of the fluorouracil schedule.

Drug administration route

Intravenous administration of fluorouracil 1 g has been compared with hepatic arterial infusion (133). When fluorouracil was administered over 2 hours, systemic drug exposure was 0.7 times lower and clearance 1.5 times higher with hepatic arterial infusion. When the duration of infusion was extended to 24 hours, systemic drug exposure was 0.4 times lower and the clearance was two- to three-fold higher with hepatic arterial infusion. For the 24-hour infusion, co-treatment with angiotensin II (given temporarily to increase tumor blood flow) and albumin microspheres, given to increase drug uptake by the liver via the hepatic artery produced an additional two-fold reduction in systemic fluorouracil exposure. Further evaluation is planned to determine if this will improve the therapeutic index of regionally administered fluorouracil.

Intraperitoneal administration of fluorouracil has been reported to produce a desirable regional advantage (134). The results of a phase I trial of intraperitoneal fluorouracil in escalating concentrations for 4 hours, along with a fixed dose of cisplatin 90 mg/m^2 every 28 days, has been used (135). There was dose-limiting neutropenia at a fluorouracil concentration of 20 mmol/l, although individual patients tolerated concentrations as high as 30 mmol/l.

© 2006 Elsevier B.V. All rights reserved.

Other toxic effects included mild-to-moderate nausea and vomiting; diarrhea occurred less often. Peak plasma concentrations occurred 1 hour after instillation and there was a significant linear relation between the intraperitoneal fluorouracil dose and the peak plasma fluorouracil concentration. At every dose, the mean peak intraperitoneal fluorouracil concentration exceeded that in the plasma by two to three log units.

Drug overdose

Cases of deliberate overdosage are unknown, but excessive duration or dosage of therapy will produce life-threatening toxicity because of the hematological effects and other symptoms and signs that are qualitatively similar to the adverse effects. There is no specific antidote to fluorouracil toxicity; treatment consists of supportive care, including G-CSF and antidiarrheal agents.

Drug–Drug Interactions

Allopurinol

Concurrent administration of allopurinol with fluorouracil inhibits the intracellular formation of fluorouridine monophosphate from fluorouracil in normal tissues. In tumor cells that activate fluorouracil by alternative pathways, antitumor responses are still seen (2). Allopurinol increased the half-life of high-dose fluorouracil when it was given by intravenous bolus but not when it was given by 5-day continuous infusion (2).

Allopurinol ameliorates fluorouracil-induced granulocytopenia and possibly lessens the severity of mucositis (136). Allopurinol mouthwash (450 mg total in methylcellulose) given immediately and 1, 2, and 3 hours after fluorouracil reduced the incidence and severity of mucositis in six patients (137) and in another study of 42 patients there was significant reduction of oral toxicity and prolonged pain relief (138). In a randomized, double-blind, placebo-controlled trial, in 44 patients, allopurinol mouthwashes resolved stomatitis in nine of 22 treated patients, and diminished its intensity in 10 (139). However, in another randomized, double-blind, crossover study of allopurinol, mouthwash in 77 patients did not ameliorate fluorouracil-induced mucositis (140), nor did allopurinol reduce the toxicity of intravenously administered fluorouracil (141). Allopurinol is not currently recommended in the prophylaxis of fluorouracil-induced mucositis.

Cimetidine

Pre-treatment for 4 weeks with cimetidine 1 g/day increased the oral systemic availability of fluorouracil by 74%; the AUC was increased by 27% and total body clearance was reduced by 28% (142).

Dipyridamole

The pharmacokinetics of fluorouracil have been studied with escalating doses as a 72-hour intravenous infusion alone or in combination with a fixed dose of dipyridamole, a nucleoside transport inhibitor, and an enhancer of fluorouracil cytotoxicity (143). Stomatitis was dose-limiting at a fluorouracil dose of 2300 mg/m^2/day. For courses given with fluorouracil alone, the pharmacokinetics were linear for doses of 185–2300 mg/m^2/day; however, above this dose total body clearance fell significantly. Dipyridamole increased the total body clearance of fluorouracil, resulting in significantly lower mean steady-state fluorouracil plasma concentrations over the dose range studied. The clinical observation that dipyridamole did not appear to modulate fluorouracil-induced mucositis or leukopenia can be explained by lower exposure to fluorouracil. The basis for this pharmacokinetic interaction is not understood but it serves to underscore the importance of incorporating pharmacokinetic analysis in clinical trials involving new drug combinations.

Interferons

Initial studies have suggested that interferons may have synergistic activity with fluorouracil (144,145). Interferon alfa-2b has also been associated with an 80% increase in fluorouracil AUC (146).

Leucovorin

When combined with fluorouracil, leucovorin enhances the binding of the fluorouracil metabolite fluorouridine monophosphate to thymidylate synthetase. DNA-directed toxicity is increased, whilst RNA-directed toxicity is not affected (146). A qualitative alteration in toxicity is reported with increased gastrointestinal toxicity (2).

Methotrexate

There is sequence-dependent synergy between fluorouracil and methotrexate. Pretreatment with methotrexate enhances the formation of fluorouridine monophosphate and hence fluorouridine triphosphate and RNA-directed toxicity. In studies in which methotrexate has been given 1 hour before fluorouracil, response rates did not differ significantly. However, when it was given 4 hours or more before, there were significantly better response rates (147).

Metronidazole

Pretreatment with metronidazole increased the toxicity of fluorouracil given by daily bolus dose (148). The clinical significance of this is yet to be determined.

Pyridoxine

The dose and duration of protracted infusional fluorouracil is limited by mucositis, diarrhea, and/or palmar–plantar erythrodysesthesia. Typically, palmar–plantar dysesthesia begins several weeks to months after starting treatment. Although the dysesthesia abates within several weeks of discontinuing the infusion, it rapidly recurs when the infusion is resumed. Five patients who developed palmar–plantar dysesthesia during infusion of fluorouracil were treated with oral pyridoxine, 50 or 150 mg/day, once it reached moderate severity (149). The severity of the skin toxicity improved, with resolution of pain in four of the five patients, despite continued administration of fluorouracil. The ability of pyridoxine to modulate fluorouracil-induced cutaneous toxicity is currently undergoing evaluation in the randomized trial (150).

Other Environmental Interactions

Ionizing radiation

Fluorouracil increases the activity and toxicity of ionizing radiation (2).

Fluoxetine

See also Selective serotonin re-uptake inhibitors (SSRIs)

General Information

Fluoxetine is a selective serotonin re-uptake inhibitor (SSRI). The manufacturers of fluoxetine have published a review of the adverse effects that were noted in 1378 patients who took it for up to 2 years (1).

In a meta-analysis based on 9087 patients in 87 different randomized clinical trials fluoxetine was more effective than placebo from the first week of therapy (2). In bulimia nervosa, fluoxetine was as effective as other agents. It was as effective as clomipramine in the treatment of obsessive-compulsive disorder.

The major adverse effects of fluoxetine confirm its stimulant profile and its relative lack of anticholinergic actions. The most frequent adverse effects, which occurred in 10–25% of patients, were nausea (25%), nervousness, insomnia, headache, tremor, anxiety, drowsiness, dry mouth, sweating, and diarrhea (10%). Most of these adverse effects occurred early in treatment and seldom led to drug withdrawal.

Organs and Systems

Cardiovascular

Fluoxetine appears not to have the cardiovascular effects associated with tricyclic compounds, but 10 patients did discontinue treatment because of tachycardia, palpitation, and dyspnea (3). Two older women each had a myocardial infarction and subsequently died, although these events may not have been drug-related.

In general, SSRIs are assumed to be safe in patients with cardiovascular disease, although there have been few systematic investigations in these patients. In a prospective study of 27 depressed patients with established cardiac disease, fluoxetine (up to 60 mg/day for 7 weeks) produced a statistically significant reduction in heart rate (6%) and an increase in supine systolic blood pressure (2%) (4). One patient had worsening of a pre-existing dysrhythmia and this persisted after fluoxetine withdrawal. These findings suggest that, relative to tricyclic antidepressants, fluoxetine may have a relatively benign profile in patients with cardiovascular disease. However, the authors cautioned that in view of the small number of patients studied, these findings cannot be widely generalized.

The effects of fluoxetine (20 mg/day for 12 weeks) on sitting and standing blood pressures have been reported (5). Fluoxetine modestly but significantly lowered sitting and standing systolic and diastolic blood pressures by about 2 mmHg. Patients with pre-existing cardiovascular disease showed no change. This study confirms that fluoxetine has little effect on blood pressure in physically healthy depressed patients and in those with moderate cardiovascular disease.

Fluoxetine-induced remission of Raynaud's phenomenon has been reported (SEDA-18, 20) (6).

Cardiac dysrhythmias

Fluoxetine has reportedly caused prolongation of the QT_c interval (7).

- A 52-year-old man had an abnormally prolonged QT_c interval of 560 ms, with broad-based T-waves. He had taken fluoxetine 40 mg/day over the previous 3 months, before which an electrocardiogram had shown a normal QT_c interval (380 ms). The fluoxetine was withdrawn, and 10 days later the QT_c interval was 380 ms. His only other medication was verapamil which he had taken for 3 years for hypertension.

Systematic studies of fluoxetine as monotherapy have not shown evidence of QT_c prolongation. It is possible in this case that fluoxetine interacted with verapamil to produce a conduction disorder.

An elderly man developed atrial fibrillation and bradycardia shortly after starting fluoxetine, and again on rechallenge (SEDA-16, 9). Dose-dependent bradycardia with dizziness and syncope has also been reported in a few patients taking fluoxetine (SEDA-16, 9) and in a presenile patient (8).

Nervous system

Several cases in which fluoxetine worsened parkinsonian disability have been described, and the problem of exacerbation of Parkinson's disease by fluoxetine has been reviewed (SEDA-18, 19).

Five patients taking fluoxetine developed akathisia, perhaps due to enhanced serotonergic inhibition of dopamine neurons (9). A causal link between fluoxetine-induced akathisia and suicidal behavior has been suggested (SEDA-17, 19) (SEDA-18, 19), and akathisia has also been associated with "indifference" (SEDA-18, 19).

One case of neuroleptic malignant syndrome has been described with fluoxetine (10).

One case of tics after long-term fluoxetine therapy has been described; the symptoms subsided several months after withdrawal (SEDA-18, 19).

One case of migraine associated with fluoxetine has been reported, with no further attacks when the drug was withdrawn (SEDA-18, 20).

Stuttering has been reported with fluoxetine (11).

Two patients who had been maintained successfully on fluoxetine (20 mg/day) for 6 and 10 years respectively began to have agitation, tension, and sleep disturbance (12). There had been no recent changes in medications or life events to explain these symptoms, which closely resembled the kind of adverse effects that can occur shortly after the start of SSRI treatment. Both patients improved after downward titration of the dose of fluoxetine. Blood concentrations of fluoxetine were not reported, so it is possible that for some reason (for example a change in diet or activity) plasma fluoxetine concentrations had recently increased in these subjects. However, the development of characteristic adverse effects after such a long trouble-free period suggests that patients taking maintenance medication need long-term follow-up, or at least ready access to specialist advice.

Seizures

Fluoxetine has been associated with seizures, both in therapeutic doses (3,13) and in overdose (3,14). It has also been shown to lengthen seizure duration during electroconvulsive therapy (SEDA-17, 20). Four patients had suspected seizures during studies (3) and one who took a 3000 mg overdose (3) had unequivocal convulsions but recovered.

Sensory systems

Tricyclic antidepressants can precipitate acute glaucoma through their anticholinergic effects. There are also reports that SSRIs can cause acute glaucoma, presumably by pupillary dilatation (see the monograph on Paroxetine).

In a placebo-controlled study in depressed patients a single dose of fluoxetine (20 mg) increased intraocular pressure by 4 mmHg (15). This increase is within the normal diurnal range, but could be of clinical consequence in individuals predisposed to glaucoma. However, post-marketing surveillance has not suggested an association between the use of fluoxetine and glaucoma (16).

Blurred vision has occasionally required withdrawal of fluoxetine (3).

Psychological, psychiatric

An analysis of severe adverse effects that caused drug withdrawal showed that psychotic reactions occurred in nine of 1378 patients; in four cases this appeared to

© 2006 Elsevier B.V. All rights reserved.

be a stimulant psychosis and in three a conversion to mania (3).

Cognitive function can be impaired by fluoxetine; a negative effect on learning and memory has been described (SEDA-17, 20).

Reports of acute mania and manic-like behavior after treatment with fluoxetine or fluvoxamine have appeared (SEDA-13, 12) (SEDA-17, 20) (SEDA-18, 20), but there are not enough data to estimate the incidence.

Suicidal ideation has been described after 2–7 weeks of fluoxetine (17) and other case reports (SEDA-16, 9) (SEDA-17, 19). A causal link was initially questioned (SED-12, 57) (SEDA-15, 15) (SEDA-17, 19), and in one controlled trial there was no increase (SEDA-16, 9). Furthermore, a meta-analysis of controlled trials did not point to a greater risk of suicide attempts or suicidal ideation with fluoxetine than with tricyclic antidepressants (1).

In a meta-analysis based on 9087 patients in 87 different randomized clinical trials with fluoxetine there was no increased risk of suicide (2).

In an analysis of data from the National Institute of Mental Health Collaborative Depression Study in 643 patients with affective disorders who were followed up after fluoxetine was approved by the FDA in December 1987 for the treatment of depression, nearly 30% (n = 185) took fluoxetine at some point (18). There was an increased rate of suicide attempts before fluoxetine treatment in those who subsequently took fluoxetine. Relative to no treatment, fluoxetine and other antidepressants were associated with non-significant reductions in the likelihood of suicide attempts or completions. Severity of psychopathology was strongly associated with increased risk, and each suicide attempt after admission to the study was associated with a marginally significant increase in the risk of suicidal behavior. The authors concluded that the results did not support the speculation that fluoxetine increases the risk of suicide.

Endocrine

Fluoxetine causes weight loss, in contrast to tricyclic antidepressants (19). In one study there was a mean fall in weight of 3.88 pounds over 6 weeks compared with a gain of 4.6 pounds with amitriptyline (20).

Serotonin pathways are involved in the regulation of prolactin secretion. Amenorrhea, galactorrhea, and hyperprolactinemia have been reported in a patient taking SSRIs.

- A 71-year-old woman who had taken fluoxetine (dose unspecified) for a number of weeks noted unilateral galactorrhea and had a raised prolactin of 37 ng/ml (reference range 1.2–24 ng/ml) (21). She was also taking estrogen hormonal replacement therapy, benazapril, and occasional alprazolam. Withdrawal of the fluoxetine led to normalization of the prolactin concentration and resolution of the galactorrhea.

Estrogens also facilitate prolactin release, and so hormone replacement therapy may have played a part in this case.

Hematologic

Petechiae and prolongation of bleeding time have been reported in association with fluoxetine (SEDA-16, 10). In one case a 31-year-old woman taking fluoxetine developed bruising (22).

Aplastic anemia with fever, pleuritic chest pain, and pancytopenia developed in a 28-year-old woman (23) after 6 weeks of fluoxetine therapy. Bone-marrow examination confirmed acute marrow aplasia. She recovered 19 days after withdrawal. Neutropenia occurred rapidly after rechallenge. Another report described severe neutropenia during fluoxetine treatment (24).

Gastrointestinal

Gastrointestinal adverse effects are one of the major disadvantages of SSRIs (see General section). Two women developed stomatitis while taking fluoxetine; in one it recurred on rechallenge (25).

Liver

Chronic hepatitis associated with fluoxetine has been reported in a 35-year-old man (26).

In a post-marketing surveillance study there were some cases in which fluoxetine alone appeared to have precipitated hepatitis, which remitted when treatment was withdrawn (27). Fluoxetine can cause mild increases in liver enzymes, with a rate in clinical trials of about 0.5%. Rarely this can progress to hepatitis.

Skin

Rashes due to fluoxetine occur in a few percent of patients (28). Fluoxetine has been implicated in two cases of psoriasis (SEDA-17, 20). A woman taking fluoxetine monotherapy had painful burning, persistent erythema, and blisters on sun-exposed areas (SEDA-20, 8).

Hair

Reversible hair loss has been reported in patients taking fluoxetine (SEDA-16, 10) (SEDA-17, 20).

Sexual function

Fluoxetine can impair sexual function in both sexes, and particularly causes delayed orgasm or anorgasmia (SEDA-14, 14) (SEDA-17, 21) (SEDA-18, 21), in 5–10% of patients (29,30).

Fluoxetine has been implicated in one case of prolonged erection (SEDA-18, 21).

Yawning, clitoral engorgement, and spontaneous orgasm have been associated with fluoxetine (31).

Penile anesthesia has been reported in association with fluoxetine and sertraline (SEDA-17, 20).

Immunologic

Vasculitis has been attributed to fluoxetine (32,33).

- A patient who took fluoxetine for a manic-depressive disorder developed pulmonary inflammatory nodules with non-caseating giant cell granulomas, interstitial pneumonia, and non-necrotizing vasculitis, but remained asymptomatic (34). The diagnosis was made by open lung biopsy. The pulmonary nodules progressively resolved after withdrawal and the chest X-ray returned to normal in 9 months.

Second-Generation Effects

Fetotoxicity

Fluoxetine can occasionally cause cardiac dysrhythmias in adults, and may have done so in a fetus, whose mother took fluoxetine during pregnancy.

A woman took fluoxetine (20–30 mg/day) from the 28th week of pregnancy (35). The fluoxetine was withdrawn during the 37th week, and at 38 weeks a male infant (2700 g) was born by spontaneous vaginal delivery. Both before and after delivery the baby was noted to have multiple atrial and ventricular extra beats. Echocardiography showed a normal heart and the baby was otherwise well. By discharge on day 5 the frequency of extra beats had fallen, and on follow-up 1 month later they were no longer present.

The long half-life of fluoxetine and its active metabolite, norfluoxetine, means that the active drug would have been present in the mother and baby for some weeks after withdrawal. However, as the authors pointed out, the baseline incidence of atrial extra beats in a fetus in utero is about 1–2%. It is therefore possible that treatment with fluoxetine in this case was coincidental.

Fluoxetine-related withdrawal effects have been reported in a neonate whose mother had taken fluoxetine during pregnancy (SEDA-18, 21).

Drug Administration

Drug overdose

Nine patients took overdoses of fluoxetine in amounts up to 3000 mg (37 times the recommended dose) (3). One, who also took several other drugs, including amitriptyline, died, but the other eight all recovered with relatively minor symptoms in most cases. Four patients had suspected seizures during studies (3) and one who took a 3000 mg overdose had unequivocal convulsions but recovered.

Overdosage of fluoxetine has been implicated in the development of seizures, but usually only when taken with other substances.

- A 15-year-old girl had a tonic-clonic seizure after overdosage of fluoxetine alone; she recovered uneventfully (36).

Drug–Drug Interactions

Beta-blockers

An interaction between metoprolol and fluoxetine with severe bradycardia has been described (SEDA-18, 23).

Carbamazepine

Fluoxetine can increase plasma concentrations of carbamazepine (SEDA-17, 21) (SEDA-18, 23).

Digoxin

Fluoxetine has been reported to increase serum digoxin concentrations (37).

- A 93-year-old woman with congestive cardiac failure, paroxysmal atrial fibrillation, and hypertension developed depression after the death of her daughter. For several months she had been taking captopril 25 mg bd, furosemide 40 mg/day, digoxin 0.125 mg/day, and ranitidine 150 mg bd. She was in sinus rhythm and her serum digoxin concentration was 1.0–1.4 nmol/l. She was treated with fluoxetine (10 mg/day), but a week later she developed anorexia. At that time the serum digoxin concentration was 4.2 nmol/l. Both digoxin and fluoxetine were withdrawn and the digoxin concentration returned to the target range within 5 days, with resolution of the anorexia. Digoxin was restarted and concentrations in the usual target range were achieved during the next 3 weeks (0.9–1.4 nmol/l). Because of persisting depressive symptoms, fluoxetine (10 mg/day) was given again, but the digoxin concentrations rose and after 4 days were 2.8 nmol/l. Both digoxin and fluoxetine were then withdrawn.

Because digoxin has a narrow therapeutic range, this interaction, if confirmed, may be of clinical significance. The mechanism is not clear, because digoxin is not a substrate for the cytochrome P450 enzymes that are inhibited by fluoxetine. The authors speculated that fluoxetine may reduce the renal clearance of digoxin; if so, it might do that by inhibiting the P-glycoprotein that is responsible for the active tubular secretion of digoxin.

Lithium

A report has been published of lithium toxicity induced by combined treatment with fluoxetine (38).

Monoamine oxidase inhibitors

The problem of the long half-life of fluoxetine, leading to interactions with monoamine oxidase inhibitors, even after withdrawal, has been discussed previously (SEDA-13, 12), and caused the manufacturer to circulate a warning to that effect.

Pseudopheochromocytoma, with hypertension, palpitation, and headache, has been reported in a patient taking fluoxetine and selegiline (SEDA-18, 23).

Phenytoin

Several case reports and one in vitro study have suggested that combined administration of fluoxetine with phenytoin can significantly increase phenytoin serum concentrations, leading to toxicity (19,39,40).

Risperidone

Combined treatment with atypical neuroleptic drugs and SSRIs is common and case reports have suggested that SSRIs can increase risperidone concentrations and increase the risk of extrapyramidal disorders (SEDA-23, 18).

- Severe parkinsonism with urinary retention occurred when fluoxetine 20 mg/day was added to risperidone 2 mg/day in a 46-year-old man with schizophrenia. Risperidone had been prescribed at this dose for 1 month without any adverse effects, and the authors considered that a pharmacokinetic interaction between fluoxetine and risperidone was the most likely mechanism (41).

© 2006 Elsevier B.V. All rights reserved.

In a systematic open study in 11 hospitalized patients taking a steady dose of risperidone (4–6 mg/day), fluoxetine (20 mg/day) increased plasma concentrations of active antipsychotic medication (combined concentrations of risperidone and 9-hydroxyrisperidone) by 50% after treatment for 25 days (42). Despite this, the treatment was well tolerated and there were improvements in rating scales of psychosis and depressed mood. Whether this was due to the introduction of fluoxetine or the higher plasma concentrations of risperidone is not clear. Fluoxetine and norfluoxetine would require at least a further 2 weeks to reach steady state, so additional increases in risperidone concentrations might be anticipated over this time.

Triptans

Caution has been advocated when SSRIs such as fluoxetine are combined with the triptans that are used to treat acute episodes of migraine (SEDA-24, 16). There are case reports of symptoms suggestive of serotonin toxicity when fluoxetine has been combined with sumatriptan, perhaps because the SSRI can potentiate the 5-$HT_{1B/1D}$ agonist effects of the triptan (SEDA-22, 14).

The effect of fluoxetine 60 mg/day for 8 days on the pharmacokinetics of almotriptan has been studied in 14 healthy volunteers (43). Fluoxetine produced a significant increase in the peak concentration of almotriptan, but the AUC was not altered. These results suggest that CYP2D6 plays a minor role in the metabolism of almotriptan. The combined treatment was reported to be well tolerated, but this does not exclude the possibility of occasional cases of serotonin toxicity in some individuals.

Flupentixol

See also Neuroleptic drugs

General Information

Flupentixol is a thioxanthene neuroleptic drug.

Organs and Systems

Nervous system

Autoamputation of the tongue in a patient who was taking flupentixol has been explained as being secondary to an acute, atypical, neuroleptic drug-induced orolingual dyskinesia (1).

- A 21-year-old man, who had been mentally retarded from birth, was given intramuscular flupentixol 50 mg/day and oral diazepam 7.5 mg/day for disruptive and inappropriate behavior, and 84 hours later began chewing his tongue repetitively, with resultant edema and bleeding from multiple lacerations. The biting abated within 2 hours after intravenous biperiden 5 mg and diazepam 5 mg; ampicillin, cloxacillin, and metronidazole were also given. One week after admission to hospital, he had an autoamputation of the distal one-third of his tongue.

Fluphenazine

See also Neuroleptic drugs

General Information

Fluphenazine is a phenothiazine neuroleptic drug.

In a double-blind comparison of a group of stabilized outpatients taking a low dosage of fluphenazine enanthate (1.25–5 mg every 2 weeks) with a group taking a standard dosage (12.5–50 mg every 2 weeks), relapse rates were higher in the low-dose group (56%) than in the standard-dose group (7%) (1). However, patients in the low-dose group had a better outcome in terms of some measures of psychosocial adjustment and family satisfaction. Patients in the low-dose group had fewer signs of tardive dyskinesia, and relapses led less often to re-admission to hospital; they also responded more readily to treatment with temporary increases in medication than patients treated with standard doses.

In a comparison of a low dose of fluphenazine decanoate (5 mg) with a standard dose (25 mg) every 2 weeks, there was no significant difference in relapse at 1 year (2), nor was there a difference in survival at 1 year, but at 2 years, survival was significantly better with the 25 mg dose (64%) than with the 5 mg dose (31%) (3).

Organs and Systems

Gastrointestinal

Neuroleptic drugs, particularly phenothiazine derivatives, have been reported to cause colitis (SED-14, 150) (4) (SEDA-20, 43). The mechanism was thought to be an anticholinergic effect. Two other cases have been reported (5,6), one with positive rechallenge.

- A 41-year-old man developed acute abdominal pain with profuse diarrhea and fever (39°C) while receiving intramuscular fluphenazine decanoate 125 mg once every 3 weeks. During the previous 3 months he had also taken oral alimemazine 50 mg/day, levomepromazine 50 mg/day, and amitriptyline 100 mg/day. Colonoscopy showed necrotic ulcers in the mucosa of the sigmoid and descending colon. After three weeks of parenteral nutrition, there was a marked reduction in the colonic lesions and he recovered. Levomepromazine 50 mg/day and fluphenazine decanoate 100 mg/day were reintroduced. Two days later he complained again of abdominal pain, and tomodensitometry confirmed distension.

© 2006 Elsevier B.V. All rights reserved.

Second-Generation Effects

Fetotoxicity

Severe rhinorrhea and respiratory distress occurred in a neonate exposed to fluphenazine hydrochloride prenatally (7).

Drug–Drug Interactions

Vitamin C

In one patient, ascorbic acid reduced serum fluphenazine concentrations, perhaps by liver enzyme induction or by reduced absorption (8).

Flupirtine

General Information

Flupirtine is a non-opiate, centrally acting analgesic, with muscle relaxant properties. It causes predominantly nervous system adverse effects (visual, disorientation, confusion, tremor). About 26% of patients develop minor adverse reactions (1).

Reference

1. Galasko CS, Courtenay PM, Jane M, Stamp TC. Trial of oral flupirtine maleate in the treatment of pain after orthopaedic surgery. Curr Med Res Opin 1985;9(9):594–601.

Fluproquazone and proquazone

See also Non-steroidal anti-inflammatory drugs

General Information

Fluproquazone and proquazone, quinazoline derivatives, are analgesics of minor importance. Gastrointestinal adverse effects are the most frequent (SEDA-4, 69) (SEDA-5, 197) (SEDA-10, 88). Because fluproquazone caused hepatic injury in 14% of patients in clinical trials, evaluation was halted (1).

Reference

1. Lewis JH. Hepatic toxicity of nonsteroidal anti-inflammatory drugs. Clin Pharm 1984;3(2):128–38.

Flurbiprofen

See also Non-steroidal anti-inflammatory drugs

General Information

In a short-term multicenter study of flurbiprofen only 6% of patients were withdrawn because of adverse effects (1). However, in a prolonged open study in 1200 patients, more than 50% reported adverse reactions and therapy had to be withdrawn in l9% (2).

Organs and Systems

Nervous system

Nervous system effects with flurbiprofen are less common than with indometacin (3). Flurbiprofen precipitates extrapyramidal reactions, albeit rarely (SEDA-15, 101), and a parkinsonian syndrome has been reported in a predisposed patient (SEDA-15, 101).

Gastrointestinal

Flurbiprofen causes more gastrointestinal adverse effects than naproxen or ibuprofen. In a series of controlled double-blind studies, adverse reactions occurred in 27–42% of patients and were most commonly gastrointestinal in origin (18–28%) (SEDA-12, 85).

Local tolerance of flurbiprofen suppositories is often satisfactory, but discomfort, irritation, tenesmus, and diarrhea have been observed (4).

© 2006 Elsevier B.V. All rights reserved.

Urinary tract

Interstitial nephritis with the nephrotic syndrome and one case of renal papillary necrosis have been recorded (SEDA-12, 86) (SEDA-17, 110). Flurbiprofen can cause a membranous nephropathy (SEDA-21, 105).

Skin

There have been two reports of a dermatitis herpetiformis-like eruption in patients taking flurbiprofen (SEDA-18, 104).

Immunologic

Leukocytoclastic vasculitis caused by flurbiprofen has been observed in a patient with rheumatoid arthritis (SEDA-15, 101).

Susceptibility Factors

Age

Elderly patients seem to be particularly sensitive to and intolerant of flurbiprofen; one study reported adverse effects in 80% (SED-11, 183) (5).

Drug Administration

Drug administration route

Intramuscular flurbiprofen was effective and well tolerated in ureteric colic; local adverse effects were slight (SEDA-20, 93).

Drug–Drug Interactions

Acenocoumarol

Flurbiprofen potentiates the anticoagulant effect of acenocoumarol (SEDA-7, 112).

Furosemide

Flurbiprofen reduces the diuretic action of furosemide (6).

Quinolone antibiotics

The Japanese regulatory authority has suggested that the data sheet for flurbiprofen should include a warning that it can cause convulsions, which has mainly been described in patients taking quinolone antibiotics (SEDA-18, 104); quinolones should not be used concomitantly (SEDA-18, 104).

Flurotyl

General Information

Flurotyl, a hexafluorinated ether, has been used as a therapeutic inhalational convulsant in psychiatry (SED-13, 11). Its intravenous use in a polyethylene glycol solution has been discontinued because of possible renal damage. In most Western and North American countries, flurotyl is not recommended because of variations in response and dosing difficulties.

Organs and Systems

Respiratory

Flurotyl is excreted via the lungs and there has been concern about the possibility of apnea, cardiac arrest, or vascular collapse; it has therefore been recommended that resuscitation facilities be available when it is used (1).

Nervous system

The main adverse effects of flurotyl are restlessness, confusion, dysphasia, headache, and dysmelia (SED-8, 5). Prolonged muscle twitching can occur, as can intermittent jerky movements of the limbs (SED-9, 2).

Psychological, psychiatric

Flurotyl caused toxic delirium in two of 135 patients with schizophrenia (SED-13, 12).

Drug–Drug Interactions

General

Flurotyl should not be used in combination with drugs that lower the seizure threshold, such as monoamine oxidase inhibitors and phenothiazines.

Flutamide

See also Cytostatic and immunosuppressant drugs

General Information

Flutamide is a non-steroidal antiandrogen that is used to treat prostatic cancer. Its most common adverse effects are liver damage and photosensitivity.

Organs and Systems

Respiratory

Flutamide has been associated with interstitial pneumonitis.

- An 88-year-old man with prostate cancer took flutamide 375 mg/day for 3 weeks and developed dyspnea and bilateral pulmonary interstitial infiltrates; glucocorticoid therapy and withdrawal of flutamide resulted in clinical improvement (1).

Metabolism

Flutamide has been implicated in cases of pseudoporphyria (2,3).

- A 75-year-old man with prostatic carcinoma took flutamide for 18 months and developed blisters on the back of the hands and fingers after exposure to the sun (4). The bullae were associated with skin fragility and atrophic scarring. Histopathology and direct immunofluorescence showed ultrastructural features similar to those described in porphyria cutanea tarda. However, porphyrin concentrations in the urine and blood were normal. Flutamide was withdrawn and the lesions healed, without relapse after 11 months.

Hematologic

Although it is the commonest of all antineoplastic adverse effects, there are sometimes peculiarities of hematological toxicity that make it worthy of comment (5).

Flutamide can cause methemoglobinemia (6–8) or sulfhemoglobinemia (5). The latter occurred in a 70-year-old man who had taken flutamide 150 mg tds for 1 month and developed cyanosis and anemia that was not responsive to methylthioninium chloride (methylene blue).

In 45 patients with prostatic cancer taking flutamide 250 mg tds, there was no evidence of methemoglobinemia (9). It is possible that anecdotal reports of this adverse effect are in patients with a particular susceptibility that was not represented in this study.

Gastrointestinal

Among 440 patients taking flutamide, gastrointestinal adverse effects (abdominal pain/distension, diarrhea, constipation, nausea/vomiting, and anorexia) occurred in about 22% (10).

Ischemic colitis has been attributed to flutamide (11).

Liver

Flutamide can cause liver damage, which can occasionally be fatal (12).

- A 74-year-old man developed life-threatening acute liver failure while taking flutamide (13). Other causes of acute liver failure were ruled out and there was no evidence of active prostate cancer or liver metastases.

The authors suggested that mitochondrial dysfunction is implicated in flutamide-associated liver damage.

Three patients with advanced prostate carcinoma who took flutamide 250 mg tds for 20–22 weeks developed signs of liver damage (jaundice, anorexia, nausea, dark urine) and changes in liver function tests (high transaminases and bilirubin), indicative of acute hepatitis; flutamide was withdrawn and there was spontaneous remission over the next 8 weeks (14).

In a retrospective study of 185 patients who had taken flutamide for 151 (range 4–443) days, 9 had liver damage (15). The most common features were weakness, anorexia, weight loss, nausea, vomiting, and jaundice. No patient had evidence of hypersensitivity. In two patients there was fulminant liver failure; one had a liver transplant and the other died. The authors suggested that liver function tests should be monitored during the first months of flutamide therapy and that the drug should be withdrawn if transaminases begin to rise.

Of 123 patients who had taken flutamide, 33 had liver disorders, mostly within 9 months (16). Three variables, body mass index, a past history of liver disorders, and raised transaminases were significantly related to the incidence of liver disorders. Smoking was related to a lower incidence.

Urinary tract

Flutamide rarely causes renal damage.

- A 54-year-old man with metastatic prostate cancer developed non-oliguric acute renal insufficiency while taking flutamide; after withdrawal his renal function returned to normal within 4 weeks (17). After rechallenge his blood urea nitrogen and serum creatinine rose again and recovered completely after withdrawal.

Skin

Flutamide can cause photosensitivity reactions (18–20) and can cause residual vitiligo (21,22). The spectrum of the effect is in the UVA range (23).

- A 68-year-old man had a photosensitive drug eruption while taking flutamide (24). The minimal erythema dose with ultraviolet A light was reduced to 2 J/cm^2 and recovered to over 16 J/cm^2 after withdrawal, without changing reactivity to ultraviolet B. The absorption spectrum of flutamide was not altered after ultraviolet A irradiation.

The authors thought that flutamide has low potency to act as a photohapten, and that a non-photohaptenic mechanism is responsible for this photosensitivity or that its active metabolite may act as a photosensitizer.

© 2006 Elsevier B.V. All rights reserved.

Musculoskeletal

In 26 men who took androgen deprivation therapy for prostate cancer for 10 years there was reduced bone mineral density with increasing duration of androgen deprivation therapy across the whole 10-year period (25). The authors also noted that patients taking intermittent therapy had similar loss of bone mineral density at years 2 and 4, but less bone loss from year 6 onwards.

Susceptibility Factors

Renal disease

The pharmacokinetics of flutamide and its pharmacologically active metabolite, hydroxyflutamide, have been studied in 26 men with normal or reduced renal function, some of whom were undergoing hemodialysis; the pharmacokinetics were not altered by renal impairment or hemodialysis (26).

Fluvastatin

See also HMG Co-A reductase inhibitors

General Information

It has been suggested that the pharmacokinetics of fluvastatin, including extensive biliary excretion and absence of circulating active metabolites, might be associated with a low incidence of systemic adverse effects compared with other statins. In over 1800 patients treated for an average of 61 weeks, fluvastatin was safe and tolerable (SEDA-19, 408). Pooled data from clinical trials have shown that gastrointestinal symptoms occurred in 14% of fluvastatin recipients compared with 9% taking placebo; other complaints occurred

© 2006 Elsevier B.V. All rights reserved.

0.5–5% more often with fluvastatin, including insomnia, sinusitis, hypesthesia, tooth disorders, and urinary tract infections. Fluvastatin was withdrawn because of adverse events in 3.5% of 2585 patients taking monotherapy and in 3.2% of 842 patients taking placebo (1).

Organs and Systems

Liver

Hepatotoxicity has been reported with fluvastatin.

- Cholestatic hepatitis developed in a 71-year-old man with nephrotic syndrome (2). Hepatic function was normal after several months of fluvastatin 20 mg/day. Some weeks after the dose was increased to 40 mg/day, his gamma-glutamyl transpeptidase activity rose from normal to 1818 IU/l, with negative serology for viruses. After normalization, re-introduction of fluvastatin 20 mg/day was not tolerated, but he did tolerate simvastatin 20 mg/day.
- A 61-year-old woman developed symptoms of acute hepatitis 6 weeks after she began to take fluvastatin sodium 20 mg/day for hypercholesterolemia (3). Ultrasonography and liver biopsy confirmed the diagnosis of non-obstructive intrahepatic jaundice. Studies of viral markers and autoimmune factors excluded viral hepatitis and autoimmune hepatitis. There was a high serum concentration of a metabolite of fluvastatin, suggesting a possible anomaly of drug metabolism. All liver function tests normalized 8 weeks after the withdrawal of fluvastatin.

Pancreas

Acute pancreatitis has been attributed to fluvastatin (4).

- A 36-year-old man took fluvastatin 40 mg/day for 3 months and developed mild acute pancreatitis, which settled with medical treatment. Other causes were ruled out. Some months later, he started taking fluvastatin again and had a recurrence of pancreatitis within a few days.

According to the authors, statin-induced acute pancreatitis can occur on the first day of therapy or after several months. It is generally mild and runs a benign course; no deaths have been reported. Its frequency is unknown but it is probably rare.

Musculoskeletal

In a pooled analysis of a large population of patients with hypercholesterolemia taking fluvastatin 20 mg/day, 40 mg/day, and fluvastatin modified-release 80 mg/day, the frequency of significant rises in creatine kinase activity was low and not different from placebo (5). This applied to men and women both above and below the age of 65 years. There were no increases in the frequency of rises in creatine kinase activity with higher doses of fluvastatin.

Immunologic

- A 67-year-old woman had a fatal reaction 1 week after she started to take fluvastatin 20 mg/day. When the drug was withdrawn 10 weeks later, she had arthralgia, myalgia, an erythematous maculopapular rash, and breathlessness due to a widespread alveolitis (6).

Drug Administration

Drug formulations

Once-daily administration of modified-release formulation of fluvastatin 80–320 mg/day was generally safe and well tolerated in 40 patients with primary hypercholesterolemia over 13 days (7). However, fluvastatin 640 mg in this formulation was not well tolerated: six of seven patients had adverse events, including diarrhea, headache, and rises in serum transaminases. In addition, the pharmacokinetics of fluvastatin were non-linear at this dose, possibly because of saturation of first-pass metabolism, causing higher than expected serum drug concentrations.

Drug–Drug Interactions

Bezafibrate

Concomitant administration of fluvastatin and bezafibrate resulted in a 50% increase in the AUC of fluvastatin (SEDA-21, 460).

Ion-exchange resins

The systemic availability of fluvastatin is reduced by bile acid sequestrants (1).

Rifampicin

The systemic availability of fluvastatin is reduced by the hepatic enzyme inducer rifampicin (1).

Fluvoxamine

See also Selective serotonin re-uptake inhibitors (SSRIs)

General Information

Fluvoxamine is a non-sedating antidepressant with fewer anticholinergic adverse effects than clomipramine or imipramine (1–3). Its major adverse effects, like those of other SSRIs, include nausea and vomiting. It has a half-life of 15 hours, and peak plasma concentrations occur at 1–8 hours after oral administration (4). It is metabolized (by oxidation, oxidative deamination, and hydrolysis) to nine metabolites, none of which is pharmacologically active (5). Studies of single versus multiple dosing have shown no significant differences (6,7). Usual doses are in the range of 150–300 mg/day, and once-a-day dosing is possible.

Fluvoxamine appears to have no specific effects on laboratory tests (4,8,9); although some have reported a significant fall in platelet count and an increase in serum creatinine, most of the values remained well within the reference ranges (10).

Organs and Systems

Cardiovascular

A slight, clinically unimportant reduction in heart rate has been reported with fluvoxamine (11,12). There has been one report of supraventricular tachycardia in a woman with no previous cardiovascular disease, but the association with fluvoxamine was unclear since there was no rechallenge (SEDA-16, 9).

Nervous system

In a yearlong study of 31 patients there was agitation, which required withdrawal in two patients early in treatment, dry mouth, tremor, and insomnia (13). Increased agitation and insomnia may require the addition of a sedative or hypnotic.

Acute dystonia has been described in association with fluvoxamine (SEDA-18, 20).

Seizures have been reported in a predisposed subject given fluvoxamine (SEDA-17, 20).

Treatment with serotonin-potentiating drugs in usual therapeutic doses can sometimes produce the serotonin syndrome. There are also case reports of this reaction with single doses of SSRIs (see also the monograph on Sertraline) (14).

- An 11-year-old boy was brought to the emergency room about 2 hours after taking a single tablet of fluvoxamine (50 mg) prescribed for treatment of attention-deficit disorder. He was also taking benzatropine and perphenazine (dosages not stated). On arrival, he was agitated and unresponsive, with bilateral ankle clonus, muscle rigidity, fasciculations, and profuse sweating. His temperature rose to 39.7°C. He was paralysed, intubated, and ventilated, after which his condition improved. Two days after admission, he had fully recovered.

The dopamine receptor antagonist properties of perphenazine may have played a part in producing the syndrome in this case.

SSRIs can cause insomnia and daytime somnolence; however, the symptoms seem to reflect a sleep–wake cycle disorder. It is conceivable that disruptions in the normal pattern of melatonin secretion, particularly a delay in the normal early morning fall in plasma concentrations, could be involved in the pathophysiology of these symptoms. The fact that these sleep disorders were seen only with fluvoxamine would also support a role of melatonin (see the section on Endocrine in this monograph).

Psychological, psychiatric

Reports of acute mania and manic-like behavior after treatment with fluoxetine or fluvoxamine have appeared (SEDA-13, 12) (SEDA-17, 20) (SEDA-18, 20), but there are not enough data to estimate the incidence.

Endocrine

Fluvoxamine causes increased plasma melatonin concentrations. In an in vitro preparation, melatonin was metabolized to 6-hydroxymelatonin by CYP1A2, which was inhibited by fluvoxamine at concentrations similar to those found in the plasma during therapy (15). This effect was not shared by other SSRIs or by tricyclic antidepressants, which do not have prominent effects on melatonin secretion. Whether increased concentrations of melatonin and loss of its normal circadian rhythm might cause symptoms is unclear. However, melatonin is believed to play a role in the regulation of circadian rhythms, including entrainment of the sleep–wake cycle. There have been 10 cases of circadian rhythm sleep disorder associated with fluvoxamine (16). All the patients had delayed sleep-phase syndrome, which is characterized by delayed-sleep onset and late awakening. The delay in falling asleep and waking up in the morning was 2.5–4 hours. In nine of the cases withdrawal of fluvoxamine or a reduced dosage led to resolution of the sleep disorder. When the patients were given alternative serotonin potentiating agents, such as clomipramine or fluoxetine, the sleep disorder did not recur.

Serotonin pathways are involved in the regulation of prolactin secretion. Amenorrhea, galactorrhea, and hyperprolactinemia have been reported in a patient who was already taking an antipsychotic drug after starting treatment with fluvoxamine (SEDA-17, 20).

Three cases of fluvoxamine-induced polydipsia, attributed to the syndrome of inappropriate ADH secretion (SIADH), have been reported (SEDA-18, 20).

Hematologic

Fluvoxamine-associated bleeding has been described (17–19).

Skin

A case of toxic epidermal necrolysis after fluvoxamine has been described; although the patient was taking other drugs, the authors concluded that the skin reaction was probably due to fluvoxamine (SEDA-18, 20).

© 2006 Elsevier B.V. All rights reserved.

Hair

Hair loss has been associated with fluvoxamine (20).

Long-Term Effects

Drug withdrawal

Withdrawal symptoms have been reported with fluvoxamine (SEDA-17, 20) (SEDA-18, 21).

Second-Generation Effects

Lactation

In two cases, treatment of breast-feeding mothers with fluvoxamine (300 mg/day) was associated with undetectable concentrations of fluvoxamine (below 2.5 ng/ml) in the plasma of both infants (21). These results are encouraging, but further data will be needed before it can be concluded that fluvoxamine has an advantage over other SSRIs in this respect.

Drug Administrations

Drug overdose

There have been four cases of overdosage with fluvoxamine in amounts ranging from 600 to 2500 mg (22).

Drug–Drug Interactions

Buspirone

In 10 healthy volunteers, fluvoxamine (100 mg/day for 5 days) significantly increased the peak concentrations of the anxiolytic drug buspirone. Concentrations of the active metabolite, 1-(2-pyrimidinyl)-piperazine, were reduced (23). These effects were probably mediated through inhibition of CYP3A4 by fluvoxamine.

Clozapine

In a prospective study fluvoxamine, in a low dosage of 50 mg/day, produced a threefold increase in plasma clozapine concentrations (n = 16) (24).

Other reports have confirmed that fluvoxamine increases plasma concentrations of clozapine and its metabolites (25,26) (SEDA-21, 12). The mechanism is probably inhibition of CYP1A2.

Methadone

Fluvoxamine increases methadone concentrations in patients taking methadone maintenance treatment for the management of opioid dependence (SEDA-19, 11). The addition of sertraline (200 mg/day) produced a modest (16%) increase in methadone concentrations in 31 depressed opioid-dependent subjects after 6 but not 12 weeks of combined treatment (27). The increase in methadone concentrations was more modest than that reported with fluvoxamine, presumably because sertraline is a less potent inhibitor of CYP1A2 and CYP3A4, both of which are involved in methadone metabolism.

Olanzapine

The atypical antipsychotic drug olanzapine is also metabolized by CYP1A2.

- A 21-year-old woman with schizophrenia and depression, who had been taking fluvoxamine (150 mg/day) and olanzapine (15 mg/day) for several months, developed an extrapyramidal movement disorder, including rigidity and tremor (28). The plasma fluvoxamine concentration was 70 ng/ml (usual target range is 20–500 ng/ml), while that of olanzapine was 120 ng/ml (usual target range is 9–25 ng/ml). The dosage of olanzapine was reduced to 5 mg/day and the plasma olanzapine concentration fell to 38 ng/ml, with resolution of the tremor and rigidity. When fluvoxamine was replaced with paroxetine (20 mg/day) the olanzapine concentration fell further to 22 ng/ml.

Of the SSRIs, fluvoxamine is the most potent inhibitor of CYP1A2 and is therefore likely to increase plasma olanzapine concentrations. The extrapyramidal effects in this case were presumably due to excessive blockade of dopamine D_2 receptors by raised olanzapine concentrations.

Phenytoin

Fluvoxamine inhibits CYP2C9 and CYP2C19, the enzymes responsible for the metabolism of phenytoin.

- A 45-year-old woman taking phenytoin 300 mg/day had a plasma phenytoin concentration of 66 μmol/l (29). When she became depressed fluvoxamine 50 mg/day was added. A month later her depressive symptoms had improved, but she was ataxic and the plasma phenytoin concentration was 196 μmol/l. The fluvoxamine was withdrawn and the phenytoin dose reduced to 150 mg/day. Her plasma phenytoin concentration fell to 99 μmol/l, with resolution of the ataxia.

In vitro studies suggest that fluvoxamine is the most potent SSRI in terms of its ability to inhibit phenytoin metabolism. Inhibition of CYP2C19 or CYP2C9 could be responsible, although fluvoxamine is a relatively weak in vitro inhibitor of CYP2C9. However, in 14 healthy volunteers fluvoxamine (150–300 mg/day for 5 days) significantly reduced the clearance of tolbutamide (30). This suggests that fluvoxamine should be used with caution when it is co-administered with drugs such as tolbutamide, phenytoin, and warfarin, which are substrates for CYP2C9.

Thioridazine

Fluvoxamine inhibits CYP1A2, and a low dosage (50 mg/day) produced a 225% increase in plasma thioridazine concentrations in 10 patients with schizophrenia (31). This was not reflected in an increased incidence of clinical adverse events; however, thioridazine prolongs the QT_c interval, which was not measured.

Tolbutamide

In 14 healthy volunteers fluvoxamine (150–300 mg/day for 5 days) significantly reduced the clearance of tolbutamide (30). This suggests that fluvoxamine should be used

© 2006 Elsevier B.V. All rights reserved.

with caution when it is co-administered with drugs that are substrates for CYP2C9, such as tolbutamide, phenytoin, and warfarin.

Tricyclic antidepressants

Fluvoxamine is a potent inhibitor of cytochrome CYP1A2, which may lead to interactions with several tricyclic antidepressants and theophylline (32).

Folic acid, folinic acid, and calcium folinate

See also Vitamins

General Information

Folic acid (pteroylglutamic acid) is a vitamin of the B group, whose Average Dietary Requirement in adults has been set at 140 micrograms/day, with a Population Reference Intake of 200 micrograms/day. Red cell folate concentrations above 150 ng/ml indicate sufficiency (1). However, higher doses are used for specific purposes, including in pregnancy, apparently without ill effects. Neural tube defects can be prevented in offspring by periconceptual ingestion of

© 2006 Elsevier B.V. All rights reserved.

400 micrograms/day (2). One aspect of folate metabolism concerns the recycling of the putatively atherogenic amino acid, homocysteine (3). For reasons that are not clear, homocysteine accumulates in the blood of dialysis patients, and this accumulation is inversely related to folate status. Because of the association of folate with a risk factor for atherosclerosis—it is the major cause of morbidity and mortality in dialysis patients—folate supplementation has been widely recommended as a strategy to reduce homocysteine concentrations, and a daily dose of 800 micrograms has been proposed as part of a mass strategy to reduce the risk of heart attacks and strokes by over 80% (4).

Folinic acid is a reduced form of folic acid. The adverse effects of antifolate drugs that are tetrahydrofolate reductase inhibitors, such as methotrexate, cannot be prevented by giving folic acid, since antifolate drugs inhibit the conversion of folic acid to folinic acid. Folinic acid is therefore given instead, as calcium folinate (leucovorin). However, in patients who take antifolate drugs intermittently (for example methotrexate once a week in psoriasis or rheumatoid arthritis) folic acid taken on another day is adequate.

Recommendations that women who plan to become or have just become pregnant should take daily oral folic acid supplements in order to prevent neural tube defects were issued by health authorities in several European countries from 1991 onwards (5). The recommendations generally follow the lead of the US Public Health authorities which recommended a supplementation dose of 400 micrograms/day (6). This is what a woman would consume if she followed the US Dietary Guidelines and Dietary Pyramid (7). The etiology of neural tube defects is not entirely clear; the condition may have several different causes, only some of which may be responsive to folate (8,9). Rates of neural tube defects vary considerably between countries; in the USA rates of neural tube defects isolated from other birth anomalies fell over the period 1968–89 (10). The justification for a recommendation for general high-dose supplementation or food fortification is still under discussion (11). The debate elicited by this recommendation has spurred interest in possible adverse effects, and a thorough review published in 1998 (12) identified the following potential safety issues of folic acid supplementation in addition to those mentioned above: folate neurotoxicity, reduced zinc absorption, association with malignant neoplasms, hypersensitivity reactions, and increased susceptibility to malaria. However, the data are weak and consist predominantly of case series and individual reports. Furthermore, it is likely that even if such adverse effects did occur, the benefit to harm balance would still be highly favorable.

The main argument against an increase in folic acid supply to the population as a whole is the possible masking of vitamin B_{12} deficiency by normalization of the blood count (see the section *Does folic acid mask vitamin B_{12} deficiency?* in this monograph). However, while certain animal findings and some case reports have actually suggested worsening of the neurological effects of vitamin B_{12} deficiency when patients are treated with folic acid, these do not prove a causal relation (see the section *Does folic acid enhance the neurological symptoms of vitamin B_{12} deficiency?* in this monograph). Nevertheless, because the available data do not exclude such an effect, in the US-Canadian "Dietary Reference Intakes" in adults the upper limit has been set at 1000 micrograms/day folic acid in supplements or enriched food preparations and in children (1–18 years of age) the upper limit has been set at 300–800 micrograms. At doses of 5 mg/day in more than 100 patients there was progression of neurological complications, but there have only been eight case reports of the effect of lower doses of folic acid. Because there is no NOAEL (no observed adverse effect level), a LOAEL (lowest observed adverse effect level) of 5 mg/day had to be used for the upper limit. In contrast, in 1996 the FDA fixed an upper limit of 1000 micrograms/day folic acid (natural and synthetic preparations) (6,13). It was also argued that in children of vegetarians natural folate had masked vitamin B_{12} deficiency. These previous values have now been re-evaluated by the FDA. Dietary supplementation with both folic acid and vitamin B_{12} offers a solution to this problem. No risks of increasing the supply of vitamin B_{12} are expected, but the dosage that would correct vitamin B_{12} deficiency remains to be defined (6,12).

General adverse effects

Negative effects resulting from dietary intake of high concentrations of folic acid have only rarely been documented in some older case reports and uncontrolled intervention studies. Some of these negative effects were not confirmed in subsequent randomized, controlled intervention studies (14).

In humans the toxicity of folic acid is low, even after long-term use (12,15,16). Only in one trial in 14 volunteers (six women, eight men, aged 22–57 years) were there adverse effects, such as gastrointestinal disturbances, insomnia, irritability, or depressive states (17). As a possible cause the authors suggested a high folic acid concentration in the cerebrospinal fluid (5–10 times higher than that in serum). However, these findings were not confirmed in subsequent trials with high-dose folic acid supplementation.

Does folic acid mask vitamin B_{12} deficiency?

Vitamin B_{12} deficiency most frequently is seen in people over 60 years of age (11). Deficiency of vitamin B_{12} in younger adults is rare, but can occur as a result of reduced absorption of vitamin B_{12}, for example in pernicious anemia, atrophic gastritis type B, long-term use of blockers of acid secretion, or short bowel syndrome after resection of the terminal ileum (18,19). Vitamin B_{12} deficiency in children usually depends on inborn defects of vitamin B_{12} metabolism or on insufficient support during pregnancy and breastfeeding.

Vitamin B_{12} deficiency can present as hematological, gastrointestinal, and neurological disturbances. The anemia of B_{12} deficiency is actually due to functional deficiency of folic acid, and results from accumulation of folic acid derivatives in the form of 5-methyltetrahydrofolate, which prevents regeneration of tetrahydrofolic acid and consequently, by interfering with the synthesis of purines and DNA, reduces cell proliferation. Therefore, giving folic acid to patients with vitamin B_{12} deficiency can abolish the hematological effects but will not affect the neurological symptoms. Normalization of

© 2006 Elsevier B.V. All rights reserved.

the blood count requires high doses of folic acid in the absence of B_{12} replacement therapy. Treatment with folic acid 0.3–1 mg/day normalizes the blood count in 50% of patients with B_{12} deficiency, while at doses over 5 mg/day the hematological changes are normalized in most patients (20). However, the hematological effects can recur, even after treatment with high doses of folic acid (5–500 mg/day), if the vitamin B_{12} deficiency is not treated.

Concerning possible masking of vitamin B_{12} deficiency by folic acid, blood counts in 11–33% of the patients with neurological symptoms of vitamin B_{12} deficiency are in the reference range. That means that in patients with severe funicular myelosis, a vitamin B_{12} deficiency psychosis, changes in the blood count may not occur, while on the other hand in patients with severe pernicious anemia neurological symptoms are not inevitably present.

Organs and Systems

Nervous system

Does folic acid enhance the neurological symptoms of vitamin B_{12} deficiency?

The results of some animal experiments and case reports have suggested that high doses of folic acid can enhance or worsen the neurological effects of vitamin B_{12} deficiency. Thus, in animals with vitamin B_{12} deficiency being treated with folic acid, neurotoxicity developed more rapidly than in the untreated controls (21–23). Some unproven hypotheses about how folic acid could enhance the neurological symptoms of vitamin B_{12} deficiency have been discussed, for example redistribution of B_{12} from the nervous system into the bone marrow, accompanied by a fall in serum concentration and reticulocytosis (20). There have also been some reports that in patients with vitamin B_{12} deficiency neurological complications occurred for the first time or increased in severity when folic acid was given, the severity and onset of the complications correlating with the dose of folic acid.

Whether folic acid is responsible for these observations or whether the neuropathy depends on progressive vitamin B_{12} deficiency and simply coincides with the administration of high doses of folic acid cannot be determined from these reports. In patients who were treated beforehand with liver extracts the neurological changes were weaker and occurred later than in patients who were treated with folic acid exclusively. This suggests that progressive reduction in cobalamin pools is as important for the development of the neurological complications as the supply of folic acid. Furthermore, rapid worsening of neurological changes in patients with cobalamin deficiency has also been seen in patients who have not received folic acid.

Because there have been no double-blind, placebo-controlled intervention studies of the effect of folic acid, the question of whether folic acid in patients with vitamin B_{12} deficiency aggravates the neurological complications cannot be answered definitively. From the data at hand we cannot exclude the possibility that folic acid may exacerbate the effects of vitamin B_{12} deficiency. For that reason an upper limit of 1 mg/day folic acid (in supplements or a vitamin-enriched diet) has been set in the "Dietary Reference Intakes" (15).

Folic acid and seizures

In patients with a history of seizures, worsening of the seizures and an increase in their frequency have been reported in relation to folic acid (24).

- A 26-year-old woman with a family history of spinal amyotrophy and multiple sclerosis sought prepregnancy counselling and was given folic acid 800 micrograms/day to prevent neural tube defects. At 2 years of age, 6 months after a chickenpox infection, she had had recurrent fits and language regression, successfully treated with ethosuximide. At 12 years of age she developed seizures nearly every month, characterized by sensations of fear, loss of contact, fixed eyes, motor automatism, and postictal aphasia. This had responded to carbamazepine. After starting to take folic acid she had a generalized tonic-clonic seizure for the first time and a significant increase in seizure frequency.

There has been some discussion as to whether an adverse effect of folic acid on seizures represents a direct epileptogenic effect or results from interference with the effects of anticonvulsants. Initially, it was supposed that folic acid provokes seizures, and the first report of an epileptic patient with megaloblastic anemia in whom folate therapy resulted in an exacerbation of seizures was published in 1960. Although several subsequent controlled studies failed to show any adverse effect on seizure frequency linked to folic acid supplementation, case reports and uncontrolled studies have documented worsening seizure frequency in some patients given folic acid, but the susceptibility factors at play have not been identified.

Antiepileptic drugs reduce serum folate concentrations. Conversely, the use of folic acid can reduce the effects of antiepileptic drugs such as phenytoin and can reduce their serum concentrations (25,26).

Besides its effect on antiepileptic drugs, folic acid in animal experiments was neurotoxic and epileptogenic (27). However, when the neurotoxicity of folic acid was investigated in two groups of patients—the newborns of mothers who had taken folic acid during pregnancy and patients with parkinsonian syndromes—neurotoxicity was not found in either group (12).

Metal metabolism

The authors of the "Dietary Reference Intakes" (15) have concluded that reports of the effect of folic acid supplementation on the intestinal absorption of zinc are controversial, but that the recent literature shows that folic acid supplementation has either no effect or an extremely weak effect on zinc supply.

Hematologic

High doses of folic acid and vitamin B_{12} increase the reticulocyte count. Use of either of these vitamins can therefore mask a deficiency of the other (SEDA 17, 440). If anemia due to deficiency of either of these nutrients is suspected, serum concentrations of both vitamin B_{12} and folic acid should be assessed (28).

© 2006 Elsevier B.V. All rights reserved.

Immunologic

There have been some reports of hypersensitivity after oral, parenteral, and intradermal administration of folic acid, and a case has recently been reported with folinic acid (29).

- An 80-year-old woman had a colonic resection for Duke's C stage adenocarcinoma and was then given fluorouracil 400 mg/m^2/day and folinic acid 200 mg/m^2/day for 5 days every 4 weeks. She later developed metastases and a second course of chemotherapy included irinotecan (180 mg/m^2), fluorouracil 400 mg/m^2, followed by a continuous infusion of 2400 mg/m^2 over 2 days, folinic acid 200 mg/m^2, ondansetron, and atropine. During the first course of chemotherapy she developed urticaria following the administration of ondansetron and folinic acid. The ondansetron was withdrawn and replaced by metoclopramide and prednisone. During the next course, just after the administration of folinic acid, metoclopramide, and prednisone, she had more urticaria and profound hypotension and required intravenous adrenaline. Folinic acid was withdrawn and subsequent courses were uneventful.

Using a published method (30) the reaction in this case was considered to be very probably due to folinic acid.

IgE-antibodies to folic acid have been demonstrated in a woman with anaphylactic reactions to two multivitamin formulations containing folic acid (31).

Long-Term Effects

Tumorigenicity

In a large US cohort study folic acid was associated with an increased risk of cancer in general and of cancers of the oropharynx and hypopharynx (32). However, the authors pointed to the possibility that the observed association could have depended on confounding by alcohol and smoking.

Second-Generation Effects

Pregnancy

High doses of folic acid (commonly 4–5 mg) have been used in pregnancy to prevent neural tube defects, without apparent ill effects (33). In a non-randomized, Swedish study in 2569 women the number of twin births in those who took folic acid supplements during early pregnancy was increased (34). In those who took folic acid the rate of twin births was 2.8% compared with 1.5% overall. However, in the large, randomized, multicenter MRC study with high doses of folic acid (4 mg/day) there was no increase in the frequency of twin births (33). Because of the higher rate of complications in twin pregnancies and twin births, the authors suggested that folic acid prophylaxis in countries with low frequencies of spina bifida might be harmful rather than useful. Similar results have also been seen in other studies (35,36).

Drug–Drug Interactions

Anticonvulsant drugs

An interaction of anticonvulsant drugs with the metabolism of folate has been described (SEDA-13, 348) (see also the section on *Nervous system* in this monograph).

Folic acid can alter the metabolism of phenytoin. In one case folic acid 5 mg/day reduced the serum phenytoin concentration to below the target range, and a breakthrough seizure occurred (25). The Km of phenytoin metabolism was significantly reduced, suggesting competitive inhibition of metabolism. In another series folic acid reduced the serum concentrations of phenytoin (37). Furthermore, the administration of folic acid to treat folate deficiency can reduce the beneficial effects of anticonvulsants (38). Rare but serious cases in which this epileptogenic effect of folic acid has been very pronounced have been reported (39). However, folic acid is well tolerated by many other patients with epilepsy who require folic acid.

Fluorouracil

Reduced folates are co-factors for the 5-fluorodeoxyuridine monophosphate-thymidilate synthetase reaction. Leucovorin (calcium folinate) therefore potentiates the toxicity of 5-fluorouracil, and fatal adverse effects have been reported in patients over 65 years of age receiving high-dose treatment with leucovorin simultaneously with fluorouracil. This has led some groups to recommend that initial dose levels of fluorouracil should be lowered by 20% and that therapy be stopped temporarily at the first sign of distal gastrointestinal adverse effects (SEDA-15, 414).

Methotrexate

Methotrexate is an antagonist of folic acid and is used for treating neoplastic diseases and non-neoplastic diseases such as rheumatoid arthritis and psoriasis. As methotrexate reduces the activity of dihydrofolate reductase, supplementation with folic acid and especially with folinic acid could reduce the beneficial effects of methotrexate. This assumption has been supported by the results of an intervention study (40). Patients with rheumatoid arthritis treated with methotrexate (15 g/week) had an increase in symptoms. An open intervention trial of folinic acid 45 mg/week also showed an increase in arthritis symptoms (41). However, other trials showed no effects of this sort, and administration of folic acid or folinic acid is important in preventing methotrexate-induced blood dyscrasias.

Follitropin

General Information

The first gonadotropins available for clinical use were extracted from the urine of postmenopausal women. Human menopausal gonadotropin (hMG) is in limited supply and contains other proteins, which may be allergenic, as well as luteinizing hormone. Purified preparations of follicle-stimulating hormone (FSH; urofollitropin and highly purified urofollitropin) are also extracted from

© 2006 Elsevier B.V. All rights reserved.

human urine. Recombinant FSH (follitropin-alfa) prepared from a Chinese hamster ovarian cell line is likely to replace other gonadotropins because of its purity and ease of patient self-administration.

Follitropin treatment for infertility has been reviewed in detail (1,2). Multiple pregnancy occurs in 20% of patients, 80% being twin pregnancies. There is no documented increase in congenital abnormalities in children conceived after ovulation induction with follitropin.

Organs and Systems

Nervous system

- A 32-year-old woman who was not obese developed benign intracranial hypertension in association with ovarian hyperstimulation syndrome after ovulation induction using goserelin, follitropin, and human chorionic gonadotropin (hCG) (3). The syndrome did not recur during a second pregnancy in which follitropin and hCG were not used

Reproductive system

Ovarian hyperstimulation syndrome (OHSS) is characterized by massive ovarian enlargement and fluid shift from the intravascular space to the peritoneal, pleural, and pericardial cavities. Rates of up to 20% for all grades and 1–2% for severe OHSS have been documented and do not differ between preparations of follitropin. Women with polycystic ovarian syndrome are at higher risk of this complication. In rare cases women have died of pulmonary embolism, disseminated intravascular coagulation, or adult respiratory distress syndrome. If the patient is pregnant, OHSS is more severe and prolonged (1). Generally, it resolves within 7 days if the patient is not pregnant or in 10–20 days if she is. The underlying cause of this adverse effect is not known.

Fomivirsen

General Information

Fomivirsen (ISIS 2922) is an antisense oligonucleotide that specifically inhibits replication of human cytomegalovirus. It has been developed for intravitreal administration to treat cytomegalovirus retinitis in patients with AIDS.

Organs and Systems

Sensory systems

The most common adverse effects of fomivirsen reported in clinical trials have been increased intraocular pressure and mild to moderate uveitis (1,2). These events were generally transient or reversible with topical glucocorticoids.

In 150 patients who were given intravitreous fomivirsen 165 micrograms/injection (35 eyes, 30 patients) or two different regimens of 330 micrograms/injection (142 eyes, 110 patients), anterior chamber inflammation and increased intraocular pressure were dose-related and schedule-dependent: 165 micrograms/injection, 4.1 events/patient-year; 330 micrograms/injection, 6.6 events/patient-year (less intense regimen) and 8.4 events/patient-year (more intense regimen) (3). A large number of other ocular adverse events may not have been related to the drug.

In 309 eyes of 238 patients there were two cases of bull's-eye maculopathy, which resolved after withdrawal (4).

Retinal pigment epithelial changes have been noted at doses of fomivirsen that overlap with those used to treat CMV retinitis (2). In one case there was nyctalopia and reduced visual acuity (20/50 OD) in conjunction with mid-peripheral epithelial pigmentation and cotton-wool spots around the perifoveal capillary network (5).

Fondaparinux

General Information

Fondaparinux is a synthetic pentasaccharide that mimics the site of heparin that binds to antithrombin III and inhibits factor Xa activity, which in turn inhibits thrombin generation. It does not release tissue factor pathway inhibitor. It is nearly completely absorbed after subcutaneous

© 2006 Elsevier B.V. All rights reserved.

administration, has a rapid onset of action and a long half-life (14–20 hours), and is excreted by the kidneys. Its pharmacology, clinical pharmacology, and uses have been reviewed (1–16).

Fondaparinux has been approved in some countries for the prophylaxis of venous thrombosis after orthopedic surgery in a fixed dose of 2.5 mg/day without monitoring. A structural analogue, idraparinux sodium, has additional methyl groups, a long half-life, and once-weekly administration. Both drugs are being developed as antithrombotic drugs for venous and arterial thrombosis, acute coronary syndrome, and stroke, and as adjuncts to thrombolytic therapy.

There is currently no specific antidote for fondaparinux: it is not neutralized by protamine sulfate. Fondaparinux shows no cross-reactivity with antibodies associated with heparin-induced thrombocytopenia.

Comparative studies

There have been two double-blind, randomized comparisons of fondaparinux 2.5 mg/day or enoxaparin 40 mg/day after hip fracture surgery (17), or elective major knee surgery (18). Fondaparinux reduced the risk of thromboembolism by 56% in the first study ($n = 1250$) and by 55% in the second ($n = 724$). There were no significant differences between the two groups in the first study in the incidence of death or clinically important bleeding. In the second study, major bleeding occurred more often with fondaparinux, but there were no significant differences between the two groups in the incidence of bleeding leading to death or reoperation, or occurring in a critical organ.

In a double-blind, randomized study of 2309 consecutive patients undergoing elective hip replacement, postoperative subcutaneous fondaparinux 2.5 mg/day was compared with preoperative enoxaparin 40 mg/day (19). By day 11, venous thromboembolism had occurred in 85 (9%) of 919 patients assigned to enoxaparin and in 37 (4%) of 908 patients assigned to fondaparinux, a relative risk reduction of 56% (95% CI = 33, 73). In a similar comparison of postoperative fondaparinux 2.5 mg/day and enoxaparin 30 mg bd in 2275 consecutive patients undergoing elective hip replacement, by day 11 venous thromboembolism had occurred in 48 (6%) of 787 patients assigned to fondaparinux and in 66 (8%) of 797 patients assigned to enoxaparin, a relative risk reduction of 26% (95% CI = 11, 53) (20).

In a meta-analysis of these studies, bleeding was slightly, but not significantly, more frequent with fondaparinux than with enoxaparin (21,22).

Drug–Drug Interactions

Aspirin

In healthy volunteers, steady-state fondaparinux did not alter the pharmacodynamic effects of a single dose of aspirin 975 mg (23). Aspirin did not alter the pharmacokinetics of fondaparinux.

Digoxin

In a randomized, crossover study in 24 healthy volunteers, the pharmacokinetics of fondaparinux sodium 10 mg/day subcutaneously for 7 days were unaffected by digoxin 0.25 mg/day orally for 7 days (24).

Piroxicam

In healthy volunteers, steady-state fondaparinux did not alter the pharmacodynamic effects of a single dose of piroxicam 20 mg (23). Piroxicam did not alter the pharmacokinetics of fondaparinux.

Warfarin

There was no pharmacodynamic interaction of subcutaneous fondaparinux 4 mg with warfarin in 12 healthy men (25).

Formaldehyde

See also Disinfectants and antiseptics

General Information

Aldehydes such as formaldehyde, glyoxal, and glutaral (glutaraldehyde) are used as solutions and vapours for disinfection and sterilization. They are irritating and sensitizing and cause contact dermatitis in health-care workers (SEDA-21, 254).

Formulations

Formaldehyde is released by numerous agents, such as paraformaldehyde, dichlorophene, Dowicil 75 and Dowicil 200 (*cis*-1-(3-chloroalkyl)-3,5,7-triaza-l-azonia-adamantane chloride), bronopol, Biocide DS 52–49 (1,2-benzoisothiazoline-3-one plus a formaldehyde releaser), and Bakzid (cyclic aminoacetal). Formalin is an alternative name for an aqueous solution of formaldehyde, but the latter name is preferred, since formalin is also used as a brand name in some countries.

Free formaldehyde is used in cosmetics, especially in hair shampoos, and in many disinfectants and antiseptics. The solid paraformaldehyde is used as a source of formaldehyde vapor for the disinfection of rooms. Noxythiolin, polynoxylin, hexamidine, and taurolidine act by slow release of formaldehyde. Formaldehyde solution contains 34–38% of formaldehyde methanol as a stabilizing agent to delay polymerization of the formaldehyde. Formaldehyde gel contains 0.75% of formaldehyde and is used to treat warts.

Formaldehyde cannot be applied safely to the skin or the mucous membranes in the concentration necessary to rapidly kill microbes, and formaldehyde solutions have to be diluted before use to a 2–8% solution to disinfect inanimate objects and to a 1–2% solution for disinfection by scrubbing. For fumigation of air a concentration of 1–2% is used.

General adverse effects

Discussion about the toxicity, mutagenicity, and potential carcinogenicity of formaldehyde relates more to occupational and environmental exposure, caused by its release from urea formaldehyde resins used for wood products and from foams for cavity-wall insulation, than its use in disinfection and sterilization (SEDA-11, 476) (SEDA-12, 569). However, the concentrations of formaldehyde that are found in the air after scrubbing with formaldehyde-containing disinfectants can be several hundred percentage higher than the maximum safe workplace concentration, even when scrubbing is carried out properly (1). Very high concentrations have also been found in pathologists' workrooms. In the pathology departments of two Italian hospitals the highest values of 2.6 and 6.0 ppm were measured in the dissection laboratories; in the histology and cytology laboratories, concentrations were less than 1 ppm, except when technicians handled formaldehyde solutions (2).

Primary irritant effects of formaldehyde

The minimum amount of formaldehyde that can be detected by odor varies considerably between individuals and ranges from 0.1 to 1.0 ppm (0.12–1.2 mg/m^3), close to the concentration at which minimal irritant effects are felt in the eyes and in the pulmonary airways (3). Thus, the fundamental toxicity of formaldehyde lies in primary irritation to the eyes, nose, and throat when the subject is exposed to concentrations in the range of 1–5 ppm. Concentrations above 2–5 ppm cause irritation of the pharynx, lungs, and eyes, and some erythema of vaporized areas of the skin, such as the face and neck. Acute exposure to concentrations of formaldehyde of the order of three times the maximum threshold of detection of the

© 2006 Elsevier B.V. All rights reserved.

odor will most likely produce severe acute pulmonary edema after only a few minutes.

Acute toxicity after local administration of formaldehyde-containing solutions

Dilute solutions of 1–10% formalin have been instilled into the bladder to treat inoperable profusely bleeding tumors or intractable hemorrhagic cystitis. Anuria was a severe complication. This was due either to edematous obstruction of the ureter or to tubular or papillary necrosis, probably caused by systemic absorption. Bladder perforation with intraperitoneal spillage, peritonitis, and finally death was described in an elderly patient with a carcinoma of the uterine cervix (SEDA-11, 476).

In 1983, Godec and Gleich reviewed all published results of treatment of intractable hematuria with formalin. Dilutions of 1–10% formalin (containing 0.37–3.7% formaldehyde) were used; the most commonly used concentration of formalin was 10%. The authors concluded that formalin was probably the most effective tool for controlling massive hematuria, but also probably the most dangerous. The review covered 23 articles and 118 patients; in 104 cases, treatment was successful. However, in only 10 reports had the treatment been used without serious adverse effects; the other 13 articles listed four deaths and many serious local and systemic complications. The complication rate increased when the formalin concentration was higher, but the contact time and the volume instilled did not influence the occurrence of adverse effects. The most frequent local complications were reflux and hydronephrosis. Fibrosis of the bladder with reduced capacity was the usual clinical outcome. A systemic effect was tubular necrosis with anuria, with two deaths. Another complication was ureteric obstruction, which was not related to ureteric fibrosis or bladder wall fibrosis obstructing the intramural ureter; in two cases the obstruction appeared to be due to retroperitoneal fibrosis (SEDA-11, 476) (4).

In 1989, Donahue and Frank (SEDA-12, 569) (SEDA-14, 205) (5) published a systematic review of 235 cases of intravesical hemorrhagic cystitis treated with intravesical instillations of diluted formalin in concentrations of 1, 5, or 10%. Complete response rates were 71, 78, and 83% respectively. The average duration of a complete response was 3–4 months; the recurrence rate fell gradually with the use of higher concentrations. Complications were divided into two groups: "minor complications" included all mild or transient problems not requiring surgical intervention (fever, tachycardia, transient or minor rises in blood urea nitrogen or creatinine, mild hydronephrosis, grades I and II uricourethral reflux, increased urinary frequency, urgency, incontinence, suprapubic pain, or a reduction in bladder capacity not requiring urinary diversion); "major complications" were those that required surgical intervention, resulting in loss of renal function or causing damage to the supravesical urinary tracts (stricture formation), including anuria, acute tubular necrosis, papillary necrosis, ureteric or retroperitoneal fibrosis, uterovesical or uteropelvic junction obstruction, severe hydronephrosis, grades III or IV vesicoureteric reflux, any vesical fistula, or a reduction in bladder capacity requiring urinary diversion. Major complications occurred in all treatment groups, including those treated with 1% formalin. The higher rate observed with 10% formalin was not significantly different from the rates associated with the use of 1 or 5% formalin. The mortality rates were 2.2% in all the formalin groups, but the rates were not significantly different. Formalin 10% resulted in a higher and favorable response rate, a lower recurrence rate, equal numbers of major complications and mortality rate, and a three-fold higher rate of minor complications than 5% formalin in patients with hemorrhagic cystitis due to radiotherapy for bladder tumors. In contrast, formalin 5% was more effective than formalin 10% in treating patients with intractable hematuria due to unresectable bladder tumors or cyclophosphamide-induced cystitis.

The use of 2 or 4% formaldehyde as a scolecidal agent for injection into hydatid cysts and for peritoneal lavage was followed by shock in seven cases and resulted in death in three. All three patients who died had undergone a peritoneal lavage with 2–8 liters of 2 or 4% formaldehyde (SEDA-11, 476).

Immunogenicity

Formaldehyde is one of the most frequent contact allergens. If the responses in some individuals to acute exposure to formaldehyde are immunogenically mediated, they are of serious clinical significance. These individuals should not be exposed to any concentration of the agent. However, the intensity and nature of the immunogenic response can so resemble a primary irritant effect that a different diagnosis is not possible.

Mutagenicity and carcinogenicity

Formaldehyde is mutagenic in vitro and although there is conflicting evidence about its carcinogenicity, this should be taken seriously.

Organs and Systems

Respiratory

Formaldehyde-induced bronchial asthma occurred in a laboratory technician and in a neurologist preparing brain specimens for a student demonstration (6).

In a renal dialysis unit, five of 28 members of the staff had respiratory symptoms associated with formaldehyde, and in two cases, attacks of wheezing could be provoked by exposure to formaldehyde. One nurse was particularly affected, the asthmatic wheeze persisting for 8 days after exposure (7).

Of 230 people who had been exposed to formaldehyde and had asthma-like respiratory symptoms with a bronchial provocation test, 12 were considered to be caused by specific sensitization to formaldehyde, 11 were triggered by a concentration of 2.5 mg/m^3, and one by 1.2 mg/m^3 (SEDA-11, 477) (8). The authors concluded that formaldehyde-induced asthma, although apparently rare, is under-reported.

Biliary tract

Three cases of secondary sclerosing cholangitis developed during the early postoperative phase of surgical treatment of hydatid liver cysts in which formaldehyde was used; one

© 2006 Elsevier B.V. All rights reserved.

patient died within 3 months and the remaining two underwent liver transplantation following biliary sclerosis. Another group also reported three cases of sclerosing cholangitis. Both groups of authors concluded that because of the risk of complication and the unproven efficacy of intracystic injection of a scolecidal solution in preventing dissemination of the parasite, this technique should be abandoned in the surgical treatment of hydatid disease of the liver. However, in 560 patients, there were no cases of sclerosing cholangitis when the concentration was not more than 2% and the solution was injected only into cysts that contained clear fluid content (SEDA-11, 476) (9).

Skin

Formaldehyde-releasing preservatives, such as quaternium-15, diazolidinyl urea, and imidazolidinyl urea, are widely used in cosmetics and topical medications and are well-known contact sensitizers. In spite of positive patch test reactions to these preservatives in a number of patients, only some of these patients will react when they use the corresponding commercial formulations. This is because the concentrations of preservatives in the commercial products are often below the threshold necessary to produce a clinical reaction. This finding confirms the importance of using commercial formulations of topical agents in estimating the clinical relevance of patch test results (10).

The formaldehyde concentration in patch-testing, which has been lowered to 1% in the standard series in recent years, has been studied in a comparison of concentrations of 1% and 2% in 3734 consecutively patch-tested patients (11). Since there was no significant difference between 1 and 2% formaldehyde with respect to the frequency of positive patch test reactions, while there were more irritant reactions with 2%, a 1% patch test concentration can still be recommended.

Allergic dermatitis has been demonstrated from direct skin contact and from exposure to gaseous formaldehyde in the air. Various forms of reaction occur, from simple erythema to maculopapular lesions, hyperesthesia, and angioedema. Five patients developed an allergic contact dermatitis to plaster casts, caused by free formaldehyde released by a melamine–formaldehyde resin incorporated in the plaster.

Urticaria with acute Quincke's edema was reported following the use of a formaldehyde-containing dental paste (SEDA-11, 477) (12).

The first published case of photosensitivity to formaldehyde was reported in 1982 in a man who developed pruritus, burning, and redness of the skin within minutes of exposure to sunlight; photopatch tests showed specific photosensitivity to formaldehyde (13).

Immunologic

Aldehydes are irritating and sensitizing and cause contact dermatitis in health-care workers (SEDA-21, 254). The incidence of allergy to aldehydes has been examined in 280 health-care workers with skin lesions (14). Allergy was diagnosed in 64 (23%). Most (86%) were sensitive to only one aldehyde. Formaldehyde caused allergy slightly more often (14%) than glutaraldehyde (12%). Only five (1.9%) were sensitive to glyoxal. This hierarchy of sensitivity was also confirmed in animal testing.

Immediate-type allergy to formaldehyde mediated by ice occurred during the use of a formaldehyde reconditioned dialyser in a 20-year-old woman without a personal or familiar history of atopy.

A specific cold agglutinin cross-reacting with anti-N was detected in the sera of 68 (21%) of 325 hemodialysis patients; each had used a dialyser that had been sterilized with formaldehyde. The results of transfusion experiments suggested in vivo hemolytic activity of this antibody. The authors postulated that such in vivo exposure to formaldehyde might make the MN-receptor on erythrocytes immunogenic, thus inducing the formation of the anti-N-like antibody.

The commonly used Clinitest reaction for residual formaldehyde in reused dialysers fails to detect concentrations below 50 ppm (15). The use of Schiff reagent in ratios of 1:1 to 3:1, which can detect formaldehyde at concentrations of 3.6–5.0 ppm, has therefore been recommended (SEDA-12, 571) (16). It can also be used in combination with a glucose-containing dialysate.

Long-Term Effects

Mutagenicity

Formaldehyde is mutagenic in many laboratory test systems, for example fruit flies (Drosophila), grasshoppers, flowering plants, fungi, bacteria, and cultured human bronchial fibroblasts.

Formaldehyde may be genotoxic by a dual mechanism: direct damage to DNA and inhibition of repair of mutagenic and carcinogenic DNA lesions by other chemical and physical carcinogens.

Marked chromosomal abnormalities and chromosomal breaks were found in metaphases in direct bone marrow preparations from 40 patients undergoing maintenance hemodialysis (SEDA-11, 477) (17). During the period of these cytogenetic studies, the dialysers were reused after sterilization with formaldehyde, and each patient may have received residual amounts of as much as 127 (sd 51) mg of formaldehyde during each dialysis.

Tumorigenicity

There is evidence of possible carcinogenicity of formaldehyde from two inhalation studies on rats and mice (SEDA-10, 423) (SEDA-11, 477) (SEDA-12, 571) (13).

In man, a number of epidemiological studies using different designs have been conducted (17) on the health risks of non-medical exposure to formaldehyde and also in health-care professionals (18–23), with contradictory results. Cancers in excess in more than one study were: Hodgkin's disease (24,25), leukemia (18,19,22,23,26), cancers of the buccal cavity and pharynx (particular the nasopharynx) (18,19,25,27,28), lung (18,24,27,29–31), nose (32–36), prostate (19,24,26), bladder (19,23,26), brain (20), colon (18–20,25,27), skin (18,25), and kidney (27).

There was no association between formaldehyde exposure and lung cancer in a case-referral study among Danish physicians working in departments of pathology, forensic medicine, and anatomy (21).

© 2006 Elsevier B.V. All rights reserved.

Mortality from prostatic cancer was increased among embalmers (19) and industrial workers (24,26), but the excess was statistically significant only among embalmers (19). A slight excess of mortality from bladder cancer (19,22,26), a significant excess of colon cancers (18,19,27), and a significant excess mortality from skin cancer (18,25) were noted among British pathologists (22), embalmers (18,19), and industrial workers (25–27).

Excess mortality from leukemia and cancer of the brain was generally not seen among industrial workers, which suggests that the increased rates of these cancers among professionals (anatomists (20), pathologists (22), embalmers (18,19), and undertakers (23)) is due to factors other than just formaldehyde.

It is of course possible that the studies that have provided positive evidence of a link between formaldehyde and cancer related to more intensive exposure; for example, reports on the risk associated with chronic exposure to low concentrations of formaldehyde suggest that formaldehyde cannot be a potent carcinogen; if it were, the high degree of environmental exposure would result in much clearer evidence of risk. However, any compound that produces cancer in experimental animals or mutagenicity in several test systems should be considered as a potential cancer risk to human subjects, even though humans and animals may differ in their susceptibility to formaldehyde. The contradictory evidence from human studies should therefore be taken seriously and efforts should be made to reduce exposure.

The need to re-evaluate the rationale underlying the use of formaldehyde, formocresol, and paraformaldehyde in dentistry has been stressed, since the clinical use and delivery of these products are considered to be arbitrary and unscientific (37).

Formoterol

See also Beta$_2$-adrenoceptor agonists

General Information

Formoterol is a long-acting selective beta$_2$-adrenoceptor agonist that is more potent than salmeterol (1) and has a similar duration of action (12 hours) but a rapid onset of effect similar to that of salbutamol. It is available as a multidose, pressurized aerosol and as a dry powder inhaler, delivering 0.006 or 0.012 mg per dose. The usual dose is 0.012 mg bd.

The pharmacokinetics and pharmacodynamics of a single oral dose of formoterol 168 μg have been studied in eight healthy men. Plasma concentrations reached a maximum of 94 pg/ml 70 minutes after administration. The biological effects peaked later, at 4 hours. Plasma potassium fell from 3.98 mmol/l to 2.33 mmol/l. There was a fall in blood eosinophil count from 277 $\times$ 10^6/l to 47 $\times$ 10^6/l (2).

In a postmarketing surveillance study of the long-acting beta$_2$-adrenoceptor agonist formoterol in the UK using the technique of prescription event monitoring, exposure and outcome data in 5777 patients aged 3–96 years were collected (3). The most commonly reported events, excluding those related to respiratory disease, were headache, tremor, palpitation, cramp, and nausea and vomiting, events known to be associated with beta$_2$-adrenoceptor agonists (4). However, the frequencies of nausea and vomiting (1.3%) and pruritus (0.5%) differed from the frequencies reported in the premarketing trials.

Therapeutic studies

Observational studies

The cardiovascular and metabolic responses to increasing doses of formoterol 12, 24, 48, and 96 μg administered from a dry powder inhaler have been assessed in a randomized, double-blind, crossover study in 20 patients with mild to moderate asthma. There was no difference in the maximum effects of formoterol 12 micrograms and placebo. The 24 micrograms dose significantly reduced plasma potassium (average fall 0.2 mmol/l) and increased blood glucose (average rise 1.8 mmol/l). After formoterol 96 micrograms the rise in heart rate was 9/minute greater than after placebo, systolic blood pressure rose by an average of 4 mmHg, and diastolic pressure fell by an average of 3 mmHg. Plasma potassium fell by an average of 0.5 mmol/l and blood glucose rose by an average of 2.6 mmol/l. The effects on extrapulmonary parameters would only be of clinical significance at the highest dose of formoterol studied (5).

A 3-month, open, uncontrolled, multicenter trial has been carried out in 1380 patients with moderate to severe persistent asthma taking inhaled corticosteroids (6). Formoterol was given via a single-dose, breath-activated device (Foradil). There were significant increases in peak flow and a three-fold reduction in the need for rescue treatment with short acting beta$_2$-adrenoceptor agonists. By the end of the study, 72% of the patients were taking formoterol 12 micrograms bd and 29% were taking 24 micrograms bd. Physician evaluation indicated that tolerability was very good or good in 93% of the patients. There were only minor drug-related adverse events similar to those produced by other beta$_2$-agonists.

Placebo-controlled studies

In a double-blind, crossover study 12 healthy subjects were randomized to receive either inhaled placebo or inhaled budesonide 1.2 mg bd for 7 days, with a minimum 7-day washout period between the two treatments (7). They used formoterol 24 micrograms bd during both treatment periods. A dose-response curve for systemic beta$_2$-adrenoceptor responses to inhaled salbutamol (0.8–3.2 mg) was carried out before and after 7 days of each treatment. The pretreatment value of plasma cortisol averaged 407 nmol/l and fell to 22 nmol/l after 7 days of budesonide; placebo had no effect. There was a significant reduction in the peak heart rate response to salbutamol when formoterol was given with placebo. This was partially reversed when formoterol was combined with budesonide. The peak rise in heart rate with salbutamol after formoterol and placebo was 24/minute and increased to 35/minute when formoterol was given with budesonide. The peak fall in potassium with salbutamol after formoterol and placebo was 0.48 mmol/l and did not change significantly when formoterol was combined with budesonide (0.36 mmol/l).

In multiple dose studies with formoterol (Oxis, Turbuhaler, Astra) 6, 12, and 24 micrograms bd, terbutaline 0.5 mg qds, or placebo in a total of 1199 patients, at least one adverse event was reported by 65% of the patients in each treatment group (8). Adverse events related to the respiratory system were reported by 37% of the patients and were attributed to underlying disease. Tremor was reported by 2% of patients taking formoterol 6 micrograms bd, by 4% with 12 micrograms bd, and by 12% with 24 micrograms bd. Tremor was reported by 5% of patients taking terbutaline 0.5 mg qds. No patient reported tremor with placebo.

© 2006 Elsevier B.V. All rights reserved.

In 397 adults with mild to moderate asthma randomly allocated to one of three treatments for 12 weeks (formoterol 6 micrograms bd, terbutaline 0.5 mg qds, and placebo), formoterol was significantly more effective than either terbutaline or placebo in reducing asthma symptoms (9). It also resulted in significantly higher evening peak flow readings and less use of rescue medication. The bronchodilator response to the study drugs and an additional 1.25 mg of terbutaline was similar before and at the end of the 12 weeks. This suggested that there was no loss of beta-adrenoceptor mediated bronchodilatation in any of the treatment groups. No patient in any group reported a clinically relevant adverse effect.

Of 31 patients with asthma and a mean FEV_1 of 1.97 litres in a double-blind, randomized, placebo-controlled, crossover study of single inhaled doses of placebo or formoterol, 6, 12, 24, or 48 micrograms on five separate days, most had at least a 50% increase in specific airway conductance within 1–4 minutes (10). The maximum increase in FEV_1 was dose-dependent, rising by 12% (6 micrograms), 18% (12 micrograms), 19% (24 micrograms), and 26% (48 micrograms). At 12 hours after the administration of 6, 12, 24, and 48 micrograms of formoterol, the mean increases in FEV_1 were still 7, 15, 18, and 27%, respectively, above the value seen with placebo. The most frequently reported adverse effect was headache, which occurred with all treatments, including placebo. After inhalation of formoterol 48 micrograms, three patients had mild tremor lasting for less than 1 hour. One patient had the same effect for 3 hours after placebo.

Comparative studies

Formoterol has been compared with various other $beta_2$-adrenoceptor agonists.

Fenoterol and salbutamol

Formoterol 24 micrograms, fenoterol 0.4 mg, and salbutamol 0.4 mg all caused an increase in heart rate and plasma glucose, and a fall in diastolic blood pressure and plasma potassium (1). Fenoterol had a greater maximum effect on heart rate than either salbutamol or formoterol. Formoterol and fenoterol caused a similar maximum reduction in plasma potassium greater than that seen with salbutamol.

Salmeterol

The relative efficacy of the long-acting $beta_2$-adrenoceptor agonists formoterol and salmeterol has been studied in a randomized, double-blind, crossover trial in 15 patients with asthma taking regular corticosteroids and salbutamol (11). The patients had methacholine challenges performed after varying single doses of formoterol (12, 60, and 120 micrograms) and salmeterol (50, 250, and 500 micrograms). The maximal protective effect of salmeterol against methacholine challenge was reached at 250 micrograms, whereas formoterol showed a dose-response relation, with maximum protection at the highest dose. This confirmed the authors' hypothesis that salmeterol is a partial agonist at beta-adrenoceptors compared with formoterol. The higher affinity of formoterol for beta-adrenoceptors also produced more adverse effects. There was a significant fall in serum potassium concentration after 60 micrograms of formoterol but not after 250 micrograms of salmeterol. The serum potassium concentration was also significantly lower with the highest dose of formoterol compared with the highest dose of salmeterol (minimum concentration 3.1 mmol/l). The highest dose of formoterol also resulted in more tremor than the highest dose of salmeterol. The increases in heart rate and QT interval were similar with the two drugs. It should be noted that the doses used in this study were higher than recommended. It is unclear whether the partial agonist activity of salmeterol is clinically important, but this seems unlikely.

Terbutaline

In 12 stable asthmatic patients who took high doses of formoterol or terbutaline, terbutaline had significantly greater systemic effects than formoterol, as indicated by pulse, blood pressure, and heart rate. Baseline serum potassium concentrations were all within the reference range (3.7–5.3 mmol/l). There was no significant difference between the mean potassium-lowering effects of formoterol 72 micrograms and terbutaline 6 mg. Mean maximal systolic blood pressure rose from 150 to 155 mmHg with formoterol 72 micrograms and from 139 to 153 mmHg with terbutaline 6 mg. The difference between treatment groups, 5 mmHg, was statistically significant. Diastolic blood pressure fell significantly with both formoterol (from 86 to 70 mmHg) and terbutaline (from 85 to 66 mmHg). Heart rate rose from 61/minute to 79/minute on day 3 in patients taking formoterol 72 micrograms/day compared with a rise from 63/minute to 86/minute with terbutaline 6 mg; this difference was statistically significant.

Formoterol 120 micrograms had significantly smaller effects than terbutaline 10 mg/day on serum potassium concentrations, pulse, and heart rate. During treatment with formoterol 120 micrograms/day, potassium concentrations were under 3.7 mmol/l in 10 patients on day 1, six patients on day 2, and five patients on day 3. With terbutaline 10 mg the corresponding numbers were 12, 10, and 9. However, the effect of terbutaline 10 mg was significantly greater than formoterol 120 micrograms over the three treatment days. Formoterol 120 micrograms/day caused a rise in baseline systolic blood pressure from 134 to 145 mmHg; terbutaline 10 mg produced a rise from 131 to 141 mmHg. The difference between the groups, 0.6 mmHg, was not statistically significant. With formoterol 120 micrograms/day the heart rate rose from 65/minute to 78/minute, and with terbutaline 10 mg/day it rose from 63/minute to 86/minute. The difference in mean heart rate rise of 8/minute was statistically significant. A patient taking formoterol 72 micrograms/day developed atrial fibrillation on day 1. Minor adverse events occurred in seven patients taking formoterol 72 micrograms/day and six patients taking terbutaline 6 mg/day. Eight patients reported adverse events when taking formoterol 120 micrograms/day, as did 10 patients taking terbutaline 10 mg/day. Minor adverse effects included headache, muscle cramps, fatigue, and tremor with all four treatments. Tremor was reported in two of 12 patients taking terbutaline 6 mg and in five of 15 patients taking terbutaline 10 mg. The corresponding numbers for formoterol were none with formoterol 72 micrograms and one of 15 with formoterol 120 micrograms (12).

© 2006 Elsevier B.V. All rights reserved.

High-dose formoterol (Oxis Turbuhaler) and terbutaline (Bricanyl Turbuhaler) have been compared in a randomized, double-blind trial in 48 patients with obstructive airways disease (mean FEV_1 0.98 liter or 33% predicted) (13). Patients with acute bronchoconstriction received either a cumulative dose of 90 micrograms inhaled formoterol or 10 mg inhaled terbutaline (corresponding to 20 puffs each) within the first 3 hours of admission. Treatment included intravenous prednisolone 40 mg after 1.5 hours and oxygen during the first 3 hours. FEV_1 improved similarly in both treatment groups, serum potassium concentration fell in both groups but to the same extent, and the mean 12-hour pulse rate was significantly higher with terbutaline. The authors concluded that formoterol is at least as safe and equally well tolerated as terbutaline.

Organs and Systems

Cardiovascular

The cardiac effects of formoterol and salmeterol have been studied in 12 patients with COPD, hypoxemia (PaO_2 below 60 mmHg), and cardiac disease. Holter monitoring showed that the heart rate was higher after formoterol 24 micrograms than after either formoterol 12 micrograms or salmeterol 50 micrograms. Supraventricular or ventricular extra beats occurred more often after formoterol 24 micrograms. Formoterol 24 micrograms caused a significant reduction in the plasma potassium concentration for 9 hours after administration. The authors suggested that in patients with COPD, hypoxemia, and pre-existing cardiac dysrhythmias, long-acting $beta_2$-adrenoceptor agonists can cause adverse cardiac effects. However, the recommended single dose of salmeterol or formoterol allows a higher safety margin than inhaled formoterol 24 micrograms (14).

The non-pulmonary effects of formoterol have been carefully studied in an uncontrolled observational trial in 10 patients with asthma who were already taking regular inhaled budesonide (400 micrograms bd) (15). A 24-hour Holter recording was taken at baseline, and after a 2-week treatment period with formoterol 12 micrograms bd, there were no significant changes in blood pressure, heart rate, cardiac morphology, or the circadian rhythm of autonomic regulation as assessed by measurements taken from the Holter monitor after the treatment period.

Respiratory

The effect of formoterol 18 micrograms on histamine-induced plasma exudation into sputum has been investigated in 16 healthy subjects in a double-blind, placebo-controlled, crossover study. Plasma exudation into the airways was produced by inhalation of histamine. Sputum was induced by inhalation of hypertonic (4.5%) saline. Induced sputum was obtained at baseline and then at 30 minutes and 8 hours after histamine inhalation. Sputum concentrations of $alpha_2$-macroglobulin were measured as a marker of microvascular-epithelial exudation of bulk plasma. Histamine-induced plasma exudation 30 minutes after placebo was considerably greater than at baseline. The median difference was 11 μg/ml (95% CI = 0.9, 90) expressed as $alpha_2$-macroglobulin. The effect of histamine was reduced by 5.1 μg/ml (CI = 0.9, 62) 30 minutes after formoterol compared with placebo. At 8 hours, histamine exudation was much less and was no longer inhibited by formoterol (16).

Nervous system

The non-pulmonary effects of formoterol have been carefully studied in an uncontrolled observational trial in 10 patients with asthma who were already taking regular inhaled budesonide (400 micrograms bd) (15) There was a significant increase in upper limb tremor with formoterol and this was assessed as discomfort by one patient. This was considered due to stimulation of $beta_2$-adrenoceptors in skeletal muscle.

Long-Term Effects

Drug tolerance

Several studies have shown that regular use of formoterol results in the development of tolerance to its bronchoprotective effects, even with treatment periods as short as 1 week. The significance of this tolerance is unclear, but it is potentially important clinically.

A randomized, double-blind, placebo-controlled, crossover trial was designed to see whether formoterol given once daily was associated with less subsensitivity. Ten asthmatics using inhaled steroids were given inhaled formoterol dry powder 24 micrograms od or bd or identical placebo for 1 week. Bronchoprotection was estimated by measuring the PC_{20} for adenosine monophosphate (AMP) 12 hours after the first and last doses of each treatment. The PC_{20} is the concentration of AMP that causes a 20% fall in the FEV_1 and is directly proportional to the degree of bronchoprotection. With placebo, the PC_{20} values for AMP at the start and end of one week were 71 μg/ml and 75 μg/ml. There was a significant loss of bronchoprotection after 1 week of treatment with twice-daily formoterol. The PC_{20} for AMP at the start was 475 μg/ml, indicating significant bronchoprotection by formoterol compared with placebo. After 1 week the PC_{20} had fallen to 127 μg/ml, a near four-fold loss of the bronchoprotective effect of formoterol. When formoterol was given daily for a week the PC_{20} values were 367 μg/ml and 127 μg/ml, a three-fold loss of bronchoprotection. There was no significant difference in the effects of formoterol given once or twice a day (17).

A randomized, parallel-group, double-blind study in 67 patients with stable asthma requiring inhaled glucocorticoids used the PC_{20} for inhaled methacholine as a measure of bronchoprotection. The patients were treated for 2 weeks with formoterol 12 micrograms od, 6 micrograms bd, or 24 micrograms bd, terbutaline 500 micrograms qds, or placebo. Each of the four active treatments caused a significant fall in the PC_{20} for metacholine, and there was no significant difference between them. In contrast to the reduced bronchoprotective effect the bronchodilator effect of formoterol was maintained over the 2-week treatment period (18).

The effect of a bolus of inhaled budesonide on formoterol-induced subsensitivity in airway beta-adrenoceptors has been studied in a randomized, double-blind, crossover study in 10 asthmatic patients taking regular inhaled

© 2006 Elsevier B.V. All rights reserved.

glucocorticoids (19). Challenge testing with AMP was performed at baseline and after one week of regular formoterol (24 micrograms bd). Before the second challenge the patients were given either a dose of inhaled budesonide (1600 micrograms) or placebo via a dry powder inhaler. After one week of formoterol, the PC_{20} for the second challenge fell significantly (by a factor of 3.9). However, when the second challenge was performed after a bolus of budesonide, there was no fall in the PC_{20}, suggesting protection against formoterol-induced tolerance. Lymphocyte beta-adrenoceptor density fell with regular formoterol, but not after a bolus of budesonide. These results have implications for the treatment of acute severe asthma in patients taking regular long-acting $beta_2$-adrenoceptor agonists. It may be appropriate to give a bolus dose of inhaled glucocorticoids to these patients early in an acute asthma attack, particularly if they are poorly responsive to initial therapy with short-acting bronchodilators.

Susceptibility Factors

Age

The use of long-acting beta-adrenoceptor agonists in the management of asthma in children has been comprehensively reviewed (20). In children, as in adults, regular long-acting beta-adrenoceptor agonists can produce bronchodilator subsensitivity to short-acting beta-agonists and tolerance to the bronchoprotective effects of long-acting beta-agonists against challenges with exercise and methacholine. The clinical significance of these findings is unclear. Formoterol and salmeterol have similar adverse effects profiles, similar to that of salbutamol. The most common medication-related adverse effects are cardiovascular, such as increased heart rate and palpitation, or tremor and headache. Small changes in serum potassium and glucose can also be seen, but all changes are minor. The exact role of long-acting beta-adrenoceptor agonists in childhood asthma remains to be defined.

Drug Administration

Drug formulations

Formoterol 12 and 24 micrograms, delivered from either a multidose pressurized aerosol or a dry powder inhaler, did not affect heart rate. However, at doses of 48 and 96 micrograms the heart rate rose significantly after the dry powder formulation. Tremor was significantly higher after the 48 micrograms dose of dry powder compared with the multidose pressurized aerosol. The two formulations were equipotent in producing bronchodilatation (SEDA-21, 184).

Drug–Drug Interactions

Salbutamol

The interaction of formoterol and salmeterol with salbutamol has been studied in a randomized, double-blind, crossover study in 16 asthmatic patients (21). The patients were taking regular inhaled corticosteroids and were responsive to methacholine challenge, with a PD_{20} (that is the dose of methacholine that produced a fall in FEV_1 of 20%) of less than 500 μg. The patients had methacholine challenges performed 12 hours after a single dose of formoterol 12 micrograms, salmeterol 50 micrograms, placebo, and either a low dose (400 micrograms) or a high dose (1600 micrograms) of salbutamol. With placebo, challenge after high-dose salbutamol resulted in a higher PD_{20} than after low-dose salbutamol (as expected). However, after both formoterol and salmeterol, the higher dose of salbutamol did not give as great an increase in PD_{20} over the lower dose of salbutamol. This suggests that prior treatment with formoterol and salmeterol can antagonize the protective effect of salbutamol against bronchoconstriction. This effect may be important in patients with acute asthma.

Foscarnet

General Information

Foscarnet (trisodium phosphonoformate hexahydrate) is a pyrophosphate analogue that interacts with the enzymatic action of polymerases and inhibits the cleavage of pyrophosphate from the nucleoside triphosphate. Because of this mechanism, the antiviral activity of the drug is broad. Foscarnet is a non-competitive inhibitor of herpesvirus DNA polymerase, hepatitis B virus DNA polymerase, and reverse transcriptases (1). Intravenous foscarnet has been used for the treatment of mucocutaneous disease due to acyclovir-resistant *Herpes simplex* (2) and for the treatment of severe CMV infection (3,4). Foscarnet has been shown to be as effective as ganciclovir in the treatment of gastrointestinal CMV and CMV retinitis in patients with AIDS (5). The two drugs differ, however, in their respective toxicity profile, and in a comparison in CMV retinitis, ganciclovir was better tolerated (6). Treatment-limiting adverse effects are renal toxicity, hypocalcemia, and mucosal ulceration.

Organs and Systems

Electrolyte balance

Significant electrolyte abnormalities have been attributed to foscarnet in a bone marrow transplant recipient on parenteral nutrition (7).

- A 39-year-old man with acute myelogenous leukemia developed a fever after allogeneic bone marrow transplantation and was given prophylactic ganciclovir and antibiotics. Parenteral nutrition was started when severe mucositis and diarrhea limited oral nutrition. On the 18th day after transplantation CMV DNA was detected in his blood and he was given foscarnet. His requirements for potassium, calcium, magnesium, and phosphorus increased dramatically, while his sodium requirements fell. Electrolyte depletion occurred within 24 hours and was accompanied by deteriorating renal function (serum creatinine 106–220, reference range 60–125 μmol/l). On withdrawal of foscarnet, the serum creatinine fell within 24 hours and the electrolyte concentrations returned to normal.

Mineral balance

The second most common adverse effect of foscarnet is symptomatic hypocalcemia, which may be responsible for the cardiac dysrhythmias and seizures that occur after acute overdose or excessively rapid infusion of foscarnet. Foscarnet stimulates the release of parathyroid hormone, which raised concerns about long-term administration (8). However, in a study of seven patients receiving a 14-day foscarnet induction regimen, there were no changes in calcium or phosphate metabolism (9).

Recognizing that foscarnet is a potent chelator of divalent cations, and that acute ionized hypocalcemia and hypomagnesemia are common adverse effects, a trial of intravenous magnesium sulfate has been conducted for foscarnet-induced hypocalcemia and hypomagnesemia in 12 AIDS patients with CMV infection (10). Increasing doses of magnesium sulfate reduced or eliminated foscarnet-induced ionized hypomagnesemia but had no discernible effect on ionized hypocalcemia, despite significant increases in serum parathyroid hormone concentrations. On this basis, intravenous supplementation for patients with normal serum magnesium concentrations was not recommended during treatment with foscarnet.

Urinary tract

Alterations in creatinine clearance or acute renal insufficiency occur in 10–20% of patients with AIDS receiving intravenous foscarnet (11), due to acute tubular damage. Severe renal insufficiency can be prevented in most cases by careful hydration before and during therapy (12). To minimize the residual incidence of nephrotoxicity, the dose of foscarnet should be frequently recalculated, based on the estimated creatinine clearance.

Patients who have undergone renal transplantation and then require treatment for cytomegalovirus infection are at special risk of renal damage due to foscarnet.

- One renal transplant recipient developed the nephrotic syndrome, with microscopic hematuria and non-oliguric acute renal insufficiency within 15 days after starting foscarnet therapy for cytomegalovirus infection (13). A kidney biopsy showed crystals in all glomeruli and in the proximal tubules. The crystals consisted of several forms of foscarnet salts. Renal function and proteinuria nevertheless improved progressively, and a second transplant biopsy 8 months after the first one showed

© 2006 Elsevier B.V. All rights reserved.

fibrotic organization of half of the glomeruli and of the interstitial tissues, and a reduction in the amount of crystals.

The renal damage caused by foscarnet can itself alter the drug's kinetics; the dosage needs to be substantially reduced when renal complications occur, and appropriate guidelines have been developed (14).

Skin

Painful oral, penile, and vulvar ulceration can occur during foscarnet therapy (15), most probably due to local accumulation of the drug (SEDA-17, 338). Penile ulcers have been reported to be the reason for discontinuation of foscarnet therapy in up to 10% of patients (16).

Eosinophilic folliculitis is a common skin manifestation associated with HIV infection, but not commonly associated with medications.

- A 38-year-old patient with AIDS was given intravenous foscarnet 400 mg tds and no other medications (17). On the second day, a pruritic, erythematous, maculopapular, urticarial rash was noted on the limbs and trunk. The infusion was stopped and the reaction disappeared. On restarting the infusion, the reaction recurred but did not clear after withdrawal. Histology showed a pattern consistent with eosinophilic folliculitis. After UVB phototherapy for 2 months the folliculitis resolved.

Fosfomycin

General Information

Fosfomycin is a broad-spectrum antibiotic used to treat uncomplicated lower urinary tract infections. It penetrates interstitial space fluids of soft tissues well and reaches concentrations sufficient to substantially inhibit the growth of relevant bacteria at the target site (1).

Fosfomycin has relatively low toxicity. Its penetration into tissues, including bones and joints, and into the cerebrospinal fluid is good. When given orally (2–3 g/day), it can produce gastrointestinal distress; when injected intramuscularly, it can cause local pain. Fosfomycin is recommended in daily doses of 4–16 g intravenously for the treatment of severe infections resistant to other commonly used antibiotics. Fosfomycin diffuses moderately well into bone tissue (2).

During systemic administration, rises in the activities of serum transaminases and lactate dehydrogenase, skin reactions, eosinophilia, and altered vision have been noted (3).

© 2006 Elsevier B.V. All rights reserved.

Comparative studies

In a multicenter trial in 749 ambulatory women aged at least 12 years with an acute uncomplicated urinary tract infection, a single dose of fosfomycin tromethamine 3 g had an equivalent bacteriological and clinical cure rate as a 7-day course of nitrofurantoin (4). Adverse events were reported by 5.3% of fosfomycin-treated patients (versus 5.6%). The most common adverse effects were diarrhea (2.4%), vaginitis (1.8%), and nausea (0.8%), and 1.9% of fosfomycin-treated patients were withdrawn owing to adverse events (versus 4.3%).

Organs and Systems

Nervous system

Fosfomycin concentrations in brain interstitium were measured in two patients after the intravenous administration of 4 g (5). Brain C_{max} values were above MIC for relevant pathogens, such as *Streptococcus pneumoniae* and *Neisseria meningitidis*. Variability in brain penetration might be explained by the degree to which the integrity of the blood–brain barrier is disrupted by the underlying disease.

Hematologic

The effects of fosfomycin on several indices of neutrophil function have been studied in vitro (6). Phagocytosis was unaffected but there was enhanced bactericidal ability, increased intracellular calcium concentrations, raised extracellular reactive oxygen intermediate production, and reduced chemotaxis; fosfomycin did not affect intracellular oxygen intermediate production or chemokinesis.

Liver

Fosfomycin-induced recurrent liver toxicity occurred in a patient with cystic fibrosis (7).

Urinary tract

In Japanese children the use of fosfomycin within the first two days for treatment of illness caused by *Escherichia coli* O157 reduced the risk of subsequent hemolytic–uremic syndrome (8). However, treatment with oral fluoroquinolones may be preferable (9).

In rats, co-administration of fosfomycin significantly reduced the nephrotoxicity of vancomycin (10).

Immunologic

The immunomodulatory effect of fosfomycin may in part be explained by an effect on cytokine production, as shown in mice in vivo (11).

Infection risk

Bacterial biofilms develop on a number of living and inert surfaces within the urinary tract, producing chronic intractable urinary tract infections. Combination therapy with fosfomycin and a fluoroquinolone (or a fluoroquinolone and a macrolide) may be the most effective regimen available at present. Nevertheless, management of the local urinary condition and removal of the local underlying disease are the most effective approaches for treating urinary biofilm infection (12).

Long-Term Effects

Drug tolerance

There is a serious reduction in the susceptibility of strains of *E. coli* to amoxicillin (due to R-TEM enzymes), to co-trimoxazole, and to trimethoprim. However, fosfomycin trometamol remains highly active against urinary *Enterobacteriaceae*, and over 90% of *E. coli* are susceptible (13). Fosfomycin is as active as fluoroquinolones or better for treating intestinal infections caused by *Salmonella* species, pathogenic *E. coli*, *Campylobacter* species, and *Shigella* species (14).

Drug–Drug Interactions

Cisplatin

Fosfomycin is both otoprotective and nephroprotective against cisplatin-induced toxicity, without inhibiting the tumoricidal activity of cisplatin (15). Mice treated with cisplatin and fosfomycin also survived longer than animals treated with cisplatin alone, probably owing to lessening of immediate cisplatin systemic toxicity (16).

Fosinopril

See also Angiotensin converting enzyme inhibitors

General Information

Fosinopril is a phosphorus-containing ester prodrug of the ACE inhibitor fosinoprilat. Its clinical pharmacology, clinical use, and safety profile have been reviewed (1).

Organs and Systems

Respiratory

Claims that cough is less often observed with fosinopril than with other ACE inhibitors are primarily based on a single open unconvincing study (2).

Liver

Hepatic injury has been described from time to time with ACE inhibitors. Severe, prolonged cholestatic jaundice has been reported with fosinopril (3). The evidence of a link to fosinopril was convincing.

- A 61-year-old man developed weakness, severe jaundice, pruritus, and weight loss over 2 weeks. He had started to take metoprolol, fosinopril, and diazepam for hypertension 5 weeks before. He had raised hepatic transaminases and bilirubin. A liver biopsy showed cholestasis in a normal cellular architecture. A lymphocyte transformation assay showed reactivity to fosinopril but not diazepam or metoprolol. Bilirubin concentrations took 4 months to normalize and pruritus persisted for 6 months.

Skin

There is a recognized association between the use of ACE inhibitors and the development of pemphigus vulgaris, for example with enalapril (SEDA-26, 235). A case of worsening of pemphigus vulgaris with fosinopril, and a subsequent in vitro mechanistic study, has been published (4).

- A 64-year-old woman with insulin-dependent diabetes mellitus and pemphigus vulgaris controlled by deflazacort 12 mg/day was given fosinopril 10 mg/day for hypertension. Within 1 month her skin lesions worsened and an indirect immunofluorescence test became positive. Fosinopril was withdrawn and her skin lesions improved without modification of her steroid regimen; 10 months later the immunofluorescence test was negative.

Following this, normal human skin slices (obtained after informed consent from mammoplasty patients) were incubated with increasing concentrations of either fosinopril or captopril for 2–24 hours. Sera from patients with pemphigus vulgaris, containing antidesmoglein-3 antibodies (anti-Dsg3) were tested on the skin samples incubated with fosinopril and captopril, as well as control skin samples incubated with 0.9% saline. Indirect immunofluorescence testing showed that captopril at a concentration of 1.7×10^{-9} mmol/l blocked the binding of anti-Dsg3 to the keratinocyte surface, probably because captopril blocked adhesion molecules. In contrast, fosinopril only had this effect at a concentration of 1.7×10^{-2} mmol/l, a concentration much higher than would occur in vivo. The authors proposed that captopril produces acantholysis by blocking adhesion molecules, but that fosinopril does not have this effect, and that another mechanism must have been involved in the case that they reported.

Fosmidomycin

General Information

Fosmidomycin is an antimicrobial drug that acts by inhibiting 1-deoxy-D-xylulose 5-phosphate reductoisomerase, a key enzyme of the non-mevalonate pathway of isoprenoid biosynthesis. It inhibits the synthesis of isoprenoids by *Plasmodium falciparum* and suppresses the growth of multidrug-resistant strains in vitro.

© 2006 Elsevier B.V. All rights reserved.

In an open, uncontrolled study, fosmidomycin was administered for 3–5 days (1.2 g every 8 hours) to 27 adults with malaria, of whom 16 reported possibly drug-related adverse events (1). The most frequent adverse events were headache, weakness, myalgia, abdominal pain, and loose stools. There were two cases of raised alanine transaminase activity.

Fragrances

General Information

The fragrance mix, introduced in 1977 by Larsen (1), is used to detect sensitivity to fragrances in, for example, cosmetics and household products (SEDA-20, 149) (2). The mix contains eight widely used fragrance compounds. Additional indicators of fragrance allergy are balsam of Peru and colophony.

Organs and Systems

Immunologic

Contact sensitivity to fragrance mix is not infrequent and reflects the ubiquitous presence of these substances (3). The frequency of positive patch tests to the fragrance mix has increased over recent years. However, the mix has been estimated to miss 15% of relevant contact allergies (4). In a study of 1855 consecutive patients, patch tests with additional fragrance allergens has shown that lyral (2.7% positive reactions), citral (1.1%), and farnesol P (0.5%) are valuable additions when patch-testing to detect a fragrance allergy. Several other compounds that were tested at the same time were positive less often (5). A similar study in 1606 consecutively tested patients showed that ylang-ylang oil I (2.6% positive patch tests), ylang-ylang oil II (2.5%), lemongrass oil (1.6%), narcissus absolute (1.3%), jasmine absolute (1.2%), and sandalwood oil (0.9%) are the most important ingredients (6). In this series, limonene was positive in 0.6% of cases, but in another series of 2273 consecutive patients it was positive in 2.8%, of whom 57% did not react to the fragrance mix (7).

These and other compounds were patch-tested in another series of fragrance-sensitive patients (8). Of the 218 subjects tested, 76% were positive to the fragrance mix. Ten fragrances were not detected by the fragrance mix: benzenepropanol; beta, beta, 3-methylhexylsalicylate; dl-citronellol; synthetic ylang-ylang oil; benzyl mixture (containing benzyl alcohol, benzyl salicylate, and benzyl acetate); cyclohexylacetate; eugenyl methyl ether; isoeugenyl methyl ether; 3-phenyl-1-propanol; and 3,7-dimethyl-7-methoxyoctan-2-ol. In earlier studies by this group, significant additional reactions were found to sandela, geranium oil bourbon, spearmint oil, galaxolide (1,3,4,6,7,8-hexahydro-4,6,6,7,8,8-hexamethylcyclopenta-gamma-2-benzopyran), omega-6-hexadecenlactone, and tripal (dimethyltetrahydrobenzaldehyde) (9,10).

Patients with chronic venous insufficiency and venous leg ulcers are at risk of sensitization to topical medications. The frequency of sensitization in these patients is up to 67% (11). In a study using an expanded European standard series and 20 different wound dressings for patch-testing in 36 patients with chronic venous insufficiency, sensitization to fragrance mix was found in three cases (12).

Fructose and sorbitol

General Information

Attention has been drawn to the use of fructose-based and sorbitol-based solutions for parenteral administration in Germany and German-speaking countries, where they are available for routine fluid replacement and intravenous feeding, and are widely prescribed, even after minor surgical procedures (1). Their main advantage is claimed to be the avoidance of a blood glucose raising effect, particularly in severely ill patients with glucose intolerance. In such cases it may be possible to avoid insulin therapy, since the first steps in the metabolism of these carbohydrates are insulin-dependent.

Organs and Systems

Metabolism

Infusions of fructose or sorbitol can cause lactic acidosis (2,3), particularly in combination with ethanol.

- In one patient, blood lactate concentration was monitored frequently over 5 days during intravenous feeding with a sorbitol-ethanol-amino acid mixture. During the first five infusions, blood lactate rose only moderately, but with the final infusion, lactate rose to 11 mmol/l and the patient had a severe metabolic acidosis. In retrospect the patient had had worsening renal and hepatic function tests during the preceding 24 hours. On ending the infusions, the blood lactate concentration fell rapidly.

The problems that can result from the administration in total parenteral fluid infusions of D-fructose or sorbitol have been reviewed (4). Either of these can cause life-threatening hypoglycemia, unless glucose is administered concurrently, in patients who have underlying hereditary fructose intolerance. Unless there is a clear clinical history of the condition, it may not be readily identified. In some countries, fructose and D-glucitol (sorbitol) have been eliminated from the pharmacopoeia for this reason.

Acid–base balance

The combination of fructose with sorbitol (which is converted to fructose by sorbitol dehydrogenase) causes lactic acidosis and hyperuricemia (reflecting purine nucleotide breakdown in the liver). The assimilation of fructose (as the free monosaccharide or derived from the oxidation of sorbitol or hydrolysis of sucrose) differs from that of sucrose. Fructose is phosphorylated rapidly in the intestine and liver by the catalytic action of ketohexose kinase (fructokinase) at the 1-carbon position. Cleavage of fructose-1-phosphate by aldolase B ensures its metabolic incorporation into the pathways of glycolysis and gluconeogenesis. Inherited deficiency of aldolase B occurs in hereditary fructose intolerance, an autosomal recessive condition (5). After ingestion of fructose and related sugars in this disorder, high concentrations of fructose-1-phosphate accumulate in the liver, intestine, and proximal renal tubules, and a profound metabolic disturbance occurs. Metabolic acidosis, hypophosphatemia, hypoglycemia, and hyperuricemia result, and functional impairment and pathological injury occur in these tissues with continued administration (6).

Severe lactic acidosis, with serum lactate concentrations of 8.7, 8.6, and 7.9 ml developed in three patients with hyperosmolar syndromes (7). Each had received rehydration treatment with 5% fructose in water (fructose dosage was 0.5 g/kg/hour). After correction of the electrolyte disturbances, continued infusion of fructose in the same dosage increased the plasma lactate concentration in two of the patients to 4.9 and 4.0 mmol/l, indicating near normalization of hepatic lactate utilization. In addition to peripheral insulin resistance and reduced muscular glucose utilization, the hyperosmolar state was also associated with reduced tolerance to fructose. It follows that in rehydration therapy for hyperosmolar syndromes infusion solutions containing fructose should not be used. This "functional fructose intolerance" is thought to be due to impaired gluconeogenesis. In order to administer 50 g of fructose, infusion rates up to 1000 ml/hour are necessary to achieve a positive fluid balance and to match the osmotic diuresis that is produced. Failure to maintain proper balance can cause serious metabolic complications, such as hyperlactemia, lactic acidosis, and circulatory shock.

Hereditary fructose intolerance affects one in 21 000 persons, and there have been more than 12 severe complications caused by these solutions, several lethal. Since a prior history of fructose intolerance is often not obtained, it has been argued that the use of fructose- and sorbitol-containing infusion fluids must be regarded as offering doubtful advantage but carrying definite lethal risk, and that their use should be discontinued. A modified intravenous fructose tolerance test should at least be carried out before infusions of fructose or sorbitol are given (8).

Liver

Four children aged 2.5–14 years were given infusions of fructose, sorbitol, and xylitol after sustaining head trauma ($n = 3$) or after attempting suicide with carbromal ($n = 1$). After transitory polyuria, renal insufficiency of varying severity set in 3–6 days after the start of treatment. Serum osmolality fell to 265–274 mosmol/kg, the hematocrit to 0.25–0.31, and hyponatremia developed. Serum creatinine rose to a maximum of 256–930 μmol/l. Liver damage developed in parallel with renal insufficiency. Two of the children died of acute liver atrophy. The other patients were given symptomatic treatment with balanced equalization of the hyponatremia, administration of furosemide, and carbohydrate substitution. They were discharged after 4 and 8 weeks respectively, with normal renal and hepatic function. Dialysis was not required. The hepatic and renal abnormalities were attributed to the large amounts of fructose, sorbitol, and xylitol that had been administered, to totals of 7.1–23.0 g/kg on the first day (9).

Susceptibility Factors

Genetic factors

Hereditary fructose intolerance is an autosomal recessive disorder with reduced activity of aldolase B in the liver, kidney, and small intestine. Ingestion of only a few grams

© 2006 Elsevier B.V. All rights reserved.

of fructose, sorbitol, or sucrose causes abdominal pain and vomiting (SEDA-13, 479). Affected individuals develop an aversion to sugary foods and drinks, and in severe cases exposure during infancy may result in progressive liver damage and death. Exclusion of fructose from the diet allows them to develop and grow normally.

- A 16-year-old girl died after an uncomplicated appendicectomy (10). She had undiagnosed hereditary fructose intolerance and had been given sorbitol and fructose postoperatively.

Fumaric acid esters

General Information

Fumaric acid esters are used to treat a variety of skin disorders, including psoriasis (1), cutaneous sarcoidosis (2), necrobiosis lipoidica diabeticorum (3), and disseminated granuloma annulare (4).

In 39 patients with psoriasis (12 women, 27 men) in a randomized, double-blind, placebo-controlled study, three different treatments were used: (a) tablets containing a combination of topical dimethylfumarate plus different salts of monoethylfumarate, (b) octylhydrogen fumarate tablets, and (c) placebo (5). Five patients dropped out because of adverse effects or aggravation of the skin lesions. The patients who used the combination of monoethylfumarate plus dimethylfumarate had a significantly better therapeutic response than those who took placebo or octylhydrogen fumarate. Adverse effects of the fumarate-containing tablets were flushing, diarrhea, a reversible rise in transaminases, lymphocytopenia, and eosinophilia. One patient developed impaired renal function, which normalized after withdrawal.

In 83 patients with severe psoriasis vulgaris, the fumaric acid ester formulations Fumaderm initial and Fumaderm caused adverse effects in 62%, mainly flushing and gastrointestinal complaints, which decreased in frequency during the course of the study (6).

Of 101 patients with severe psoriasis vulgaris, 70 completed the treatment period of 4 months (7). Discontinuation was due to adverse events in 7, lack of efficacy in 2, and other reasons, such as non-attendance, in 22. There was a slight overall reduction in lymphocyte count, which was more than 50% below baseline in 10 patients. During weeks 4 and 8, mean eosinophil counts were above the reference range, but by the end of the therapy the eosinophil counts had returned to normal. None of the patients had changes in renal function. Adverse events were reported in 69%, consisting mainly of gastrointestinal complaints (56%) and flushing (31%). In five patients gastrointestinal complaints and in two patients flushing led to withdrawal from the study.

In 66 patients with severe psoriasis who took fumaric acid esters for up to 14 years, there were adverse events in 73%, usually mild and mainly consisting of flushing (55%), diarrhea (42%), nausea (14%), tiredness (14%), and stomach complaints (12%) (8). There was a relative lymphocytopenia in 76%, resulting in permanent withdrawal in four patients. There were transient eosinophilia in 14%, and moderate liver enzyme rises were observed in 25%.

The effect of systemically and/or topically administered ethyl fumarate on psoriasis was studied in six patients. Two patients who had been treated with locally applied ointments, consisting of 3 or 5% ethyl fumarate in petrolatum, developed symptoms of renal toxicity (9).

Organs and Systems

Skin

Topical monoethyl fumarate caused contact dermatitis in a patient with atopic eczema and a generalized, partly pustulous, exanthema in a patient with psoriasis (10). The authors suggested that the mechanism was non-immunological contact urticaria.

In 12 healthy volunteers, topical monoethyl fumarate caused spontaneous persistent erythema and systemic administration caused flushing (11). In patients with

© 2006 Elsevier B.V. All rights reserved.

urticaria pigmentosa the effect was significantly greater in the diseased skin than in the healthy skin, suggesting that monoethyl fumarate causes mast cell degranulation.

Furaltadone

General Information

Furaltadone, 5-morpholinomethyl-3-(5-nitrofurfurylidenamino)oxazolidin-2-one), is a crystalline antibiotic powder, which is added to animal feeds.

Organs and Systems

Immunologic

Furaltadone can provoke contact allergic reactions (1). A case of contact allergy to the antibiotic in eardrops, with positive patch tests, has been reported (2).

Furazolidone

General Information

Furazolidone is used in the treatment of giardiasis. Its adverse effects are usually mild and transient: abdominal discomfort, nausea, and vomiting. The urine may be dark-colored (SEDA-11, 597). Metabolites of furazolidone inhibit monoamine oxidase (1) and there is therefore the potential for interactions with foods containing tyramine (2) and with opioid analgesics; hyperpyrexia has been reported in rabbits that were given furazolidone and pethidine (3).

Furosemide

See also Diuretics

General Information

Furosemide is the classic member of the group of so-called high-ceiling or loop diuretics, which can achieve a much greater peak diuresis than the thiazides. It is widely and frequently used both orally and parenterally over a wider dosage range than the thiazide diuretics, because its concentration-effect curve is steeper and because it is effective in patients with moderate renal insufficiency (creatinine clearance 5–25 ml/minute), in

© 2006 Elsevier B.V. All rights reserved.

whom the thiazide diuretics and most related compounds are ineffective.

Furosemide is quickly and almost completely excreted by kidney unmetabolized. The usual oral dose is 20–120 mg, but much larger doses (for example 1000 mg) have been used in renal insufficiency. It is very effective after intravenous injection, and doses of 500 mg and more can be used in emergencies (renal insufficiency, pulmonary edema). The majority of adverse effects occur with the use of high doses, 95% of the reactions being dose dependent (1).

General adverse effects

Disturbances of fluid and electrolyte balance, such as hyponatremia, hypokalemia, and dehydration with circulatory disturbances (such as dizziness, postural hypotension, and syncope), have been reported. Rarely gastrointestinal symptoms are problems with high dosages and in the elderly. Pancreatitis and jaundice seem to occur more often than with the thiazide diuretics, but deterioration of glucose tolerance seems to be less common. At serum concentrations over 50 μg/ml, tinnitus, vertigo, and deafness, sometimes permanent, have been reported. Hematological disorders, particularly thrombocytopenia, and serious skin disorders occur occasionally, as do hypersensitivity reactions. Neither tumor-inducing effects nor second-generation effects have been documented.

Organs and Systems

Cardiovascular

Because furosemide, apart from its diuretic effect, has transient but pronounced vasodilator properties (changes in both venous capacitance and peripheral arteriolar resistance have been described in anephric patients), it can cause postural hypotension and syncope, particularly if given together with other blood pressure-lowering drugs (SED-8, 458) (SED-9, 349) (SED-9, 350). Ischemic complications have been reported in elderly patients. Reactions due to extracellular volume depletion accounted for 9% of all adverse effects observed in 535 patients treated with furosemide (1). Neuroendocrine activation and resultant increased peripheral resistance (afterload) after furosemide reduce cardiac output and stroke volume and increase cardiac work, with the possibility of worsening myocardial and tissue ischemia. Since many patients with heart failure have underlying myocardial ischemia or infarction, initial symptomatic benefit from furosemide can be followed by detrimental effects on myocardial perfusion, with extension or completion of myocardial necrosis.

When it is used in cardiac failure, furosemide acts in two ways: besides its diuretic effect it produces an immediate fall in left ventricular filling pressure, which is independent of and precedes diuresis. If furosemide is given intravenously in stable chronic heart failure (which it normally is not), this can be an unwanted effect, causing deterioration (SEDA-11, 199), particularly in patients with pure right ventricular failure.

Nervous system

Visual disturbances and drowsiness have been described, but it is not clear whether these were caused by reduced cerebral perfusion or by a direct effect of the drug itself.

Sensory systems

At high doses, and especially if serum concentrations are over 50 μg/ml, furosemide can cause ototoxic reactions, such as tinnitus, vertigo, and even deafness, sometimes permanent (SED-9, 351). Subclinical, audiometrically determined, high-tone deafness has been reported to occur in 6.4% of furosemide-treated patients (2). It is generally considered advisable to use another diuretic in patients whose hearing is already impaired, and to avoid using furosemide along with other ototoxic drugs, such as the aminoglycosides.

Sensorineural hearing loss occurs in a small proportion of very premature babies who are given furosemide. Various causative mechanisms have been suggested, including bilirubin, drugs, infection, and/or hypoxic brainstem injury. In a case-control study of 15 children and 30 controls born before 33 weeks of gestation, renal insufficiency and/or aminoglycoside use in conjunction with furosemide was associated with sensorineural hearing loss (3).

Endocrine

Furosemide rarely causes the syndrome of inappropriate antidiuretic hormone secretion (SIADH) (although it has been found useful in treating some patients with SIADH who cannot tolerate water restriction (4)). In furosemide-induced cases (SEDA-7, 246), serum ADH concentrations were raised, total body sodium was normal, total body potassium greatly reduced, and intracellular water raised at the expense of extracellular fluid volume. However, such cases are rare, and no new cases have been published since this complication was reported in SEDA-7.

Nutrition

Patients with congestive heart failure taking high doses of furosemide can develop thiamine deficiency, which is improved by thiamine supplementation. There is whole-blood thiamine phosphate deficiency, but no reduction in the storage form of thiamine, thiamine diphosphate. These observations suggest that thiamine supplementation may not be necessary in elderly patients taking furosemide for congestive heart failure (5).

Hematologic

Agranulocytosis, thrombocytopenia, and hemolytic anemia have been reported occasionally (SED-8, 484) (SED-9, 350) (SEDA-1, 180). The commonest complication is thrombocytopenia (6), although it is often mild and asymptomatic (7).

Gastrointestinal

With normal doses, nausea, vomiting, and diarrhea are very uncommon, accounting for less than 1% of all

© 2006 Elsevier B.V. All rights reserved.

adverse reactions (SED-9, 350). The incidence rises with higher doses and in the presence of uremia.

Liver

Although furosemide is very hepatotoxic in experimental animals, only a few cases of jaundice have been reported (SED-8, 484) (SED-8, 485), and no fully documented cases have so far been published. However, in patients with cirrhosis furosemide readily precipitates hepatic encephalopathy (SED-8, 485), even when low doses are used (1).

Biliary tract

Biliary colic has been attributed to furosemide (SED-11, 427).

Pancreas

Increases in serum isoamylase (SEDA-6, 213) and pancreatitis have been reported in patients taking furosemide.

Urinary tract

Excessive diuresis and dehydration often cause a transient reduction in glomerular filtration rate and a rise in serum urea (about 8% of all adverse reactions) (SED-8, 350). The sudden diuresis can cause loin pain, particularly in elderly patients, and acute urinary retention and overflow incontinence in elderly men with prostatic hyperplasia.

Although it is often described in children, medullary nephrocalcinosis with furosemide has been rarely described in adults.

- A 40-year-old woman who had taken furosemide (40–160 mg/day) for 15 years developed medullary nephrocalcinosis (8).

Chronic tubulointerstitial nephritis has been reported with furosemide.

- A 25-year-old woman developed biopsy-proven chronic tubulointerstitial nephritis with accompanying distal renal tubular acidosis in association with furosemide abuse (up to 1.2 g/day for several months) (9).

Four children with the nephrotic syndrome developed transient hypercalciuria and intraluminal calcification in renal histopathological specimens without radiological evidence of renal calcification. These children were resistant to corticosteroids and were receiving furosemide plus albumin for the management of edema (10). This result stresses the pervasive effect of furosemide, and probably all loop diuretics, in increasing urinary calcium excretion, with resultant nephrocalcinosis. Whenever possible, steps should be taken to limit the hypercalciuric effect of loop diuretics. Such maneuvers could include limiting the sodium content of the diet and/or combining the loop diuretic with a thiazide diuretic.

Skin

Rashes seem to be just as common with furosemide (SED-8, 484) as with other oral diuretics, but severe skin reactions (exfoliative dermatitis, erythema multiforme, acquired epidermolysis bullosa), which are rare with other diuretics, have been occasionally reported with high doses of furosemide in renal insufficiency (SED-12, 503) (SEDA-18, 234).

Cases of furosemide-induced lupus-like syndrome (11), bullous pemphigoid (12,13), and lichenoid drug eruptions (14) have been reported.

A review of furosemide-induced skin reactions included a description of a unique case of an 88-year-old man who developed an eruption that clinically and histologically simulated Sweet's syndrome (acute febrile neutrophilic vasculitis) after 6 weeks (15). Atypical features and rapid resolution suggested a drug eruption rather than true Sweet's syndrome. However, a similar mechanism may have been implicated a hypersensitivity reaction involving immune complexes.

Linear IgA bullous dermatosis associated with the administration of furosemide has been reported (16).

- An 86-year-old woman, with a history of stable schizophrenia, chronic obstructive pulmonary disease, ischemic cardiomyopathy, and type 2 diabetes, was admitted with cardiac insufficiency, which was treated by introduction of enalapril. A chest infection was treated with co-amoxiclav with gradual alleviation of symptoms over 10 days. At this point, furosemide was begun, because of persistent signs of heart failure. After 3 days, erythema and bullae were noted on her palms and soles, and later on the trunk, extremities, hard palate, and buccal mucosa. Biopsy showed the characteristic features of linear IgA bullous dermatosis, with linear deposition of IgA along the basement membrane. Co-amoxiclav and furosemide were withdrawn; no new lesions were noted thereafter.

Furosemide has previously been related to other bullous dermatoses, particularly bullous pemphigoid (SED-14, 671). In this case only a temporal relation was demonstrated, as rechallenge was judged to be unethical. The other putative offending drug, co-amoxiclav, was regarded as unlikely to be causative, because it had been given many times before without noticeable skin lesions.

Furosemide has been associated with disseminated superficial porokeratosis, a heritable disorder of cornification (17).

A man developed acute generalized exanthematous pustulosis while taking furosemide (18). A positive lymphocyte transformation test suggested an immunological mechanism.

Immunologic

It has long been thought that loop and thiazide diuretics pose a theoretical risk of cross-sensitivity in patients with sulfonamide allergy because of their common structures. However, the available literature does not provide sufficient numbers of well-documented cases to support this impression (19). It seems that careful administration of diuretics is permissible in patients with documented sulfonamide allergy, but as always such a drug challenge should not be attempted without careful follow-up. A furosemide rechallenge protocol, based on a method that has been used to rechallenge with a sulfa-containing antimicrobial agent, safely allowed the long-term reinstitution of loop diuretic therapy with furosemide (20).

© 2006 Elsevier B.V. All rights reserved.

Body temperature

Several cases of furosemide-associated fever have been reported (SEDA-20, 204) (SEDA-21, 229) (SEDA-22, 238). These had certain features in common: (1) the affected infants were in their first year of life; (2) there was congestive heart failure as a result of congenital abnormalities or cardiomyopathy; (3) the temperature was raised to 38.5–40°C and there was a resemblance to septic fever; (4) concomitant treatment with digoxin; (5) negative physical examination and investigations for a source of infection; (6) withdrawal of furosemide was followed by disappearance of fever within 1–2 days. In some cases, the use of furosemide in lower dosages or on alternate days avoided fever. The mechanism of this adverse effect is unclear, but it appears to be dose-related. Consideration of furosemide as a cause of fever in such patients may save unnecessary laboratory studies and lead to early resolution.

Long-Term Effects

Drug withdrawal

The more intensive diuretic treatment is the greater the risk from sudden withdrawal. In one series of 38 patients, taking 20–40 mg furosemide or equivalent, generally for heart failure, withdrawal was attempted when all had been free of heart failure or hypertension for at least 3 months; it was followed by clinical or radiological relapse in 29% and one of the patients died (21). In another five patients, withdrawal in three led to severe symptoms necessitating admission to hospital (SEDA-10, 192) (SEDA-10, 193). The best advice is to withdraw intensive diuretic treatment only with the utmost caution and not to attempt withdrawal at all if there is any radiological evidence of heart failure. In patients with congestive heart failure, independent predictors of the need for continued diuretic were furosemide dosage greater than 40 mg/day, a left ventricular ejection fraction less than 0.27, and hypertension (22).

The effects of furosemide withdrawal on postprandial blood pressure have been assessed in 20 elderly patients (mean age 73 years) with heart failure and preserved left ventricular systolic function (ejection fraction 61%) (23). In 13 who were able to discontinue furosemide (mean dose 32 mg/day), maximum systolic blood pressure fell significantly from 25 mmHg to 11 mmHg and diastolic blood pressure from 18 to 9 mmHg over 3 months. In the continuation group (mean furosemide dose 21 mg/day), there was no change in the postprandial fall.

However, there are sometimes opportunities for withdrawal of furosemide (SEDA-22, 237). If diuretics are withdrawn suddenly in patients with a normal sodium intake, there will be rebound retention of sodium and water, because compensatory mechanisms that maintain sodium balance in the face of diuretics continue to act for several days after the diuresis has worn off. There are two methods of mitigating rebound retention of sodium and water: gradual reduction of the dosage or institution of a low sodium diet so that only a small amount of sodium can be retained when the diuretic is withdrawn. Rebound retention of sodium and water, with consequent edema, may convince the doctor that continued diuretic therapy is necessary, and the patient is then committed to life-time exposure. Even in patients with heart failure, reduced intake of salt may remove the need for diuretics or allow the use of lower dosages.

Second-Generation Effects

Pregnancy

Although furosemide has embryotoxic properties in some animal species, it has been widely used in pregnant women without any adverse effects. Nevertheless, it should be used with great caution, since hypovolemia can lead to reduced uterine and placental blood flow. Careful monitoring of fetal heart action is necessary. Furosemide passes the placenta and increases fetal urine production. It can also increase acid concentrations in maternal serum, fetal serum, and amniotic fluid, thus masking a useful index for the development of pre-eclampsia (24). Its use in pregnant women should therefore be restricted to the treatment of cardiac failure.

Lactation

Furosemide passes into the breast milk in a concentration 80% of that in serum at pH 7.0, but the total amount of drug ingested is probably too low to affect the neonate (25).

Susceptibility Factors

Age

In premature infants furosemide can cause persistent patent ductus arteriosus (SEDA-9, 208). The use of furosemide in this age group needs to be re-evaluated (SEDA-14, 182) (SEDA-15, 217).

Renal disease

High doses of furosemide in uremia are potentially ototoxic (26).

Hepatic disease

Although high-dose furosemide can be very useful in incipient acute renal insufficiency, it should be used with extreme caution in patients with severe hepatic insufficiency (SEDA-14, 183) and not at all in hepatic coma.

Drug–Drug Interactions

ACE inhibitors

Acute renal insufficiency with severe hyponatremia has been attributed to vigorous diuretic treatment (metolazone, furosemide, spironolactone) with an ACE inhibitor (27). Because ACE inhibition impairs renal protection against reduced perfusion, the combination of an ACE inhibitor with high-dose furosemide causes a reduction in glomerular filtration rate linearly related to the change in blood pressure.

In congestive heart failure, single conventional doses of captopril (25–75 mg) attenuated the natriuretic response to furosemide, while a low dose (1 mg) significantly enhanced furosemide-induced natriuresis (SEDA-17, 268) (SEDA-18, 236). The mechanism of this interaction is uncertain, but captopril did not affect delivery of furosemide to its site of action (28). In the long-term, intensive treatment with captopril enhanced the natriuretic response to furosemide (SEDA-17, 268).

Allopurinol

Interstitial nephritis with granulomatous hepatitis has been attributed to an interaction of furosemide with allopurinol (29). As in previous reports (SEDA-11, 198) the evidence for this interaction is not convincing. The role of allopurinol in causing the illness is credible, but the role of furosemide is doubtful.

Aminoglycoside antibiotics

Furosemide increases the ototoxic risks of aminoglycoside antibiotics (30,31) by reducing their clearance by about 35% (32); permanent deafness has resulted from the use of this combination.

- A 60-year-old woman developed moderately severe sensorineural hearing loss bilaterally after receiving five doses of gentamicin and one of furosemide 20 mg (33).

The cumulative dose and duration of aminoglycoside therapy are more important than serum concentrations in the development of gentamicin ototoxicity, except when interacting medications such as furosemide are co-administered.

Aspirin

Furosemide inhibits the absorption of aspirin (34), and aspirin 75 mg/day and 300 mg/day inhibits the venodilator effect of furosemide (35). These data raise the issue of whether aspirin should be routinely used in patients with congestive heart failure using furosemide.

Cephaloridine

The nephrotoxic effects of cefaloridine are potentiated by concurrent administration of furosemide (36,37), perhaps by a direct interaction and probably also because furosemide lowers the clearance of the antibiotic (38). Such combinations are better avoided.

Digoxin

It is advisable to monitor serum potassium concentrations closely if furosemide is combined with any cardiac glycoside.

Lithium

Furosemide can cause lithium toxicity by inhibiting the renal tubular excretion of lithium ions (39).

Mannitol

The combination of furosemide with mannitol can rapidly cause acute renal insufficiency (40) and potentiate the effect of curare (41).

NSAIDs

Furosemide inhibits the absorption of indometacin (42), while the diuretic and hypotensive effects of most diuretics are blunted by indometacin and probably also other NSAIDs (43). Intravenous furosemide is commonly given to patients with acute heart failure to relieve pulmonary congestion. Symptomatic relief occurs before the onset of diuresis, and the beneficial effect is believed to result from a venodilator action of furosemide, which precedes its diuretic effect. This venodilator response is inhibited by indometacin, suggesting that it occurs through local prostaglandin release.

Furosemide inhibits the absorption of meloxicam (44), an NSAID that is relatively selective for COX-2, sparing the physiologically important isoform that mediates vasodilator prostaglandins, which maintain renal function.

Phenytoin

The diuretic response to furosemide is reduced by approximately 50% during concurrent administration of phenytoin (45), probably through reduction of furosemide absorption (46).

Potassium-wasting drugs

The hypokalemic effects of furosemide can be potentiated by drugs such as licorice (47) and carbenoxolone (48).

Theophylline

Furosemide increases steady-state theophylline concentrations (SED-11, 428) (SED-14, 673).

A randomized, controlled study has shown an enhanced diuretic response to furosemide in infants taking theophylline during extracorporeal membrane oxygenation (49). The underlying mechanism was uncertain, but may have been an increase in glomerular filtration rate.

Thiazide diuretics

The use of thiazide and loop diuretics in combination to treat resistant hypertension often causes severe deterioration in renal function (50,51). It is not clear whether this is the result of excess diuresis or excessive blood pressure reduction.

Vancomycin

Ten preterm infants receiving regular theophylline for apnea of prematurity, who subsequently received vancomycin and furosemide, have been studied (52). When vancomycin was introduced in the infants who were established on furosemide and theophylline, there was a consistent failure to achieve therapeutic concentrations. Starting furosemide in infants who were already receiving vancomycin resulted in falls in serum vancomycin to subtherapeutic concentrations in all but one case. Serum concentrations fell by a mean of 24% (range 12–43%), in the 24 hours after the start of furosemide treatment. Two of the 10 infants had persistence

© 2006 Elsevier B.V. All rights reserved.

of coagulase-negative staphylococcal sepsis while vancomycin concentrations were suboptimal. While the mechanism of this interaction is uncertain, the changes in serum vancomycin concentration may indicate acute changes in glomerular filtration rate. Preterm infants receiving theophylline and furosemide need shorter vancomycin dosage intervals to avoid therapeutic failure.

Warfarin

In patients taking warfarin, furosemide, like other diuretics, reduces the prothrombin time without changing the plasma warfarin concentration (SEDA-22, 238). The reduced anticoagulant effect is probably secondary to diuretic-induced volume depletion, mediating increases in clotting factors. Any effect is likely to be short-lived.

Fusidic acid

General Information

Fusidic acid is the best-known representative of a group of antibiotics with steroid structures, which are eliminated primarily by biliary excretion as microbiologically inactive metabolites. The antibacterial action of fusidic acid is bacteriostatic, although it can be bactericidal at higher concentrations. It exerts its antibacterial effect by inhibiting protein synthesis, but the exact mechanism by which this inhibition occurs has not yet been elucidated. It has a narrow antibiotic spectrum, with a bacteriostatic or slow bactericidal effect mainly directed at both coagulase-negative staphylococci and *Staphylococcus aureus* (1). Fusidic acid may also have a role as a clinically useful suppressor of immunoinflammatory processes (2).

Fusidic acid is adequately absorbed from the gastrointestinal tract, but has also been used topically. It has the important property of good tissue penetration, including entry into bones and joints, but does not reach the cerebrospinal fluid. Elimination of fusidic acid is primarily by non-renal mechanisms, and a proportion is metabolized to several breakdown products detectable in bile. Systemic clearance is increased by hypoalbuminemia, reduced by severe cholestasis, and is unchanged in renal insufficiency (3).

General adverse effects

The most common adverse effects of fusidic acid are minor and are related to the gastrointestinal tract (discomfort, diarrhea). Rare adverse events include granulocytopenia, thrombocytopenia, venous spasm, and skin reactions (4). Fusidic acid has detergent properties and can cause hemolysis when injected intravenously or can induce tissue damage when given intramuscularly. However, its systemic toxicity is relatively low.

Bacterial resistance has been an obstacle to the widespread use of fusidic acid; it develops in a single step in vitro and has also been observed in patients, particularly during prolonged administration (5).

Organs and Systems

Gastrointestinal

Oral fusidic acid can cause *Klebsiella oxytoca*-associated colitis (6).

Liver

Fusidic acid is chemically very similar to bile acids and hence competes with them for elimination and metabolism. A patient with a past history of alcohol-induced cirrhosis developed cholestatic jaundice after taking oral fusidic acid for 2 days (7).

Urinary tract

Severe hypocalcemia and acute renal insufficiency developed in two diabetic patients who took oral fusidic acid 500 mg tds (8).

Skin

Acanthosis nigricans has been associated with fusidic acid (9).

Sensitization to sodium fusidate is rare, and most often found in patients with stasis dermatitis or atopic dermatitis.

- Allergic contact dermatitis has been reported in a 26-year-old Korean woman after treatment of an abrasion

© 2006 Elsevier B.V. All rights reserved.

on the left knee with fusidic acid ointment and povidone iodine (Betadine) (10). The diagnosis was confirmed by a strongly positive patch test for sodium fusidate.

Immunologic

Fusidic acid may have an immunomodulatory effect that seems to be partly mediated by suppression of cytokine production. The effect on several diseases has been investigated, but it remains to be characterized more in detail whether there is any therapeutic usefulness (4).

Positive patch tests occurred in three of 1119 patients who had used topical fusidic acid (11). In the second part of this study, all cases of positive patch tests to fusidic acid over the previous 20 years were reviewed; the average frequency was 1.62 patch-tested patients per year (1.45%) of those who were patch-tested.

Long-Term Effects

Drug tolerance

Mechanisms of resistance to fusidic acid include alterations in elongation factor G (whose inhibition at the ribosome level mediates the effect of fusidic acid), altered drug permeability, binding by chloramphenicol acetyltransferase type 1, and enhanced efflux (12).

Most studies show low levels of resistance in staphylococci, with a slightly higher rate in methicillin-resistant *S. aureus* (MRSA) (12). This has been confirmed in recent studies. Only 1 of 106 isolates of methicillin-resistant *S. aureus* was also resistant to fusidic acid (13). Only very little resistance to fusidic acid has been reported from Wales (14). However, clonal spread of fusidic acid-resistant methicillin-resistant *S. aureus* has been documented in Norway (15). A resistance rate of about 50% has been found in coagulase-negative staphylococci isolated in eight Swedish intensive care units between 1995 and 1997 (16). A high rate of resistance to fusidic acid was also found in bacteria that were cultured from blood after dental treatment (17).

Pathogenic nocardia may inactivate fusidic acid (18). In an in vitro study, salicylate and related compounds increased the MIC in strains of *S. aureus* both resistant and susceptible to fusidic acid (19).

In a prospective randomized trial, oral fusidic acid alone (500 mg tds for 7 days) failed to eradicate methicillin-resistant *S. aureus* colonization but resulted in the emergence of fusidic acid-resistant strains (20).

In an in vitro susceptibility study of 170 clinical isolates of *Mycobacterium tuberculosis* to fusidic acid, 19 isolates were resistant to at least one first-line antituberculosis drug (21). In all, 1.8% of the isolates were resistant to fusidic acid. Fusidic acid can be a potential supplementary drug for the treatment of infections due to multidrug-resistant strains of *M. tuberculosis*.

Susceptibility Factors

Other features of the patient

The half-life of fusidic acid was shortened in ten patients with severe burns treated with 500 mg tds intravenously (22). This effect may be explained by translesional extrahepatic clearance and an increase in hepatic clearance.

Drug–Drug Interactions

HIV protease inhibitors

In a 32-year-old man infected with HIV plasma concentrations of ritonavir, saquinavir, and fusidic acid were significantly raised when these drugs were administered in combination, possibly from mutual inhibition of metabolism (23).

Phenazone

Activation of the CYP450 enzyme system, demonstrated by an increase in the metabolism of phenazone (antipyrine), has been found in 30 HIV-positive drug abusers (24). This activating effect was demonstrated after 28 but not after 14 days of treatment with fusidic acid 500 mg/day, suggesting time dependency.

Statins

Acute rhabdomyolysis has been attributed to an interaction of fusidic acid with simvastatin (25).

- A 66-year-old kidney transplant recipient developed a gangrenous lesion on the left foot infected with *S. aureus* and *Escherichia coli*. He was given ciprofloxacin and clindamycin for 6 weeks and then fusidic acid 1500 mg/day for 2 weeks. He became ill, with myalgia and no active movement of his legs, and rhabdomyolysis was established by laboratory tests. He had also taken atorvastatin 10 mg/day and he slowly recovered after withdrawal of both atorvastatin and fusidic acid.

The authors identified only one previous report of a patient with rhabdomyolysis who had taken simvastatin and fusidic acid.

Gabapentin

See also Antiepileptic drugs

General Information

Gabapentin is used as adjunctive treatment for partial seizures and may be useful in some non-epileptic disorders, such as neuropathic pain. It has a favorable tolerability profile and is devoid of significant interactions with other anticonvulsants (1).

The use of gabapentin has been reviewed (2). Its adverse effects are limited to neuropsychological disorders, namely dizzy spells, drowsiness, fatigue, and headache. The risk of interactions is also limited.

The efficacy of gabapentin in dosages up to 3600 mg/day as adjunctive therapy has been studied in 2016 patients with partial seizures (3). The four most commonly reported adverse events were somnolence (15%), dizziness (10%), weakness (5.8%), and headache (4.5%).

In an uncontrolled trial using dosages up to 6000 mg/day in 50 patients with refractory partial epilepsy, tiredness, dizziness, headache, and diplopia were the most common adverse effects (4). At dosages above 3600 mg/day three patients developed flatulence and diarrhea and two had myoclonic jerks. At least in some patients, gabapentin gastrointestinal absorption did not become saturated within the explored dosage range.

The effectiveness of gabapentin has been studied in 22 patients with bipolar disorder who had an incomplete response to other mood stabilizers (5). Somnolence was common (six patients); adverse events that occurred in two patients each included irritability, memory impairment, headache, and tremor. One patient dropped out because of a mild rash.

In 237 children aged 3–12 years with refractory partial seizures gabapentin 24–70 mg/kg/day was used as add-on therapy over 6 months (6). There was a more than 50% reduction in partial seizures in 34% of the children. Somnolence was the most common adverse event related to gabapentin. Emotional lability and hostility were related to gabapentin in 3.4 and 3.0% of the patients respectively.

In a non-interventional observational cohort study, using the technique of prescription-event monitoring, patients taking gabapentin were identified from dispensed National Health Service prescriptions (7). Outcome data were obtained from questionnaires sent to the doctor 6 months after the initial gabapentin prescription. The cohort included 3100 patients, of whom 136 (4%) were children. The median duration of treatment was 8.1 months. The most frequently reported adverse events during the first month of treatment were neurological: drowsiness/sedation (6.7% of patients), headache/migraine (3.6%), malaise/lassitude (3.5%), dizziness (2.4%), and nausea/vomiting (2.6%). These events were also the commonest reasons for withdrawal of gabapentin and were reported as suspected adverse drug reactions. There were no congenital anomalies in the 11 babies born to women who used gabapentin during the first trimester of pregnancy. The crude mortality rate was five times that in the general population but similar to that in other published studies in patients with epilepsy. Thus, this report does not disclose new unrecognized adverse effects of gabapentin.

Comparative studies

Gabapentin and lamotrigine have been compared in an open, parallel-group, add-on, randomized study in 109 patients with uncontrolled partial epilepsy and learning disabilities (8). The two drugs were similarly efficacious, with similar incidences of adverse events and serious adverse events. Neither lamotrigine nor gabapentin exacerbated any of the challenging behaviors observed in these patients. The most common adverse effect of gabapentin was somnolence, which was mostly reported during the initial titration phase.

In a double-blind comparison of gabapentin and lamotrigine in 309 patients with new-onset partial or generalized seizures, the target doses were gabapentin 1800 mg/day and lamotrigine 150 mg/day (9). Severe adverse events were reported in 11% of patients taking gabapentin and 9.3% of patients taking lamotrigine. Two patients had serious adverse events thought to be related to the study drug; one took an overdose of gabapentin and the other had convulsions with lamotrigine. The most frequent treatment-related adverse events in both treatment groups were dizziness, weakness, and headache; 11% of patients taking gabapentin and 15% of those taking lamotrigine withdrew because of adverse events. There was an increase of over 7% in body weight from baseline in 14% of the patients taking gabapentin and 6.6% of those taking lamotrigine. There were benign skin rashes in 4.4% of those taking gabapentin and 11% of those taking lamotrigine.

Organs and Systems

Ear, nose, throat

Rhinitis is uncommon with gabapentin (10).

Nervous system

Drowsiness, dizziness, fatigue, or ataxia are seen in 10–20% of patients who use gabapentin (SEDA-19, 70) (SEDA-20, 62) (10). Of 240 adults followed for about 1 year, only 4% discontinued treatment because of adverse events (SEDA-19, 70). Adverse effects reported by more than 10% of patients were nystagmus, somnolence, diplopia, tremor, ataxia, and dizziness.

Gabapentin occasionally exacerbates absence and myoclonic seizures and causes de novo myoclonus (SEDA-21, 71). Myoclonus has been studied in 104 patients taking gabapentin for epilepsy (11). There were 13 cases of mild myoclonus, which did not significantly interfere with daily activities. All the patients had refractory epilepsy and were taking other antiepileptic drugs. Six had a severe chronic static encephalopathy; five had no medical diagnosis other than seizures. Ten developed multifocal myoclonus and three developed focal myoclonus, contralateral to their epileptic focus. Two had an

© 2006 Elsevier B.V. All rights reserved.

exacerbation of pre-existing myoclonus. Withdrawal led to rapid resolution.

Choreoathetosis, dyskinesias, dystonic or myoclonic movement disorders (including oculogyric crises), and stuttering have been reported rarely (SEDA-21, 71) (SEDA-22, 87).

- Sensory neuropathy occurred in a 58-year-old man who had been given up to 2400 mg/day for over 5 months for the treatment of head pain (12). A mild pruritic rash had been present since starting treatment. Neuropathic symptoms included a burning sensation in the legs and hips. After withdrawal, reduced perception of tactile and noxious stimuli and neurogenic bladder dysfunction (with an associated syncopal episode) were recorded. The neuropathy improved over several months.

Gabapentin is used often to treat neuropathic pain, and its role in causing the sensory neuropathy in this patient was uncertain.

Gabapentin-induced myoclonus may be more common than initially thought. In a retrospective survey, 13 of 104 consecutive patients developed myoclonus at gabapentin dosages of 800–3200 mg/day (11). Six of the patients had severe chronic static encephalopathy. Three had focal myoclonus, contralateral to the epileptic focus, and two had exacerbation of pre-existent myoclonus. In all cases the myoclonus was mild and did not interfere with daily activities. The fact that in three patients the electroencephalogram did not show epileptiform discharges suggests that, at least in some cases, the myoclonus is non-epileptic in nature.

In a comparison of twice- and thrice-daily gabapentin, 29 stable responders were selected and followed for 3 months (13). The mean number of seizures per month was 4.2 at baseline, 1.0 during the thrice-daily and 0.9 during the twice-daily period. Adverse effects were reported by 11 patients during the thrice-daily period and by five patients during the twice-daily period; sedation and vertigo were the most frequent.

The efficacy and safety of gabapentin in relieving the symptoms of panic disorder have been studied in 103 patients in a randomized, placebo-controlled, double-blind study for 8 weeks (14). Adverse events included somnolence, headache, and dizziness. One patient had a serious adverse event, a car accident, while taking gabapentin.

Of 12 patients with moderate to severe dementia and severe behavioral disorders given gabapentin (200–1200 mg/day) for 8 weeks, 5 had adverse events such as gait instability, emotional instability, and sedation; two patients discontinued treatment prematurely because of severe adverse effects (15).

The role of gabapentin in patients with neuropathic pain has been evaluated in a systematic review (16). The most common adverse events were dizziness and somnolence, which occurred in about 25% of patients; ataxia occurred in about 8%. Adverse effects were dose-related.

- A 68-year-old man with essential tremor who was taking propranolol 80 mg/day had several daily episodes of paroxysmal dystonic movements in both hands 2 days after the addition of gabapentin 900 mg/day (17). The dose of propranolol was reduced to 40 mg/day and the dystonic movements resolved. The authors suggested that there had been a synergistic effect between propranolol and gabapentin.
- A 60-year-old woman with post-herpetic neuralgia developed asterixis after having taken gabapentin for 4 days (18). The authors proposed that the mechanism was GABAergic.

Two cases of gabapentin-related dyskinesia have been reported (19). The patients were 60 and 41 years old and took gabapentin 900–1200 mg/day for generalized anxiety. Generalized dyskinetic movements and facial tics appeared after 3 days and disappeared after 2 days of withdrawal.

Psychological, psychiatric

Gabapentin has rarely been implicated in psychiatric reactions. Two cases, one of mania (20) and one of catatonia (21), have been reported.

- A 35-year-old woman with epilepsy without a history of psychiatric disorders developed elevated mood after being stabilized on gabapentin monotherapy (3200 mg/day). After 5 months she developed a manic episode, which remitted when gabapentin was withdrawn.
- Catatonia was reported in a 48-year-old woman with bipolar disorder within 48 hours of withdrawal of gabapentin, 500 mg/day. The condition lasted for several days and disappeared after treatment with a benzodiazepine.

In the first case the presentation was strongly suggestive for a causative role of the drug. In the second it was speculated that the condition might have been provoked by altered GABAergic transmission after gabapentin withdrawal.

Two women, aged 37 and 38 years, took gabapentin and after a few days developed behavioral changes associated with euphoria (22). In one case the symptoms were transient and in the other they resolved after withdrawal. The behavioral changes were not related to seizure activity.

In a double-blind, crossover comparison of the cognitive effects of carbamazepine (mean dose 731 mg/day) and gabapentin (2400 mg/day), each given for 5 weeks, in 35 healthy volunteers performance on gabapentin was better than on carbamazepine for 8 of 31 variables (visual serial addition test, choice reaction times at initiation and total, memory paragraph I and delayed recall, Stroop Word and Interference, Vigor measure), whereas carbamazepine was better than gabapentin on none (23). Although these data suggest that gabapentin produces fewer cognitive effects than carbamazepine, the applicability of the findings to long-term therapy in epileptic patients is uncertain.

Behavioral disturbances, including aggressiveness, irritability, hyperactivity, and/or dysphoric changes, occur in up to 22% of patients. Children and patients with mental retardation or a history of similar disorders may be at special risk (SEDA-20, 61). In a recent study, hyperactivity, irritability, and agitation occurred in 15 of 32 mostly

© 2006 Elsevier B.V. All rights reserved.

mentally retarded children, and required drug withdrawal in four (24).

The cognitive effects of carbamazepine and gabapentin have been compared in a double-blind, crossover, randomized study in 34 healthy elderly adults, of whom 19 subjects withdrew (15 while taking carbamazepine, probably due to excessively rapid dosage titration) (25). The primary outcome measures were standardized neuropsychological and mood state tests, yielding 17 variables. Each subject had cognitive testing at baseline (pre-drug), the end of the first drug phase, the end of the second drug phase, and 4 weeks after completion of the second drug phase. Adverse events were frequently reported with both antiepileptic drugs, although they were more common with carbamazepine. There were significant differences between carbamazepine and gabapentin for only 1 of 11 cognitive variables, with better attention/vigilance for gabapentin, although the effect was modest. Both carbamazepine and gabapentin can cause mild cognitive deficits in elderly subjects, and gabapentin has a slightly better profile.

Gabapentin has been associated with hostility, especially in children. Two cases of aggression in adults taking gabapentin for bipolar disorder have been reported (26). Neither patient had a history of aggression. In one the symptoms appeared after 3 days of treatment (1200 mg/day), and in the other after 48 hours (600 mg/day). In the second case, aggression was associated with auditory hallucinations. It is hard to associate new antiepileptic drugs with psychiatric adverse effects in patients with severe psychiatric disorders, and rechallenge with the offending drug should ideally have been tried before postulating a causal relation.

Endocrine

A 28-year-old woman with bipolar depression developed clinical and biochemical evidence of hyperthyroidism, ascribed to thyroiditis, while taking gabapentin (4800 mg/day) in a clinical trial (27). The condition cleared after withdrawal, and subsequent exposure to a lower dose of gabapentin (1500 mg/day) was uneventful.

Whether gabapentin was responsible for the thyroiditis is doubtful.

Metabolism

Weight gain occurs in up to about one-third of patients and may be more frequent at high dosages (SEDA-20, 61) (SEDA-22, 87). Of 44 patients given mean dosages of 3520 mg/day for at least 12 months, 10 gained more than 10% and 15 gained between 5 and 10% of their initial weight (28). The weight gain started after 2–3 months and tended to stabilize after 6–9 months.

Hematologic

In one case of reversible granulocytopenia attributed to gabapentin, cause and effect was dubious (SEDA-22, 88).

Gastrointestinal

Nausea and vomiting are uncommon with gabapentin (10).

Liver

Hepatotoxicity is exceedingly rare. The role of gabapentin in one patient with markedly raised liver enzymes after 12 weeks of treatment was unclear (SEDA-22, 88).

Gabapentin-induced cholestasis has been reported (29).

- A 50-year-old man was given gabapentin for diabetic neuropathic pain. He had also taken metformin, amitriptyline, dihydrocodeine (30 mg as required), and ramipril for over 12 months. After taking the gabapentin for 2 weeks, he developed clinical and biochemical evidence of cholestasis. Liver function tests were: bilirubin 199 μmol/l, aspartate transaminase 104 U/l, alkaline phosphatase 210 U/l, and gamma-glutamyltransferase 839 U/l. He had negative hepatitis A, B, and C serology and negative antinuclear antibody and anti-smooth muscle antibody. A blood count, renal profile, and liver ultrasound scan were also normal. A liver biopsy showed normal liver architecture with evidence of patchy steatosis, cholestasis, and some foci of chronic inflammation, thought to be consistent with a drug-induced etiology. Gabapentin was withdrawn and his symptoms and liver function tests improved gradually over 7–12 weeks.

The authors attributed the cholestasis to gabapentin because of the temporal relation. However, they failed to mention whether they withdrew other concomitant medications that could also have caused liver damage, a more likely explanation. Moreover, the number of dihydrocodeine tablets the patient took before admission was not stated.

Urinary tract

Urinary incontinence occurs rarely (SEDA-22, 88). Of 119 adults with partial seizures, 5 (4%) developed urinary incontinence which resolved after gabapentin withdrawal (30). Four of the five patients had signs of spasticity, suggesting that this may be a predisposing factor.

- A 27-year-old man with bipolar disorder had an increased serum creatinine concentration (up to 1.7 mg/dl, 150 μmol/l) after taking gabapentin 2000 mg/day for several weeks, the change being reversible after drug withdrawal (31).

The possibility of renal dysfunction as a rare adverse effect should be considered. The patient had a history of allergic reactions to lithium, carbamazepine, clozapine, haloperidol, and lamotrigine.

A renal transplant recipient with a long-term stable functioning allograft developed reversible acute renal dysfunction after beginning gabapentin therapy for chronic pain in diabetic neuropathy (32). The authors suggested that this was due to renal afferent vasoconstriction.

Patients on chronic hemodialysis are at risk of gabapentin toxicity. A patient undergoing hemodialysis and

© 2006 Elsevier B.V. All rights reserved.

taking gabapentin 400 mg/day developed a very high serum concentration (56 μg/ml) and clinical toxicity manifested by stupor (33). A subsequent pharmacokinetic analysis suggested that in patients undergoing chronic hemodialysis, gabapentin should be started at 300 mg/day and post-hemodialysis dosing should be reduced to 100 mg/day, at least in some patients.

Skin

Skin rashes are rare with gabapentin.

There has been one case of diffuse alopecia reversible after drug withdrawal (SEDA-22, 88).

- A 32-year-old woman with HIV infection and cerebral toxoplasmosis developed histologically confirmed Stevens–Johnson syndrome after taking gabapentin (300–900 mg/day) for 3 days (34). Although other drugs were given, the condition resolved after withdrawal of gabapentin alone.

Whether the underlying condition played a role is open to speculation.

- In a 26-year-old woman who had severe Stevens–Johnson syndrome induced by phenytoin and later by carbamazepine, gabapentin resulted in an erythematous pruriginous skin eruption limited to the legs without mucosal involvement (35).

Although gabapentin has a lower allergenic potential than most other anticonvulsants, patients with a history of severe drug-induced idiosyncratic reactions may be at higher risk of gabapentin-induced skin reactions.

Sexual function

Anorgasmia has been quoted in the Physicians Desk Reference as an infrequent adverse effect.

- Anorgasmia was reported by a 52-year-old man while he was taking gabapentin, 900–1500 mg/day, for the treatment of neuropathic pain (36). The condition lasted for over 2 months and remitted when gabapentin was replaced with mexiletine.
- A 25-year-old man taking gabapentin 900 mg/day reported anorgasmia during sexual intercourse (37). He was given valproate instead and his symptom resolved within 12 days.
- Gabapentin-induced anorgasmia and reduced libido have been reported in two women (38). Both were taking relatively low doses of gabapentin (900–1800 mg). In one case the symptoms disappeared with dosage reduction but in the other gabapentin had to be withdrawn.

Immunologic

- A hypersensitivity syndrome secondary to gabapentin has been described in a 72-year-old patient after 9 days (39). The symptoms (altered mental status, fever, diffuse macular rash, and an enlarged spleen) resolved after withdrawal.

However, the concomitant use of levofloxacin made the association of gabapentin with the hypersensitivity syndrome unclear.

Body temperature

Gabapentin may be effective in the treatment of hot flushes (hot flashes), and by the same token has been reported to have increased the frequency of hypothermic episodes in a 38-year-old man with hypothalamic dysfunction (40).

Long-Term Effects

Drug withdrawal

Three cases of withdrawal symptoms after abrupt withdrawal of high-dose gabapentin have been reported in adults with psychiatric conditions (41). The patients were restless and anxious, with sweating and tachycardia. The symptoms improved after gabapentin was reintroduced.

Drug Administration

Drug dosage regimens

Two different regimens of add-on gabapentin have been compared in a double-blind, randomized trial (42). In 574 patients randomized to either slow initiation (300 mg on day 1, 600 mg on day 2, then 900 mg/day) or rapid initiation (900 mg/day immediately after the placebo lead-in), the four most common adverse events, which occurred equally in the two groups, were somnolence, dizziness, ataxia, and fatigue. The frequency of adverse events in a subgroup of elderly patients was similar to that in younger adults.

Drug overdose

- A 30-year-old woman with renal insufficiency on hemodialysis three times a week suffered no significant toxicity after ingesting 600 mg tds of gabapentin for 3 weeks, a large dose in view of her impaired kidney function (43). The blood gabapentin concentration was 496 μmol/l.

These data suggest that gabapentin poses no major risk in overdose, partly because large doses are poorly absorbed.

Gadolinium

General Information

Gadolinium chelates for MRI (SEDA 18, 446) (SEDA-20, 419) (SEDA-21, 475) (SEDA-22, 503) are inert, non-metabolized, small molecules, with essentially the same pharmacokinetic properties as the iodinated contrast agents. They are rapidly distributed in the extracellular fluid spaces, both intravascular and extravascular, although they do not cross the normal blood–brain barrier, and are almost entirely excreted by glomerular filtration, with no significant active tubular excretion or re-absorption. Hepatic excretion occurs in patients with

© 2006 Elsevier B.V. All rights reserved.

severely impaired renal function, and trace amounts are normally excreted in the saliva, sweat, and tears (SEDA-21, 475).

Gadolinium-based contrast agents of intermediate size act like blood-pool contrast agents during the first pass (1). However, because they diffuse into the interstitium, they later act like extracellular agents. Examples are P760 (gadolinium tetra-azacyclododecanetetra-acetic acid, Gd-DOTA) and Gadomer-17 (gadolinium diethylenetriaminepenta-acetic acid, Gd-DTPA). Intermediate-sized agents are used for the following purposes:

- the detection of small, slow-flowing, tortuous vessels;
- the detection of increased capillary permeability in sufficiently injured tissues;
- improved and prolonged demonstration of zones of myocardial ischemia;
- estimating myocardial blood flow;
- tumor characterization.

The classical macromolecular blood-pool contrast agents are based on gadolinium DTPA or gadobenate dimeglumine, which are linked to albumin, dextran, or polylysine (1). Albumin-based agents are not considered optimal for clinical development, as it is difficult to obtain highly consistent synthetic products. There are also problems with cardiovascular toxicity and retention of gadolinium in bones and liver. Dextran-based agents appear to be safer, and an agent called CMD-A2-gadobenate dimeglumine (CMD = carboxymethyldextran) has a favorable toxicity profile.

Gadolinium chelates include ionic high-osmolar agents, such as gadolinium pentetate dimeglumine (Gd-DTPA) and low osmolar non-ionic agents, such as gadodiamide. They generally have similar MR relaxivities, pharmacokinetics, and biodistribution, behaving as non-specific extracellular fluid space agents analogues to iodinated contrast media. The similar safety and efficacy of ionic and non-ionic gadolinium-based extracellular contrast agents suggests that the choice of contrast medium will in future be determined by economic rather than clinical considerations (2).

The use of gadolinium-based contrast agents as an alternative to iodinated contrast agents has been reported in a patient with a history of allergy to the latter (3).

- A 77-year-old woman had a gadolinium-enhanced MRI scan followed by gadolinium-enhanced spiral CT pulmonary angiography for suspected pulmonary embolism. Gadodiamide 0.4 mmol/kg (60 ml) was injected intravenously at a rate of 2 ml/second. There were no adverse reactions.

Note on brand names

The various gadolinium salts are often known by their brand names, because their chemical names are complex. The following is a key to various brand names:

- AngioMARK: gadofosveset
- Dotarem, Guerbet SA: gadolinium tetra-azacyclododecanetetra-acetic acid (Gd-DOTA)
- Gadovist: gadobutrol (Gd-BT-DO3A)
- Magnevist: gadopentetate dimeglumine; the di-*N*-methylglucamine salt of gadopentetate (gadolinium diethylenetriamine penta-acetic acid, Gd-DTPA)
- MultiHance: gadobenate dimeglumine (Gd-BOPTA)
- Omniscan: gadodiamide
- OptiMARK: gadoversetamide (Gd-DTPA-BMEA).
- Primovist (Eovist): gadoxetic acid
- ProHance: gadoteridol.

Comparative studies

In a multicenter, randomized, double-blind comparison of the safety, tolerability, and efficacy of gadoversetamide (a non-ionic gadolinium chelate) and gadolinium DTPA in 99 patients during contrast-enhanced hepatic imaging, both agents were well tolerated and there were no serious or unexpected adverse events (2). A total of 154 adverse events were recorded in 82 patients, of which 33 (21%) were thought to be related to either agent. Headache and taste disturbances were the most common adverse effects; they occurred in about equal frequency in the two groups. There were no clinically relevant changes in electrocardiography or any laboratory parameter in either group.

The efficacy and the safety of gadoversetamide and gadopentetate dimeglumine have been compared in a multicenter, randomized, double-blind, parallel-group study in patients with suspected central nervous system pathology who required MRI examination (4). They were randomized to receive 0.1 mmol/kg of either gadoversetamide ($n = 262$, aged 1–80 years, mean volume of contrast medium injected 15 ml) or gadopentetate dimeglumine ($n = 133$, aged 20–73 years, mean volume of contrast medium injected 16 ml). There were no significant differences in adverse effects or diagnostic efficacy between the two groups. Of those given gadoversetamide, 71 patients (27%) had adverse events, severe in only 5 (1.9%). Of those given gadopentetate dimeglumine, 31 patients (23%) had adverse events, severe in only 5 (3.8%). The adverse effects included headache, chest pain, taste disturbance, and leg cramps.

In controlled studies, gadobenate dimeglumine has been compared with gadolinium chelates in 222 patients and with placebo in 189 patients (5). There were no serious events and no differences in the incidence of adverse effects between the groups. Adverse effects included vomiting, dizziness, and rashes. Similarly, there were no differences between children and adults or between subjects with renal or liver insufficiency. The authors concluded that gadobenate dimeglumine is safe, with a very low incidence of serious events, and that it compares favorably with other MR contrast agents, such as gadolinium DTPA.

Gadobenate dimeglumine, in cumulative doses of 0.15 and 0.2 mmol/kg, has been compared with gadodiamide 0.3 mmol/kg in 205 patients (aged 20–88 years) with suspected central nervous system lesions (6). Gadobenate dimeglumine was well tolerated and the safety profile was similar to that observed with gadodiamide. In the three groups, adverse effects occurred in 28, 23, and 32% respectively. The most common adverse events of gadobenate dimeglumine were headache (16%), dizziness (4.6%), and taste disturbances (4.6%); the most common adverse events of gadodiamide were headache (7.2%),

© 2006 Elsevier B.V. All rights reserved.

nausea (5.8%), and taste disturbances (5.8%). All adverse events were classified as mild to moderate. There were no significant changes in vital signs, hematology, or serum chemistry in any group. There were no significant differences in the diagnostic quality of the examination.

General adverse effects

The reported rate of adverse reactions of gadolinium chelates at a dose of 0.1 mmol/kg is 2.4%. Most of these reactions tend to be mild and do not require treatment (SEDA-15, 505). Serious reactions are extremely rare. However, several severe anaphylactoid reactions and angioedema have been reported (SED-12, 1187) (SEDA-16, 537) (SEDA-17, 538) (SEDA-18, 446) (7). The incidence of adverse effects is slightly higher in patients with a history of asthma or allergy (3.7%). For patients with a history of a previous reaction to an MRI or iodinated X-ray contrast agent, the reported adverse reaction rates were 21 and 6% respectively (SEDA-20, 419). Adverse effects at a dose of 0.3 mmol/kg included urticaria, vomiting, diarrhea, flushing, paresthesia, and headache, which have previously been reported with standard doses. The most common adverse effects were nausea and a metallic taste. In a study of 79 patients given 0.3 mmol/kg no adverse effects were recorded (SEDA-22, 503).

There is no significant difference in the incidence of adverse effects between ionic and non-ionic gadolinium chelates (SEDA-21, 483).

Gadobenate dimeglumine (Gd-BOPTA)

Gadobenate dimeglumine is a novel paramagnetic contrast agent that combines the properties of a conventional extracellular contrast agent with those of a liver-specific contrast agent. It has potential for both hepatic and non-hepatic targeted imaging. Unlike standard gadolinium chelates, which are excreted by the kidneys, 3–5% of gadobenate dimeglumine is taken up by functioning hepatocytes and is excreted unchanged in the bile. It also has an inherently higher T1 relaxivity than conventional gadolinium chelates, and so causes very marked enhancement of the liver parenchyma on T1 images, which persists for up to 2 hours. Liver tumors generally do not contain functioning hepatocytes and therefore do not take up gadobenate dimeglumine; they therefore appear as unenhanced hypointense lesions.

In 74 patients over the age of 18 years with possible metastatic brain disease, a total cumulative dose of 0.2 mmol/kg of gadobenate dimeglumine injected intravenously over 20 minutes was safe and enhanced the assessment of brain secondaries (8).

The safety and efficacy of gadobenate dimeglumine in phase 1, 2, and 3 studies have been reviewed in 732 patients, of whom 168 received 0.05 mmol/kg and 564 received 0.1 mmol/kg (9). The overall incidence of adverse events was 14% with the lower dose and 9.9% with the higher dose. The vast majority of events were mild, transient, and self-limiting. There were no sex-, age-, or dose-related differences and no clinically important effects on vital signs or laboratory parameters. The most common adverse events were hypertension (1.37%), nausea (1.09%), tachycardia (0.96%), and albuminuria (0.75%). The authors concluded that gadobenate dimeglumine is safe and efficacious as a contrast agent for use in hepatic MRI.

The safety of gadobenate dimeglumine has been confirmed in phase 2 and phase 3 studies in Japan (10,11). The overall adverse reaction rate was 3.5–5% and all the reactions were mild or moderate. There were no differences in the rates of adverse reactions with different dosage regimens (0.05–2.0 mmol/kg).

A safety evaluation of gadobenate dimeglumine in patients with renal impairment has also been reported (12). In a placebo-controlled, double-blind study there were no changes in laboratory parameters or vital signs and no clinically important adverse events.

The safety of gadobenate dimeglumine has been evaluated in 2367 adults aged 18-88 years and 173 children. The overall incidence of adverse events was 20%. Events related to the contrast agent were reported in 15% of the adults. Most of the adverse events were mild and transient and resolved spontaneously. Headache, injection site reactions, nausea, taste disturbance, and vasodilatation were the most common, with frequencies of 1.0–2.6%. Serious adverse events potentially related to the contrast agent were reported in 0.2%. These events included laryngospasm, which developed 10 minutes after the contrast injection in a 51-year-old woman, severe vomiting in a 5-year-old child, and pulmonary edema in a 65-year-old patient.

Gadobenate dimeglumine (intravenous bolus injection of 0.05 mmol/kg) was well tolerated by 103 patients (mean age 56 years) with acute myocardial infarction (13). Minor adverse effects in 27 patients included injection site reactions (13%), paresthesia (6.8%), dry mouth (6.8%), taste disturbance (2.9%), and headache (1.9%). The authors concluded that the use of a bolus dose of gadobenate dimeglumine 0.05 mmol/kg up to 6 days after acute myocardial infarction is safe.

The safety of intravenous gadobenate dimeglumine 0.025, 0.05, 0.1, and 0.2 mmol/kg in MR angiography has been assessed in 94 patients (mean age 58 years). Diagnostic accuracy was optimal at a dose of 0.1 mmol/kg (14). All the doses were well tolerated and there were no significant changes in safety parameters. Six patients reported mild adverse effects related to the contrast agent, including urticaria ($n = 2$), nausea ($n = 2$), and mild increases in liver enzymes (gamma-glutamyl transpeptidase, alanine transaminase, and aspartate transaminase) ($n = 2$). All the adverse events resolved spontaneously.

Similar observations were made in another study using similar doses of gadobenate dimeglumine for MR angiography (15). There were no important adverse effects, and the authors concluded that gadobenate dimeglumine is safe for MR angiography and that the optimal diagnostic dose is 0.1 mmol/kg.

Gadobutrol

Gadobutrol 1.0 is an extracellular neutral gadolinium chelate belonging to the class of macrocyclic neutral gadolinium complexes. It has the lowest osmolality of gadolinium-based contrast agents (1.60 osmol/kg). In preclinical evaluation there was good tolerance up to a dose of 0.5 mmol/kg, and this has been confirmed in phase I

© 2006 Elsevier B.V. All rights reserved.

clinical studies. In a phase II study, 89 patients with suspected cerebrovascular insufficiency received Gadovist 1.0 in doses of 0.1 ($n = 11$), 0.2 ($n = 21$), 0.3 ($n = 21$), 0.4 ($n = 21$), or 0.5 ($n = 15$) mmol/kg (16). There were no significant changes in vital signs or any serious adverse reactions. Two patients had nausea and dry mouth. A dose of 0.3 mmol/kg was diagnostically adequate.

Gadodiamide

Adverse events associated with the non-ionic, gadolinium-based contrast agent gadodiamide have been reported in 1–2% of patients. Most of the commonly reported adverse events have been headache, dizziness, or nausea and vomiting.

The safety and effectiveness of gadodiamide-enhanced magnetic resonance angiography (MRA) with single and triple doses in the assessment of abdominal arterial stenosis has been investigated in 105 patients, of whom 53 (aged 45–83 years) received 0.1 mmol/kg and 52 (aged 38–85 years) received 0.3 mmol/kg (17). There were no serious adverse events. Six patients in the single-dose group felt a sensation of heat or warmth in the abdomen, lumbar spine, upper legs, hips, or groin; five of these events were mild and one was moderate; one patient felt a mild cold sensation at the injection site. Six patients in the triple-dose group felt a warm discomfort in the abdomen, pelvis, or buttocks (two mild and four moderate); four other patients felt a cold sensation at the injection site or in the arm (three mild and one moderate). The authors concluded that gadodiamide-enhanced MRA performed with single and triple doses is safe and effective in assessing major abdominal arterial stenosis. Triple-dose MRA was better at evaluating image quality and the degree of arterial stenosis.

The safety of gadodiamide-enhanced MRI in staging suspected or recurrent soft tissue tumors of the head and neck has been investigated in 48 patients (aged 37–86) (18). There was only one adverse event, moderate thirst. The authors concluded that the use of gadodiamide for MRI contrast-enhanced examination of the head and neck is safe and provides more diagnostic information than unenhanced images.

Gadofosveset

Gadofosveset (MS-325) is a gadolinium-based small molecular weight chelate, which binds strongly and reversibly to human serum albumin after injection (19). Because of albumin binding it has a long half-life and increased relaxivity ($RI = 48\ mM^{-1}sec^{-1}$ at 0.47 T and 37°C, which is 10 times higher than gadolinium DTPA). These properties are particularly useful for contrast-enhanced, three-dimensional MRA. Furthermore, MS-325 can be given as a bolus, allowing dynamic arterial imaging. Prolonged blood-pool retention also allows steady-state imaging. There are promising results from early studies of carotid and coronary arteries. No serious adverse effects have been reported after the injection of gadofosveset, although transient nausea and paresthesia were reported in two of seven volunteers (1).

The safety and diagnostic efficacy of gadofosveset in MRA of the carotid arteries has been investigated in 26 patients aged 42–81 years with suspected carotid artery stenosis. It was given intravenously to 4, 9, and 13 patients in single doses of 0.01, 0.03, or 0.05 mmol/kg respectively. There were no serious or severe adverse events. Two patients who received 0.05 mmol/kg had five adverse events within 3 hours after the injection (nausea, cramps, metallic taste, and pruritus), which were rated as mild. There were no significant changes in serum chemistry. High-quality MRA scans were obtained in all the patients.

Gadopentetate dimeglumine

Gadopentetate dimeglumine (1 ml mixed with 4 ml of 5% saline) has been used in myelocisternography in four patients (aged 28–62 years) to demonstrate the exact site of cerebrospinal fluid (CSF) leakage in patients with CSF rhinorrhea (20). All tolerated the examination without adverse effects or complications.

Gadoversetamide

The safety of intravenous gadoversetamide, 0.1, 0.3, and 0.5 mmol/kg, has been confirmed in a study of its pharmacokinetics, safety, and tolerability in 163 patients with nervous system or liver pathology and varying degrees of renal function (21). All the adverse events that were thought to be related to gadoversetamide were mild or moderate, and there was no difference between doses. There were no changes in laboratory parameters. Gadoversetamide was well tolerated, even in patients with prolonged elimination due to renal impairment.

The safety of gadoversetamide at doses of 0.1–0.7 mmol/kg has been evaluated in 18 clinical studies (22). Adverse events related to the contrast agent were reported in 31% of injections. There were no serious adverse events.

Gadoxetic acid

Gadoxetic acid (gadolinium ethoxybenzyl diethylenetriaminepenta-acetic acid) was developed as a tissue-specific contrast agent for the liver and biliary system to be used in MRI and is a derivative of gadolinium DTPA with higher lipophilicity. It is taken up into hepatocytes and undergoes biliary excretion. Intravenous gadoxetic acid disodium has been used to assess liver enhancement and detect lesions in CT scanning of 15 patients with known liver metastases. The contrast agent was administered as an intravenous infusion over 20 or 30 minutes in doses of 0.2, 0.35, and 0.5 mmol/kg. There were three mild adverse reactions and one moderate reaction. Two patients reported a burning sensation at the site of infusion or retrosternally, which resolved when the flow rate of the infusion was reduced. Two other patients reported right upper quadrant pain, which began 4 hours after the infusion; this resolved spontaneously after a few hours. There were also minor reversible alterations in liver enzymes in some patients. Overall patient tolerance was acceptable and the images showed good or excellent liver enhancement, liver to tumor attenuation difference, and tumor visualization in the majority of cases with doses of 0.35 and 0.5 mmol/kg (SEDA-22, 504).

Uses of gadolinium other than in MRI scanning

Gadolinium can sufficiently attenuate X-rays to be visualized with digital subtraction angiography, although the

© 2006 Elsevier B.V. All rights reserved.

quality of image is consistently inferior to that produced by iodinated agents. Of 13 patients who underwent transplant angiography with 16–20 ml of either gadopentetate dimeglumine (0.5 mmol/ml) or gadolinium (0.5 mmol/ml), there was no significant deterioration in renal function in 11 patients (23). In the other two there were significant increases that were not considered to be due to either gadolinium or the administration of CO_2. These findings are consistent with previous studies (SEDA 22, 504) showing that gadolinium compounds are not nephrotoxic.

Organs and Systems

Pancreas

Acute pancreatitis has been attributed to gadodiamide.

- A 58-year-old man was given intravenous gadodiamide (non-ionic gadolinium chelate) 16 ml (0.2 mmol/kg) for hepatic MRI and immediately after the injection developed fatigue, nausea, vomiting, sweating, and later intense upper abdominal pain (24). His serum amylase was 4262 IU/l and abdominal MRI showed a diffusely enlarged pancreas, confirming the diagnosis of acute pancreatitis. A full history and biliary tract ultrasound excluded other causes. The attack was mild and the clinical course uneventful.
- A 68-year-old woman with long-standing peripheral vascular disease and chronic renal insufficiency (serum creatinine 334 μmol/l) underwent peripheral angiography with gadodiamide (dose not stated) and 6 hours later developed nausea, epigastric pain, and two episodes of vomiting, with further epigastric pain 5 hours later (25). Her serum amylase and lipase activities were 246 and 1314 U/l respectively (reference ranges 0–140 and 0–200 U/l). The next morning they were 684 and 1646 U/l respectively. Ultrasound scan of the liver and gallbladder was normal. She subsequently developed acute renal insufficiency, electrolyte imbalance, and pulmonary edema. Urine microscopy showed muddy brown casts consistent with acute tubular necrosis. Her pancreatitis resolved without any further complications.

The authors of the second case highlighted the fact that there is no recommended maximum safe dose of gadolinium, nor a minimum creatinine clearance below which gadolinium should not be used.

Urinary tract

Intravenous gadoterate meglumine 35 ml has been used as a contrast agent for arm venography using digital fluorography in 45 patients with end-stage renal insufficiency (age 26–88 years, serum creatinine 262–1360 μmol/l) before the creation of an arteriovenous fistula (26). The mean serum creatinine did not change significantly. There were no significant adverse effects. Only one patient developed vomiting. A good diagnostic examination was obtained in all cases.

The use of gadolinium-DTPA as a suitable contrast agent in patients with renal insufficiency undergoing vascular intervention with standard X-ray screening has been reported (SEDA-22, 504). During angiography two patients received gadolinium DTPA 50–60 ml without alterations in serum creatinine or any other adverse effect.

- A 55-year-old woman with polycystic kidney disease and chronic renal impairment (serum creatinine concentration 181 μmol/l) received gadodiamide (Omniscan) for cerebral angiography; there were no adverse effects and the serum creatinine was unchanged. (27)

The authors concluded that gadodiamide is a safe alternative to iodinated contrast media in patients with renal impairment.

However, the use of large volumes of gadolinium-based contrast agents can cause deterioration in renal function, and the safety of these agents in relation to the kidney when a large volume is used is not known (27).

The use of gadolinium-DTPA has been described in 28 patients (22 men, 6 women, mean age 51 years) for angiography (28). The mean dose of gadolinium was 35 (range 20–60) ml. All the patients had renal impairment (serum creatinine over 133 μmol/l). Gadolinium was well tolerated, but 17 patients noted a mild heat sensation and one complained of transient pain during the injection. Only one patient, who received 40 ml, developed worse renal function, with an increase in serum creatinine from 360 to 450 μmol/l. Although the gadolinium was well tolerated in this group of patients, gadolinium-based contrast agents should be used with extreme care, particularly in patients with renal impairment, as they can be nephrotoxic in large doses.

A prospective, randomized, double-blind, placebo-controlled trial has also confirmed the safety of gadolinium infusion in 32 patients with renal impairment in dosages typically used during MRI examination (29). Nine patients had moderate renal impairment (mean age 57 years, creatinine clearance 30–60 ml/minute) and 11 had severe renal impairment (mean age 63 years, creatinine clearance 10–29 ml/minute). They were given an intravenous bolus of gadobenate dimeglumine 0.2 mmol/kg. A comparable control group received an injection of isotonic saline. There was no significant deterioration in renal function in any group during the following 7 days.

- A 67-year-old woman with chronic renal insufficiency secondary to interstitial nephritis had rapid deterioration over several months, with a rise in serum creatinine from 150 to 290 μmol/l (30). Renal artery stenosis was suspected. She had anaphylaxis during spiral CT angiography with an iodinated contrast medium (details not given), which showed right renal artery stenosis. After further deterioration in renal function (serum creatinine 480 μmol/l) she underwent renal arteriography with 30 ml of a gadolinium-based contrast agent (0.3 mmol/kg) injected into the abdominal aorta just above the renal arteries. Her renal function was monitored for 15 days after the procedure, and there was no further rise in serum creatinine.
- A 64-year-old obese man with a history of radiocontrast-induced nephropathy had an MRI scan, which confirmed the presence of an aortic aneurysm from just below the renal arteries to the aortic bifurcation (31). Percutaneous stenting of the aortic aneurysm

Table 1 European Society of Urogenital Radiology (ESUR) position statement on the use of gadolinium-based contrast media for radiographic examinations (34)

Legal position	Gadolinium-based contrast media are not approved for X-ray examinations
Reported uses of gadolinium-based contrast media for X-ray examinations	Significant renal impairment Prior severe generalized adverse reaction to iodinated contrast media Imminent thyroid treatment with radioactive iodine
ESUR position	The use of gadolinium-based contrast media for radiographic examinations is not recommended to avoid nephrotoxicity in patients with renal impairment, since they are more nephrotoxic than iodinated contrast media in equivalent X-ray attenuating doses The use of gadolinium-based contrast media in approved intravenous doses of up to 0.3 mmol/kg will not give diagnostic radiographic information in most cases

was carried out with 0.5 mol/l gadoteridol solution 90 ml (0.375 mmol/kg) instead of an iodinated contrast agent. There was no further deterioration in renal function.

The authors of the second report erroneously concluded that gadolinium-containing contrast agents are not nephrotoxic, and they recommended their use in patients in whom conventional iodinated contrast agents are contraindicated. However, gadolinium-based contrast agents have more nephrotoxic potential than iodinated contrast agents in equimolar concentrations. Their use in patients with renal impairment should be carried out with care and the dosage should not exceed 0.3 mmol/kg.

This case underlines the fact that there is still misunderstanding about the nephrotoxic potential of gadolinium-based contrast agents. They should not replace iodinated contrast agents in patients with renal insufficiency. The recommended doses of up to 0.3 mmol/kg will not give satisfactory radiographic diagnostic information in most cases.

Susceptibility Factors

Renal disease

The use of gadolinium-based contrast media for radiographic examination as an alternative to iodinated contrast media in patients with impaired renal function has been erroneously endorsed by several authors. For example, in a German study gadopentetate dimeglumine (average dose 0.34 mmol/kg) was used in 29 patients (mean age 61 years) with renal impairment (mean baseline serum creatinine 318 μmol/l) as an alternative to an iodinated contrast agent for angiographic procedures (32). Only one patient developed contrast medium-induced renal damage, defined as an increase in serum creatinine by more than 88 μmol/l within 72 hours of injection of the contrast agent. The authors suggested that gadopentetate dimeglumine is a safe alternative to iodinated contrast agents for radiographic examinations in patients with renal impairment.

In another study, gadodiamide was used as an alternative for angiographic procedures in patients with contraindications to iodinated contrast media; 17 patients (mean age 74 years) received a mean volume of 136 ml of gadodiamide (range 60–200 ml) (33). The contraindications to iodinated contrast injection were renal impairment (12 patients, serum creatinine 200–500 μmol/l), a history of iodinated contrast reaction ($n = 3$), and hyperthyroidism ($n = 4$). Several of the patients had renal artery stenosis, and renal function improved after successful angioplasty. There were no cases of nephrotoxicity. The authors concluded that patients with contraindications to iodinated contrast injection can safely receive gadolinium-based contrast media for radiographic examinations.

The authors of these reports have erroneously suggested that gadolinium-based contrast media are less nephrotoxic than iodinated contrast media. However, at equimolar concentrations gadolinium-based contrast media are more nephrotoxic than iodinated contrast media, and at equivalent X-ray attenuation gadolinium-based contrast media are actually more nephrotoxic. The Contrast Media Safety Committee of the European Society of Urogenital Radiology has recently produced a report on the use of gadolinium-based contrast media for radiographic examinations, and its position is summarized in Table 1.

The safety and dialysability of gadobutrol 0.1 or 0.3 mmol/kg have been investigated in 11 patients (median age 42 years) with end-stage renal insufficiency who required hemodialysis (35). The patients were monitored for 120 hours. There were no important changes in hematology, clinical chemistry, or vital signs. Hemodialysis was effective in removing the gadolinium contrast agent from the body, and by the third session, 98% of the injected dose had been eliminated.

Hepatic disease

The safety of gadobenate dimeglumine has been evaluated in 16 subjects with liver impairment, 11 of whom (mean age 48 years) received gadobenate dimeglumine (0.1 mmol/kg) intravenously and five of whom (mean age 42 years) received placebo (36). There were no important adverse effects and no significant changes in laboratory parameters. The pharmacokinetics of the contrast agent were not different from those with normal liver function.

Drug Administration

Drug administration route

The safety of intrathecal gadopentetate dimeglumine has been investigated in 95 patients (aged 1 month to 78 years) (37). The contrast agent was injected into the

© 2006 Elsevier B.V. All rights reserved.

subarachnoid space via a lumbar puncture needle; 3–5 ml of cerebral spinal fluid were withdrawn and mixed with 0.5, 0.7, 0.8, or 1 ml of gadopentetate dimeglumine. There were no significant behavioral changes, neurological changes, or seizure activity, but 19 patients had headache after lumbar puncture, 6 had nausea, and 2 had vomiting. All the adverse effects resolved within the first 24 hours with bed rest.

Gallamine triethiodide

See also Neuromuscular blocking drugs

General Information

Gallamine is a non-depolarizing muscle relaxant. For intubation about 2 mg/kg (some authors say 3–4 mg/kg) are necessary, and the duration of effect is then similar to the usual intubating doses of D-tubocurarine or pancuronium. A dose of 1–1.5 mg/kg is usually sufficient to produce apnea and adequate abdominal relaxation. Such doses are said to be short-acting (20 minutes) but can provide clinical relaxation (75% or more depression of twitch height) for some 30–40 minutes. Individual variation is considerable, and complete spontaneous reversal of blockade is relatively slow.

Organs and Systems

Cardiovascular

Tachycardia invariably accompanies the use of gallamine. It is seen after doses as low as 20 mg and reaches a maximum at around 100 mg in adults (1). It is often extreme, rates above 120 per minute being not uncommon. The increase in heart rate outlasts the neuromuscular blocking effect (1). Usual clinical doses also result in a slight increase in mean arterial pressure, a slight fall in systemic vascular resistance, and a marked rise in cardiac index (2,3). These cardiovascular effects are principally accounted for by the strong vagolytic action of gallamine, the cardiac muscarinic receptors being almost as sensitive to its blocking action as the acetylcholine receptors of the neuromuscular junction (4). Blockade of noradrenaline reuptake and an increased release of noradrenaline from cardiac adrenergic nerve endings (5,6) may contribute, although an inotropic effect in man is disputed (7). Ganglion-blocking activity is slight and is not seen in the usual dose range. The possible mechanisms have been reviewed (8–10). Gallamine should therefore not be used when tachycardia has to be avoided.

Immunologic

Histamine release may be associated with the use of gallamine more often than was previously believed, according to several studies involving large numbers of patients (11–14). There have been several reports of reactions involving skin flushing, bronchospasm, or cardiovascular collapse possibly due to gallamine, including anaphylactoid reactions to small precurarizing doses (15,16).

Second-Generation Effects

Fetotoxicity

Placental transfer has been variously reported, usually only small amounts being detected in the umbilical blood, with no clinically obvious effects on the newborn (17).

© 2006 Elsevier B.V. All rights reserved.

Susceptibility Factors

Renal disease

Gallamine does not undergo biotransformation and depends entirely on glomerular filtration for its excretion (17). In renal insufficiency the neuromuscular blockade that it causes is considerably prolonged and gallamine is contraindicated.

Drug–Drug Interactions

Azathioprine

Azathioprine reduces sensitivity to gallamine in experimental animals, possibly as a result of phosphodiesterase inhibition, increasing transmitter release (SEDA-4, 87) (18), (SEDA-13, 104).

Gallium

General Information

Gallium is a metallic element (symbol Ga; atomic no. 31) that has been used in the form of a radiopharmaceutical (^{67}Ga as the citrate) in diagnostic imaging of cancers, inflammation, and infection (1–3). The mechanisms of the therapeutic activity of gallium have been reviewed (4).

Gallium nitrate is being increasingly used as a therapeutic agent in certain malignancies (5), since it has been shown to be concentrated in various neoplasms in both animals and man and to have antitumor activity (6), and the anticancer activity of new compounds, such as gallium maltolate, doxorubicin gallium transferrin conjugate, and trisquinolinolato gallium, is being explored (7).

Abnormal uptake of ^{67}Ga is reported as an adverse effect in diagnostic procedures, as in three cases:

- A 72-year-old man with acute lymphocytic leukemia who had normal ^{67}Ga uptake in all tissues except the liver (8).
- A 26-year-old pregnant woman with a mediastinal lymphoma that did not accumulate ^{67}Ga (9).
- A 49-year-old man with fever and increased ^{67}Ga uptake in the lungs but no other evidence of infection or cancer (10).

Gallium nitrate has been used as an alternative to bisphosphonates in hypercalcemia of malignancy (11), in which it is effective but associated with a higher frequency of renal toxicity (10%) and of nausea and vomiting (14%) than the bisphosphonates. The pathophysiology and treatment of hypercalcemia of malignancy has been reviewed and the role of gallium nitrate considered (12,13).

An early Phase I evaluation and subsequent reports presented similar pictures, with predominant renal and hematological adverse effects (14,15), but as a rule gallium has been used alongside other cytostatics and it is not possible to determine which of these has produced any particular effect. Other adverse effects observed have been nausea and/or vomiting, maculopapular skin rash, a metallic taste, and diarrhea (16).

Gallium alloys are still considered to be useful alternatives to amalgams in dental medicine, in spite of their tendency to corrosion, their controversial biocompatibility, and lack of knowledge about gallium's environmental impact (17).

© 2006 Elsevier B.V. All rights reserved.

Organs and Systems

Sensory systems

- A patient developed bilateral visual loss after systemic administration of gallium nitrate (SEDA-22, 244) (18). The condition worsened after oral corticosteroid therapy and partial recovery of optic nerve function in both eyes was present only after 12 months of oral ferrous sulfate administration.

Ototoxicity has been reported in a few patients taking gallium nitrate (19).

Hematologic

Hematological toxicity of gallium nitrate has been noted, for example granulocytopenia and anemia (19).

Mouth and teeth

Gallium is used in dental prostheses and is a source of increased sensitivity to postoperative dental pain (20). In a pilot study of a direct-placement gallium alloy (Galloy) in nine patients, 30 dental restorations were inserted and assessed over 3 years (21). The initial 18-month results were encouraging, but at 21 months there was one fractured tooth and within another year two molars had the cracked-tooth syndrome (incomplete tooth fracture). The fractured teeth were restored with amalgam. Tarnish and a rough surface were noted on many of the gallium restorations. These results suggest that Galloy, used with either of two sealing resins, is not a suitable dental restorative material.

Urinary tract

An early Phase I clinical evaluation indicated dose-related nephrotoxicity and this has led to much caution in dosage (19). At least one death from kidney failure has been reported. Maintaining adequate diuresis with 5% dextrose/saline may reduce the risk of nephrotoxicity.

In a comparative study of gallium nitrate and etidronate in acute control of cancer-related hypercalcemia, a significantly higher proportion of the patients treated with gallium nitrate developed asymptomatic hypophosphatemia (22).

Reproductive system

Gallium used in semiconductors has been found in animal studies to adversely affect male sperm count and to raise the proportion of abnormal sperm (SEDA-21, 235).

Immunologic

- A 40-year-old woman had multiple bone injuries, severe sepsis, and coma after a car accident; a retroperitoneal hematoma caused by lumbar fractures was drained, but she continued to be pyrexial (23). She had prominent accumulation of ^{67}Ga, which had been used for bone scanning, in her multiple recent fractures and an area of accumulation in the soft tissue related to a fractured vertebra. Post-traumatic paravertebral calcifications had accumulated ^{67}Ga and simulated the presence of an infected hematoma.

Susceptibility Factors

Renal disease

Because it is nephrotoxic, gallium nitrate should be avoided in renal dysfunction and in patients taking nephrotoxic drugs. Renal dysfunction also alters the kinetics of gallium (SED-12, 519).

Drug–Drug Interactions

Aminoglycosides

Concomitant treatment with aminoglycoside antibiotics in two cases resulted in acute renal insufficiency (24).

Gammahydroxybutyrate

General Information

Sodium gammahydroxybutyrate (GHB or sodium oxybate) is an endogenous compound, a precursor of GABA, which increases the release of dopamine and acetylcholine in the brain. It was first synthesized in 1960 as a potential anesthetic, and was popular in the late 1980s and early 1990s as a dietary supplement (as a replacement for L-tryptophan after it had been recalled from the market), an aid to sleep, and a bodybuilding agent. It was subsequently used in the treatment of narcolepsy. However, it has also been used as a party drug, since it causes alcohol-like effects and aroused sexuality. In large doses it can cause disorientation, nausea and vomiting, and muscle spasms. It is also known as BDO, Blue Nitro, Enliven, GBH, Liquid ecstasy, Midnight Blue, RenewTrient, Reviarent, Serenity, and SomatoPro. An analogue, gammavalerolactone (GVL), is a precursor and has also been used recreationally, but it is very expensive.

In 1990 the FDA limited the availability of gammahydroxybutyrate, and in March 2000, the Drug Enforcement Agency made it a Schedule I drug. In 2001 the Expert Advisory Committee on Drugs (EACD) in New Zealand advised the New Zealand Medicines and Medical Devices Safety Authority to schedule gammahydroxybutyrate under the Misuse of Drugs Act 1975 (1). In June 2003 gammahydroxybutyrate was categorized as a Class C drug in the UK.

Ingestion of 0.5–3 teaspoons of sodium gammahydroxybutyrate can produce vomiting, drowsiness, hypotonia, and/or vertigo; loss of consciousness, irregular respiration, tremors, or myoclonus can follow. Seizure-like activity, bradycardia, hypotension, and/or respiratory arrest have also been reported. The severity and duration of symptoms depend on the dose and on the presence of other nervous system depressants, such as alcohol.

In a double-blind, randomized, placebo-controlled, crossover study in 24 patients with narcolepsy, gammahydroxybutyrate 60 mg/kg in a single night-dose for 4 weeks reduced the daily number of hypnagogic hallucinations, daytime sleep attacks, and the severity of subjective daytime sleepiness, and tended to reduce the number of daily attacks of cataplexy (2). It reduced the percentage of wakefulness during REM sleep and the number of awakenings out of REM sleep, and tended to increase slow wave sleep. Adverse events were few and mild.

Organs and Systems

Nervous system

In a double-blind, double-dummy comparison of clomethiazole and gammahydroxybutyrate in ameliorating the symptoms of alcohol withdrawal, alcohol-dependent patients were randomized to receive either clomethiazole 1000 mg or gammahydroxybutyrate 50 mg/kg (3). There was no difference between the treatments in ratings of alcohol withdrawal symptoms or requests for additional medications. After tapering the active medication, there was no increase in withdrawal symptoms, suggesting that physical tolerance did not develop to either clomethiazole or gammahydroxybutyrate during the 5-day treatment period. The most frequently reported adverse effect of gammahydroxybutyrate was transient vertigo, particularly after the evening double dose.

Drug Administration

Drug overdose

Some who have taken gammahydroxybutyrate without knowing what it was have subsequently awakened in hospital having been deeply comatose for a few hours, without after-effects (4).

Ganciclovir

General Information

Ganciclovir (dihydroxypropoxymethylguanine) is a nucleoside analogue with antiviral activity in vitro against herpesviruses. Intracellular phosphorylation of ganciclovir to its triphosphate derivative, which acts as a competitive inhibitor of deoxyguanosine triphosphate, leads to the inhibition of viral DNA synthesis. Because its toxicity profile is more favorable than those of foscarnet and cidofovir, it should be considered first-line treatment of life-threatening or sight-threatening cytomegalovirus (CMV) infections in immunocompromised patients. Ganciclovir is administered by infusion or by intravitreal injection (1). Oral ganciclovir as maintenance therapy for CMV retinitis in patients with AIDS has been reviewed (2). Oral ganciclovir has also been the subject of a pilot study in hepatitis B infection (3).

Observational studies

In 261 patients with CMV retinitis given oral ganciclovir 3–6 g/day or intravenous ganciclovir 5 mg/kg/day the most common adverse effects were on the gastrointestinal tract (nausea in 29–43%, vomiting in 17–23%, diarrhea in 33–52%, and flatulence in 2–18%) (4). There were rashes in 9–32%, a low neutrophil count (below 0.5×10^9/l) in 12–16%, a low hemoglobin concentration (below 8 g/dl) in 8–15%, a low platelet count (below 25×10^9/l) in 0–3%, and a raised serum creatinine in 17–27%.

General adverse effects

The proportion of patients in whom ganciclovir therapy is subsequently interrupted or withdrawn because of adverse effects is estimated at 32% (1).

Fever, rash, and abnormal liver function values are each reported to occur in about 2% of ganciclovir recipients (1). Other infrequently reported adverse effects, which may or may not be associated with ganciclovir, include chills, edema, malaise, vomiting, anorexia, diarrhea, dyspnea, reduced blood glucose, alopecia, impaired renal function, inflammation, pain, or phlebitis at the infusion site (1). These effects may also be due to the underlying illness in such patients.

Organs and Systems

Nervous system

Adverse effects of ganciclovir involving the central nervous system occur in about 5% of patients and include confusion, seizures, abnormal thinking, psychosis, hallucinations, nightmares, anxiety, tremor, dysesthesia, ataxia, coma, headache, and somnolence (1,5,6).

- A clear case of encephalopathy has been described in a patient who had received a bone marrow transplant; the problem resolved on withdrawal (7).

Sensory systems

Adverse effects reported in patients receiving intravitreal ganciclovir include foreign body sensation, conjunctival hemorrhage, mild conjunctival scarring, scleral induration, bacterial endophthalmitis, and retinal detachment (1).

For HIV-infected patients who have failed the intravenous CMV treatment options, intravitreal injections may be the last line. In one case only mild iris atrophy was noted, despite high-dose intravitreal ganciclovir (3 mg twice weekly) and high-dose intravitreal foscarnet (2.4 mg twice weekly) (8).

Endophthalmitis with scleral damage has been associated with a ganciclovir implant (9).

- A 39-year-old woman complained of increasing pain and complete loss of vision in the left eye 1 month after insertion of a ganciclovir implant. The eye was enucleated and pathological examination showed a vitreous abscess; the implant suture tab was intrasclerally located.

The authors concluded that intraocular infection had resulted from a foreign body (the surgical implant) in the scleral gap.

Metabolism

Six infants with cholestasis (aged 3–16 weeks) and signs of CMV infection were given intravenous ganciclovir for 3–7 weeks (10). One patient with septo-optic dysplasia and hypothyroidism had episodes of symptomatic hypoglycemia during treatment, which was withdrawn.

Hematologic

The adverse hematological effects of ganciclovir are generally rapidly reversible after withdrawal (1).

Pure red cell aplasia has been reported in one bone marrow transplant recipient (11) and hemolysis has been observed in two other patients (5).

Neutropenia is the most frequent adverse effect of ganciclovir. It usually occurs before a total dose of 200 mg/kg has been given. Other hematological adverse effects include thrombocytopenia, anemia, and lymphopenia. Since ganciclovir maintenance treatment is often necessary, concomitant use of G-CSF is often required in patients with AIDS with ganciclovir-associated neutropenia (12).

In a study of oral ganciclovir in 36 severely immunocompromised HIV-positive children with CMV disease, toxicity was minimal and manageable and similar to that in adults in controlled trials of the oral formulation (13). About 20% of the children withdrew, mainly as a result of intolerance of the large volume of oral suspension or numerous capsules. As in adults, neutropenia was the main toxic effect and it was successfully treated with G-CSF.

Of 40 patients who had achieved engraftment after allogeneic hemopoietic stem cell transplantation, 23 of whom had high-risk features, including transplant from an HLA-mismatched or unrelated donor, or associated acute graft-versus-host disease, 19 had pre-emptive therapy with ganciclovir in an initial dose of 5 mg/kg/day (4). There were no significant adverse effects attributed

© 2006 Elsevier B.V. All rights reserved.

to ganciclovir, except low total leukocyte counts (below 0.5×10^9/l) in three patients, lasting 3, 4, and 14 days, while they were treated with granulocyte colony-stimulating factor.

Second-Generation Effects

Fertility

Animal data suggest that ganciclovir can inhibit spermatogenesis and fertility (14), but in one study there was no significant change in serum gonadotropin hormone concentrations in 32 men during ganciclovir therapy (15).

Drug Administration

Drug administration route

Treatment options for CMV retinitis include the intravitreal insertion of ganciclovir implants. This method of drug delivery has the attraction of avoiding systemic drug toxicity, but the inherent danger of introducing bacterial infection has been highlighted (16).

- A 42-year-old man with AIDS and a history of CMV retinitis developed pain in his right eye and reduced visual acuity 10 days after receiving a ganciclovir intraocular implant into that eye. A therapeutic vitrectomy was performed and a vitreal tap produced frank pus and white fluffy debris. Cultures grew oxacillin-resistant *Staphylococcus aureus* sensitive only to vancomycin, rifampicin, and co-trimoxazole. The ganciclovir implants were removed and he was given a 4-week course of vancomycin and rifampicin. The bacterial endophthalmitis left him blind in his right eye.

Drug–Drug Interactions

Trimethoprim

The interaction kinetics and safety profile of oral ganciclovir when co-administered with trimethoprim have been investigated in HIV- and CMV-seropositive patients (17). Trimethoprim significantly reduced the renal clearance of ganciclovir and prolonged its half-life, although the changes are unlikely to be clinically important. Ganciclovir did not alter trimethoprim pharmacokinetics, with the exception of a 13% increase in C_{min}. Ganciclovir was well tolerated when given alone or in this combination.

Zidovudine

Zidovudine and ganciclovir have overlapping toxicity profiles with respect to adverse hematological effects. Severe life-threatening hematological toxicity has been reported in 82% of patients treated with a combination of zidovudine and ganciclovir (18). The combination of ganciclovir with didanosine was much better tolerated (19).

Food–Drug Interactions

A well-controlled investigation using high doses of oral ganciclovir in HIV- and CMV-seropositive subjects has shown that food markedly increases the systemic availability of ganciclovir. For example, there is a doubling of blood concentrations and AUC if the drug is given within 30 minutes after a meal rather than on an empty stomach (20). Whatever dosage instructions are given, it seems clear that the relation to meal times should be explained, for example with a firm recommendation to take the drug consistently with food.

Garenoxacin

See also Fluoroquinolones

General Information

Garenoxacin is an orally and parenterally available 6-des-fluorinated quinolone, which has a high degree of in vitro activity against a broad range of bacterial pathogens (1).

Organs and Systems

Musculoskeletal

In dogs garenoxacin concentrations in plasma and joint tissue were higher than those of ciprofloxacin and norfloxacin (2). However, the articular toxicity of garenoxacin was much less than that of the other two quinolones.

Gatifloxacin

See also Fluoroquinolones

General Information

Gatifloxacin is an 8-methoxyfluoroquinolone with enhanced activity against Gram-positive, atypical agents, and some anerobes, and broad-spectrum activity against Gram-negative bacteria (1–4). It is bactericidal and produces a post-antibiotic effect in Gram-positive and Gram-negative bacteria. Gatifloxacin is well absorbed from the gastrointestinal tract (oral availability almost 100%), and concomitant administration of a continental breakfast, 1050 kcal, had no effect on its availability (5). The standard dose is 400 mg od and both oral and intravenous formulations are available (6,7).

Since gatifloxacin has a high oral systemic availability (96%), oral and intravenous formulations are bioequivalent and interchangeable (8). It has a large volume of distribution (about 1.8 l/kg), low protein binding (about 20%), broad tissue distribution, and is primarily excreted unchanged in the urine (over 80%) (7). After daily repeated administration, there was predictable modest accumulation; steady state concentrations were reached after the third dose (9).

The in vitro antibacterial spectrum of gatifloxacin has been tested against a variety of clinically important microorganisms (10). It is two to four times more potent than ciprofloxacin and ofloxacin against staphylococci, streptococci, pneumococci, and enterococci. However, it is two times less potent than ciprofloxacin, but the same as or two times more potent than ofloxacin against *Enterobacteriaceae*. Gatifloxacin and ofloxacin have similar antipseudomonal activity, while ciprofloxacin is two to eight times more potent. Gatifloxacin is highly potent against *Hemophilus influenzae*, *Legionella* species, and *Helicobacter pylori*, and also has activity against *Bacteroides fragilis* and *Clostridium difficile*. Like other quinolones, it has poor activity against *Mycobacterium avium* intracellulare, but is 8–16 times more potent against *Mycobacterium tuberculosis*.

Intravenous gatifloxacin can cause dose-related local reactions (8).

Gatifloxacin does not interact with drugs metabolized by the CYP450 enzyme family, as assessed in 14 healthy adult men using midazolam as a probe (11).

Organs and Systems

Cardiovascular

Although early studies suggested that gatifloxacin has little effect on the QT interval of the electrocardiogram (7,12), clinical trial data and data from phase IV studies

© 2006 Elsevier B.V. All rights reserved.

have shown that it prolongs the QT interval (13). Four cases of gatifloxacin-associated cardiac toxicity have been reported in patients with known risk factors for this adverse event (14).

Nervous system

In patients taking gatifloxacin there have been reports of myoclonus and generalized seizures (15) and ataxia and generalized seizures (16).

Metabolism

Gatifloxacin was well tolerated in patients with non-insulin-dependent diabetes mellitus maintained with diet and exercise (17). It had no significant effect on glucose homeostasis, beta cell function, or long-term fasting serum glucose concentrations, but it caused a brief increase in serum insulin concentrations.

Gastrointestinal

Diarrhea and nausea were the most common adverse events in several clinical studies of gatifloxacin (4,18–20).

Liver

Gatifloxacin can cause hepatitis (21,22).

- A 44-year-old woman developed acute hepatitis while taking gatifloxacin for chronic sinusitis (23). After 5 days she developed nausea, lethargy, and abdominal pain, all of which progressed over the next few days. Liver function tests were abnormal, and the bilirubin peaked at 161 μmol/l. A percutaneous liver biopsy showed acute hepatitis with eosinophilic infiltrates, consistent with drug-induced hepatitis.

Susceptibility Factors

Age

Gatifloxacin can be administered without dose modification in the elderly (24).

Sex

Gatifloxacin can be administered without dose modification in women (24).

Hepatic disease

Gatifloxacin can be administered without dose modification in patients with hepatic impairment (25).

Drug–Drug Interactions

Oral hypoglycemic drugs

Four cases of severe persistent hypoglycemia due to gatifloxacin 400 mg/day have been reported in adults with diabetes mellitus who were taking oral hypoglycemic agents (repaglinide, glibenclamide, glimepiride) (26,27).

Oxycodone

Oral oxycodone and gatifloxacin can be co-administered without a significant reduction in systemic availability (28).

Warfarin

Enhanced hypoprothrombinemia has been reported when gatifloxacin was given with warfarin (29).

Gemcitabine

See also Cytostatic and immunosuppressant drugs

General Information

Gemcitabine is an S-phase-specific pyrimidine nucleoside analogue of deoxycytidine (2′,2′-difluorodeoxycytidine) that is structurally similar to cytosine arabinoside. It has been used to treat metastatic urothelial carcinoma of the bladder, pancreatic cancer, and some other solid tumors.

General adverse effects

In a retrospective study of the adverse effects of gemcitabine 1000 mg/m^2 on days 1 and 8 in patients with non-small cell lung cancers, the adverse effects of gemcitabine involved the gastrointestinal system (nausea, vomiting, and diarrhea) and the hemopoietic system (leukopenia, neutropenia, thrombocytopenia, and anemia), but only in the last (8th–11th) cycles (1). There was grade 4 vomiting in three patients, grade 4 thrombocytopenia in two, and grade 3 leukopenia in three. Other adverse effects were mild. None of the patients died during chemotherapy.

Organs and Systems

Cardiovascular

In a retrospective chart review of patients with gemcitabine-associated thrombotic microangiopathy diagnosed between January 1997 and February 2002, the cumulative incidence was 0.31% (8 cases among 2586 patients), higher than previously reported (0.015%) (2). The median age was 53 years, the median time to development was 8 (range 3–18) months, and the cumulative dose was 9–56 g/m^2. New or exacerbated hypertension was a prominent feature in seven of nine patients and preceded the diagnosis by 0.5–10 weeks. Treatment included withdrawal of gemcitabine, antihypertensive therapy, plasma exchange, and dialysis. Six patients survived and three died of disease progression; none died as a direct result of thrombotic microangiopathy, but two developed renal insufficiency requiring dialysis, and one developed chronic renal insufficiency.

Gemcitabine can occasionally cause systemic capillary leak syndrome (3,4).

Respiratory

Gemcitabine can cause pulmonary toxicity. The clinical presentation is subacute and often non-specific. Chest X-ray usually shows reticulonodular interstitial infiltrates (5).

- A 75-year-old man with non-small cell lung cancer developed acute respiratory distress syndrome after intravenous gemcitabine monotherapy (6). The total dose of gemcitabine was 1500 mg, and the latent period was 3 days. Chest X-rays and a high resolution CT scan showed bilateral ground-glass opacity. He died on the fourteenth postchemotherapeutic day in respiratory failure. Postmortem examination of the lung showed mixed exudative and fibrotic stages of diffuse alveolar damage.

In one study, the incidence was as high as 15%, even with low-dose gemcitabine 600 mg/m^2 on days 1, 8, and 15 and docetaxel 60 mg/m^2 on day 1; all resolved after withdrawal of treatment and administration of glucocorticoids (7).

In a retrospective review pulmonary toxicity was defined as dyspnea, interstitial pneumonitis, lung disorder, lung edema, lung fibrosis, pneumonia, respiratory disorder, and respiratory distress syndrome (8). Based on 4448 patients, the incidences of dyspnea and other

© 2006 Elsevier B.V. All rights reserved.

serious pulmonary toxicity were 0.45 and 0.27% respectively. Based on an estimated 217 400 patients treated with commercial gemcitabine worldwide, the crude incidences of dyspnea and other serious pulmonary toxicity were 0.02 and 0.06% respectively.

In a retrospective study of 312 patients treated with gemcitabine over 5 years, 18 developed episodes of acute dyspnea; 6 were attributed to the drug; 4 had a notifiable industrial disease secondary to asbestos exposure (OR = 85, 95% CI = 13, 546); and 5 were active smokers (5).

Liver

- Fatal cholestatic liver failure occurred in a 45-year-old woman with metastatic breast cancer who was given gemcitabine and carboplatin and pre-existing liver damage. After four courses of gemcitabine + carboplatin she developed severe decompensated cholestatic hepatitis (9). Liver biopsy showed marked cholestasis and hepatocellular injury consistent with drug-induced hepatotoxicity.

Urinary tract

Hemolytic–uremic syndrome has occasionally been attributed to gemcitabine (10–12). The manufacturers reviewed their database of 78 800 patient exposures, which confirmed that gemcitabine causes hemolytic–uremic syndrome with a crude overall incidence rate of 0.015% (13).

Skin

Erythema multiforme has been attributed to gemcitabine (14). Toxic epidermal necrolysis has been reported in an elderly man receiving gemcitabine for a transitional cell carcinoma of the bladder (15).

- Scleroderma-like changes of the legs occurred after treatment with gemcitabine in a patient with metastatic carcinoma of the bladder (16). There was initial inflammatory edema and subsequent scleroderma-like changes after 2 cycles of gemcitabine. Cutaneous biopsies showed diffuse sclerosis without involvement of the fascia or muscle. Withdrawal of gemcitabine resulted in resolution of the edema, softening of the skin, and partial reversibility of the fibrotic process.

Patients occasionally develop erysipeloid skin reactions, often, although not always, associated with previous radiotherapy or lymphedema (17).

A cutaneous reaction mimicking acute lipodermatosclerosis has been attributed to gemcitabine (18).

Immunologic

Two patients developed necrotizing enterocolitis after a first cycle of chemotherapy for epithelial ovarian/peritoneal cancer; both were due to vasculitis (19).

- In a 56-year-old man with a transitional cell carcinoma of the bladder gemcitabine plus cisplatin caused extensive necrotizing vasculitis with muscle damage after the second course of therapy (20). Chemotherapy was withdrawn immediately but the symptoms of severe myalgia and swelling persisted, and he needed additional treatment, consisting of cyclophosphamide and prednisolone.

Other cases of vasculitis have been reported (21).

- A 70-year-old woman with a bladder cancer was given gemcitabine 1700 mg on days 1 and 8 and 3–4 days later developed paresthesia of the fingers, Raynaud's phenomenon, an intermittent fever, digital necrosis, and fingertip gangrene (22). Angiography showed occlusion of the digital arteries of the second, third, and fourth fingers. Skin biopsy showed hyperkeratosis, acanthosis, and papillomatosis, with endothelioangiitis and nonspecific arterial inflammation.

Radiation recall consists of inflammatory reactions triggered by cytotoxic drugs in previously irradiated areas; most are skin reactions. Gemcitabine has been implicated in several cases. The authors of a literature review discovered 12 cases of radiation recall caused by gemcitabine and reported a case of myositis in the rectus abdominis muscle of a patient with pancreatic adenocarcinoma as an effect of radiation recall (23). Most of the cases had inflammation of internal organs or tissues and 30% had dermatitis or mucositis. This is different from the effect of other agents that commonly cause radiation recall (anthracyclines and taxanes), with which 63% are skin reactions. Compared with anthracyclines and taxanes, the interval from the completion of radiation therapy to the start of chemotherapy is less with gemcitabine (median time 56 days, compared with 218 days for the taxanes and 646 days for doxorubicin).

Gemeprost

See also Prostaglandins

General Information

Gemeprost is an analogue of PGE_2. Vaginal gemeprost is effective in inducing first and second trimester abortion and in cervical priming before vacuum aspiration. Pyrexia, vomiting, and diarrhea were experienced in 20% of patients (1).

In a double-blind, randomized, controlled trial, 896 healthy women requesting a medical abortion (57–63 days gestation, mean age 25 years) were randomized to a single oral dose of mifepristone 200 or 600 mg, both followed in 48 hours by gemeprost 1 mg vaginally (2). The complete abortion rates were similar with the lower and higher doses of mifepristone (92 versus 92%). The incidences of adverse effects were similar, with the exception of nausea at 1 week, which was less frequent in the low-dose group (3.6 versus 7.6%).

Organs and Systems

Cardiovascular

Two women developed myocardial ischemia during treatment with gemeprost for termination of pregnancy (3).

- A 29-year-old woman, a smoker with a history of renal insufficiency, obesity, hypertension, hypercholesterolemia, and cardiac dysrhythmias, underwent termination of pregnancy at 10 weeks with a pessary of gemeprost 1 mg and 5 hours later dilatation and evacuation, followed by tubal ligation. After surgery, her blood pressure became unmeasurable, her heart rate dropped to 40/minute, and she developed ventricular fibrillation. She was given streptokinase and intravenous heparin for suspected pulmonary embolism; her blood pressure rose and was maintained with adrenaline and noradrenaline. Angiography showed an 80% stenosis of her right coronary artery and complete occlusion of the anterior interventricular branch. Blood flow was re-established by coronary angioplasty.
- A 32-year-old woman, a smoker, had an evacuation after the death of her fetus at 18 weeks. Two pessaries of gemeprost 1 mg were inserted 7.25 hours apart, and about 90 minutes later she became unconscious, apneic, and cyanotic, and had dilated pupils and no detectable blood pressure or pulse. She was given 100% oxygen, intravenous adrenaline and dobutamine, and a crystalloid infusion. Her systolic pressure rose to 100 mmHg. Coronary angiography showed left and circumflex coronary artery spasm.

The author commented that the myocardial ischemia experienced by both of these patients was thought to be due to prostaglandin-induced coronary spasm. It would be prudent to monitor every woman treated with gemeprost during the course of an abortion.

Skin

Toxic epidermal necrolysis has been attributed to mifepristone/gemeprost (4).

Gemifloxacin

See also Fluoroquinolones

General Information

Gemifloxacin is a fluoroquinolone that has enhanced affinity for topoisomerase. Compared with other fluoroquinolones, gemifloxacin was the most potent against penicillin-intermediate and penicillin-resistant pneumococci, methicillin-susceptible and methicillin-resistant *Staphylococcus epidermidis* isolates, and coagulase-negative staphylococci (1,2). It has excellent activity against *Haemophilus influenzae* and *Moraxella catarrhalis* and is unaffected by beta-lactamases. It is generally twofold less active than ciprofloxacin against most *Enterobacteriaceae* (3). Atypical respiratory pathogens (*Legionella*, *Mycoplasma*, and *Chlamydia* species) and *Neisseria gonorrheae* are highly susceptible (4).

The pharmacokinetics of oral gemifloxacin have been characterized in healthy male volunteers (5). About 20–30% of the dose was excreted unchanged in the urine. The renal clearance was 160 ml/minute on average after single and multiple doses, which was slightly greater than the accepted glomerular filtration rate. There were no adverse effects.

Observational studies

In phase II trials oral gemifloxacin 320 mg/day produced bacteriological responses in 94% of patients with acute exacerbations of chronic bronchitis (6–8) and in 95% of patients with uncomplicated urinary tract infections. Adverse events included nausea, abdominal pain, headache, and a mild rash in both patients and healthy volunteers.

After a single dose of 20–800 mg of gemifloxacin, there were no significant changes in clinical chemistry, hematology, or urinalysis, vital signs, or 12-lead electrocardiograms in healthy men, irrespective of dose (9).

Gemifloxacin 320 mg od and trovafloxacin 200 mg od have been compared in 571 patients with community-acquired pneumonia in a multicenter, double-blind, parallel-group, randomized study (10). Gemifloxacin was slightly more effective (88%) than trovafloxacin (81%). Gemifloxacin was well tolerated and the incidence of transient liver function abnormalities was very low.

The effect of oral gemifloxacin 320 mg for 7 days on the human intestinal microflora has been investigated in 10 healthy subjects (11). The numbers of enterobacteria, enterococci, and streptococci were reduced. No other aerobic microorganisms were affected. The numbers of anerobic cocci and lactobacilli were reduced. The microflora normalized 49 days after withdrawal. There was no selection or overgrowth of resistant bacterial strains or yeasts.

Organs and Systems

Hematologic

Gemifloxacin reached intracellular concentrations in human polymorphonuclear leukocytes eight times higher than extracellular concentrations. Uptake was rapid, reversible, and non-saturable and was affected by environmental temperature, cell viability, and membrane stimuli (12).

Gastrointestinal

In a randomized, double-blind, multicenter comparison of a 5-day course of gemifloxacin 320 mg/day with a standard 7-day regimen of clarithromycin 500 mg bd in 712 patients with acute exacerbations of chronic bronchitis, the most frequently reported gemifloxacin-related adverse events were diarrhea (5.1%) and nausea (4.3%) (13).

Liver

Gemifloxacin was generally well tolerated in a pharmacokinetic study, although one subject was withdrawn after 6 days at 640 mg because of mild, transient rises in alanine transaminase and aspartate transaminase not associated with signs or symptoms (5).

Skin

Gemifloxacin has a low potential for mild phototoxicity (14).

Drug–Drug Interactions

Iron

In an open, randomized, single-dose, five-way crossover study of the effects of ferrous sulfate on the systemic availability of gemifloxacin, there were no changes when gemifloxacin was given at least 2 hours before or at least 3 hours after ferrous sulfate (9).

Sucralfate

In an open, randomized, single-dose, five-way crossover study of the effects of sucralfate on the systemic availability of gemifloxacin, there were no changes when gemifloxacin was given at least 2 hours before sucralfate (9).

Food–Drug Interactions

Food had a minor and clinically insignificant effect on the systemic availability of gemifloxacin (320 and 640 mg) (15).

Gemtuzumab ozogamicin

See also Monoclonal antibodies

General Information

Gemtuzumab ozogamicin (Mylotarg) consists of a humanized anti-CD33 monoclonal antibody conjugated to the cytotoxic enediyne antibiotic calicheamicin. It has been used to treat a subset of patients with acute myeloid leukemia in association with topotecan + cytarabine. Its most common adverse effects are myelosuppression, increased hepatic enzyme activity, infections, fever and chills, bleeding, nausea and vomiting, and dyspnea.

Infusion-related adverse effects of gemtuzumab ozogamicin can be treated with a brief course of an intravenous glucocorticoid. Of 143 patients with refractory myeloid leukemia treated with gemtuzumab ozogamicin, 110 received paracetamol 650 mg orally with diphenhydramine 50 mg intravenously and 33 received the same premeditations plus methylprednisolone sodium succinate 50 mg intravenously before the infusion and repeated 1 hour later (1). There were grade 2 or worse infusion-related adverse events in 32 (29%) of the former, but in only one of the latter (3%).

Organs and Systems

Liver

Hepatotoxicity, with raised bilirubin and liver enzymes, is common with gemtuzumab (30–50%) and is mostly reversible. A more severe complication, hepatic veno-occlusive disease, a syndrome consisting of hyperbilirubinemia, painful hepatomegaly, and fluid retention or ascites, is less common and is mostly seen in patients previously undergoing bone marrow transplantation (4–5%). It occurs most commonly after high-dose chemotherapy and hemopoietic stem cell transplantation. Patients with severe veno-occlusive disease die from progressive multiorgan failure. Close monitoring of patients receiving gemtuzumab is necessary, even if they have not had previous bone marrow transplantation (2).

In 119 patients (92 with acute myeloid leukemia, 25 with advanced myelodysplastic syndrome, and two with chronic myeloid leukemia), who did not receive concomitant stem cell transplantation, 14 developed veno-occlusive disease (3). Five of these 14 patients had not received prior antileukemic therapy, and in two cases gemtuzumab ozogamicin was used as single-agent chemotherapy.

Of eight patients who were given an infusion of gemtuzumab 9 months after hemopoietic stem cell transplantation, seven had normal serum bilirubin concentrations, and all eight had transaminase and alkaline phosphatase activities that were less than 1.5 times the upper limit of the reference range (4). Six had no evidence of hepatotoxicity. One developed abdominal pain, ascites, and mildly raised transaminases. A CT scan showed no evidence of hepatic disease. This patient did not meet the criteria of veno-occlusive disease. Patient 8 did meet the criteria of veno-occlusive disease 3 days after infusion

© 2006 Elsevier B.V. All rights reserved.

with gemtuzumab. She developed multi-organ failure and died.

Of 17 patients who were given gemtuzumab, three developed grade 3 hyperbilirubinemia, and five developed grade 3–4 hepatic transaminitis after a median of 13 days, including one who developed veno-occlusive disease (4). This patient had abrupt onset of weight gain, associated with ascites, abdominal distension, acute hepatic failure, and right upper quadrant pain, and died. As a possible mechanism gemtuzumab may selectively target CD33-expressing cells in hepatic sinusoids, activate stellated cells, damage sinusoidal endothelial cells, and cause sinusoidal vasoconstriction or ischemic hepatocyte necrosis. Liver histology showed sinusoidal injury with extensive sinusoidal fibrosis, centrilobular congestion, and hepatocyte necrosis (5).

Immunologic

There has been one report of an anaphylactic reaction in a patient receiving gemtuzumab (6).

Genaconazole

See also Antifungal azoles

General Information

Genaconazole is an *N*-substituted triazole with a wide antifungal spectrum. Its absorption is slow, with peak concentrations 2–4 hours after a single dose and mean peak concentrations markedly higher after 16 days of administration. The mean elimination half-life is about 90–100 hours (1). It has high tissue penetration, including the CNS, and good broad-spectrum antifungal activity. However, it causes hepatocellular carcinoma in animals and the manufacturers stopped developing it because of concerns about toxicity.

General anesthetics

See also Individual agents

General Information

The inhalational and injectable agents that are covered in separate monographs are listed in the table below.

Inhalational	Injectable
Halogenated	*Barbiturates*
Chloroform	Methohexital
Desflurane	Thiamylal
Enflurane	Thiopental
Halothane	*Others*
Isoflurane	Alfadolone/alfaxolone
Methoxyflurane	Etomidate
Sevoflurane	Ketamine
Trichloroethylene	Propanidid
Others	Propofol
Anesthetic ether	
Cyclopropane	
Nitrous oxide	
Xenon	

The inhalational agents in common use share similar adverse effects, albeit with differing incidences. Initial hopes that new agents will be less problematic generally fade as their use increases and familiarity with their adverse effects grows. Although some untoward reactions related to inhalational anesthetics are unpredictable, it is important for the anesthetist/anesthesiologist to determine which patients are primarily at risk, so that safer use of anesthetic agents and better supervision of surgical patients can be achieved.

Anesthetic combinations

The importance of multiple anesthetics should not be overlooked. For example, patients in whom halothane anesthesia is given twice, at an interval of less than 6 weeks, are at major risk of developing jaundice. Some anesthetists avoid any second exposure to this agent. However, there are several reasons why single agents are often insufficient in anesthesia: different problems require separate treatments; the severity of the adverse effects of individual drugs can sometimes be reduced by

© 2006 Elsevier B.V. All rights reserved.

the use of combinations; and repeated administration of a single agent can lead to cumulative effects. Drug interactions in anesthesia are therefore potentially common and have been reviewed, both systematically (1) and as uncritical listings (2,3). Many of the interactions are beneficial, the concurrent use of two or more different agents improving the quality of anesthesia. Several reviews of this have appeared (4–6). Disadvantages of combinations include unpredictability of synergistic actions or toxicity, mutual alterations in pharmacokinetics, increased likelihood of errors in drug administration, and difficulties in planning drug therapy when adverse effects occur and are not attributable to a particular drug.

Dental anesthesia

Adverse effects of dental anesthesia represent a special problem, about which reliable data are hard to obtain. Several studies of the safety of dental anesthesia have been performed in the USA (SEDA-18, 113); unfortunately, all have weaknesses. More informative is an American survey in which 47 oral and maxillofacial surgeons were approached directly, and all responded (7). Among the 74 871 patients to whom they had given general anesthesia, there were 250 cases of laryngospasm, 51 of phlebitis, 30 of dysrhythmias sufficiently severe to require therapy, 17 of hypotension requiring drug therapy, and 13 of bronchospasm. A few patients had allergic reactions requiring drug therapy ($n = 4$), convulsions ($n = 4$), hypertension ($n = 2$), myocardial infarction ($n = 2$), or vomiting with aspiration ($n = 2$); in one case an injection was inadvertently given into an artery.

Sedation for endoscopy

Gastrointestinal endoscopy is one of the most commonly performed invasive procedures in clinical practice (for example about 500 000 procedures per annum in Australasia). Propofol is a short-acting intravenous anesthetic with a rapid onset of action and a short half-life, making it eminently suitable for day procedures. However, the use of propofol by non-anesthetists has been controversial because of the perceived risks of its low therapeutic ratio.

The incidence of adverse events related to an endoscopy sedation regimen that included propofol (in addition to midazolam and fentanyl), delivered by specially trained general practitioners, has been examined in a prospective audit (8); 28 472 procedures were performed over 5 years. There were 185 sedation-related adverse events, 107 with airway or ventilation problems; 123 interventions were necessary to maintain ventilation. No patients required tracheal intubation and there were no deaths. The authors concluded that appropriately trained general practitioners encountered a low incidence of adverse events and could safely use propofol for sedation during endoscopy. It should be noted that all the general practitioners had some experience in anesthesia or intensive care and were individually trained by the Director of Anesthesia.

Sedation for surgery under regional anesthesia

Sedation during prolonged surgical procedures under regional anesthesia can be quite challenging. The $beta_2$ adrenoceptor agonist dexmedetomidine has potent sedative and analgesic-sparing properties. In therapeutic doses it does not cause respiratory depression, making it attractive for infusion sedation. However, it causes reduced sympathetic outflow, which might cause untoward hemodynamic upset during intraoperative sedation. Dexmedetomidine has been compared with propofol in a prospective randomized trial in 40 patients (9). Dexmedetomidine provided slightly slower onset and offset of sedation, higher intraoperative blood pressure, and better postoperative analgesia.

Remifentanil is a highly selective OP_3 (μ) opioid receptor agonist with an extremely short onset and offset of action, allowing rapid and accurate titration of infusion rate to drug effect with rapid down-titration in case of respiratory adverse effects. This makes it attractive for sedation. The efficacy and adverse effects profiles of remifentanil and propofol have been compared in a randomized, single-blind trial in 125 patients undergoing surgery with regional anesthesia (10). In those given remifentanil, nausea and vomiting were more frequent (27 versus 2%) and there was significantly more respiratory depression (46 versus 19%).

Sedation in intensive care

It has been proposed that a combination of propofol and midazolam may have advantages over either drug alone, reducing adverse effects while preserving the potential benefits ("co-sedation"). Propofol combined with a constant low dose of midazolam (1.0 mg/hour) has been compared with propofol alone for postoperative sedation in a randomized, placebo-controlled, double-blind trial in 60 patients undergoing coronary artery surgery under high-dose fentanyl anesthesia (11). Target sedation was achieved more readily with co-sedation (91 versus 79%) but at the expense of prolonged weaning from mechanical ventilation (432 versus 319 minutes). However, it is not clear whether this slightly prolonged time on the ventilator affected length of stay in the ICU.

It remains a source of much concern that those working in operating theaters spend their time in such a polluted environment, in spite of attempts to introduce scavenging of waste anesthetic gases (12). This is not without its effects. There is, for example, a relation between asthma and occupational exposure to various respiratory hazards, including anesthetic gases (13).

Comparative studies

Halothane versus propofol

A randomized prospective trial in 60 children undergoing outpatient anesthesia showed a 30% shorter time from discontinuation of anesthesia to eye opening and return to full wakefulness in patients receiving propofol alone compared with halothane + nitrous oxide anesthesia (14). Propofol was associated with a 17% incidence of emesis compared with 58 and 53% for halothane + nitrous oxide and propofol + nitrous oxide anesthesia respectively.

Isoflurane + nitrous oxide versus propofol

The risk of postoperative nausea and vomiting has been studied in a randomized, controlled trial of total intravenous anesthesia with propofol versus inhalational

© 2006 Elsevier B.V. All rights reserved.

anesthesia with isoflurane and nitrous oxide in 2010 patients (15). It was accompanied by an economic analysis. Propofol total intravenous anesthesia reduced the absolute risk of postoperative nausea and vomiting up to 72 hours postoperatively from 61 to 46%, in inpatients (NNT = 6) and from 46 to 28% in outpatients (NNT = 5). Both anesthetic techniques were otherwise similar. Anesthesia drug costs were more than three times higher for propofol total intravenous anesthesia (as propofol is substantially more expensive than isoflurane + nitrous oxide). However, the patients preferred propofol.

Isoflurane versus sevoflurane

A study of single vital-capacity breath inhalational induction using either isoflurane or sevoflurane combined with 67% nitrous oxide in 67 adults showed that isoflurane was unsuitable for this technique (16). There was an 87% incidence of induction complications with isoflurane, including involuntary movements, cough, laryngospasm, and failure of induction.

In 75 patients of ASA grades 1 or 2, recovery from anesthesia after maintenance with isoflurane + nitrous oxide was significantly slower than with sevoflurane + nitrous oxide (17).

Isoflurane and sevoflurane have been compared in a randomized study in 180 patients undergoing knee arthroscopy (18). In those given sevoflurane there were significantly more respiratory and cardiovascular complications and increased nausea and vomiting.

In a comparison of sevoflurane and isoflurane anesthesia in 2008 patients there was a 3–4 minute reduction in time to recovery end-points with sevoflurane (19). These differences became larger in anesthetics lasting over 3 hours and were trivial in cases less than 1 hour. Patients aged over 65 years had a 5-minute increase in recovery times after receiving isoflurane. There was no significant difference in the incidence of nausea or vomiting between isoflurane, sevoflurane, and propofol.

Propofol versus sevoflurane

Sevoflurane is pleasant to breathe and has a rapid onset and offset of action. It is challenging the tradition of intravenous anesthetic induction in adult patients. In a meta-analysis of 12 studies in 1102 adult patients, intravenous bolus doses of sevoflurane 7–8% and propofol for anesthetic induction were compared (20). Anesthesia maintenance included nitrous oxide 50–70% and either propofol infusion or sevoflurane inhalation, and spontaneous ventilation via a laryngeal mask. Patients in the sevoflurane group were significantly more likely to have postoperative nausea and vomiting (odds ratios 4.2 and 3.2). There were non-significant trends toward greater patient dissatisfaction and a longer induction time in the sevoflurane group, and more frequent apnea in the propofol group. There were no significant complications in either group. Both agents are suitable for anesthetic induction, but propofol retains a small advantage in having better recovery characteristics.

Single-agent induction and maintenance of anesthesia has been compared in a randomized study of 44 patients undergoing elective spinal surgery (21). Patients received either propofol 4–6 μg/ml via a target-controlled infusion or sevoflurane 8% for induction, and sevoflurane 3.5% + 67% nitrous oxide for maintenance plus alfentanil as required. Patients in the propofol group required a significantly larger dose of opiate during the procedure (2.2 mg versus 0.3 mg). Two patients who received propofol complained of pain on injection. There was no significant breath-holding or laryngospasm in either group. Heart rate was significantly lower in the sevoflurane group compared with propofol both before and after incision. The numbers of adjustments to the patient's depth of anesthesia were similar in both groups. The authors concluded that either technique was suitable for spinal surgery. The inclusion of nitrous oxide in the sevoflurane group accounted for the differences in opioid requirements.

The effects of hypercapnia on cerebral autoregulation during sevoflurane or propofol anesthesia have been studied in a randomized, crossover study in eight healthy patients (22). Hypercapnia began to inhibit cerebral autoregulation, as measured by transcranial Doppler at a mean value of 56 mmHg P_aCO_2 with sevoflurane 1.0–1.1% and at 61 mmHg P_aCO_2 with propofol 140 μg/kg/minute. Patients also received remifentanil for analgesia, a drug with no known effects on cerebral autoregulation. The study is important, because one advantage of both propofol anesthesia and sevoflurane anesthesia is the lack of inhibition of cerebral autoregulation at standard doses. Clearly, careful control of ventilation is required for this to be true.

The effects of isoflurane, sevoflurane, and propofol on jugular venous oxygen saturation (S_jO_2) in patients undergoing coronary artery bypass surgery have been studied (23). S_jO_2 values were significantly lower in the propofol group 1 hour after bypass, suggesting an imbalance of oxygen supply and demand with propofol. Because anesthetic agents also reduce the cerebral metabolic rate, the implications of this finding are uncertain. However, low S_jO_2 values have previously been associated with postoperative neuropsychiatric dysfunction after cardiopulmonary bypass.

Vital capacity inhalational induction of anesthesia with sevoflurane has been compared with intravenous induction using propofol in 56 adults undergoing ambulatory anesthesia (24). The patients were randomized to either sevoflurane 8% + nitrous oxide 75% mixture at 8 l/minute ($n = 32$), or propofol 2 mg/kg bolus ($n = 24$), without any premedication. Induction time was significantly shorter with sevoflurane (average 51 seconds) than propofol (average 81 seconds). Adverse effects were different in the two groups: sevoflurane caused cough and hiccups, while propofol caused a fall in blood pressure and reduced movements. The overall incidence of adverse effects was similar. Postoperatively, there was mild nausea in 78% of the patients who received sevoflurane compared with 50% for propofol. However, no antiemetics were needed and discharge times were not delayed.

The characteristics of sevoflurane anesthesia have been compared with those of target-controlled infusion of propofol in 61 day-case adults undergoing surgery (25). All received nitrous oxide 50% and fentanyl 1 μg/kg. After insertion of a laryngeal mask airway the propofol target concentration was reduced from 8 to 4 μg/ml and the

© 2006 Elsevier B.V. All rights reserved.

inspired concentration of sevoflurane was reduced from 8 to 3% and subsequently titrated to clinical effects. Mean times to loss of consciousness and laryngeal mask airway insertion were significantly longer after sevoflurane (73 and 146 seconds respectively) than with propofol (50 and 116 seconds respectively). Sevoflurane was associated with a lower incidence of intraoperative movements (10 versus 55%), necessitating less adjustment to the dose. The incidence of movement in the propofol group was comparable to other studies. Emergence was faster after sevoflurane (5.3 versus 7.1 minutes) but sevoflurane was associated with more postoperative nausea (30 versus 17%) and vomiting (3 versus 0%), resulting in delayed discharge times (258 versus 193 minutes) and a higher total cost. The finding of significantly earlier discharge times after propofol anesthesia was unusual.

Propofol + alfentanil + nitrous oxide anesthesia has been compared with sevoflurane + nitrous oxide anesthesia in 44 patients undergoing dilatation and evacuation of the uterus (26). There was significantly less intraoperative uterine bleeding, as estimated by the gynecologist, with propofol. Above-average bleeding occurred in 5% of the patients with propofol anesthesia and 27% of patients with sevoflurane. This result was not surprising, given that sevoflurane reduces uterine tone, while propofol has no effect.

In a prospective randomized study of 120 day-surgery patients, desflurane and sevoflurane were associated with shorter times to awakening, extubation, and orientation than propofol infusion (27). Average times to awakening at the end of anesthesia were 5, 5, and 8 minutes respectively. There were no significant differences in time-to-home readiness or actual discharge times. A review of 436 patients undergoing either sevoflurane or propofol-based anesthesia showed no difference in similar recovery end-points (19).

There has been a prospective randomized comparison of 185 patients who received propofol 6–8 mg/kg/hour and sevoflurane 1.5% for maintenance of anesthesia (28). The patients were ventilated via a laryngeal mask and no muscle relaxants were given. Both agents were suitable for this technique. Emergence was significantly faster after sevoflurane but associated with more excitatory phenomena and tachycardia.

Sevoflurane versus thiopental

Sevoflurane 8% plus nitrous oxide 66% has been compared with thiopental 4 mg/kg for induction of anesthesia in brief outpatient procedures (29). Sevoflurane was safer, more efficacious, and better accepted by 78 unpremedicated adults with laryngeal cancer undergoing direct laryngoscopy for staging and biopsy. All received suxamethonium 50 mg on loss of the eyelash reflex and the surgeon then performed the laryngoscopy. Hemodynamic stability was greater and immediate recovery was faster after sevoflurane (9.7 versus 11.4 minutes). The incidence of dysrhythmias was also higher with thiopental (19 versus 12 patients). The dysrhythmias were predominantly ventricular extra beats with sevoflurane and ventricular bigemini with thiopental. The high incidence of dysrhythmias was partly due to the lack of opioid medication as part of the anesthetic.

Organs and Systems

Cardiovascular

Volatile anesthetic agents depress cardiac output, especially in the elderly. A study of 80 patients aged over 60 years compared the effects of halothane and isoflurane with and without nitrous oxide 50% (104). Doses were carefully adjusted to be equipotent in all four groups. Isoflurane caused a 30% reduction in systolic and diastolic arterial pressures compared with a 17% reduction with halothane. The reductions in cardiac index were similar with the two agents, about 17%. The addition of nitrous oxide attenuated the reductions in arterial pressure. In the case of the combination of isoflurane with nitrous oxide, there was a small increase in cardiac index and a small reduction in the halothane/nitrous oxide group. Systemic vascular resistance was reduced by a greater extent with isoflurane compared with halothane and little altered by the addition of nitrous oxide. The result suggests that nitrous oxide supplementation may be advantageous in the elderly, but interpretation is limited by the fact that it does not include the effects of surgery on these important cardiac parameters.

The long QT syndrome is associated with potentially fatal ventricular dysrhythmias under anesthesia. The effect of halothane and isoflurane on the QT interval was studied in 51 healthy children (31). Isoflurane 2.3–3.0% increased the average QT interval from 425 to 475 milliseconds at the time of induction. Halothane reduced the average QT interval from 428 to 407 milliseconds. The result suggested that halothane may be the more desirable agent in children with a prolonged QT interval.

The frequencies of cardiac dysrhythmias during halothane and sevoflurane inhalation have been compared in 150 children aged 3–15 years undergoing outpatient general anesthesia for dental extraction (32). They were randomized into three groups and received either halothane or sevoflurane in 66% nitrous oxide whilst breathing spontaneously. One group received 0.75% increments of halothane every two to three breaths to a maximum of 3.0% for induction, and then 1.5% for maintenance of anesthesia. One group received sevoflurane in 2% increments to a maximum of 8% and then a maintenance dose of 4%. The final group received 8% sevoflurane for induction and then a maintenance dose of 4%. The children who received halothane had a 48% incidence of dysrhythmias, significantly higher than the 16% incidence in the sevoflurane group and 8% in the incremental sevoflurane group. The halothane-associated dysrhythmias mainly occurred during dental extraction or emergence from anesthesia, and were usually ventricular. Six children in the halothane group had ventricular tachycardia. The longest run of ventricular tachycardia lasted 5.5 seconds, and one child had 13 separate episodes. Sevoflurane-associated dysrhythmias were mainly single supraventricular extra beats, and did not differ between the two administration methods. Although there was insufficient evidence to suggest that transient dysrhythmias associated with halothane in dental anesthesia can lead to cardiac arrest, sustained ectopic ventricular activity, including ventricular tachycardia, even if self-limiting, results in reduced cardiac output and cannot be ignored. These results imply that sevoflurane may be the preferable agent in this setting.

© 2006 Elsevier B.V. All rights reserved.

The hemodynamic responses to induction and maintenance of anesthesia with halothane have been compared with those of sevoflurane in 68 unpremedicated children aged 1–3 years undergoing adenoidectomy (30). The children received either sevoflurane 8% or halothane 5% + nitrous oxide 66% for induction of anesthesia and tracheal intubation, without neuromuscular blocking drugs. Anesthesia was maintained by adjusting the inspired concentration of the volatile anesthetic to maintain arterial blood pressure within 20% of baseline values, and the electrocardiogram was continuously recorded. The incidence of cardiac dysrhythmias was 23% with halothane and 6% with sevoflurane. Most of the dysrhythmias were short-lasting/self-limiting supraventricular extra beats or ventricular extra beats. Although the overall incidence of dysrhythmias was low in both groups, the result again shows that sevoflurane causes fewer dysrhythmias in children and may be the preferable agent.

QT dispersion, defined as the difference between QT_{max} and QT_{min} in the 12-lead electrocardiogram, is a measure of regional variation in ventricular repolarization (33). It is greater in patients with dysrhythmias. The effects of halothane and isoflurane on QT dispersion have been studied in 46 adult patients undergoing general anesthesia. QT dispersion was increased in both groups both with and without correction for heart rate. The increase was significantly greater with halothane than with isoflurane. The clinical significance of this finding is not known. In isolation, QT dispersion reflects an abnormality in ventricular repolarization and correlates with dysrhythmic events. Although there were no overt dysrhythmias in this study, the effect suggests a reason for the variable results of past studies of the QT interval: most studies showed prolongation of the QT interval, but some showed no change, or shortening. Larger studies are needed to elaborate on the possible clinical importance of this phenomenon, but it may be a significant cause of dysrhythmias with volatile anesthetics.

Respiratory

The incidence of perioperative respiratory complications has been studied prospectively in 602 children aged 1 month to 12 years undergoing elective surgery using a halothane-based anesthetic (34). Exposure to environmental smoke was assessed using the history of exposure to cigarette smoke and measurement of urinary cotinine concentrations, and the respiratory complications of laryngospasm, bronchospasm, stridor, breath holding, coughing, and excessive mucus production were recorded. The incidence of respiratory concentrations in patients with a urinary cotinine concentration over 40 ng/ml was 42%, dropping to 24% in patients with a urinary cotinine concentration less than 10 ng/ml. Female sex and lower socioeconomic status of the mother increased the incidence of respiratory complications. The study showed the importance of factors other than the anesthetic drugs and techniques used in determining complications precipitated by anesthesia.

The respiratory effects of sevoflurane and halothane have been investigated in 30 infants aged 6–24 months (35). Respiratory depression was greater in the sevoflurane group, with a mean minute ventilation of 4.5 compared with 5.4 l/minute/m^2 and respiratory rate was lower at 38 compared with 47 breaths/minute. There was a lower incidence of thoracoabdominal asynchrony with sevoflurane, but no difference in respiratory drive, as evidenced by the flow pressure generated during 100 milliseconds of occlusion of the airway.

The effects of desflurane and sevoflurane on bronchial smooth muscle reactivity have been compared in a randomized study of 40 patients (36). Anesthesia was induced with thiopental, followed by muscle relaxation and ventilation. Airway pressures were recorded during administration of desflurane or sevoflurane at one minimal alveolar concentration (MAC). Airway resistance increased by 5% in the desflurane group and fell by 15% in the sevoflurane group. The increase in airways resistance was greater in smokers and with desflurane, but did not differ with sevoflurane. The result was a surprise, given that desflurane stimulates the sympathetic nervous system. Thiopental also increased airways resistance by 10%. The result is important, because induction of anesthesia can cause bronchospasm and desflurane can exacerbate this.

Nervous system

The effects of sevoflurane and isoflurane anesthesia on interictal spike activity have been studied in 12 patients with refractory epilepsy (37). The patients were undergoing insertion of subdural electrodes and were also given fentanyl during surgery. Electroencephalogram spike frequency increased significantly in all patients during 1.5 MAC sevoflurane anesthesia compared with awake recordings; hypocapnia did not change this increased spike activity. The electrocorticographic interictal spike frequency was also significantly higher in all patients during 1.5 MAC sevoflurane anesthesia and in eight of 10 patients during 1.5 MAC isoflurane anesthesia, compared with 0.3 MAC isoflurane anesthesia. In susceptible individuals, both sevoflurane and isoflurane can provoke interictal spike activity. This effect is only well described for enflurane, but it is a dose-dependent feature of most volatile agents.

Convulsions during anesthesia are of concern because with the use of muscle relaxants they may go unrecognized. The epileptogenic properties of isoflurane and sevoflurane have been compared under a range of different ventilatory conditions in 24 ASA I or II mentally handicapped patients undergoing dental operations (38). Half had a history of epilepsy and half did not. Each patient was ventilated with 100% oxygen (end-tidal carbon dioxide = 40 mmHg; A), then 50% oxygen 50% nitrous oxide (end-tidal carbon dioxide = 40 mmHg; B), and then 100% oxygen (end-tidal carbon dioxide = 20 mmHg; C). With each different mode of ventilation, isoflurane was given at 1 MAC then at 1.5 and 2.0 MAC. The process was repeated 3 months later with sevoflurane. The electroencephalogram was concurrently recorded. The spike and wave index increased significantly from 2.0% during 1.0 MAC sevoflurane to 6.1% during 2.0 MAC in group A in those with epilepsy, while no spike activity was seen in those without epilepsy. Only a few spikes were observed in the isoflurane group in A, with none in B or C. Supplementation with nitrous oxide

© 2006 Elsevier B.V. All rights reserved.

or hyperventilation suppressed the occurrence of spikes. The authors concluded that sevoflurane has stronger epileptogenic properties than isoflurane, but that this can be counteracted by nitrous oxide or hyperventilation.

There has been an impressive French study of the risks of occupational exposure of hospital personnel to anesthetics among the staff of 18 Paris hospitals (excluding doctors) over 12 years (39). Among 557 staff who had been exposed to anesthetics and 566 workers who had been less exposed, neuropsychological and neurological symptoms (tiredness, nausea, headaches, memory impairment, reduced reaction time, tingling, numbness, cramps) were reported some three times more commonly by workers in theaters that had been less often scavenged than by controls; no difference was found between workers from well-scavenging theaters and controls. Neuropsychological symptoms were reported in several earlier papers (40).

Neuromuscular function

Both desflurane and sevoflurane significantly increase the neuromuscular blocking effects of rocuronium compared with isoflurane or propofol (41,42). The effective doses of rocuronium for 50% depression of single twitch height were 95, 120, 130, and 150 μg/kg for desflurane, sevoflurane, isoflurane, and propofol respectively. There were no differences in recovery profiles between the four drugs using equieffective doses. Desflurane, sevoflurane, and to a lesser extent isoflurane, also potentiated the neuromuscular blocking effect of cisatracurium by 30% compared with propofol (43,44).

Hematologic

Hemostasis can be impaired by both surgery and general anesthetics (45). Fentanyl, halothane, and enflurane enhance fibrinolytic activity significantly (46). In addition, there was a raised plasma beta-thromboglobulin concentration (a good indicator of platelet activation) in 61 patients after the use of nitrous oxide, oxygen, and halothane compared with controls (47).

In an in vitro study of the inhibitory effects of thiopental, midazolam, and ketamine on human neutrophil function, thiopental and midazolam inhibited chemotaxis, phagocytosis, and reactive oxygen species production at clinically relevant concentrations (48). Ketamine only impaired chemotaxis. These results may be relevant in guiding anesthetic drug therapy in septic patients.

Gastrointestinal

In a prospective study of 556 adults using isoflurane-, halothane-, or enflurane-based anesthesia for ear, nose, throat, and eye procedures, the incidences of emesis in the various groups over the ensuing 24 hours were 36, 41, and 46% respectively (49). Other drugs given during anesthesia included midazolam, thiopental, morphine, and nitrous oxide. Antiemetic requirements were also less with isoflurane: 12% of patients required an antiemetic compared with 23% with halothane and enflurane. There were no differences in the overall incidences of headache or analgesic requirements in the three groups.

In another prospective study of nausea and vomiting in 50 patients undergoing arthroscopy, sevoflurane was compared with desflurane (50). Other drugs given during anesthesia included propofol and alfentanil. There was no difference in the incidence of nausea, 8 and 16% respectively, and no vomiting in either group. The desflurane group had a significantly higher incidence of sore throat (32 versus 8%). These studies have confirmed that the newer volatile anesthetics isoflurane, sevoflurane, and desflurane cause less nausea and vomiting than halothane or enflurane.

Because population measures of anesthetic dosages do not consider the individual's anesthetic needs, anesthetists often err on the side of relative overdosage during balanced anesthesia, in order to prevent the devastating consequences of unintentional awareness during surgery. This excessive depth of anesthesia contributes to delayed recovery and more adverse effects, which is particularly important in ambulatory surgery. Monitoring of the bispectral index-processed electroencephalogram has enabled anesthetists to monitor the depth of anesthesia and has brought greater precision to the administration of intravenous and inhaled anesthetics and opioids. The hypothesis that titration of the maintenance dose of sevoflurane during outpatient gynecological surgery using bispectral index monitoring reduces postoperative vomiting and improves recovery has been tested in a randomized, controlled study in 22 patients (51). The monitored patients had significantly less vomiting than the controls (16 versus 40%).

Several small clinical trials have suggested that total intravenous anesthesia with propofol reduces the incidence of postoperative nausea and vomiting and results in shorter emergence times. However, a systematic review (52) and a meta-analysis (53) have shown that most studies were small, did not have follow-up for more than 6 hours postoperatively, and were sponsored by industry. The results were difficult to combine, owing to heterogeneous definitions of postoperative nausea and vomiting.

A simplified risk score for predicting postoperative nausea and vomiting in adult patients undergoing general anesthesia has been developed. In a study of 520 adults from Finland and 2202 patients from Germany who had received anesthesia that included benzodiazepine premedication, thiopental, fentanyl or alfentanil, isoflurane, enflurane or sevoflurane, and non-steroidal or opioid drugs for postoperative analgesia no antiemetic prophylaxis was given (54). The final derived score consisted of four predictors: female sex, a history of motion sickness or postoperative nausea and vomiting, non-smoking, and the use of postoperative opioids. The incidence of postoperative nausea and vomiting was 10% when there were no risk factors, 21% (one risk factor), 39% (two risk factors), 61% (three risk factors), and 79% (four risk factors). Only one of the four risk factors related to the drugs used.

Postoperative nausea and vomiting in children has been reviewed in detail, including multimodal strategies for management and prevention (55).

Urinary tract

Methoxyflurane, enflurane, isoflurane, and sevoflurane all release inorganic fluoride ions as a result of hepatic metabolism. Fluoride is nephrotoxic.

© 2006 Elsevier B.V. All rights reserved.

Renal function and fluoride ion release after anesthesia using not more than 2.4% sevoflurane or 1.9% isoflurane have been studied in 50 patients of ASA grades 1–3 undergoing operations lasting at least 1 hour (56). Serum fluoride ion concentrations were significantly increased in both groups, peaking at 28 μmol/l after sevoflurane and 5 μmol/l after isoflurane, both at 1 hour. Of more concern, three of the patients in the sevoflurane group had peak fluoride ion concentrations above 50 μmol/l; two of them had increases in serum blood urea nitrogen and creatinine at 24 hours after surgery. The half-life of fluoride ion was 22 hours.

Nephrotoxicity has been found with methoxyflurane when serum fluoride ion concentrations exceeded 50 μmol/l (SEDA-20, 106). Although this safety threshold has been applied to other volatile anesthetics as well, renal toxicity has not been reported for the other three anesthetics, even though the threshold can be exceeded during prolonged anesthesia.

Volatile agents do not cause nephrotoxicity in adults with normal renal function (57). However, using sensitive urinary markers, both sevoflurane and isoflurane caused mild transient glomerular and tubular functional impairment in 13 patients aged 70 years or over undergoing gastrectomy. The patients received epidural analgesia combined with inhalation anesthesia using 5 l/minute fresh gas flow. The mean dose of sevoflurane was 5.1 MAC-hours and of isoflurane 3.7 MAC-hours. The mean urinary albumin excretion increased from 65 to 148 mg/g creatinine in the sevoflurane group and from 44 to 197 mg/g creatinine in the isoflurane group, and returned to preoperative values on the first postoperative day. The mean urinary β_1 and β_2 microglobulin concentrations also increased markedly in both groups, from 9.3 and 0.8 mg/g to 31 and 6.2 mg/g with sevoflurane and from 7.4 and 0.7 mg/g to 44 and 11 mg/g with isoflurane. These values had returned to normal by day 7 postoperatively. The mean urinary *N*-acetyl-β-D-glucosaminidase concentration also increased significantly. These changes suggest transient renal tubular injury in both groups. There has not been any agreement on how these results should be interpreted, and larger studies are warranted.

Musculoskeletal

A spectrum of muscle reactions to all inhalational agents has been described. Masseteric muscle spasm can occur as an isolated phenomenon or can progress either to rhabdomyolysis with renal insufficiency or to malignant hyperpyrexia (58–61).

Generalized muscle rigidity and hypercapnia, followed by raised creatine kinase activity, have been reported in a child undergoing general anesthesia (62).

- A 2-year-old girl with a past history of asthma, developmental delay, short neck, and lumbar lordosis, but no known genetic defect or syndrome underwent anesthesia with midazolam and paracetamol premedication, halothane and nitrous oxide induction, and isoflurane plus nitrous oxide for maintenance of anesthesia. Difficulty with mouth opening was noted and endotracheal intubation was difficult. Limb rigidity developed rapidly. Thiopental and cisatracurium were given and the muscle rigidity abated over the next 10 minutes. The procedure was continued with a propofol infusion. No treatment for malignant hyperpyrexia was undertaken and no other markers for malignant hyperpyrexia were observed. She made a normal recovery from anesthesia. Creatine kinase activities were raised at 2370 U/l intraoperatively and 18 046 U/l at 20 hours postoperatively.

The case is interesting in that although episodes of masseter spasm, rigidity, rhabdomyolysis, and malignant hyperpyrexia are well known after the use of halothane and suxamethonium, they have only rarely been reported when suxamethonium was not used.

Immunologic

The issue of hypersensitivity reactions during general anesthesia is a matter of concern. However, despite considerable work on the subject, there is divergence in interpretation (63). In patients with no pre-anesthetic immunological anomaly, general anesthesia is unlikely to affect immune status significantly (64).

Widespread erythema and edema, the most dangerous form of which affects the glottis, occur in some cases of hypersensitivity. Hypotension is also seen, together with compensatory tachycardia. Bronchospasm is a common respiratory finding (65).

There were significant immunological changes in the peripheral blood film of personnel working in unscavenged operating theaters in Croatia (66). Some of the effects persisted beyond a 4-week period away from that environment.

In a review of 23 444 anesthetics given during 12 months, one patient in 630 had generalized erythema and edema and one in 1230 had erythema and hypotension (67). One patient died of shock. Female patients aged 15–25 with a history of allergy, subjects with excessive anxiety, and those who had previously undergone general anesthesia had a statistically significant higher risk of developing non-allergic anaphylactic reactions. The incidence of allergic anaphylactic reactions (with IgE antibodies) is said to be one in 4500–20 000 general anesthetics per year (68). However, the diagnosis is often missed (69).

The patient's history is hardly helpful; neither the presence nor the absence of a previous reaction gives guidance as to the likelihood of its occurring on future exposure. The mechanisms underlying such reactions may or may not involve histamine release, but the distinction between allergic anaphylactic and non-allergic anaphylactic (anaphylactoid) reactions is often unclear, for lack of definitive and easily available investigations. Furthermore, because anesthetic drugs are often given rapidly and in combination, it can be impossible to decide which was responsible for the reaction. Intradermal injection of a test dose is of limited predictive value (70); false-positive and false-negative results are often obtained, particularly with opiates, tubocurarine, and atracurium. What is more, the test is dose-dependent and can itself precipitate a hypersensitivity reaction (71). It has been suggested that leukocyte histamine release on exposure to drugs can be used in combination with paper radioallergosorbent testing for IgE antibodies, to detect the precise cause of any anaphylactic reaction: these techniques point

© 2006 Elsevier B.V. All rights reserved.

to neuromuscular blocking drugs as being most commonly implicated in anaphylaxis (70).

In a French study, 1585 patients underwent diagnostic investigations after anaphylactic shock during anesthesia; 813 of them had a reaction of immunological origin. The drugs involved were muscle relaxants (70%), latex (13%), anesthetic drugs (5.6%), opioids (1.7%), colloids (4.7%), and antibiotics (2.6%) (72). Among the 45 patients in whom anesthetics were involved, the agents implicated were thiopental ($n = 18$), propofol ($n = 10$), ketamine ($n = 1$), midazolam ($n = 7$), diazepam ($n = 5$), and flunitrazepam ($n = 4$). These data did not differ from those reported in a UK study (73). In both studies there was a high proportion of cases in which muscular relaxants were used alongside anesthetics, resulting in a two-fold risk of hypersensitivity.

Body temperature

Malignant hyperthermia

Malignant hyperpyrexia is a life-threatening condition that involves sustained muscle contraction, muscle damage, and the production of vast quantities of metabolic heat, carbon dioxide, and potassium. Although it is a rare complication of general anesthesia, it remains a topic of considerable interest (74).

The incidence is difficult to determine, but it is currently estimated at one in every 10 000–20 000 anesthetics.

Diagnosis

Generalized muscle rigidity (found in 70% of the patients involved) and a progressive rise in body temperature (sometimes beyond 43°C) are the main clinical features, often associated with tachycardia, hypoxia, metabolic acidosis, cardiac dysrhythmias and, less often, disseminated intravascular coagulation, cerebral edema, and acute renal insufficiency. Diagnosis relies on the clinical signs, that is muscle rigidity and hyperpyrexia, and on raised serum activities of skeletal and cardiac muscle enzymes, for example aldolase and creatine kinase.

Genetic markers for malignant hyperpyrexia may soon make identification of risk groups simpler than the currently used muscle biopsy technique (75).

Susceptibility factors and prophylaxis

Although malignant hyperthermia is usually associated with the muscle relaxant suxamethonium, all inhalational anesthetics have been implicated and will be unsafe if risk factors for this condition are present, for example a family history or one of the congenital muscle disorders (76). This must be considered in patients at risk, as there are readily acceptable alternatives, such as propofol (77) and midazolam (78).

Malignant hyperthermia is probably due to the inability of certain individuals to control calcium concentrations in the muscle fiber and may involve a generalized alteration in cellular or subcellular membrane permeability, as suggested from research on pigs. This anomaly is genetically determined, but pre-anesthetic evaluation of susceptibility to malignant hyperthermia is a matter of controversy: measurement of blood creatine kinase, ATP muscle depletion, or myophosphorylase A, histological examination of muscle fibers, and in vitro exposure to caffeine or halothane have all been proposed. However, if susceptible patients require general anesthesia, despite the risk, prophylactic use of intravenous dantrolene 2.4 mg/kg during induction of anesthesia has been recommended (79).

Treatment and prognosis

Around 1970, mortality was as high as 70%, but it is now less than 10%. This reduction in mortality has been due to the use of dantrolene, the only specific treatment available, and also to an increased understanding of the condition (74).

Treatment is by withdrawal of the anesthetic, hyperventilation with 100% oxygen, cooling, and dantrolene. Doses of dantrolene of 2.5–5 mg/kg are usually recommended, given as early as possible to ensure rapid and complete resolution of the hyperthermic response (80).

Death

Correct estimates of the incidence of anesthetic deaths are difficult to obtain, since many deaths are multifactorial. Mortality due to anesthetic drugs is one in 10 000–20 000 (81). The adverse effects of anesthetics have been reviewed (82). Dose-related reactions are common and carry a low mortality, while non-dose-related reactions are less common and carry a high mortality.

A national prospective survey of complications related to anesthesia was carried out in France from 1978 to 1982 (83,84). In 198 103 anesthetic procedures, only 63 deaths were recorded, of which only 15 were definitely attributed to anesthesia (85). The Confidential Enquiry into Perioperative Deaths, conducted a decade ago in three British Health Regions (86) and covering a total of 555 248 patients, showed that the incidence of death within 30 days of surgery and anesthesia was 0.73% (4034 cases). Only about 14 of these deaths were considered to be partly or totally attributable to the anesthesia, and indeed in most cases other factors were also involved, including the surgery itself, the presurgical condition, and intercurrent illnesses. In a review of 25 deaths during anesthesia in 1982–86, only six were considered to be drug-related; of these, two were due to overdose and two more were the result of adverse effects of non-anesthetic agents (87).

Finally, except for certain specific effects that have a clear relation to a particular agent (for example liver damage after halothane), it is difficult to designate one anesthetic as being more risky than another. It has been authoritatively concluded that "the current level of research effort cannot distinguish mortality and serious morbidity between the most common anesthetic agents, and the clear differences in hemodynamic patterns among these anesthetic agents have an unknown, perhaps non-existent, relationship with mortality and serious morbidity" (88).

Long-Term Effects

Mutagenicity

Genetic damage was demonstrated in 10 non-smoking veterinary surgeons exposed to isoflurane and nitrous oxide compared with 10 non-smoking, non-exposed

veterinary physicians acting as controls (89). The surgeons were monitored for 1 week in a working environment comparable to that of pediatric anesthesia, with the use of uncuffed endotracheal tubes and open-circuit breathing systems during operations on small animals. The overall calculated 8-hour time-weighted average exposure of cases was 5.3 ppm for isoflurane and 13 ppm for nitrous oxide. The European exposure limits are 10 ppm and 100 ppm respectively, and the corresponding values recommended by USA-NIOSH are 2 ppm and 25 ppm respectively. These values therefore violated the USA-NIOSH limit for isoflurane. The mean frequency of sister chromatid exchanges in peripheral blood lymphocytes was significantly higher in exposed workers than in controls (10 versus 7.4) and the proportion of micronuclei was also significantly higher in exposed workers (8.7 versus 6.8 per 500 binucleated cells). These measures reflect the mutagenicity of isoflurane and nitrous oxide. The findings are comparable to smoking 11–20 cigarettes a day. However, this study did not distinguish between the potential genotoxic effects of isoflurane and nitrous oxide; nor did it show a dose-dependency of genotoxicity, owing to the small sample size.

Second-Generation Effects

Fertility

Nitrous oxide may be the most serious of anesthetic pollutants; female dental assistants exposed to large amounts of nitrous oxide (5 hours or more of exposure per week) are significantly less fertile than women who are not exposed or who are exposed to lower amounts (90).

Pregnancy

The pharmacology and adverse effects of anesthetic drugs used for cesarean section have been reviewed (91).

Teratogenicity

In an epidemiological study, anesthetists had significantly greater exposure and perhaps more adverse effects than other operating-room personnel (92). Among women, exposure certainly causes an increased risk of spontaneous abortions in the first trimester, although teratogenicity is less clear-cut (93).

Susceptibility Factors

Underlying disease

Underlying disease is probably one of the most complex risk factors. Although general anesthesia is potentially more hazardous in patients with underlying disease in general (94) or specifically suffering from intracardiac conduction disturbances (95), severe hypertension (96), hypothyroidism (97), or cancer (98), it is extremely difficult to provide clear-cut recommendations, because the relative severity of disease in a given patient and the patient's response to the pathological process needs to be taken into account: while, for instance, thiopental may precipitate cardiovascular collapse, both pre-existing cardiac status and the dose of the drug are relevant.

Critically ill patients

Drug metabolism is reduced in critically ill patients. When the serum from five critically ill patients was incubated with microsomes prepared from three different human livers, the activity of CYP3A4, assessed by metabolism of midazolam to 1-hydroxymidazolam, was significantly inhibited compared with serum from healthy volunteers (99). The authors pointed out that many other drugs are also metabolized by this enzyme, including alfentanil, ciclosporin, cortisol, erythromycin, lidocaine, and nifedipine. This observation accounts for past reports of very slow metabolism of midazolam in seriously ill patients, resulting in high blood concentrations and delayed awakening.

Pre-anesthetic drug therapy

The consequences of pre-anesthetic drug therapy as a risk factor are obviously closely related to those of the underlying disease. The problem has attracted considerable attention in recent years and has been extensively reviewed (100). Interactions of drugs with anesthesia are dealt with here primarily in monographs on the drugs concerned. Although many pharmacological interactions with general anesthesia are firmly established, others remain ill-explained or unpredictable. Individual factors are likely to play a major role. Moreover, pre-anesthetic drug withdrawal in itself can be more dangerous than continuation of therapy, as exemplified by the case of the antihypertensive drug clonidine (101) or beta-blockers (102).

Driving

The hazard of driving shortly after general anesthesia is still difficult to evaluate. Although abstention from driving has been recommended for 48 hours after general anesthesia (103), it is still difficult to draw clear-cut conclusions from the available data. The matter is also referred to under individual anesthetic drugs.

Gentamicin

See also Aminoglycoside antibiotics

General Information

Gentamicin is well established for the treatment of several bacterial infections, especially those caused by Gram-negative bacteria, including *Pseudomonas aeruginosa*, *Klebsiella* species, and *Serratia marcescens*. In adults, it is usually given in daily doses of 240–360 mg.

Observational studies

In 17 patients with suspected postoperative endophthalmitis treated with 0.2 mg vancomycin and 0.05 mg gentamicin intravitreally, there were adequate intravitreal vancomycin and gentamicin concentrations for over a week; there were no adverse effects (1).

Intratympanic gentamicin therapy has gained some popularity in the treatment of vertigo associated with Menière's disease, as it offers some advantages over traditional surgical treatment. In a 2-year follow-up of 15 patients with Menière's disease, gentamicin solution 0.5 ml (20 mg/ml) injected intratympanically once a week minimized the risk of hearing loss in the treated ear, allowing complete control of vertigo in eight patients after two doses and in 14 patients after four doses (2).

In an open, randomized, controlled trial, once-daily and thrice-daily gentamicin were compared in 173 children aged 1 month to 12 years; there was no nephrotoxicity or ototoxicity (3). Daily doses of gentamicin in both groups were 7.5 mg/kg (under 5 years old), 6.0 mg/kg (5–10 years old), and 4.5 mg/kg (over 10 years old).

Organs and Systems

Respiratory

Acute respiratory failure with near-fatal bronchoconstriction has been reported in an adult with bronchiectasis and chronic *P. aeruginosa* airways colonization immediately after the first inhalation of a commercially available gentamicin solution (4).

Nervous system

Intraventricular gentamicin can cause aseptic meningitis (5).

Sensory systems

The frequency of aminoglycoside-associated hearing loss is 2–45%. Since gentamicin-induced ototoxicity in most cases only involves vestibular function, the symptoms are easily overlooked in severely ill patients who are unable to sit. If diagnosed early, the vestibular damage is usually reversible. In some cases, severe long-term disability has been described (6). Six patients presented with unilateral vestibulotoxicity after systemic gentamicin therapy (7). All had ataxia and oscillopsia, but none had a history of vertigo. The authors suggested that a subacute course of vestibulotoxicity with time for compensation or asymmetrical recovery of vestibular function after bilateral

© 2006 Elsevier B.V. All rights reserved.

vestibular loss could have explained the lack of vertigo in these patients.

The risk of ototoxicity from gentamicin in children is probably less than in adults. In many studies of serious neonatal infections treated with gentamicin there have been very few cases that have provided unequivocal evidence of gentamicin-induced ototoxicity. Gentamicin can be an excellent drug in neonatal sepsis, and its potential toxicity should not preclude its use when it is needed.

Gentamicin ear-drops can cause serious adverse effects (for example vertigo, imbalance, ataxia, oscillating vision, hearing loss, and tinnitus) when they are used by patients with perforated tympanic membranes or tympanostomy tubes (8).

The symptom complex known as visual vestibular mismatch can be caused by peripheral vestibular disease. In a retrospective study of 28 patients with Menière's disease, 17 had visual vestibular mismatch; gentamicin therapy increased the number of positive answers (9).

In a retrospective analysis of 85 patients treated with intratympanic gentamicin, using a fixed-dose regimen of 26.7 mg/ml tds on 4 consecutive days, hearing loss occurred in 26% of individuals (10).

The characteristics of ototoxicity of topical gentamicin have been studied retrospectively in 16 patients (11). All used ear-drops for more than 7 days before the development of symptoms, and all had some degree of vestibulotoxicity, but only one had a worsening of cochlear reserve. Even if the tympanic membrane is intact, one should hesitate to use gentamicin in ear-drops or in other topical forms for the treatment of otitis media.

In patients with acute bacterial conjunctivitis there were adverse drug reactions in 4 of 103 treated with gentamicin (12). The adverse effects included redness, itching, and burning, and none was serious.

In two animal studies methylcobalamin or dimethylsulfoxide inhibited the ototoxic adverse effects of gentamicin (13,14).

Psychological, psychiatric

There are several case reports of acute toxic psychoses due to gentamicin (15).

Mineral balance

Gentamicin-induced magnesium depletion is most likely to occur in older patients when large doses are used over long periods of time (16). Under these circumstances, serum concentrations and urinary electrolyte losses should be monitored.

Liver

Increases in alkaline phosphatase after gentamicin have been described (17).

Urinary tract

A full course of gentamicin therapy causes nephrotoxicity in 1–55% of patients. Two types of gentamicin-induced nephrotoxicity are recognized: (1) a gradual reduction in creatinine clearance, occurring after about 2 weeks, in about 5–10% of patients receiving the drug in full doses, the reduction being rapidly reversible in most cases as soon as gentamicin is withdrawn; (2) acute renal insufficiency due to tubular necrosis, usually associated with oliguria lasting 10–12 days, followed by a diuretic phase; this type of nephrotoxicity occurs far less often than the first type.

The following order of relative nephrotoxicity has been found in many animal experiments: neomycin > gentamicin > tobramycin > amikacin > netilmicin (18,19). However, in humans, conclusive data regarding the relative toxicity of the various aminoglycosides are still lacking. An analysis of 24 controlled trials showed the following average rates for nephrotoxicity: gentamicin 11%; tobramycin 11.5%; amikacin 8.5%; and netilmicin 2.8% (20). In contrast to this survey, direct comparison in similar patient groups showed no significant differences between the various agents in most trials (21–27). In fact, the relative advantage of lower nephrotoxicity rates observed with netilmicin in some studies may be limited to administration of low doses. One prospective trial showed a significant advantage of tobramycin over gentamicin (28). However, these findings could subsequently not be confirmed (29). The risk of gentamicin nephrotoxicity is increased in biliary obstruction (SEDA-20, 235).

In a few cases, gentamicin nephrotoxicity was associated with a Fanconi syndrome, with raised serum enzymes activities in the urine. Among these, muramidase seemed to be especially useful in checking for proximal tubular dysfunction (30).

Gentamicin is of considerable value in the management of sepsis in immunosuppressed patients and renal transplant recipients. Although it has been suggested that gentamicin should be avoided in such patients because of potential renal toxicity in the allograft (31,32), experienced physicians have felt that gentamicin may be given, provided the dosage schedule is adapted to the degree of allograft function and that blood concentrations are monitored.

After a full course of gentamicin 1–55% of patients have nephrotoxicity. The increased serum creatinine concentration peaks on day 6 of therapy and is reversible in most cases within 30 days. Nephrotoxicity appears to be more common among patients with pre-existing renal impairment, longer treatment duration (over 7 days), repeated courses of aminoglycosides, and after the coadministration of other nephrotoxic drugs (for example amphotericin, cisplatin, daunorubicin, furosemide, and vancomycin). Animal studies have suggested that hydrocortisone, angiotensin converting enzyme inhibitors, and hypercalcemia can also increase aminoglycoside nephrotoxicity, whereas acetazolamide, bicarbonate, ceftriaxone, lithium, magnesium, melatonin, piperacillin, polyaspartic acid, pyridoxal-5′-phosphate, and a high protein diet may be protective (33,34).

In 87 patients with intertrochanteric hip fractures, preoperative antibiotic prophylaxis (gentamicin 240 mg and dicloxacillin 2 g) had no significant effect on wound infections; however, there were 16 reversible cases of nephrotoxicity and 1 irreversible case among patients who received antibiotic prophylaxis, compared with only 4 cases of reversible kidney damage among 76 patients who did not receive antibiotics (35).

© 2006 Elsevier B.V. All rights reserved.

- Acute renal insufficiency occurred in an 83-year-old woman after two-stage revision of an infected knee prosthesis with gentamicin-impregnated beads and block spacers (36). The combined use of beads and a cement block spacer, both gentamicin impregnated, may have caused this severe complication.
- A 43-year-old black woman with a 13-year history of lupus developed severe acute tubular necrosis secondary to gentamicin (37).

Since serum creatinine does not accurately reflect renal function in patients with spinal cord injury, dosage regimens of gentamicin should be individualized, based on age, sex, weight, height, the level of spinal cord injury, and renal function (38).

In animals melatonin (39,40) or l-carnitine (41) protected the kidneys against oxidative damage and the nephrotoxic effect of gentamicin.

Nephrocalcinosis occurred in 16 of 101 babies born at less than 32 weeks gestation (42). Multivariate analysis showed that the strongest predictors of nephrocalcinosis were duration of ventilation, toxic gentamicin/vancomycin concentrations, low fluid intake, and male sex.

Skin

Erythema multiforme developed in a 4-year-old girl after treatment with topical aural gentamicin sulfate (0.3%) plus hydrocortisone acetate (1%) prescribed for otorrhea (43).

Immunologic

Allergic contact dermatitis due to gentamicin is rare in patients with eyelid dermatitis, but it can occur.

- A 55-year-old housewife developed pruritic, erythematous, scaly plaques on the eyelids, spreading in a few days periorbitally after treatment with gentamicin eye-drops (Colircusi Gentamicina) (44). A positive patch test reaction to kanamycin, to which the patient had not been previously exposed, suggested cross-reactivity.

Second-Generation Effects

Teratogenicity

During pregnancy the aminoglycosides cross the placenta and they might theoretically be expected to cause otological and perhaps nephrological damage to the fetus. However, no proven cases of intrauterine damage by gentamicin have been recorded.

Susceptibility Factors

Age

In premature neonates, gentamicin clearance depends on gestational age, with a cut-off at 30 weeks: younger neonates have lower gentamicin clearance, a slightly higher volume of distribution, and a longer half-life compared with the older neonates (45). Loading doses of 3.7 and 3.5 mg/kg followed by maintenance doses of 2.8 mg/kg/day and 2.6 mg/kg/18 hours have been recommended for younger and older neonates respectively.

Drug Administration

Drug contamination

Several patients developed severe shaking chills, often accompanied by fever, tachycardia, and/or a significant reduction in systolic blood pressure within 3 hours of receiving intravenous once-daily dosing regimens of gentamicin produced by Fujisawa USA, Inc (Deerfield, Illinois). Investigations showed that gentamicin formulations that contain concentrations of endotoxin that are within the USP standards may deliver amounts of endotoxin that are above the threshold for pyrogenic reactions with once-daily dosing (46).

Of 155 patients (38% men, mean age 41 years) with pyrogenic reactions due to gentamicin, 81% received once-daily dosing (70% in a dose of 5–7 mg/kg) and 10% received a conventional dose (3 mg/kg in three divided doses (47)). Reactions typically occurred within 3 hours after infusion (98%) and lasted for less than 3 hours (96%). Patients reported chills, shaking, or shivering (75%), rigors (23%), fever (68%), tachycardia (17%), hypertension or hypotension (17%), and respiratory symptoms (47%). More serious reactions also occurred, including cyanosis (4%), oxygen saturation below 80% (7%), and pulmonary edema (one patient); 8% had severe reactions leading to hospitalization (with intubation, resuscitation, or admission to the intensive care unit in five cases), but none died. An FDA investigation showed that 10% of gentamicin lots tested had raised endotoxin concentrations, and an additional 4% of the lots would have exposed a patient to concentrations above the acceptable threshold with once-daily dosing. The two products implicated in these clusters involved the same supplier of bulk gentamicin; inadequacies in manufacturing practices had led to an increase in overall impurities (48,49).

Drug dosage regimens

Once-daily regimens are appealing for cost saving and may have a therapeutic advantage and reduced toxicity. A prolonged distribution time has been noted with high-dose gentamicin (7 mg/kg). Higher doses are used for extended-interval aminoglycoside therapy. In 12 healthy volunteers receiving extended-interval high-dose gentamicin, sampling within 90 minutes after the start of the infusion provided information that led to overestimation of peak serum concentration/minimum inhibitory concentration and inaccurate pharmacokinetic calculations (50).

Although once-daily dosing appears to be effective in limited studies in children, its role in Gram-positive coccal endocarditis, in individuals with neutropenia or cystic fibrosis, and in individuals with altered volumes of distribution remains uncertain (51).

In 18 patients receiving empirical therapy for CAPD-related peritonitis, once-daily intraperitoneal gentamicin (0.6 mg/kg) had less therapeutic benefit and peak serum gentamicin concentrations were lower than the suggested value of 4 μg/ml, whereas trough serum gentamicin

© 2006 Elsevier B.V. All rights reserved.

concentrations were higher than the minimum toxic concentration; dialysate gentamicin concentrations were higher than therapeutic concentrations for only 4.75 hours of each day (52).

In 45 neonates (53) and 123 older children (54) gentamicin 4–5 mg/kg once a day produced peak concentrations associated with greater efficacy and trough concentrations associated with less toxicity than 2.0–2.5 mg/kg bd.

In febrile neutropenic episodes after intensive chemotherapy, once-daily gentamicin (7 mg/kg/day) in combination with azlocillin was more effective than a multiple-daily dosing regimen, but the incidence of toxicity was low overall and was slightly but not significantly higher in the once-daily group (55).

For external otitis, therapeutic local antibiotic concentrations can be achieved by giving gentamicin ear-drops twice daily; more frequent administration is not needed (56).

Drug administration route

Oral administration of gentamicin in low dosages to reduce the intestinal flora is rarely practiced, although it is probably as effective as neomycin. In the presence of intestinal mucosal inflammation more than 10% of the dose can be absorbed.

Endotracheal administration of gentamicin can be used in patients with a tracheotomy. This route of administration does not produce toxic plasma concentrations, but in patients with renal insufficiency the absorption of a certain amount via the respiratory tract should be taken into account.

Topical application of gentamicin to large areas of burns has caused ototoxic effects, ranging from mild to severe loss of hearing, with decrease of vestibular function (57). Positional vertigo occurred in one patient (58). In another case a woman complained of tinnitus each time she treated her paronychia with gentamicin cream (59).

Intrathecal gentamicin can cause neurotoxic lesions (60).

Increased penetration of gentamicin through a thin sclera can lead to toxic concentrations of the drug in a localized area adjacent to the site of injection, as has been shown in rabbits (61). These toxic effects are also influenced by the degree of pigmentation and acute inflammation. In a case of accidental injection of gentamicin 20 mg into the vitreous in a 70-year-old man during vitrectomy, no toxic signs occurred after the operation (62).

There is uncertainty about the risk of ototoxicity after the topical administration of aminoglycosides into the ear when the indication was appropriate (63,64). Nine cases of iatrogenic topical vestibulotoxicity have been reported (65). All had used ear-drops containing gentamicin sulfate and betamethasone sodium phosphate for prolonged periods. Toxicity was primarily vestibular rather than cochlear. Although compensation occurred in unilateral cases, the disability in bilateral cases was typically severe and often resulted in litigation.

Drug overdose

Although aminoglycoside antibiotics are dialysable, peritoneal dialysis may not remove them from the blood after overdosage. However, hemodialysis is effective (66).

Drug–Drug Interactions

Beta-lactam antibiotics

Gentamicin and other aminoglycosides have increased activity when they are combined with beta-lactams, resulting in increased bacterial aminoglycoside uptake (33). The proposed mechanism of synergism is damage to the cell membrane by the beta-lactam, followed by improved diffusion of gentamicin across the outer bacterial membrane. A second type of synergism, pharmacodynamic synergism, occurs when high serum concentrations of aminoglycosides cause efficient bacterial killing, resulting in reduced bacterial concentrations, which are more effectively eliminated by beta-lactams, as they work more efficiently against lower bacterial concentrations. The action of gentamicin is inhibited by some antimicrobials, which are bacteriostatic rather than bactericidal; for example antagonism occurs with macrolides, tetracycline and doxycycline, and chloramphenicol. The clinical significance of this antagonism is unknown.

There are many reports of acute renal insufficiency from combined treatment with gentamicin and one of the cephalosporins (67–69). The potential nephrotoxic effect of this combination seems to be related mainly to the nephrotoxic effect of gentamicin.

Methylthioninium chloride

Gentamicin is synergistic with methylthioninium chloride (methylene blue) in vitro against *P. aeruginosa* (70).

Metronidazole

In guinea-pigs, metronidazole augmented gentamicin-induced ototoxicity, determined by the measurement of compound action potentials (71).

NSAIDs

Aminoglycosides used in combination with non-steroidal anti-inflammatory drugs can be associated with renal insufficiency.

- An adolescent with cystic fibrosis developed renal insufficiency and severe vestibular toxicity after treatment with gentamicin and standard-dose ibuprofen (72). A low intravascular volume was a possible contributing factor.

Monitoring Therapy

During multiple-daily dosing regimens peak serum concentrations of gentamicin over 5–7 μg/ml are associated with improved survival in patients with septicemia and pneumonia caused by Gram-negative bacteria (73,74). On the other hand, excessive peak concentrations (over 10–12 μg/ml) and trough concentrations (over 2 μg/ml) of gentamicin increase the risk of ototoxicity and nephrotoxicity (75).

Salivary sampling is of potential interest in monitoring drug therapy, especially in children. Although there was no correlation between serum gentamicin concentrations and salivary concentrations when gentamicin was given

© 2006 Elsevier B.V. All rights reserved.

two or three times daily in children with uncomplicated infections, there was a good correlation after once-daily dosing (76).

Eustoma (prairie gentian)
Frasera (green gentian)
Gentiana (gentian)
Gentianella (dwarf gentian)
Gentianopsis (fringed gentian)
Halenia (spurred gentian)
Lisianthius (lisianthius)
Lomatogonium (lomatogonium)
Obolaria (obolaria)
Sabatia (rose gentian)
Schultesia (wingcup)
Swertia (felwort)
Voyria (ghostplant)

hypoglycemic, an effect that has been attributed to isoorientin, which is present in several species of *Gentiana* (1) and which also has antinociceptive and anti-inflammatory effects in animals (2). Some species of *Gentiana* inhibit monoamine oxidase (3) and acetylcholinesterase (4) in vitro.

Gentian violet is a purple dye that is obtained from coal tar; it is so called because its color resembles that of the flower and it has nothing to do with *Gentiana* species.

Swertia species

Swertia species (felwort) are mutagenic in bacteria, because of the several xanthone derivatives that it contains. The clinical relevance of this remains to be established. They also have hypoglycemic effects in animals (5).

Germanium

General Information

Germanium is a metallic element (symbol Ge; atomic no. 32) that is found as the sulfide in the mineral argyrodite.

In several countries, organic or inorganic germanium has acquired a remarkable reputation in self-medication as a widely useful prophylactic and therapeutic agent, but with little scientific evidence to support it. Some germanium compounds, particularly spirogermanium, do have certain immunoregulatory activities, but germanium itself does not seem to play a role in this. There has been some attempt to use germanium in cancer chemotherapy. The unsupervised use of germanium-containing "health products" is of particular concern. Finally, there may be non-medicinal exposure, for example from some semiconductors.

Renal and other organ failure has been caused by germanium intoxication.

Organs and Systems

Nervous system

Nephropathy and neuropathy have been attributed to germanium toxicity (1).

- A 53-year-old man developed severe general weakness, anorexia, and weight loss (16 kg in 3 months). Over the preceding 17 months he had taken a total of 400 g of lysine germanium oxide in powder form. After 15 months he developed a tingling sensation in the palms and soles and weakness of the limbs, especially the legs. Neurological examination showed grade IV motor strength and negative deep tendon reflexes in the legs. Laboratory tests showed impaired renal function and anemia. Urinary concentration of beta$_2$-microglobulin was raised. The blood germanium concentration was 63 ng/ml and the urine concentration 2190 ng/l (normal less than 5 ng/ml). Renal sonography showed no morphological abnormalities. Nerve conduction studies and needle electromyography suggested a sensorimotor polyneuropathy, predominantly involving sensory nerves. Renal biopsy showed tubulointerstitial nephritis. Abstinence from germanium and conservative management of the chronic renal insufficiency resulted in slight improvement of the weakness and renal function.

Urinary tract

Occupational exposure to inorganic germanium compounds can cause slightly impaired renal function (2). However, severe nephrotoxic reactions have been described, and it has become clear that these can occur both with inorganic and organic germanium compounds (SEDA-21, 235).

A 58-year-old man developed nausea, vomiting, anorexia, and weight loss (3). He had taken germanium lactate citrate, illegally purchased in a pharmacy, recommended as a natural antioxidant, anticancer, and immunostimulatory remedy. He took a total dose of 426 g orally over

6 months and developed renal insufficiency and proteinuria, implying tubular damage. His serum TSH, fasting glucose, glycosylated haemoglobin, and C-peptide were increased. Abdominal ultrasound showed normal kidneys. Cardiac ultrasound showed a pericardial effusion. An electrocardiogram showed a sinus tachycardia. Nerve conduction studies and electromyography showed pathological spontaneous muscular activity and myotonic discharge. The neural conduction velocity was normal in the median nerve and delayed in the peroneal nerve. He received intravenous nutrition, insulin, and electrolytes. The pericardial effusion regressed but the sinus tachycardia continued. The renal dysfunction and the polyneuropathy persisted.

- A middle-aged woman who had taken germanium lactate-citrate for at least a year (with an estimated cumulative dose of 32.1 g of germanium) developed renal insufficiency with a creatinine clearance of 10 ml/minute, raised creatine kinase activity, and moderately raised liver enzymes. Biopsy showed highly vacuolated cytoplasm in the epithelial cells of the distal renal tubules and microvesicular and macrovesicular steatosis of centrilobular hepatocytes. After withdrawal of the germanium the laboratory values normalized but moderately severe renal impairment persisted (SEDA-16, 231).
- A 63-year-old man developed membranous glomerulonephritis after having taken 10–12 tablets of a germanium-containing ginseng formulation about 10 days before (4). He responded to diuretic treatment and was discharged in improved condition. However, on the day after discharge he restarted his intake of the formulation; over the next 14 days, his weight increased by 12 kg and he developed worsening edema and hypertension, despite an increase in the dosage of furosemide to 240 mg bd. He was re-admitted and given intravenous furosemide (240 mg every 8 hours). The nutritional supplements were withheld and after 48 hours diuresis took effect.

While other causes may have contributed in part to this man's poor response to furosemide, the facts strongly suggest that germanium played an important role in producing a diuretic-refractory renal dysfunction in this case.

Ginkgoaceae

See also Herbal medicines

General Information

The family of Ginkgoaceae contains the single genus, *Ginkgo*, and a single species, *Ginkgo biloba*.

Ginkgo biloba

Ginkgo biloba (maidenhair tree, silver apricot) contains ginkgolides, which inhibit platelet-activating factor, reducing aggregability; this may contribute to bleeding disorders in patients taking *G. biloba*. *Ginkgo* has small beneficial effects in patients with intermittent claudication (1) and dementias (1,2).

Extracts from the leaves of *G. biloba* are marketed in some countries for the treatment of cerebral dysfunction and of intermittent claudication. In a review it was concluded that seven out of eight controlled trials of good quality showed positive effects of *G. biloba* compared with placebo on the following symptoms: memory difficulties, dizziness, tinnitus, headache, and emotional instability with anxiety (3). For intermittent claudication, the evidence for efficacy was judged unconvincing.

No serious adverse effects have been noted in any trial. However, *G. biloba* has been associated with gastrointestinal complaints, headache, and allergic skin reactions (SED-13, 538). Bleeding has been associated with chronic *G. biloba* ingestion because of its adverse effects on platelet aggregability, since the ginkgolide constituents of *G. biloba* inhibit platelet-activating factor.

Adverse effects

Ginkgo biloba has been associated with gastrointestinal complaints, headache, antiplatelet effects, and allergic skin reactions.

Nervous system

Ginkgo biloba can precipitate seizures in patients with well-controlled epilepsy (4).

- A 78-year-old man and an 84-year-old woman with previously well-controlled epilepsy presented with recurrent seizures (4). There were no obvious reasons for these events, and the investigator suspected self-medication with *G. biloba* extracts. Both patients had started taking *G. biloba* within 2 weeks of the start of the seizures. The herbal remedy was withdrawn and both patients remained seizure-free several months later. No other change of medication was made.

The author postulated that 4-0-methylpyridoxine, a constituent of *G. biloba* and a known neurotoxin, had caused the seizures.

Hematologic

Ginkgo biloba has well-documented antiplatelet effects, and bleeding complications can occur, including strokes.

- A 59-year-old man developed bleeding complications after liver transplantation while taking *G. biloba* supplements (5). Postoperatively, he developed large hematomas in the subphrenic space and near the porta hepatis. They were drained and his hematocrit fell to 21%. Three weeks later he complained of blurring in the right eye, and a vitreous hemorrhage was diagnosed. He then admitted to taking an unknown amount of *G. biloba*, which was withdrawn. Subsequently, no further bleeding episodes occurred.
- A 78-year-old man developed progressive right-sided muscular weakness after a fall (6). A CT scan showed a subdural hematoma. He had taken 150 mg of *G. biloba* extract.
- A 56-year-old man had a stroke without apparent risk factors (7). A CT scan confirmed a right parietal hematoma. He had not taken any medications, except for a *G. biloba* extract (3 × 40 mg/day) which he had started 18 months before.
- A 34-year-old woman had a laparoscopic cholecystectomy and started bleeding into the surgical wound postoperatively (8). This led to a fall in hemoglobin from 16.5 to 12.4 g/dl. She was given blood transfusions and recovered uneventfully.
- Hyphema led to temporarily impaired vision in a man who had taken *G. biloba* for 2 weeks; no other cause was found; the lesion regressed after withdrawal and did not recur (9).
- A spontaneous cerebellar bleed occurred in a man who had taken *G. biloba* (10).

In each case the authors believed that self-medication with *G. biloba* had caused the bleeding through its effect on platelets. In some cases another factor that implicated the extract was the absence of recurrence after withdrawal, although this is a weak argument.

Spontaneous bilateral subdural hematomas and increased bleeding time have been associated with chronic ingestion of *G. biloba* (120 mg/day for 2 years) (11).

Skin

- A 40-year-old Afro-American woman developed an exfoliative rash and blistering and swelling of the tongue (12). A diagnosis of Stevens–Johnson syndrome was made. She had not taken any medications other than two doses of a formulation that contained *G. biloba*. Her condition responded to treatment with prednisolone, clotrimazole, and famotidine. *G. biloba* was withdrawn and no further events occurred. However, 5 months later she still had tenderness in the soles of the feet, peeling of the nails, and discoloration of the skin.

Formulations

Subarachnoid hemorrhage associated with *G. biloba* (13) stimulated a vigorous discussion on the differences between the usual extract sold over the counter and a ginkgolide mixture, and their respective (absence of) effects on platelet-aggregating factor and bleeding time (14,15). The dispute points to confusion that can arise when formulations of similar origin but with variable composition are available.

Drug overdose

Acute poisoning with *G. biloba* seeds is occasionally seen in East Asian countries.

- A 36-year-old woman, without any past or family history of epilepsy, developed frequent vomiting and generalized convulsions about 4 hours after taking about 70–80 ginkgo nuts, seeds of *G. biloba*, in an attempt to improve her health (16).
- A 2-year-old girl was admitted with vomiting, diarrhea, and irritability a few hours after eating a large quantity of *G. biloba* seeds and then developed an afebrile generalized clonic seizure (17). Her serum concentration of 4-methoxypyridoxine, the putative toxic agent in the seed, was extremely high at 360 ng/ml.

Administration of pyridoxal phosphate, a competitive antagonist of 4-methoxypyridoxine, which inhibits the formation of gamma-aminobutyric acid (GABA), prevented further seizures in this case.

Drug interactions

Because of its antiplatelet activity *G. biloba* can interact with anticoagulants.

- A 78-year-old woman who had taken warfarin for 5 years, took *G. biloba* for 2 months, when she developed signs of a stroke, diagnosed as intracerebral hemorrhage (13).

Even though it is impossible to establish causality in this case, it is conceivable that the stroke was the result of over-anticoagulation induced by the herbal medication (11).

Glafenine

See also Non-steroidal anti-inflammatory drugs

General Information

Glafenine, an anthranilic acid derivative, has been withdrawn in much of the world (1). Until 1991 it was sold in about 70 countries (although never marketed or accepted in others), despite a long history of severe reactions (particularly anaphylaxis, fatal hepatotoxicity, and nephrotoxicity, even with normal doses). As late as 1989 the EC Committee on Proprietary Medicinal Products (CPMP) astonishingly recommended keeping glafenine on the market but controlling its distribution and monitoring adverse effects more closely (2). Firm restrictions or prohibitions nevertheless preceded or followed this recommendation in several European countries, and the CPMP finally condemned glafenine early in 1992. See also floctafenine.

Organs and Systems

Cardiovascular

A rise in blood pressure coupled with renal adverse effects has been reported. Coronary artery spasm leading to myocardial infarction was described as part of an allergic reaction with Quincke's edema (SED-11, 190) (3).

Hematologic

Acute hemolytic anemia, probably as part of an allergic reaction (SED-9, 154) (4,5), leukopenia through an unknown mechanism, and thrombocytopenic purpura with hemorrhage have been documented (6).

Liver

Liver injury has repeatedly been described in patients taking glafenine (SEDA-4, 69) (SEDA-5, 106), with fatal hepatotoxicity as part of a general toxic reaction in several cases (7). Glafenine-associated hepatic injury is characterized by a high prevalence of jaundice, a high death rate, and a predominantly hepatocellular histological pattern of liver lesions, varying from spotty panlobular, centrilobular, and submassive necrosis (acute pattern) to fibrosis and cirrhosis (chronic pattern) (8).

Biliary tract

Gallstones containing glafenic acid have been reported in a patient taking long-term therapy (SEDA-14, 95).

Urinary tract

Many nephrotoxic features have been observed in preclinical and clinical studies of glafenine in therapeutic doses and more especially in overdosage (SEDA-4, 69). Acute oliguria, anuria, increased blood urea and creatinine, proteinuria, and raised blood pressure have been repeatedly reported. Glafenine stones have been documented in five patients (9).

Musculoskeletal

Symptoms of rhabdomyolysis, associated with other disorders, occurred in two patients a few hours after glafenine (10).

Immunologic

Although rash has sometimes occurred (11), hypersensitivity reactions have been much more serious. Many acute anaphylactic reactions have been observed (SEDA-4, 69) (SEDA-6, 98) (12,13), with shock in more than 50% of cases; it was recorded in 24 of 1517 reports on the drug collected by the Pharmacovigilance Unit in Lyons, France (11). Occasional isolated fever, confirmed by rechallenge (14), is probably also of hypersensitive origin. Interstitial nephritis, hepatitis, and pulmonary hypersensitivity have been reported.

Drug–Drug Interactions

Methotrexate

An interaction of glafenine with methotrexate has been described in a patient with rheumatoid arthritis (SEDA-14, 95).

Glaucine

General Information

Glaucine is a non-narcotic antitussive agent. The D-isomer of glaucine is an alkaloid from *Glaucium flavum Crantz*, a species of Papaveraceae. It is better tolerated in doses claimed to be equieffective with codeine. Glaucine (30 mg capsules 3 times daily for 28 days) caused mild constipation in five patients (1).

Reference

Glucagon

General Information

Glucagon, which is produced in the alpha cells of the islets of Langerhans, is used in diabetes mellitus type 1 to stimulate glucose output from the liver during hypoglycemia (1 mg subcutaneously, repeated once or twice) when glucose cannot be given intravenously. In some countries it is often used by personnel, such as family members, who are not medically qualified, as the first action when the patient cannot take sugar orally. The antihypoglycemic effect of an intramuscular injection is longer lasting and more potent than that of intravenous glucagon (1). It is sometimes given by infusion to treat chronic hypoglycemia. However, when there is insulin reserve in the pancreas, glucagon induces hypoglycemia by stimulating insulin release (2).

Glucagon has also been used to stimulate insulin and C-peptide secretion, to see whether the islets still produce insulin, as a stimulatory test during pheochromocytoma, hyperinsulinism, and Zollinger–Ellison syndrome, or as an additive in upper gastrointestinal X-ray investigations (0.5–1 mg). It has been used in myocardial infarction, although its inotropic effects may present a risk. It has also been used to treat overdoses with beta-blockers (3) and calcium channel blockers (4), although its efficacy in such cases has only been demonstrated in animals (5) and to treat overdose with tricyclic antidepressants (6,7).

During long-term administration glucagon can cause the same effects as a glucagonoma: hyperglycemia, necrolytic migratory erythema, weight loss, anemia, angular cheilitis, and venous thrombosis (8).

Organs and Systems

Cardiovascular

Glucagon has been reported to have caused myocardial ischemia (9).

Metabolism

When there is insulin reserve in the pancreas, glucagon can cause hypoglycemia by stimulating insulin secretion.

Electrolyte balance

Hyponatremia can occur during long-term administration of glucagon (10).

Hematologic

Thrombocytopenia can occur during long-term administration of glucagon (10).

Gastrointestinal

Glucagon can cause nausea, vomiting, and diarrhea (11).

Skin

Chronic administration of glucagon can cause an eczema-like maculopapular scaly rash, which can progress to necrolytic migratory erythema, as in glucagonoma (8,12,13). Erythema multiforme has also been reported (14).

Glucagon, used to treat persistent hyperinsulinemic hypoglycemia of infancy, caused erythema necrolyticum migrans in two neonates (15).

© 2006 Elsevier B.V. All rights reserved.

- In the first child, a monozygotic twin girl, delivered at 30 weeks, diazoxide, chlorothiazide, and nifedipine did not alter glucose requirements, but octreotide halved the need, and intravenous glucagon lowered it further. However, the child then developed a maculopapular rash on the face and trunk. After 4 weeks the lesions worsened, increased in size, and became superficially necrosed with thick-caked scales. The rash also involved the limbs and mucous membranes, making feeding almost impossible. When glucagon was withdrawn the skin lesions resolved from the center within 2 days and disappeared without scarring in 10 days.
- The second child, who was delivered at term, had a blood glucose of 0.8 mmol/l 6 hours after birth and suffered a seizure that was treated with subcutaneous glucagon, octreotide, and other drugs. It was impossible to give sufficient feeding, and notwithstanding subcutaneous glucagon 11 micrograms/kg/hour and octreotide 4.3 micrograms/kg/hour, she had a generalized seizure when the blood glucose was 1.4 mmol/l. At 6 months, subtotal pancreatectomy was performed. During glucagon therapy she had seborrheic skin with silvery scales and on the thoracic skin an area of pale lichenification with mild hyperkeratosis. Within 2 weeks after surgery (and withdrawal of glucagon) the skin became totally normal.

Susceptibility Factors

Age

Hypoglycemia often occurs in premature children and can usually be treated by intravenous glucose. For intractable hypoglycemia an infusion of glucagon can be used. However, it can cause thrombocytopenia and hyponatremia with convulsions (10).

- A female triplet was born at 35 weeks by cesarean section after a normal pregnancy, during which her mother had had normal glucose tolerance. At 2 hours the baby's serum glucose was 1.0 mmol/l. Intravenous glucose was not effective. At 36 hours, dexamethasone was added, but 24 hours later her blood glucose was below 2.0 mmol/l. Dexamethasone was withdrawn and glucagon 1 mg/day was added to the infusion. After 4 hours the blood glucose became stable at 4.0 mmol/l. Her serum sodium fell from 138 to 116 mmol/l at about 120 hours, her potassium rose to 7.6 mmol/l, and her platelet count fell to 13×10^9/l. The glucagon infusion was stopped and within 24 hours her sodium and platelets normalized.

Glucagon infusion in premature babies is risky; more information is necessary.

Glucagon-like peptide-1

General Information

Glucagon-like peptide-1 is an intestinal hormone that increases insulin secretion and biosynthesis, has a trophic effect on beta cells, suppresses glucagon secretion, delays gastric emptying, increases satiety, and reduces food intake (1). Its effects are glucose-dependent and it should not cause hypoglycemia. However, in healthy subjects hypoglycemia can occur after high doses or after fasting.

Although it is a candidate for the treatment of type 2 diabetes, it has to be injected and is extremely rapidly degraded by dipeptidyl peptidase IV. Analogues that are resistant to degradation and inhibitors of the degrading enzyme are being investigated.

© 2006 Elsevier B.V. All rights reserved.

In a randomized, crossover study with glucagon-like peptide-1, metformin, or the combination, there were no differences between the monotherapies (2). The combination had additive effects in lowering blood glucose and tended to reduce appetite.

In a crossover study, 20 patients with type 2 diabetes were treated for 6 weeks with glucagon-like peptide-1 or saline added to continuous subcutaneous insulin infusion; glucagon-like peptide-1 reduced appetite and caused nausea and reduced well-being (3).

In healthy volunteers, a fatty acid derivative of glucagon-like peptide-1, NN2211, which binds to albumin and has a half-life of about 12 hours, caused more dizziness, headache, nausea, and vomiting than placebo (4,5).

Organs and Systems

Metabolism

In a double-blind, randomized, crossover study in 10 healthy subjects, subcutaneous glucagon-like peptide-1 after a 16-hour fast caused a near five-fold rise in plasma insulin concentration and circulating plasma glucose concentrations fell below the reference range in all subjects (6). One subject had symptoms of hypoglycemia. A rise in pulse rate correlated with the fall in plasma glucose concentration and there was an increase in blood pressure.

In eight patients with type 2 diabetes and seven matched non-diabetics, subcutaneous glucagon-like peptide-1 and intravenous glucose caused reactive hypoglycemia in five controls but not in the patients (7). Glucagon was suppressed.

Glucametacin

General Information

Glucametacin is a glucosamide derivative of indometacin, with no advantages over indometacin and the same pattern of adverse effects, the most common of which are nausea and heartburn (1).

Glues

General Information

Hair bonds and hair extensions are being increasingly used both as cosmetic hair alterations and in localized or diffuse alopecia. The commercial glues used to affix the exogenous hair are gelatinous liquids that contain pigments, antioxidants, and natural latex.

Organs and Systems

Immunologic

Two patients developed severe type I allergic reactions to a hair bond.

- A 37-year-old atopic patient had generalized pruritus, diffuse urticaria, angioedema, rhinoconjunctivitis, and tachycardia within minutes of having glued a hair bond to her scalp. Skin tests with the glue (diluted 1:10 000 in saline) were positive, as was an IgE RAST on latex proteins (1).
- A 40-year-old woman noted palmar irritation, followed by generalized pruritus, a feeling of faintness, facial edema, and difficulty in breathing. A latex skin prick test was positive (2).

Glutaral

See also Disinfectants and antiseptics

General Information

Aldehydes such as glutaral, formaldehyde, and glyoxal are used as solutions and vapors for disinfection and sterilization.

The safety and biocidal efficacy of glutaral has led to its endorsement by the CDC and WHO as a substitute for formaldehyde in high-level disinfection and cold sterilization (1,2). Glutaral is used in a 2% aqueous solution buffered to a pH of about 8 for sterilization of endoscopic and dental equipment and for other equipment that cannot be sterilized by heat.

Occupational safety considerations for glutaral largely relate to its volatility, and stringent precautions in handling are especially needed in tropical climates (3). The lack of precautionary details for glutaral fumes, especially in warm climates is inadequate. Manufacturers should provide details of possible adverse effects that could arise from glutaral vapor, and of the precautions that should be taken to keep the air concentration below the recommended limit. The odor threshold for glutaral vapor is about 0.04 ppm, the irritation threshold about 0.3 ppm, and the recommended Ceiling Threshold Limit Value 0.2 ppm. It should not be exceeded at any time during the working day (4–6). It is likely that glutaral vapor will be smelt before reaching overexposure concentration, but there is an urgent need to develop affordable and effective methods of containing glutaral fumes.

Of 169 nurses working in 17 hospitals, especially in endoscope units, 68% had symptoms, 38% two or more. The major complaints were eye irritation in 49%, skin discoloration or irritation in 41%, and cough or shortness of breath in 34% (7). Complaints were not related to habits, atopic status, or duration of exposure. In two hospitals, the time-weighted average concentrations were estimated. The 10-minute time-weighted average was below the UK occupational exposure standard of 0.2 ppm. In a similar survey of 150 staff in two Middlesex hospitals who were exposed to glutaral, the rate of complaints was in the same range (8).

Organs and Systems

Cardiovascular

Nine of 184 implantations of glutaral-preserved mitral valves became incompetent (9). This incidence of dehiscence substantially exceeded that previously noted with synthetic valves, and the authors suggested that incomplete removal of glutaral from the prosthesis might have contributed to failure of healing. Collagen ultrastructure investigations of glutaral-treated porcine aortic valve tissue showed that the long-term mechanical durability of treated aortic valves can be substantially increased if careful consideration is given to the pressure at which initial fixation of glutaral is carried out.

Respiratory

Nurses working in endoscopy units complained of respiratory symptoms on exposure to glutaral (10). The provocation test was positive in two of these patients.

Sensory systems

The eye is particularly sensitive to glutaral. The threshold for conjunctival irritation is 0.2–0.5% and for corneal injury 0.5–1.0%. At 2%, eye injury is moderate, whereas at 5% and above it is severe (6,11). In one case, acute eye injury was caused by a leakage of retained glutaral in an anesthesia mask (SEDA-13, 648).

Gastrointestinal

Residues of glutaral in endoscopes can cause significant mucosal injury resulting in acute colitis within 12–48 hours. Symptoms include hematochezia, fever, and tenesmus. Histological findings in biopsy specimens are similar to those of ischemic colitis, with crypt dilatation followed by epithelial cell dropout and subsequent acute inflammation. It cannot be diagnosed by histological analysis alone (12,13). Distinct from the type of colitis that is caused by hydrogen peroxide, the detrimental effects of glutaral are not immediately recognizable during the endoscopic examination. It does not cause raised white mucosal plaques (“pseudolipomatosis”) (13).

Colitis was observed during endoscopy of the lower gastrointestinal tract in 21 patients (14). Some patients developed rectal bleeding, tenesmus, and increased frequency of stools, lasting 12 days.

The histological findings in 12 patients with suspected glutaral-induced hemorrhagic colitis were similar to those in rats after colonic instillation of the sterilizing solution (15).

Skin

Solutions of glutaral can cause skin irritation. With sustained contact under occlusion or on sensitive skin, the threshold for producing irritation is 0.2–0.5% (6). However, concentrations up to 5% may not be irritant if applied only briefly to non-occluded skin. The site of skin contact, the length of contact time, and whether the area is occluded are factors that determine the likelihood and severity of irritation.

A few people develop allergic contact dermatitis to glutaral (SEDA-11, 478) (SEDA-12, 572) (6,16).

Immunologic

Aldehydes are irritating and sensitizing and cause contact dermatitis in health-care workers (SEDA-21, 254). The incidence of allergy to aldehydes has been examined in 280 health-care workers with skin lesions (17). Allergy was diagnosed in 64 (23%). Most (86%) were sensitive to only one aldehyde. Formaldehyde caused allergy slightly more often (14%) than glutaral (12%). Only 5 (1.9%) were sensitive to glyoxal. This

© 2006 Elsevier B.V. All rights reserved.

hierarchy of sensitivity was also confirmed in animal testing.

Anaphylaxis occurred in a woman after the fourth intramuscular injection of a glutaral-containing pollen formulation (SEDA-11, 478) (18).

Drug Administration

Drug overdose

The symptoms of overexposure to glutaral vapor include watery and/or burning eyes, nose and throat irritation, and some respiratory discomfort. Glutaral also causes asthma-like symptoms in a few hypersensitive individuals. However, in none of these cases was there evidence that an immune-mediated process was present; these cases probably represent bronchial hyper-reactivity rather than respiratory sensitization (6).

Glycerol

General Information

Glycerol is a colorless syrupy liquid that is used medically as a laxative given orally, as an enema, or in the form of suppositories. Oral hypertonic glycerol has been used as a test for reversibility of the symptoms of Menière's disease (1); however, it causes headache, nausea, and vomiting and is of poor sensitivity and specificity.

Intravenous glycerol has been given to reduce cerebral edema and hence reduce intracranial pressure.

Iodinated glycerol is used as a mucolytic agent in respiratory disorders. Organically bound iodine is changed to unbound iodide after absorption. Iodide inhibits the binding of iodine to the tyrosine residue of the thyroglobulin molecule, inhibiting the synthesis of thyroxine and triiodothyronine. In patients with iodide-induced goiter, there is increased iodine transport, further reducing thyroid hormone synthesis and causing thyroid hyperplasia (2).

Glycerol has been injected into nerve ganglia to destroy them. In 139 patients, 260 consecutive retrogasserian glycerol rhizotomies for trigeminal neuralgia were retrospectively analysed for technical surgical difficulties and immediate and early complications (3). There were technical obstacles in 47%. In 21 cases, the surgical procedure had to be interrupted because of vasovagal reactions, cardiac arrest, or difficulty in finding the trigeminal cistern. There were either transient or persistent complications in 67%, in most cases mild sensory defects. Other complications included labial herpes (3.8%), anesthesia dolorosa (0.8%), moderately or severely impaired sensation (19%), dysesthesia (23%), chemical meningitis (1.5%), and infectious meningitis (1.5%). In five patients hearing was affected, including deterioration of pre-existing tinnitus in one case. Although the frequency of surgical difficulties was high, success was hampered only in a few procedures.

Organs and Systems

Nervous system

In 122 patients with trigeminal neuralgia who underwent percutaneous retrogasserian glycerol injection (4), complications associated with the treatment were

© 2006 Elsevier B.V. All rights reserved.

significant: 63% had marked hyperesthesia of the face and 29% unpleasant dysesthesias, including two cases of anesthesia dolorosa. Sensory disturbances were most frequent in patients who had previously undergone an alcohol block procedure. Because of the high rates of recurrence and sensory disturbances, the authors preferred microvascular decompression for the management of trigeminal neuralgia. In a study of glycerol injection in trigeminal neuralgia, paresthesia and dysesthesia were reported (5).

Rotatory vertigo with vertical nystagmus has been attributed to glycerol (6).

Sensory systems

Temporary loss of hearing has been reported after the oral administration of hypertonic glycerol in the diagnosis of Menière's disease (7).

Endocrine

Reversible hypothyroidism has been reported in nursing-home residents without a history of thyroid disease, who had been taking iodinated glycerol as an expectorant (8). Hypothyroidism has been reported after long-term treatment with iodinated glycerol (9).

Metabolism

Glycerol can increase plasma insulin concentrations and thereby worsen diabetes; it can particularly cause hyperosmolar non-ketotic hyperglycemia in patients with type 2 diabetes (10,11).

Fluid balance

Large oral doses of glycerol can cause severe derangements of water balance, which can be dangerous in patients in poor physical condition.

Hematologic

Intravascular hemolysis occurred during intravenous glycerol therapy in patients with acute stroke (12).

Gastrointestinal

Oral glycerol can cause nausea and vomiting (SEDA-20, 440) and less commonly diarrhea. Rectal administration can cause mucosal erosion.

Skin

Moisturizing creams have beneficial effects in the treatment of dry, scaly skin, but they can cause adverse skin reactions. In a double-blind, randomized study, 197 patients with atopic dermatitis, none of whom had known allergy to ingredients in the test creams, were randomized to one of three creams: 20% glycerol (55 women and 13 men, mean age 35 years), 4% urea plus 4% sodium chloride (47 women and 16 men, mean age 32 years), and vehicle (49 women and 17 men, mean age 34 years); they were asked to apply the cream at least once daily for 30 days (13). After 2 weeks the patients were asked to score the degree of smarting sensation (a sharp, local, superficial effect), stinging, itching, and dryness/irritation on a five-point scale (0–4). They were also asked to note skin dryness at the beginning of the study and after 1 month on a visual analogue scale. A dermatologist assessed dry skin at the start and after 30 days using the product of the sum of severity scores and area affected in four body regions (14). Adverse skin reactions such as smarting were significantly less common among patients who used the 20% glycerol cream (10%) compared with the urea + saline cream (24%). There were no differences in other skin reactions, such as stinging, itching, and dryness/irritation.

Glycine

General Information

Glycine is an amino acid that is often used during transurethral prostatectomy for bladder irrigation, sometimes continuously for 24 hours after surgery.

Transurethral resection syndrome

Systemic absorption of the fluid used for bladder irrigation during transurethral resection of the prostate can cause a variety of disturbances of the circulatory and nervous systems, which are often referred to as the transurethral resection syndrome. The lack of a consistent definition and varying degrees of awareness of mild forms of this complication probably explain the different figures given for the incidence of the syndrome in prospective studies, varying from 2 to 10% of all transurethral resections performed. Many urologists claim they have not encountered the transurethral resection syndrome for many years (1–3). However, the incidence and severity of symptoms of the transurethral resection syndrome on absorption of increasing volumes of glycine solution have been described (4).

The signs and symptoms of the transurethral resection syndrome were evaluated and recorded during and after 273 transurethral prostatic resections performed at two hospitals between 1984 and 1993. Glycine solution was used as the irrigant and ethanol served as a tracer for fluid absorption. The incidence and severity of symptoms that could possibly be related to the syndrome increased progressively as more glycine solution was absorbed. Patients who absorbed up to 300 ml of glycine solution had an average of 1.3 such symptoms. This number increased to 2.3 when 1000–2000 ml were absorbed, 3.1 when 2000–3000 ml were absorbed, and 5.8 for volumes greater than 3000 ml. Nausea and vomiting occurred significantly more often when 1000–2000 ml were absorbed compared with no absorption. Confusion and arterial hypotension were other prominent signs of fluid absorption, whereas hypertension was not. The severity of symptoms was markedly aggravated when more than 3000 ml were absorbed. Extravasation resulted in higher risks of bradycardia, hypotension, and failed spontaneous diuresis postoperatively than absorption by the intravascular route.

Nausea after glycine irrigation can be partly explained by toxic effects of glycine and its secondary metabolites in addition to the effects of water intoxication and hyponatremia (5).

The fact that glycine can act as an inhibitory neurotransmitter may explain why absorption of glycine-containing irrigating fluid from the pelvic cavity or directly into the blood during transurethral prostate resection has been linked to loss of sight and vivid postoperative hallucinations (6). Ammonia production due to accumulation of glycine in tissues, and the mentioned neuroinhibitory effects of glycine should be considered risk factors when deciding on glycine as an irrigating fluid (7).

Rapid and massive fluid absorption due to leakage of fluid into the peritoneal cavity has also been reported during percutaneous nephrolithotomy (8).

It has been recommended that glycine irrigation should be confined to the time of operation, and an adequate diuresis should be ensured postoperatively (9).

Glycols

General Information

Glycols are aliphatic dihydric alcohols. Primary and secondary glycols are thick liquids, and tertiary glycols (pinacones) are crystalline solids. The principal glycols to which people are or have been exposed, either occupationally or in medicinal products, are:

- Diethylene glycol $HO.CH_2.CH_2.O.CH_2.CH_2.OH$
- Ethylene glycol $HO.CH_2.CH_2.OH$
- Ethyl glycol (ethylene glycol monoethyl ether) $C_2H_5.O.CH_2.CH_2.OH$
- Methyl glycol (ethylene glycol monomethyl ether) $CH_3.O.CH_2.CH_2.OH$
- Polyethylene glycol $HO.CH_2.(CH_2.O.CH_2)_nCH_2OH$
- Propylene glycol $CH_3CH(OH)CH_2OH$.

© 2006 Elsevier B.V. All rights reserved.

Diethylene glycol

Diethylene glycol is important in the history of adverse drug reactions.

The first major drug catastrophe in the 20th-century history of the public control of drugs occurred in 1937 in the USA and involved diethylene glycol. A pharmacist introduced a drug, Elixir Sulfanilamide, that consisted of sulfanilamide dissolved in diethylene glycol. It had been tested for flavor, appearance, and fragrance, but not for safety. After taking the drug, over 100 patients died in severe pain; many were children, who were given Elixir Sulfanilamide for sore throats and coughs. Public outrage created support for proposed legislation to reinforce the public control of drugs that was pending in the US Congress (1). And so, the US 1938 Food, Drug, and Cosmetic Act came into being, and is still the country's legal foundation for the public control of drugs and devices intended for use in the diagnosis, cure, mitigation, treatment, or prevention of disease in humans or animals. It has been a model for similar legislation in many other countries.

The 1938 Food, Drug, and Cosmetic Act prohibited traffic in new drugs, unless they were safe for use under the conditions of use prescribed on their labels. The Act also explicitly required the labelling of drug products with adequate directions for use.

The burden of proof of harm of new drugs was laid on the Federal Food and Drug Agency (FDA). Companies that wanted to manufacture and sell new drugs in interstate commerce had to investigate their safety and report to the FDA. Unless the FDA, within a specified period of time, found that the safety of a drug had not been established, the company could proceed with its marketing. The FDA was also authorized to remove from the market any drug it could prove to be unsafe (2).

The US Supreme Court also established in 1941, in a legal case over drug adulteration, that responsible individuals in a company can be held personally accountable for the quality of the products manufactured by the company, and that distributors of pharmaceuticals are responsible for the quality of their products, even if they are manufactured elsewhere (3).

After the World War II, the pharmaceuticals market changed radically, as many companies started industrial production of drugs that had previously been manufactured in pharmacies. Announcements of new industrially produced drugs were hailed as part of technological advancement, as significant a sign of progress as the launching of satellites and putting a man on the moon. However, public safeguards against the risks of drugs remained unchanged in most countries. Thus, control of the effects of drugs largely lay in the hands of the manufacturers, even though the responsibility for taking precautions rested with pharmacists and doctors.

Diethylene glycol has been reported to cause acidosis and renal insufficiency (SEDA-19, 446).

Ethylene glycol, ethylene glycol monoethyl ether, and ethylene monomethyl ether

Ethylene glycol is a colorless, sweet-tasting liquid that is used as an anti-freeze, in the manufacture of polyester fibers and films, as a heat-transfer fluid, in aircraft and runway de-icing mixtures, to provide freeze-thaw stabilization to latex coatings, to improve the flexibility and drying time of paints, as a dehydrating agent in natural gas, in motor oil additives, as an additive in inks, pesticides, wood stains, and adhesives, and as a solvent and suspending medium for ammonium perborate, the conductor in most electrolytic capacitors. The monoethyl ether of ethylene glycol, 2-ethoxyethanol or ethyl glycol, has been used as an excipient in some drug formulations, in the semiconductor industry, in duplicating fluids, epoxy resins, lacquers, paints, printing inks, varnish removers, and wood stains. The monomethyl ether of ethylene glycol, 2-methoxyethanol or methyl glycol, is used as a jet fuel de-icer and as a solvent for cellulose acetate, dyes, enamels, nail polishes, resins, varnishes, and wood stains.

In one study, occupational exposure to ethylene glycol was not associated with adverse effects (4). However, other adverse effects of occupational exposure have been noted, including anemia, subfertility, and renal stones.

Ethylene glycol is sometimes used in suicide attempts. It is not itself toxic, but is converted to toxic metabolites. Conversion to glycoaldehyde by alcohol dehydrogenase is the rate-limiting step, and further metabolism yields glycolate, glyoxylate, and oxalate.

Polyethylene glycol

Polyethylene glycol is a high molecular weight inert molecule that is commonly combined with electrolytes (potassium chloride, sodium bicarbonate, sodium chloride, and sodium sulfate) in colonic lavage systems. Owing to the osmotic properties of these solutions, there is little absorption or secretion of electrolytes or water, although small amounts of polyethylene glycol and sulfates have been detected in the urine of healthy patients and higher concentrations in the urine of patients with inflammatory bowel disease (5). Common adverse effects of solutions containing polyethylene glycol and electrolytes include nausea, abdominal fullness, and bloating in up to 50% of patients. These solutions are contraindicated in patients with gastric outlet obstruction or gastroparesis, gastrointestinal obstruction or perforation, ileus, or toxic colitis (6).

Polyethylene glycol (PEG) is also used to convert certain compounds of relatively high molecular weights to more soluble products, known as pegylated derivatives. Such compounds include pegylated interferons and interleukins. The safety and activity of outpatient-based continuous intravenous interleukin-2 (IL-2) or a modified-release pegylated IL-2 have been studied in 115 HIV-positive patients with CD4 cell counts of 200–500 $\times$ 10^6/l randomized to antiretroviral therapy plus cyclical continuous intravenous IL-2 ($n = 27$), subcutaneous pegylated IL-2 ($n = 58$), or no IL-2 ($n = 30$) (7). The termination rates due to adverse events were 4% with continuous intravenous IL-2 and 7% with pegylated IL-2. The frequency and severity of grade 3 and 4 adverse events were similar in both IL-2 groups, with the exception of local erythema and induration associated with subcutaneous injections of pegylated IL-2. Fever, fatigue,

© 2006 Elsevier B.V. All rights reserved.

stomatitis, erythema, gastrointestinal symptoms, and mood alterations constituted the majority of clinically significant toxic effects. Most of the adverse events resolved by 8–15 days of each cycle. There were several unusual adverse effects of IL-2 that were not dose-related. These included worsening of pre-existing diarrhea, cardiomyopathy in a patient with a history of heroin abuse, and attempted suicide in a patient with a psychiatric history.

In 68 patients randomly assigned to receive either sulfate-free polyethylene glycol electrolyte lavage or sodium picosulfate plus magnesium sulfate, the day before colonoscopy, bowel cleansing was significantly better with picosulfate plus magnesium sulfate (8). Adverse effects were more common with polyethylene glycol electrolyte lavage, especially nausea, vomiting, and palpitation, and four patients did not complete treatment owing to adverse effects.

Propylene glycol

Propylene glycol is widely used as a solvent in topical glucocorticoids, other medicines (including diazepam, etomidate, and lorazepam), foodstuffs, cosmetics, household detergents, paints, and brake fluids.

Organs and Systems

Respiratory

Polyethylene glycol has reportedly caused fulminant pulmonary edema (9).

Nervous system

Polyethylene glycol has reportedly caused seizures (SEDA-20, 440).

Metabolism

Lactic acidosis and convulsions have been associated with the use of propylene glycol (SEDA-15, 537) and polyethylene glycol, the latter after the administration of a high dose of lorazepam (10).

Hematologic

Propylene glycol causes acute hemolysis with raised lactate dehydrogenase activity, and raised bilirubin and plasma hemoglobin concentrations after use of a stock solution during intravenous administration of glyceryl trinitrate (11).

In 53 impregnation workers from two factories making copper-clad laminate with ethylene glycol monomethyl ether as a solvent and 121 lamination workers with indirect exposure, hemoglobin, packed cell volume, and erythrocyte count in the exposed workers were significantly lower than in the controls, and the frequency of anemia was significantly higher (26 versus 3.2%); there was no difference in spermatogenesis (12).

Pancreas

Severe acute pancreatitis has been reported in a 75-year-old woman who had been given polyethylene glycol 4 litre rectally (13).

Urinary tract

In silkscreen printers exposed to glycol ethers, the excretion of calcium increased according to the urinary alkoxyacetic acid load. The excretion of ammonia and chloride was higher among exposed workers than among controls. The tendency to form urinary stones was 2.4 times higher among silkscreen printers than among office workers (14).

However, in 33 aviation workers exposed to de-icing fluid containing ethylene glycol there was no evidence of acute or chronic kidney damage that could be attributed to working in the presence of ethylene glycol (15).

Polyethylene glycol has been associated with raised creatinine concentrations in eight patients who were given a continuous intravenous infusion of lorazepam (range 2–28 mg/hour) (16).

- A 57-year-old man with a history of alcohol abuse developed acute respiratory failure and was given lorazepam up to 18 mg/hour during alcohol withdrawal (17). On day 43 (cumulative intravenous lorazepam dose 4089 mg, containing about 220 ml of polyethylene glycol 400), he developed oliguric acute tubular necrosis with proteinuria and granular casts.

The authors attributed the renal damage to polyethylene glycol, perhaps enhanced by concurrent administration of vancomycin.

Skin

Contact dermatitis has been reported after exposure to glue containing 25% 2-hydroxyethyl methacrylate and 0.4% ethylene glycol dimethacrylate (18).

Propylene glycol has also been reported to cause contact dermatitis (19–24).

Reproductive system

In one study, occupational exposure to ethylene glycol was associated with delayed fertility in women (25).

In 1150 pregnancies, 561 in female employees of semiconductor manufacturers and 589 in the wives of male employees the former had increased risks of spontaneous abortion (RR = 2.8; 95%CI = 1.4, 5.6) and subfertility (OR = 4.6; 95%CI = 1.6, 13); both of these risks had a dose-response relation with potential exposure to ethylene glycol (26).

Immunologic

Polyethylene glycol has reportedly caused anaphylaxis (SEDA-20, 440).

Propylene glycol can be used in allergic individuals, although propylene glycol itself can cause allergic skin reactions. The incidence of propylene glycol allergy among patients with eczema is thought to be greater than 2% (27). Used in dermatological formulations, propylene glycol can occasionally perpetuate eczema in hypersensitive patients (28).

Drug Administration

Drug formulations

In 1995, a topical solution of erythromycin (Erythromycine Balleul) was withdrawn from the market because of its high

content of ethylene glycol monoethyl ether, which is easily absorbed via the skin, is teratogenic in animals, and alters spermatogenesis.

Drug overdose

Ethylene glycol poisoning can cause acidosis, central nervous system depression, pulmonary edema, acute oliguric renal failure with crystalluria, liver damage due to calcium oxalate deposition, nausea, abdominal pain, and cramping, acute colonic ischemia (29), and papilledema and abducens nerve palsy (30).

- Hemorrhage in the globus pallidus occurred in a 50-year-old Afro-Caribbean alcoholic man after ethylene glycol poisoning; there was evidence of lactic acidosis and the ethylene glycol concentration was 6.06 mmol/l (31).
- A 36-year-old long-distance truck driver took 200 ml of ethylene glycol in a suicide attempt (32). He vomited, lost consciousness, and had miosis and external ophthalmoplegia. There was a severe metabolic acidosis with a wide anion gap and many crystals in the urinary sediment. Acute oliguric renal failure required continuous hemodialysis for 6 days. A CT scan of the brain showed low-density areas in the bilateral basal ganglia, midbrain, and pons. A renal biopsy showed tubular oxalate deposits. He gradually recovered within 36 days.

Treatment of ethylene glycol toxicity is with ethanol, which inhibits alcohol dehydrogenase, fomepizole, which also inhibits alcohol dehydrogenase, and bicarbonate to treat acidosis (33). In some cases hemodialysis has been used (34,35).

Propylene glycol has been reported to cause lactic acidosis after overdose (36).

Glycopyrronium

General Information

Glycopyrronium is a quaternary ammonium compound with anticholinergic properties (1).

In 22 patients with Frey syndrome (localized facial gustatory sweating and flushing) treated with topical glycopyrrolate 0.5–2% in a solution, cream or roll-on lotion, 1012 applications were recorded (SEDA-8, 160). There were seven adverse events: blurred vision (one), minor eye infections (two), itchy or dry eyes (one), and dry mouth (three). In the control group blurred vision and dry mouth were also recorded as adverse events.

Gold and gold salts

General Information

Gold is a heavy yellow-colored element (symbol Au; atomic no. 79). Its symbol derives from the Latin word aurum. It is usually found as the metallic element but can occur as salts such gold telluride (sylvanite).

Metallic gold is used in dentistry, and gold salts still form one of the mainstays of treatment for rheumatoid arthritis. The radioactive isotope ^{198}Au is used therapeutically in the treatment of certain malignancies. In Japan, chrysotherapy has a reputation for efficacy in bronchial asthma. The antitumor activity of novel gold compounds is being pursued (1). The molecular mechanisms of action of gold have been reviewed (2).

Gold salts

Sodium aurothiomalate is water-soluble and is given intramuscularly as an aqueous solution. Aurothioglucose is water-soluble and is given intramuscularly in either an aqueous solution or an oily suspension. Sodium aurothiopropanol sulfonate, aurotioprol, and aurothiosulfate have similar actions and uses to those of sodium aurothiomalate. They are given by intramuscular injection.

Auranofin

Auranofin is a triethylphosphine gold derivative for oral administration. It is in some respects strikingly different from the rest. Some 25% of an oral dose is absorbed through the intestinal wall and blood concentrations are some 15–25% of those reached with parenteral therapy. Auranofin is bound to cellular elements of the blood, is excreted mainly in the feces, and exhibits less tissue retention and total body gold accumulation than parenteral forms. It is more effective in acute inflammatory models and is a potent inhibitor of lysosomal enzyme release, antibody-dependent cellular toxicity, and superoxide production. Auranofin also affects humoral and cellular immune reactions. However, some have found auranofin to be rather less effective than parenteral gold. Auranofin is used in doses of 2–9 mg/day (generally 6 mg/day), which is less than the dose originally recommended.

In view of all this it is not surprising that auranofin has a distinct profile of therapeutic and adverse effects, the differences being so great that one actually suspects differences in the mechanism of action between oral and parenteral forms. Like the latter, however, auranofin shows no clear correlation between whole blood gold concentrations and either efficacy or adverse effects.

Use in rheumatoid arthritis

In rheumatoid arthritis the most commonly used gold salts are sodium aurothiomalate and aurothioglucose (3). There is some reason to believe that adverse effects are less frequent with the suspensions (of aurothioglucose or aurothiosulfate) than with the more rapidly absorbed solution (of sodium gold thiomalate) (SEDA-16, 233) (4).

Whereas gold was previously regarded as one of the most toxic drugs in the pharmacopeia, many authors now share the view that its adverse effects can to an important extent be contained by individually adapted dosage regimens and careful monitoring. However, it is not strictly possible to predict the nature or timing of the complications that an individual may experience, and it has to be borne in mind that some reactions are immunological (SEDA-21, 236). The prevalence of adverse gold reactions seems to be similar in patients given 25 or 50 mg of gold weekly (SED-12, 520) (5). Some studies have suggested that the frequency of mucocutaneous and renal adverse reactions may be higher in the initial

© 2006 Elsevier B.V. All rights reserved.

months of treatment. In one series of patients receiving gold sodium thiomalate, a plateau in the cumulative incidence of withdrawals due to rash was reached only after 40 months (45% of all patients), while withdrawals due to proteinuria reached a plateau after 18 months (l5%) (6). Hematological complications can occur at any stage.

It is widely considered that the patients who are most likely to develop adverse reactions to gold salts are those who react most favorably. In the past, many rheumatologists intensified treatment with high doses of gold salts until a skin eruption occurred, only then seeking to reduce to a maintenance dosage.

After withdrawal due to adverse reactions, treatment with gold compounds can be cautiously reintroduced without the previous adverse effects necessarily reappearing. However, clearly one will not take this course if life-threatening reactions have occurred. It should always be borne in mind that many adverse reactions allegedly due to chrysotherapy may have other causes, particularly in the case of skin reactions. Most patients have been or are using other drugs at the same time. The concomitant use of penicillamine can be particularly confusing, since its pattern of adverse effects closely resembles that produced by gold.

Use in dentistry

Dental gold alloys continue to be used and remain a source of contact hypersensitivity (7), including contact stomatitis and skin eruptions at sites not usually associated with dentistry. Contact dermatitis to metallic gold, for example in jewellery, has also repeatedly been observed (SED-8, 510) (SEDA-22, 245). A gold surgical clip has also caused an apparently allergic reaction, characterized by sterile abscess formation (8). However, such reactions are rare and may in part be due to other metals contained in the alloy.

General adverse effects

Intravenous gold salts

Adverse effects of gold salts occur in about one-third of systemically treated patients, the incidence varying from 25 to 40%. The dropout rate due to adverse reactions has been assessed as 22–26% (9). Children are considered to show the same pattern of adverse reactions as adults.

Cutaneous lesions are the most frequent adverse effects of gold salts, followed by involvement of the mucous membranes and kidneys. Pruritus and a wide range of skin reactions can occur. In the gastrointestinal system inflammation can occur at all levels, from the buccal cavity to the colon. Glossitis, cheilitis, and stomatitis are less common than dermatitis. Enterocolitis is a rare but very serious complication. Mild proteinuria is often seen in patients receiving chrysotherapy, while severe nephrotic syndrome is much less common. Blood dyscrasias of any type can occur either during therapy or after withdrawal. Leukopenia and thrombocytopenia are the most common hematological complications, although both are clearly less common than the mucocutaneous and renal adverse effects. Unusual reactions include pulmonary infiltration, intrahepatic cholestasis, and peripheral neuropathy. By and large, undesirable effects are transient and mild, but occasional deaths continue to be reported, usually because of hematological complications.

Apart from the "nitritoid" cardiovascular reaction, which is unique to sodium aurothiomalate, and possible differences between slowly and rapidly absorbed gold salts in the relative frequency of adverse effects, the general pattern of adverse reactions is similar for all parenteral gold salts.

Although most adverse effects of gold have traditionally been characterized as toxic, various factors show that some of the complications due to chrysotherapy are, at least in part, manifestations of hypersensitivity. Eosinophilia, raised IgE concentrations, immune complexes, and a positive reaction to gold in the lymphocyte transformation test have been observed in association with many adverse reactions to chrysotherapy and point to immunological mechanisms (10). With aurothiomalate both pemphigus and erythroderma have been described (SEDA-22, 246). It may be that gold facilitates the development of autoimmunity in patients with rheumatoid arthritis. Gold-induced membranous glomerulonephritis is believed to be an immune complex (type III) reaction, although the role of gold in the development of proteinuria has not yet been clarified. Gold-induced antibody deficiency may be more common than is usually recognized. In 22 patients with rheumatoid arthritis subnormal serum immunoglobulin concentrations developed as a consequence of gold treatment (11). There were mild deficiencies of single immunoglobulin isotypes or severe deficiencies affecting two or three isotypes. There may be transient exacerbation of rheumatoid symptoms before a therapeutic response to gold occurs. In one series of 43 patients with rheumatoid arthritis serious exacerbation of the disease occurred in 17% (12). Tumor-inducing effects have not been observed.

Auranofin

Auranofin is well tolerated by most patients; its adverse effects resemble those of parenteral gold salts, but the pattern differs, with gastrointestinal reactions predominating. Adverse reactions to auranofin are also generally less severe. Where serious adverse effects have been attributed to auranofin, cause and effect has usually remained in doubt. Adverse effects on the lower gastrointestinal tract are the most common; early studies showed a change in bowel habit in some 40% of cases, but this does not often amount to frank diarrhea (13). The same authors noted proteinuria (4%) and hematological reactions (2%). Mucocutaneous reactions (pruritus, conjunctivitis, stomatitis) often occur but are rarely severe and are less problematic than with sodium aurothiomalate. Most adverse effects occur during the first few months; age, sex, and duration of disease do not influence the risk of developing an adverse effect. The adverse effect-related withdrawal rates for injectable gold, auranofin, and placebo were 40, 14, and 6% respectively. Rashes occur in some 20% of cases but rarely require withdrawal. Tumor-inducing effects have not been observed.

Metallic gold

Dental gold alloys can cause contact hypersensitivity (7). Contact dermatitis to metallic gold, for example in jewellery, has also repeatedly been observed (SED-8, 510) (SEDA-22, 245). A gold surgical clip has also caused

© 2006 Elsevier B.V. All rights reserved.

an apparently allergic reaction, characterized by sterile abscess formation (8). However, such reactions are rare and may in part be due to other metals contained in the alloy.

Organs and Systems

Cardiovascular

Acute vasodilatory (nitritoid) reactions occur in a minority of patients receiving parenteral gold, especially sodium aurothiomalate (SEDA-22, 245). A few minutes after injection the patient experiences weakness, flushing, hypotension, tachycardia, palpitation, sweating, and sometimes syncope (14). Very rarely myocardial infarction and stroke follow (14,15). The mechanism is unknown, but it has been suggested that the vehicle might be responsible, and that aurothioglucose might therefore be preferable to sodium aurothiomalate in elderly patients or in those with a history of cardiovascular disease.

Respiratory

Gold-induced lung toxicity is an infrequent adverse effect in patients with rheumatoid arthritis and psoriatic arthritis. There are three types: interstitial pneumonitis, bronchiolitis obliterans with organizing pneumonia, and bronchiolitis obliterans; the first is the most frequent. There have been two reports of gold-induced lung toxicity in psoriatic arthritis (16).

- A 54-year-old woman with psoriatic polyarthritis was treated with aurothiomalate 50 mg/week. When the cumulative dose reached 250 mg she developed weakness, dyspnea, fever, nausea, vomiting and erythematous skin lesions. Chest X-ray and CT scan showed diffuse interstitial pneumonitis. Gold was withdrawn and she was given prednisone 60 mg/day. She recovered in 6 months.
- A 62-year old woman with psoriatic arthritis was given aurothiomalate 50 mg/week. After a cumulative dose of 135 mg she developed an itchy rash, dyspnea, and fever. Chest X-ray and CT scan suggested pneumonitis and she was given prednisone 40 mg/day. She recovered in 6 months.

More than 60 cases of "gold lung" have been reported and there must be many more unpublished cases. Beginning as a rule some weeks or months after starting treatment, the patient develops dyspnea on exertion, weakness, a dry cough, and malaise. Chest X-rays show bilateral pulmonary infiltrates of varying extent, but cases have been described in which the radiography is entirely normal (17). If chrysotherapy is continued, pulmonary insufficiency can follow. In fact two types of process need to be distinguished; fibrosing alveolitis and obliterative bronchiolitis occur and can co-exist (18); some patients develop proliferative and immunoallergic changes, perhaps even mimicking malignant processes. In treating rheumatism, it can be difficult to distinguish "gold lung" from rheumatoid lung disease (SEDA-21, 236).

Bronchoalveolar lavage in "gold lung" tends to show an increase in the total cell count and predominance of the percentage of lymphocytes with an inverse helper/suppressor ratio. The prognosis is generally good; if gold is immediately withdrawn, the pulmonary lesions as a rule subside, although incomplete regression or even persistence of dyspnea and impaired lung function have been described, despite glucocorticoid therapy (19).

The pulmonary toxicity of gold salts uncommonly causes life-threatening respiratory failure. Patients who suffer from this do not usually need mechanical ventilation, and the toxicity can be difficult to diagnose when it occurs in patients with an illness with pulmonary involvement. However, severe respiratory failure requiring mechanical ventilation has been attributed to gold salt toxicity in a patient with rheumatoid arthritis (20). Glucocorticoid therapy was life-saving and induced complete resolution of the lung damage.

Pneumonitis associated with gold has been reported in a woman with rheumatoid arthritis.

- A 77-year-old woman with rheumatoid arthritis was given sodium aurothiomalate 50 mg intramuscularly weekly, following a test dose of 10 mg (21). Her rheumatoid arthritis responded well, but after a cumulative dose of 560 mg she became progressively short of breath on exertion and generally felt unwell. She had bilateral basal inspiratory crackles and widespread ill-defined shadowing on the chest X-ray, predominantly in the middle and lower zones of both lungs. A high-resolution CT scan showed ground glass opacities, particularly in the upper zones, and thickening of the peribronchovascular interstitium and interlobular septa in the middle and lower zones. Pulmonary function tests showed a restrictive lung defect. The gold injections were discontinued and she responded well to methylprednisolone. A CT scan 10 months later showed almost complete resolution, with some heterogeneity of lung density posteriorly in the lower lobes.

Interstitial pneumonia has been described in an adult who had taken auranofin for only 6 days; glucocorticoids were required (SEDA-17, 276).

Nervous system

Gold can damage nervous tissue. Peripheral neuropathy due to gold is possibly not as rare as was previously assumed and can co-exist with a neuroencephalopathy or other symptoms, such as dizziness and nausea (22). Nervous damage can take other forms: peripheral pain, general malaise, psychiatric disorders, and insomnia can be the first uncharacteristic symptoms and can easily be overlooked as adverse effects. Acute polyneuropathy of the Guillain-Barré type (SED-12, 521) (23), myokymia (Morvan-type fibrillating chorea) (SEDA-6, 216) (24), and gold encephalopathy (25) are rare neurological complications of chrysotherapy that have, however, all been well documented from different sources (24).

- A woman in whom gold had been withdrawn because of a rash developed a severe parkinsonian tremor of the hands a week later (22).

An axonal polyneuropathy has been attributed to gold (26).

- A 63-year-old man with a 4-month history of rheumatoid arthritis developed progressive malaise, anorexia,

© 2006 Elsevier B.V. All rights reserved.

and weight loss, and had a 2-day history of diarrhea, fever, and chills. He had epigastric and periumbilical pain radiating to the back, associated with nausea, abdominal distension, and jaundice. He was taking prednisone 5 mg bd and diclofenac sodium 100 mg bd. He had recently started weekly gold injections (total dose of gold 150 mg). He received two test doses before starting induction therapy, with no adverse effects. Both gold and diclofenac sodium were withdrawn and 2 weeks later he complained of symmetrical distal paresthesia in a glove and stocking distribution. There was no weakness, parallel reflexes were diminished, and the ankle reflexes were both absent. Nerve conduction studies showed a reduction in sensory nerve action potential amplitude in the sural and median nerves, with normal motor conduction. There was a slightly increased threshold for warm and cold sensations in the foot, with normal results in the hand. A liver needle biopsy showed preserved liver architecture with marked cholestasis mainly in the central and mid zones. A positive lymphocyte transformation test to gold suggested a cell-mediated hypersensitivity reaction.

Intrathecal colloidal gold has been used as an adjunct in the treatment of childhood neoplasms, including medulloblastoma and leukemia. Long-term follow-up of patients treated with intrathecal colloidal gold has been described and the high incidence of delayed cerebrovascular complications and their management has been emphasized (27).

Between 1967 and 1970, 14 children with a posterior fossa medulloblastoma underwent treatment consisting of surgical resection, external beam radiotherapy, and intrathecal colloidal gold. All had persistent or recurrent disease and six died within 2 years of treatment. The eight surviving patients developed significant neurovascular complications 5–20 years after treatment. Three patients died as a result of aneurysmal subarachnoid hemorrhage and five developed cerebral ischemic symptoms from a severe vasculopathy that resembled moyamoya disease. Although therapy with colloidal gold results in long-term survival in a number of cases of childhood medulloblastoma, this study suggests that its severe cerebrovascular adverse effects fail to justify its use. The authors recommended routine screening of any long-term survivors after colloidal gold therapy, to exclude the presence of an intracranial aneurysm and to document the possibility of moyamoya disease.

Sensory systems

Chryseosis corneae (deposition of gold crystals in the cornea) occurs rarely in patients treated with a cumulative dose of up to 500 mg of gold, but they occur in nearly all patients who have received 1500 mg or more (28). Deposition of gold as such has no clinical consequences. Gold can occasionally cause a keratitis or keratoconjunctivitis, but these are usually associated with skin involvement and are not a consequence of gold deposits in the cornea.

Gold keratopathy has been reported in a woman with rheumatoid arthritis (29).

- A-60-year-old woman with rheumatoid arthritis who was taking prednisone, azathioprine, sulindac, plaquenil, and receiving intramuscular injections of gold sodium thiomalate (50 mg once weekly) developed intense, bilateral ocular irritation and photophobia. She had received a total of 7.4 g of gold over the past 3 years. Her conjunctivae were mildly injected, with bilateral perilimbal chemosis. The peripheral corneae showed 360° stromal edema. Mid-stromal vessels were seen entering the edematous stroma from the limbus. She was given topical prednisolone acetate hourly for rheumatoid marginal keratitis. Over the next 2 months her symptoms gradually resolved, but granular, golden-brown, pigmented deposits appeared in the corneal stroma in the same peripheral ring-like distribution as the resolved stromal keratitis. Gold was discontinued. Over the next 6 months, the stromal deposits partially cleared. She then had a milder episode of photophobia and irritation, with stromal edema in the same distribution. This was controlled by topical prednisolone. One year later, she continued to use topical prednisolone once a day and was asymptomatic, with no stromal inflammation, but persistent fine golden granules.

Conjunctivitis has occurred in some 10% of patients treated with auranofin, either early or late in treatment, and has led to withdrawal in about in 1% (30).

Metabolism

In one case, diabetes was destabilized after 3 weeks of auranofin treatment (31).

Hematologic

Because of the hematological effects of gold salts, full blood counts should be monitored regularly at least during the first 2 years of treatment (32).

Pure red cell aplasia occurred in a patient with cholestatic jaundice taking sodium aurothiomalate (SEDA-17, 275). Anemia has been reported occasionally with auranofin (0.1%) either as a direct effect or secondary to hematuria.

Eosinophilia in the peripheral blood is the most frequent hematological effect of parenteral gold salts, affecting up to 40% of patients. It is no longer believed that it is a reliable advance marker of more serious reactions of any type (33). Among the latter are severe blood dyscrasias, which sometimes appear unexpectedly, despite regular blood counts.

Auranofin has been associated with eosinophilia (range of incidence in various reports 0.1–13%). In a retrospective study of 82 patients with rheumatoid arthritis there was eosinophilia in 21% taking sodium aurothiomalate and 13% taking auranofin (33). However, early eosinophilia is not a reliable indicator of potential toxicity.

Leukopenia is rare, sometimes very mild, and not always related to gold (SED-12, 522). Granulocytopenia can evolve slowly or suddenly, and its course can be transient or prolonged. Some workers have found gold-associated granulocytopenias to be brief and self-limiting; indeed, if other marrow elements are unimpaired, full recovery can occur even from severe agranulocytosis. Full-fledged aplastic anemia and pancytopenia are the most serious and feared conditions, and although they are today uncommon,

© 2006 Elsevier B.V. All rights reserved.

deaths continue to occur (SEDA-13, 192), particularly because of superimposed infections or hemorrhage. Auranofin has been associated with leukopenia (0.1%), lymphopenia, and neutropenia (SEDA-10, 207).

Leukopenia with liver damage has been reported (34).

- A 62-year-old woman with rheumatoid arthritis developed swelling and pain of both knees. Aurothiomalate was given in a test dose of 12.5 mg, followed the next day by a dose of 25 mg, and then 50 mg twice weekly (total cumulative dose 137.5 mg). She had a leukocyte count of 2.2×10^9/l, a normochromic anemia, and a normal platelet count. Her liver enzyme activities were raised. Aurothiomalate was withdrawn and about 6 weeks later her liver function tests returned to normal and her white cell count rose to 6.9×10^9/l.

Thrombocytopenia occurs in 0.7–3% of cases and can be severe (35). It presents with petechiae, hematuria, oral mucosal bleeding, and other hemorrhagic phenomena. Some cases are due to immune reactions, others to a direct toxic effect of gold on the megakaryocytes, and it is important to distinguish the two types. For an immunologically mediated thrombocytopenia, high-dose steroid therapy should be used if necessary, followed or accompanied by immunosuppressive drugs, infusions of fresh frozen plasma or high-dose immunoglobulin, and even splenectomy. Toxic thrombocytopenia probably demands gold chelator therapy. There is no correlation between the appearance of thrombocytopenia and effects on the skin or kidney (36). Thrombocytopenia is known with auranofin but rare (0.5%). Three patients developed serious thrombocytopenia after taking auranofin for 3 months (35). Auranofin was withdrawn and two of the patients were given oral glucocorticoids; platelet counts normalized within 8 weeks.

It has been postulated that early treatment with very high doses of intravenous *N*-acetylcysteine and the use of immunomodulatory drugs, such as antithymocyte globulin and ciclosporin, can improve the recovery of hematological parameters, even in the case of pancytopenia (37). One case of gold-induced aplastic anemia, unresponsive to various treatments, recovered after therapy with antithymocyte globulin (SED-12, 522).

Lymphadenopathy is a rare complication of gold injections (SEDA-12, 188). In one case lymphadenopathy in association with a patient with rheumatoid arthritis; biopsy of the lymph nodes showed crystalline material containing gold (SEDA-16, 234).

- A 34-year-old woman was given intramuscular sodium aurothiomalate for rheumatoid arthritis after little response to anti-inflammatory drugs (38). After the sixth injection she developed enlarged neck and axillary lymph nodes. Biopsy showed subtotal infarction of a reactive node, confirmed by histochemical, immunohistochemical, and molecular techniques. Gold was withdrawn and the lymphadenopathy gradually resolved over the next 2 months. She continued to suffer from rheumatoid arthritis with no evidence of malignant lymphoma after 3 years.

This case provides strong evidence that gold salts can cause malignant lymphoma.

Although there is no direct evidence of potentiation of hematological toxicity, the concomitant use of drugs that are known to carry a risk of blood dyscrasias is unwise. Simultaneous use of glucocorticoids in small doses is not thought to detract from the beneficial effects of gold and can delay the onset of adverse reactions (39)

Mouth and teeth

Stomatitis, sometimes preceded by a metallic taste, is a frequent complication of gold. It can take the form of superficial buccal erosions, which produce mild symptoms but tend to run a protracted course (40).

There has been one unusual report of obstructive sialadenitis caused by local compression of the excretory ducts of the parotid glands due to deposits of gold in the intraparotid lymphoid tissues; there was swelling of both parotid glands on eating (41).

Gastrointestinal

Fulminant enterocolitis or panenteritis are rare manifestations of gold intolerance; more than 30 cases have been published since 1945 (42) and one-third of them have been fatal. The presenting symptoms are diarrhea, rectal bleeding, and vomiting. Bowel dilatation can develop. The course of the disease is occasionally complicated by overwhelming infection. The X-ray picture sometimes simulates regional or ischemic enteritis. Pathological findings include intense mucosal edema, ulceration, hemorrhage, and infiltration of lymphocytes and plasma cells. No treatment is known. However, there is a milder eosinophilic type of enterocolitis due to gold, which, it has been suggested, responds to treatment with cromoglicate. Two cases of ischemic colitis have also been described, presenting as abdominal pain and rectal bleeding (SEDA-21, 236) (43).

The most common adverse effects of auranofin are gastrointestinal. About half of all users have loose stools at some time during treatment; this effect can be transient, can occur at any time, and is rarely severe. No infective cause or signs of malabsorption has been found in any case and neither was gold absorption adversely affected. In a long-term study, diarrhea was mainly observed in the first 6 months of therapy with auranofin 6 mg/day; in 8% of the cases this was a reason for withdrawal (44). There is experimental evidence in animals of a direct effect of auranofin on ion and water absorption from the intestine with inhibition of enterocyte Na^+/K^+-ATPase activity (SED-12, 525).

Stomatitis occurs in about 10% of patients taking auranofin, generally early in treatment, demanding withdrawal in up to 1% (45) (SEDA-9, 217).

Two patients developed fulminant colitis with toxic megacolon during treatment with auranofin (46,47). Both recovered completely within 4–6 weeks with supportive treatment, including high doses of prednisone.

Liver

Liver injury is an extremely rare complication of gold therapy (SEDA-14, 189) (48). The underlying mechanisms are probably complex and certainly variable. Overdosage can cause centrilobular necrosis and bile

© 2006 Elsevier B.V. All rights reserved.

stasis. With normal doses intrahepatic cholestasis with an absence of necrosis is more likely, although there can be both bile duct damage and canalicular damage (49); an immunological mechanism for this disorder has been suggested. Several cases of a severe form of idiosyncratic hepatic necrosis soon after starting chrysotherapy have been described (11,50). However, most hepatic lesions as a rule resolve rapidly after withdrawal of chrysotherapy, and mild or moderate liver injury of any type is not necessarily a contraindication to gold treatment.

- A 62-year-old man with rheumatoid factor positive rheumatoid arthritis developed painless icterus, nausea and vomiting, and discolored stools (51). He had previously been given methotrexate without effect, and was instead given aurothioglucose 50 mg/week (cumulative dose 160 mg). He reported sweating, fatigue, and myalgia shortly after each gold injection. The liver was tender but not enlarged, and there were no signs of splenomegaly. Liver function tests showed a cholestatic pattern and predominantly conjugated hyperbilirubinemia. All potentially hepatotoxic drugs (aurothioglucose, naproxen, and aspirin) were withdrawn and his dose of prednisone was increased to 15 mg/day. His liver function tests normalized 4 weeks later.

Mild and transient abnormalities in serum transaminase and alkaline phosphatase activities have been reported during therapy with auranofin (0.4%). This is noteworthy, since almost all patients were taking acetylsalicylic acid or other non-steroidal anti-inflammatory drugs, which also can cause increases in transaminases. There has been a report of two cases of toxic hepatosis in patients taking auranofin (52).

Urinary tract

Mild proteinuria develops in 2–3% of patients receiving chrysotherapy; it is usually benign and reversible within a few weeks after discontinuation of therapy (53). No deterioration in creatinine clearance has been found at periodic follow-up. It is not always necessary to stop gold treatment if a patient develops proteinuria, provided there is no marked loss of renal function and proteinuria is not in the nephrotic range. Gold therapy can be continued under close monitoring for at least 10 months without causing permanent renal damage (54).

Proteinuria has been observed in many trials of auranofin, but in contrast to cases associated with parenteral gold it has only rarely progressed to nephrotic syndrome. Of 1283 auranofin-treated patients, 38 had a raised urinary protein concentration, but only in nine it was heavy, and in most patients who continued treatment the proteinuria did not persist beyond the first 12 months of treatment; seven of eight who were rechallenged, after auranofin had been withdrawn and the protein had cleared, were able to continue treatment without relapse. Biopsy showed membranous glomerulonephritis, suggesting an underlying immunopathological mechanism (55).

Microhematuria has long been considered a manifestation of nephrotoxicity from chrysotherapy, but one multicenter study showed no higher an incidence than in patients receiving placebo (SED-12, 522). Hematuria associated with auranofin has been reported in a few patients, generally after at least 2–3 months of treatment (56).

Serious nephrotoxicity is uncommon, but nephrotic syndrome can develop in about 0.3% of patients, generally among those who have experienced mild proteinuria earlier in treatment. Very exceptionally, acute renal insufficiency can occur; peritoneal dialysis has been reported to promote recovery.

The histological findings in cases of gold nephropathy range from essentially normal glomeruli to a focal increase in mesangium, glomerular basement membrane thickening or splitting, membranous glomerulonephritis (57,58), periglomerular fibrosis with proliferation of Bowman's capsule, and even hyalinization of glomeruli. Chronic interstitial nephritis can also occur (59). Fortunately, many cases of renal complications run a benign course if gold is withdrawn (58).

Gold nephropathy is often considered to be an immunological disorder, and IgG and C3 are usually present in fine granular immune complex deposits along the capillary walls of the glomeruli. Oddly, however, X-ray microanalysis fails to detect gold as a component of the deposited immune complexes, throwing doubt on the concept that gold itself acts as an antigen or a hapten. Gold might however alter the proximal tubular cells in such a way that tubular autoantigens are released, resulting in the development of antigen–antibody complexes; these would then become attached to the glomerular basement membrane, inducing membranous glomerulopathy and proteinuria. That gold does damage the tubular cells is well known, although there appears to be no correlation with dosage and duration of therapy. Gold-containing, electron-dense, filamentous, cytoplasmic inclusions have been found in proximal tubular cells. The urinary excretion of beta-glucosaminidase, leucine aminopeptidase, $beta_2$-microglobulin, and other tubular proteins has often been found to be increased in patients treated with gold compounds (SEDA-15, 229). Tubular dysfunction can persist for up to 2 years after the end of chrysotherapy.

Skin

Skin reactions are the most frequent of all adverse effects of gold; they develop in about 25% of patients, sometimes in association with other forms of gold intolerance. Up to 30% of patients taking auranofin develop mucocutaneous adverse effects and 18–24% develop a rash or pruritus, meriting withdrawal in some 4% of cases (SEDA-10, 208).

Skin reactions to gold salts can be toxic or immunological, and patch-testing is often positive (51). No increase in gold concentration in the skin has been found, nor is there any correlation with blood concentrations of gold. Skin biopsies show that both macrophages and Langerhans cells are actively involved in the pathogenesis of gold dermatitis (61).

Pruritus is the commonest and earliest manifestation of such reactions and can precede an eruption by some weeks. Lesions are of every conceivable type, ranging from transient, non-specific, localized, or generalized dermatitis (eczema) and erythematous, maculopapular rash to lichen planus-like eruptions, discoid eczema, pityriasis rosacea, erythema multiforme, erythema nodosum,

© 2006 Elsevier B.V. All rights reserved.

scaling eruptions, urticaria, photosensitivity, hyperkeratosis, seborrheic dermatitis, toxic epidermal necrolysis, and granuloma annulare. Exacerbation of pre-existing psoriasis has been reported (62). Patients receiving aurothioglucose have sometimes developed a dermatitis closely resembling contact dermatitis (SED-12, 523). More than one of these effects can occur in the same patient.

Gold can also cause pemphigus (63).

- A 53-year-old woman with rheumatoid arthritis who had reacted to D-penicillamine treatment by developing myasthenia gravis was given gold instead and 12 months later developed pemphigus vulgaris (60).

Not every gold-induced skin disorder is necessarily wholly disfiguring; in one curious case, the patient was seen to "glitter" with tiny specks of a gold-coloured (and gold-containing) material covering the skin of the neck, upper arms, and back (64).

Chrysiasis, a gray, blue, or purple pigmentation on light-exposed skin areas, is a complication that tends to be permanent (SEDA-20, 210). In one series of 40 patients receiving sodium aurothiomalate it appeared in 31 (65).

Inadvertent gold administration has reportedly caused an allergic skin rash (66).

- A 31-year-old woman developed a rash, similar to the rash she had experienced after wearing gold jewellery. The evening before she had taken about 90–120 ml of Goldschlager liquor, a cinnamon schnapps that can contain as much as 8–17 mg of gold in 750 ml. The rash was isolated to her neck, upper chest, and hands and was erythematous and pruritic with no borders or margins. Her rash resolved over 2 weeks without desquamation.

In patients with a history of localized hypersensitivity to metallic gold, allergic skin reactions can develop in the sensitized region after gold injections (SEDA-13, 193).

Worldwide experience with auranofin points to a 2% incidence of alopecia, but this included older experience at high doses; at current doses, alopecia is rather less common (30).

If skin reactions are not serious, withdrawal of gold is not essential, and some physicians deliberately increase the dosage to the point where some skin reaction occurs, as a means of securing the best possible therapeutic effect. Once troublesome reactions have appeared they can often be relieved simply by reducing the dosage or the frequency of administration. More troublesome reactions will demand withdrawal of gold, and in that case most skin lesions will begin to subside within a few days or a week, and disappear within several weeks more; it may then be possible to resume gold at a reduced dosage (67). On the other hand, some gold-induced skin lesions can run a protracted course, in certain cases necessitating topical or systemic glucocorticoid treatment. A patchy brown discoloration can persist after the disorders have resolved. When gold has been withdrawn it can often be restarted later without recurrence of the lesion.

Nails

Gold rarely causes yellow thickening of the nails and onycholysis, followed by irreversible nail dystrophy (SED-9, 373).

- A 34-year-old woman with severe rheumatoid arthritis developed yellow thickening of all 20 nails 2 years after starting gold therapy (68). She had received 50 mg of gold salts intramuscularly at intervals of 2–4 weeks after an initial course of weekly injections (total cumulative dose 90 mg/kg) over 4 years. There was associated thickening of the nail plate, increased transverse curvature, and mild subungual hyperkeratosis. There was onycholysis of both thumbnails and the right little fingernail. There was no associated chrysiasis. Gold was withdrawn. The yellow discoloration began to grow out and fingernail growth increased in the next 3 months. Six months later there was further improvement, although light yellow discoloration of all nails persisted and there was markedly increased longitudinal growth. Both thumbnails showed transverse depressions of the nail plate (Beau's lines) where the change in growth rate had presumably occurred.

Immunologic

Several patients with selective IgA deficiency and even a panhypogammaglobulinemia during intramuscular gold treatment have been described (SEDA-14, 190) (SEDA-15, 230) (SEDA-21, 237).

Polyarteritis (69) and systemic lupus erythematosus (70) have been reported after the administration of gold compounds.

- After taking sodium aurothiomalate for 10 months (cumulative dose 550 mg) a 12-year-old girl with severe exudative polyarthritis developed pericarditis, high titers of antinuclear antibodies, and antibodies to native double-stranded DNA (70). After withdrawal her symptoms rapidly disappeared and did not recur after a follow-up period of 5 years. The titers of autoantibodies fell to normal within 1 year.

In one series of some 5500 patients with juvenile rheumatoid arthritis, 105 were found to have developed secondary amyloidosis; 37 of the latter had been receiving sodium aurothiomalate. In 12 of these children the time between withdrawal of gold (because of adverse effects) and the finding of amyloid A was less than six months (SEDA-21, 237).

- A 63-year-old woman with rheumatoid arthritis was given intramuscular gold sodium thiomalate and began to have nausea, vomiting, anorexia, and watery diarrhea (71). A year later the watery diarrhea became more frequent (more than 10 times within a day) and she developed proteinuria. Biopsies from the stomach, duodenum, and kidney showed systemic amyloidosis. This was a rare case of secondary systemic amyloidosis associated with rheumatoid arthritis. It is not clear from the report what the role of gold was in this case.

Infection risk

An increased incidence of *Herpes zoster* was found in a series of patients receiving sodium aurothiomalate; the mechanism is unknown, but herpesvirus infection can also occur in association with some other heavy metals, for example in environmental poisoning.

The incidence of *H. zoster* infection in auranofin-treated patients was slightly higher (0.9%) than in patients

© 2006 Elsevier B.V. All rights reserved.

with rheumatoid arthritis not receiving gold therapy (0.4%), but less frequent than in patients given parenteral gold compounds (3.1%).

Body temperature

There may be transient exacerbation of rheumatoid symptoms before a therapeutic response to gold occurs. In one series of 43 patients with rheumatoid arthritis serious exacerbation of the disease occurred in 17% (12).

Second-Generation Effects

Teratogenicity

In 1980, alarm was caused by a report of a seriously malformed child born to a mother who had been treated with sodium aurothiomalate during pregnancy (72), particularly since a partially congruent pattern of neural abnormalities had earlier been described in rats and rabbits, and given the fact that gold crosses the placenta. On the other hand, a Danish team in 1983 studied eight children born after exposure to gold in utero from weeks 2–9 or longer; no abnormalities were found, and the children appeared to develop normally during a follow-up period averaging 8.6 years (73). In view of the lack of further incriminating evidence some physicians today adopt the view that chrysotherapy can be continued in selected pregnant women whose rheumatoid arthritis is of such severity as to warrant treatment.

Lactation

Breastfeeding is not recommended since gold salts are excreted in the milk (SEDA-12, 188) (SEDA-13, 193).

Susceptibility Factors

Genetic factors

There is good evidence that patients with rheumatoid arthritis who carry the DR3 antigen run a greater risk of proteinuria (74), mucocutaneous reactions (75), and hematological actions (76) to parenteral gold compounds as well as to penicillamine, although such patients also tend to react rather better than others to aurothioglucose (77). The same applies to the B8, DR3 haplotype (81). The prevalence of the HLA antigens DR2 and DR7 is lower among rheumatoid arthritis patients with toxic reactions than among patients without toxic reactions or among controls (79). Because of conflicting results and the low relative risk, HLA typing has not been of much practical help as a guide to forecasting the risk of therapy.

Patients with rheumatoid arthritis and poor sulfoxidation state are six times more susceptible than others to the adverse effects of sodium aurothiomalate (80). This parallels an earlier similar finding with penicillamine, which has the same sulfhydryl group in its structure.

Age

Several studies have shown that in juvenile chronic arthritis auranofin gives rise to fewer adverse reactions than in adults, but the therapeutic effect is dubious and variable (SEDA-17, 277).

Elderly patients were once thought to be more likely than younger individuals to develop severe reactions (81) but this seems not to be so (82).

Other features of the patient

There are various contraindications to gold therapy (83): active hepatic disease, impaired renal function, colitis, patients with a history of hematological disorders, and patients who have recently had radiotherapy (because of the depressant action of radiotherapy on hemopoietic tissue).

Drug Administration

Drug overdose

- Severe overdosage of sodium aurothiopropanol sulfonate (1.1 g daily for 13 days) caused jaundice and skin eruptions. Liver biopsies showed modest centrilobular necrosis and significant bile stasis. Serum hepatic enzyme activities were increased. The patient was treated with dimercaprol and recovered after 2 months, although alkaline phosphatase and gamma-glutamyltransferase activities remained high for 6 months.

It seems advisable in cases of acute gold intoxication to adopt a conservative strategy. Should severe complications occur, supportive therapy can be given in combination with such treatments as chelation, glucocorticoids, or gamma-globulin.

Drug–Drug Interactions

Glucocorticoids

In a placebo-controlled study auranofin reduced the doses of glucocorticoids needed in asthma (84). This is perhaps a parallel effect rather than an interaction since, as noted above, gold itself may have an effect in asthma.

Gonadorelin

General Information

The effects of gonadorelin depend on the duration of use. Gonadotropin release is stimulated in the short term, but is later suppressed owing to down-regulation of hypophyseal receptors. Its therapeutic indications have been summarized (SEDA-13, 1311) (1). Long-acting and depot formulations have the same adverse effects as shorter-acting analogues. The available gonadorelin analogues include buserelin, goserelin, leprorelin, nafarelin, and triptorelin (all rINNs).

Gonadorelin and its analogues cause an initial surge in follicle-stimulating hormone (FSH), luteinizing hormone (LH), and gonadal steroids. Receptor down-regulation and gonadotropin suppression occur after prolonged administration. Thus, both the clinical and adverse effects depend on the duration of administration. Biological activity and adverse effects also vary between gonadorelin agonists.

Comparative studies

In 67 premenopausal Japanese women randomized to 4-weekly, low-dose buserelin 1.8 mg or leuprorelin 1.88 mg, women given leuprorelin had a more rapid clinical response and a higher rate of hot flushes (2).

Adverse effects and quality of life have been compared in 431 men with prostate cancer treated with a gonadorelin agonist or orchidectomy (3). Of the men who reported normal sexual function before treatment, 51% had reduced libido and 69% became impotent. Of those given gonadorelin, 57% had hot flushes. Breast swelling was more common in those given gonadorelin (25% compared with 10% after orchidectomy).

Of 547 men randomized to leuprorelin plus flutamide for 3 or 8 months, those treated for 8 months had a higher overall rate of adverse events, and 87% had hot flushes, compared with 72% of those who were treated for 3 months (4).

Organs and Systems

Cardiovascular

Gonadorelin inhibits nitric oxide-mediated arterial relaxation, which disappears within 3 months after stopping treatment. This effect was abolished with "add-back" hormone replacement in a prospective, randomized study of 50 women treated for 6 months (5).

Respiratory

- A 75-year-old man developed a high fever and cough immediately after an injection of leuprorelin acetate 3.75 mg and 8 days after starting flutamide 375 mg/day (6). He died of respiratory failure after a month, and interstitial pneumonitis was confirmed postmortem.

There have been two other reports of pneumonitis associated with gonadorelin agonists.

Ear, nose, throat

Local irritation or rhinitis occurs uncommonly when gonadorelin agonists are taken intranasally.

- A 34-year-old woman had to stop using nafarelin nasal spray after 14 days because of exacerbation of maxillary sinusitis (7).

Nervous system

Pituitary apoplexy (hemorrhagic infarction presenting with sudden severe headache, often followed by pituitary hormone deficiency) has been reported after intravenous gonadorelin testing to investigate a pituitary macroadenoma and in several patients with gonadotropin-secreting pituitary macroadenomas who were given gonadorelin to treat prostate cancer (8). It may be advisable to assess gonadotropin status prior to therapy in such patients.

- A 43-year-old woman with a pituitary macroadenoma, who took quinagolide 37.5 micrograms/day for 33 months, developed a severe headache, nausea and vomiting, and photophobia 30 minutes after diagnostic testing with gonadorelin 50 micrograms intravenously (9). Although a CT scan at the time showed no evidence of hemorrhage, an MRI scan 18 months later showed a partial empty sella.
- A 67-year-old man with prostate cancer and an unsuspected pituitary macroadenoma developed a severe frontal headache, nausea and vomiting, and blindness within 12 hours of insertion of a goserelin implant (10).

Two further cases have been reported, in which gonadorelin was administered either alone (11) or with insulin (12). The mechanism of pituitary apoplexy in these cases is unclear. Gonadorelin may have a direct effect on vascular tone or may increase tumor metabolic activity.

There has been one previous report of seizure exacerbation during leuprorelin treatment, in a girl with pre-existing brain damage (13), and a case of de novo seizures has also been reported (14).

- A 13-year-old girl, who had previously had surgery and radiotherapy for a medulloblastoma, developed atypical absence seizures for the first time after 3 months of therapy with leuprorelin. The seizures stopped 1 month after treatment was withdrawn and did not recur until 30 months later. The seizures were not related to estradiol concentrations or the menstrual cycle.

Neuromuscular function

Prolonged administration of gonadorelin is commonly associated with reduced muscle bulk and voluntary muscle function. In a prospective, uncontrolled study of 62 men with prostate cancer, treatment with cyproterone acetate and goserelin caused an increase in fatigue scores and increased muscle fatiguability on objective testing within 6 weeks, in 66% of subjects (15). Fatigue was unrelated to psychological complaints or to self-reported functional ability.

Sensory systems

Blurred vision, sometimes associated with headache and dizziness, is common soon after the commencement of

© 2006 Elsevier B.V. All rights reserved.

treatment and usually resolves within 2–3 weeks. It has recurred in some patients after rechallenge (16).

Psychological, psychiatric

Depressed mood and emotional lability occur in up to 75% of gonadorelin recipients, and there are rare reports of more severe mood disturbances (17). Defects of verbal memory have been described and may be reversed by "add-back" estrogen treatment (17) and sertraline (18).

- A 32-year-old woman had psychotic symptoms of persecutory delusions, agitation, and auditory hallucinations a few days after her second injection of triptorelin (19). Her symptoms recurred after a pregnancy, suggesting that they were due to the rapid fall in estrogen in both instances.

During a 6-month, randomized trial, men randomized to gonadorelin agonists had reduced attention and memory test scores, compared with men who were not given gonadorelin agonists but were closely monitored, in whom there was no change (20).

Endocrine

Symptoms of hypoestrogenism, including hot flushes, vaginal dryness, reduced libido, and mood changes, occur in almost all women on long-term gonadorelin. Men also experience hypogonadal symptoms with prolonged gonadorelin administration, including hot flushes and reduced libido, although this is a therapeutic effect rather than an adverse effect. Gynecomastia occasionally occurs in men.

"Add-back" estrogen replacement reduces the frequency and severity of these symptoms without apparently compromising the effectiveness of gonadorelin in women with endometriosis (18,21). In a randomized, multicenter, double-blind comparison of intranasal nafarelin twice daily and depot leuprolide acetate monthly for 6 months in 192 young women with endometriosis, nafarelin caused fewer hypoestrogenic symptoms, although the difference between the two groups was statistically significant only after 3 months of therapy (22).

"Draw-back" therapy, in which the dosage of nafarelin was reduced after 4 weeks, had similar efficacy, but a smaller degree of bone loss and fewer vasomotor adverse effects compared with full-dose therapy, in a randomized study in 15 premenopausal women (23).

- A 47-year-old woman developed symptoms of thyrotoxicosis (palpitation, tremor, tachycardia, and goiter) due to Graves' disease, after using goserelin acetate for 13 months (24).
- A 45-year-old woman developed transient thyroiditis associated with antithyroid antibodies in taking leuprorelin (25).

The second patient had other risk factors for autoimmune thyroid disease, and the association was probably coincidental, but the episode may have been precipitated by low estrogen concentrations, as is hypothesized in postpartum thyroiditis.

Metabolism

In 20 premenopausal women treated with triptorelin for 8 weeks, the mean LDL concentration rose from 2.7 to 3.9 mmol/l and HDL fell from 1.6 to 1.5 mmol/l (26). Although the change in HDL was not clinically relevant in isolation, the increases in LDL and LDL:HDL ratio were significant, suggesting an increased risk of atherogenesis. "Add-back" conjugated equine estrogen did not reverse these changes over 24 weeks.

- A woman with type 2 diabetes had worse glycemic control while receiving buserelin (27). Her blood glucose returned to its previous concentration after withdrawal.

Hematologic

Leuprolide acetate has been reported to cause normochromic normocytic anemia in patients with benign prostatic hyperplasia (28). The anemia is usually transient, and the hemoglobin returns to baseline 6 months after stopping androgen suppression. There is a single case report of more serious red cell aplasia in a patient receiving gonadorelin, with resolution after treatment was withdrawn (29).

Skin

Injection site reactions are common with gonadorelin receptor agonists. In 119 women randomized to subcutaneous triptorelin a local reaction (redness, pain, or bruising) was present after 1 hour in 24% and persisted for 24 hours in 9.5% (30). In another study in 105 women randomized to leuprorelin acetate, moderate local reactions occurred in 24% and severe reactions in 1% (31).

- A 48-year-old woman developed an itchy skin eruption and spotted dark brown pigmentation 3 weeks after starting nasal buserelin 900 micrograms/day. The lesions resolved when buserelin was withdrawn, and recurred with rechallenge; some persisted for up to 2 years (32).
- A 78-year-old man treated with subcutaneous leuprorelin acetate had repeated local reactions, with erythema, induration, abscesses, and an ulcer on one hip (33).

Altered skin pigmentation has been previously reported in pregnancy and after sex hormone administration, so the initial surge in gonadotropins after gonadorelin treatment was a probable cause for the first patient's presentation. In the second case the lactic acid/glycolic acid vehicle may have caused the reaction rather than leuprorelin.

Musculoskeletal

Osteoporosis, trabecular bone being most affected, has been regularly observed in both sexes with chronic gonadorelin agonist treatment (34), and the duration of therapy for prostate cancer is inversely related to bone mineral density (35,36). Intravenous pamidronate may prevent bone loss in these patients (37,38).

- A 44-year-old woman with no previous history of widespread pain, depression, or anxiety developed a diffuse pain syndrome consistent with fibromyalgia after leuprorelin treatment. Her symptoms increased in severity with three successive monthly injections, and persisted for several months (39).

© 2006 Elsevier B.V. All rights reserved.

In 47 children treated with depot leuprolide acetate for precocious puberty for 2 years, bone mineral density decreased significantly and markers of bone turnover increased significantly during treatment but were normal for age 2 years after treatment was withdrawn (40).

Since women have a lower initial bone mass than men their fracture risk is higher. Osteoporosis is reversible in premenopausal patients after gonadorelin withdrawal (41). However, the treatment period should be limited to 6 months.

Cross-sectional (42) and longitudinal (43) studies of men with prostate cancer have shown a significant relation between the duration of gonadorelin treatment and bone loss.

Estrogens, etidronate, and parathyroid hormone have been used with partial success to prevent gonadorelin-induced bone loss. In a prospective study of 49 women treated with goserelin and randomized to estradiol plus norethisterone or placebo, bone loss persisted 6 years after stopping therapy, and the hormone replacement therapy had only a minor protective effect (44).

- An 87-year-old man developed progressive proximal limb weakness 1 year after starting leuprolide therapy for prostate cancer (45). Electromyography showed a moderately severe non-inflammatory myopathy without evidence of fiber necrosis or associated biochemical changes. Within 6 months after stopping leuprolide he was able to resume his usual activities.

Three men developed rheumatoid arthritis 1–9 months after starting antiandrogen therapy with either cyproterone acetate or leuprolide acetate (46).

Reproductive system

Ovarian hyperstimulation syndrome (OHSS) affects up to 33% of women undergoing ovulation induction with gonadorelin receptor agonists and gonadotropins given in combination (47), or with gonadotropins alone (48). Gonadotropins are usually withheld if the diagnosis is made before conception (47,49).

OHSS is characterized by cystic ovarian enlargement, increased capillary permeability, and third space fluid accumulation (that is in an extracellular compartment that is not in equilibrium with either the extracellular or intracellular fluid, for example the bowel lumen, subcutaneous tissues, retroperitoneal space, or peritoneal cavity). Risk factors include a previous history of OHSS, age under 30 years (probably because more follicles are available), and polycystic ovary syndrome. Non-pregnant patients usually recover within 14 days with supportive treatment. The severe form (with ascites or pleural effusion and hemoconcentration) occurs in 1–10% of patients (49,50). In critical cases, hypoxemia, renal insufficiency, thromboembolism, and rarely death can occur (51).

- A 29-year-old woman with polycystic ovary syndrome had her first in vitro fertilization cycle of leuprorelin acetate, FSH, and human chorionic gonadotropin (hCG) (52). Within 2 days she complained of abdominal distension, shortness of breath, and abdominal pain. Over the next few days she developed massive ovarian enlargement, ascites, hyponatremia, respiratory failure, and renal insufficiency. This was further complicated by duodenal perforation, probably due to severe physical stress.
- Ovarian hyperstimulation syndrome occurred in a woman with polycystic ovarian syndrome, 3 weeks after an intramuscular injection of leuprorelin acetate for endometriosis (53). She was later given further courses of the drug without this complication.
- A 35-year-old obese woman with a previously undiagnosed pituitary gonadotroph adenoma developed multiple ovarian cysts and abdominal distension after 1 month of leuprolide therapy (54).
- A 32-year-old woman who was not obese developed benign intracranial hypertension in association with ovarian hyperstimulation syndrome after ovulation induction using goserelin, FSH, and hCG (55). The syndrome did not recur during a second pregnancy in which FSH and hCG were not used.

It is unclear which of the hormonal agents used was responsible for this complication in the last case.

Gonadorelin receptor antagonists have been reported to lower the risk of OHSS significantly. A meta-analysis showed that cetrorelix but not ganirelix reduced the incidence of OHSS by 75%, both overall and the severe form (56).

Thromboembolism is a serious complication of OHSS (57–60).

- A previously healthy 34-year-old woman who underwent ovulation induction with leuprorelin acetate and FSH developed abdominal ascites due to OHSS, followed by acute aphasia and right hemiparesis (61). The stroke was caused by a large intracardiac thrombus.

A review identified 54 other reports of thromboembolic disease associated with ovulation induction; 60% were in upper limb veins and two-thirds of the patients had OHSS (62). The mechanism for the increased risk of thrombosis in these patients has not been determined, but hemoconcentration or a hypercoagulable state associated with high estrogen concentrations could be responsible.

Immunologic

Altered immune function has been reported in several cases associated with gonadorelin agonist therapy. This is possibly related to the initial surge in sex steroids that occurs with these agents, but there is no evidence that this is the mechanism. Cardiac allograft rejection occurred in three men within months of starting gonadorelin therapy for prostate cancer. One died of heart failure, but the other two recovered cardiac function after the gonadorelin agonist was withdrawn (63).

Systemic lupus erythematosus can be exacerbated in the initial gonadotropin-stimulating phase of gonadorelin therapy: in one case this was fatal (64).

Long-Term Effects

Tumorigenicity

Tumor flare occurs in up to 30% of treated patients after the first 4–7 days of gonadorelin therapy, due to an initial surge in gonadotropin concentrations (65). For this reason

© 2006 Elsevier B.V. All rights reserved.

antiandrogen treatment is often given before gonadorelin in men with prostate cancer. However, despite tumor flare there was no difference in survival in a prospective, multicenter comparison of gonadorelin and surgical oophorectomy in 136 patients (66).

Second-Generation Effects

Teratogenicity

Pregnancies have occurred both after low-dose gonadorelin agonist therapy for ovulation induction and after higher-dose therapy for endometriosis or other indications: these have been reviewed in the context of a report of a 36-year-old woman who stopped monthly goserelin injections at 16 weeks of gestation and delivered a healthy girl. Congenital abnormalities have been reported in a few cases, including one child with trisomy 13, one with trisomy 18, and an intrauterine death due to thrombosis; however most pregnancies have had normal outcomes (67).

Drug Administration

Drug formulations

There is no difference in the adverse effects profiles of long-acting or depot formulations compared with shorter-acting analogues used continuously.

Drug-Drug Interactions

Oral contraceptives

There were mild increases in serum triglyceride and cholesterol concentrations in 13 hirsute women treated with triptorelin and a triphasic oral contraceptive, in a randomized comparison of triptorelin with flutamide + cyproterone acetate (68). Altered lipid profiles have not been described before in patients receiving gonadorelin agonists and oral contraceptives.

Gonadorelin antagonists

General Information

The gonadorelin antagonists include abarelix, cetrorelix, degarelix, detirelix, ganirelix, iturelix, prazarelix, ramorelix, and teverelix (all rINNs).

Gonadorelin agonists suppress the release of gonadotropin after an initial surge: pituitary suppression takes up to 2 weeks to develop. Competitive antagonists at gonadorelin receptors cause immediate inhibition of gonadotropin secretion without down-regulating the receptor. This class of agents would therefore be preferable to gonadorelin agonists when a rapid clinical effect is desired, for example in controlled ovarian stimulation.

Early gonadorelin antagonists were of low potency and tended to cause histamine release (1). However, ganirelix and cetrorelix are better tolerated (1,2). They do not share the lipophilic and histamine-releasing properties of earlier generation gonadorelin antagonists and neither do they lead to depot formation. There appears to be a narrow therapeutic margin in ovarian stimulation protocols. Ganirelix concentrations correlate with body weight, and it has been suggested that the dose should be adjusted to weight to maximize pregnancy rates (3). The adverse effects of ganirelix are usually mild and include minor injection site reactions, mild nausea, and malaise (1).

Organs and Systems

Endocrine

In a small, controlled study of 10 healthy men, cetrorelix increased concentrations of insulin, leptin, and apolipoprotein A-I compared with placebo (4). The clinical significance of these findings has yet to be determined.

Skin

Local injection reactions are common and probably dose-related. In an open study of cetrorelix in its lowest effective dose of 0.25 mg/day, 3 of 346 women described local reactions (5). In another study of 154 women, 115 of whom were randomized to one 3 mg dose of cetrorelix, 25% had transitory redness or itching at the injection site (2). In a multicenter European study of 463 women randomized to ganirelix and 238 to buserelin, 17% of those given ganirelix had moderate skin redness, bruising, pain, or itching 1 hour after subcutaneous injection; this had mostly disappeared after 4 hours (6).

Five of 168 men with prostate cancer treated with abarelix had urticaria and pruritus, which resolved without treatment (7).

Reproductive system

Ovarian hyperstimulation syndrome is far less common with gonadorelin receptor antagonists than agonists in induction of ovulation (2,5). Hot flushes are rare, in contrast to gonadorelin receptor agonists: in a prospective, uncontrolled study of 346 women given cetrorelix, there was only one case of hot flushes (5).

Gonadotropins

General Information

Human chorionic gonadotropin (HCG, hCG), extracted from the urine of pregnant women, has mainly luteinizing hormone (LH) activity. Human menopausal gonadotropin (HMG, hMG) contains both follicle-stimulating hormone (FSH) and luteinizing hormone in about equal amounts. Where materials of natural origin are used, the relative amounts of follicle-stimulating hormone and luteinizing hormone in pituitary gonadotropin extracts vary with the extraction procedure used. However, in recent years, both pure recombinant versions of human FSH and human LH (rhFSH, rhLH) have become available and have increasingly replaced the natural products.

Luteinizing hormone-releasing hormone (LHRH) is used in the treatment of infertility (1). It induces pulsatile release of gonadotropin, and excessive stimulation can result. However, if used over a period of time, the receptors cease to respond and there can be a fall in the concentrations of luteinizing hormone and follicle-stimulating hormone and a fall in sex steroid concentrations to the castrato range.

Treatment schedules for induction of ovulation have been described in a number of papers, but individual sensitivity of the ovaries varies greatly. Complications are generally considered more likely when the dose is excessive compared with individual needs; their incidence varies greatly from clinic to clinic, apparently because of differences in formulations and the dosage schedule used. Problems include superovulation, multiple pregnancy, and the hyperstimulation syndrome, which consists of rapid ovarian enlargement with intraperitoneal effusion (2). Ascites and hydrothorax are occasionally seen, probably due to an increase in vascular permeability at high estrogen concentrations (3). Vascular accidents have been reported, namely thrombophlebitis (4) and obstruction of the basilar artery (SED-12, 1033) (5). Gonadotropins have also been stated, although with much less certainty, to cause cardiomyopathy and behavioral and intellectual disturbances (SED-12, 1033) (6,7).

Observational studies

The European Metrodin HP Study Group has assessed the efficacy and safety of a highly purified urinary FSH in combination with human chorionic gonadotropin in inducing spermatogenesis in 28 men with primary complete isolated hypogonadotrophic hypogonadism, of whom 25 achieved spermatogenesis (8). Mean testicular volume increased by about 7 ml during treatment. Adverse events considered to be related to human chorionic gonadotropin were acne ($n = 3$), weight gain ($n = 2$), and gynecomastia ($n = 1$). Acne can be attributed to increased testosterone. Gynecomastia is an adverse effect of human chorionic gonadotropin treatment (9), and it may be caused by raised serum estradiol concentrations.

In 71 women undergoing in vitro fertilization and embryo transfer using recombinant human follicle-stimulating hormone in doses sufficient to attain a pregnancy rate of 24% (10), the main adverse effect was mild pain at the site of injection (less than 20% of patients) but there were two cases of ovarian hyperstimulation syndrome. In less than 10% of patients, redness, swelling, or bruising was seen and one patient developed headache.

The efficacy of recombinant human luteinizing hormone (rhLH) for supporting follicular development induced by recombinant human follicle-stimulating hormone (rhFSH) has been investigated in hypogonadotropic hypogonadal women (11). A total of 42 adverse events were reported in 14 of the 53 cycles in this study. Of these, 32 adverse events occurred in 11 of the 42 cycles treated with rhLH, and 10 occurred in three of the 11 cycles not treated with rhLH. The most frequent adverse events were pelvic and abdominal pain, headache, breast pain, nausea, ovarian enlargement, and somnolence. These adverse events are similar to those reported during therapy with follicle-stimulating hormone alone (11).

Comparative studies

When recombinant and urinary versions of follicle-stimulating hormone were compared under double-blind conditions in an in vitro fertilization program in a randomized, multicenter study (12), the former was more potent. There were no clinically relevant differences in safety between the two products and no cases of ovarian hyperstimulation syndrome.

The efficacy and safety of recombinant human follicle-stimulating hormone (r-hFSH) has been compared with that of highly purified urinary follicle-stimulating hormone (u-hFSH HP) in women undergoing ovarian stimulation for in vitro fertilization, including intracytoplasmic sperm injection, in a prospective, randomized study in 278 patients, who were treated with gonadotropin-releasing hormone and then received one of the two formulations in doses of 150 IU/day subcutaneously for

© 2006 Elsevier B.V. All rights reserved.

the first 6 days; on day 7 the dose was adjusted, if necessary, according to the ovarian response (13). Human chorionic gonadotropin (10 000 IU subcutaneously) was administered once there was more than one follicle 18 mm in diameter and two others of 16 mm or larger. Rr-hFSH was more effective than u-hFSH HP in inducing multiple follicular development. There were seven cases (5.0%) of ovarian hyperstimulation syndrome in those given r-hFSH and three (2.2%) in those given u-hFSH HP; this difference was not significant.

General adverse effects

The short- and long-term effects of ovulation induction have been reported (8). In the short term, clomiphene and gonadotropins cause ovarian hyperstimulation syndrome (ovarian enlargement, bloating, and nausea) and multiple pregnancies; gonadotropins also cause ectopic pregnancy. In the long term, clomiphene may cause an increased risk of ovarian cancer.

Recombinant human chorionic gonadotropin

Recombinant human luteinizing hormone has now very largely replaced the product prepared from the urine of pregnant women (uhCG). In an open, randomized trial in 297 ovulatory infertile women in 20 US infertility centers, recombinant hCG 250 micrograms and 500 micrograms was compared with urinary hCG 10 000 U USP in assisted reproduction (14). The women were treated for a single cycle with one or the other. The mean numbers of oocytes retrieved per treatment group were equivalent (13–14). Although the numbers of fertilized oocytes on day 1 after oocyte retrieval and of cleaved embryos on the day of embryo transfer were significantly higher with 500 micrograms of recombinant hCG than with 250 micrograms, the incidence of the anticipated adverse events also tended to be higher.

More exact data on the adverse effects and relative safety of the recombinant and urinary formulations have been provided in a similar investigation in 259 women (15). In terms of safety, rhCG was well tolerated at a dose of up to 30 000 IU. Moderate ovarian hyperstimulation syndrome was reported in 12% of patients who received uhCG and 12% of those who received two injections of rhCG. There were no moderate or severe complications in patients who received a single dose of rhCG up to 30 000 IU. The results seem to show that a single dose of rhCG is effective in inducing final follicular maturation and early luteinization in in vitro fertilization and embryo transfer patients and is comparable with uhCG 5000 IU. The dose of rhCG that gave the highest efficacy to safety ratio was 15 000–30 000 IU.

The recombinant and urinary forms of human chorionic gonadotropin have also been compared in an international multicenter study, with similar findings (16), but it was notable that significantly more patients who were given uhCG reported local reactions (particularly inflammation and pain), presumably because of the presence of biological impurities.

Organs and Systems

Hematologic

Resistance of activated protein C and deep calf vein thrombosis has been reported during controlled ovarian stimulation for in vitro fertilization (17). The thrombosis occurred on the eighth day of human menopausal gonadotropin use and before human chorionic gonadotropin was given.

Reproductive system

There is a risk of ovarian hyperstimulation when an ovulation-inducing drug is followed by rapid ovarian enlargement with peritoneal effusion. The incidence of these complications varies with the product and dosage schedule used; in experienced hands, the frequency of complications may be no more than about 4%.

- In an unusual case reported in detail from Saudi Arabia, a 28-year-old woman receiving gonadotropins developed acute respiratory distress, abdominal pain, and severe hyponatremia associated with the syndrome of inappropriate antidiuretic hormone secretion (SIADH) (18). A multiple pregnancy nevertheless resulted and three fetuses went to term successfully.

While it is possible that the gonadotropins themselves induced SIADH, it seems more likely that it was a secondary complication of ovarian hyperstimulation.

The dangers of ovarian hyperstimulation with gonadotropins should not be underestimated. Quite apart from the risks of abdominal complications and even myocardial infarction, it can cause marked changes in liver function tests (19). It has been suggested that ultrasonographic monitoring is a means of detecting impending ovarian hyperstimulation, so that treatment can be suspended in good time (20).

- A 33-year-old woman developed severe symptomatic ovarian hyperstimulation after being given 10 000 IU of urinary human chorionic gonadotropin for empty follicle syndrome (21).

Although it has generally been thought that ovarian hyperstimulation would not occur when treating cases of empty follicle syndrome, this suggests that even when dealing with such patients, particularly if there is any reason to think that they are at risk of ovarian hyperstimulation, it is wise to take the usual precautions, using a much lower dose of human chorionic gonadotropin and adding progesterone for luteal support.

Just how dangerous and even life-threatening such hyperstimulation can be is illustrated by a recent case (22).

- A 28-year-old woman who had undergone attempted hormonal induction of ovulation presented some days later with ascites, oliguria, and vomiting. Over 2 weeks she developed severe hypoalbuminemia, due to a combination of intractable vomiting, intravenous rehydration, paracentesis, hypercatabolism, and proteinuria, with gross edema and progressively worsening liver function. Her serum albumin dropped to 9 g/l with liver function abnormalities: aspartate transaminase

462 IU/l, alkaline phosphatase 706 IU/l, bilirubin 26 μmol/l, prothrombin time 19 seconds. Paracentesis and total parenteral nutrition coincided with rapid clinical improvement.

Other presenting signs of ovarian hyperstimulation include ascites, hydrothorax, thrombophlebitis, and, as in one recently reported case, acute dyspnea (23).

"Prolonged coasting" may offer possibilities as a means of preventing ovarian hyperstimulation syndrome where excessive doses of gonadotropins have been given (SEDA-20, 389); it involves temporarily withholding the gonadotropins and giving only a gonadotropin-releasing hormone agonist until the plasma estradiol concentration has fallen sufficiently; however, experience to date shows that it is not foolproof and that spontaneous abortions can result where pregnancies have already started.

In vitro maturation of immature oocytes represents a potential alternative for fertility treatment in patients who are likely to suffer hyperstimulation. In two patients considered to be at risk of hyperstimulation, because of polycystic ovaries, priming with hCG 10 000 IU (specified only as the IVF-C brand) was followed by removal of the oocytes 36 hours later (24). Oocytes considered to be mature at the time of collection were inseminated using in vitro fertilization or intracytoplasmic sperm injection (ICSI), and the resulting embryos were cultured to the blastocyst stage. Transfer of these blastocysts resulted in pregnancy in both patients. Immature oocytes were matured in a culture medium containing 30% human follicular fluid, recombinant follicle-stimulating hormone 1 IU/ml, hCG 10 IU/ml, and recombinant epidermal growth factor (rhEGF) 10 ng/ml. ICSI was then carried out. Two and five expanded blastocysts were obtained after 5 days of culture and were cryopreserved. The findings suggested that one can avoid the risk of ovarian hyperstimulation when using hCG in women with polycystic ovaries and that (at least when using mature oocytes) pregnancy can be established.

Immunologic

Gonadotropins of natural origin contain various allergens, which can give rise to hypersensitivity reactions. This was a serious problem with the "PMS" gonadotropin formulations formerly made from the serum of pregnant mares but now apparently obsolete; it was also described in the past with an FSH formulation of porcine origin. However hypersensitivity reactions can also occur to extracts of human material.

- A generalized allergic reaction to human menopausal gonadotropin (Pergonal) has been described during controlled ovarian hyperstimulation (25). In this case a desensitization protocol allowed the patient to complete her treatment cycle without further problems. Subsequently recombinant follicle stimulating hormone was used successfully and uneventfully.

On occasion, there have even been such reactions to highly purified human products, notably FSH; they can be managed by changing the treatment to intramuscular recombinant follicle stimulating hormone (26).

Long-Term Effects

Tumorigenicity

In a prospective study of 1200 infertile women in Israel, including a subgroup of women who developed breast cancer, there was no statistical association with the use of fertility-inducing drugs (27).

A subfertile man treated with human menopausal gonadotropin + human chorionic gonadotropin (hMG + hCG) developed a malignant teratoma of the testis; however, in view of his history a cause-and-effect relation was dubious (28).

Malignant melanoma

Concern that the drug treatment of female infertility might predispose the user to malignant melanoma was first engendered by a US study published in 1995 (29). Among women who had used clomiphene citrate for infertility the incidence of melanoma was higher (RR = 1.8; 95% CI = 0.8, 3.5) than among American women in general. However, in a case-cohort study of nearly 4000 infertile women there was a similar increase in the incidence of melanoma among those who had been treated with human chorionic gonadotropin compared with the rest; there was no association with the use of clomiphene.

Quite apart from the inherent discrepancy in these findings, several pieces of evidence have confused the debate. In the first place, the cohort of melanoma cases was small—barely a handful. In the second place, some earlier papers had suggested that infertility in women might of itself have an association with melanoma. The same impression came from various studies, in which the incidences of cancers in infertile women were examined (30–32). If that were true, it could affect the initial findings in either direction: a high spontaneous incidence might mask a real drug effect, or it might provide a predisposition to melanoma, which the drugs might then more readily trigger.

In the meantime, data from Australia have shown no greater incidence of melanoma among women who had used fertility drugs and undergone in vitro fertilization than in the country's general female population (33). Since then there has been one more significant paper, again from Australia, using data from a specialized fertility clinic in Queensland, relating to all women who attended the center over a decade (34). Whenever possible, the women were traced and their subsequent history noted. Originally intended as a retrospective case-cohort study using a subcohort, the approach had to be amended because no cases of melanoma were found in the subcohort. The work therefore proceeded as a matched case-control study; all the data were taken and set against publicly available figures on melanoma in Queensland. After some necessary exclusions, 3186 women were included; care was taken to minimize recall bias. Fourteen women developed melanoma after fertility treatment, eight cases being invasive. The expected incidence in the general population would have been 15.8 cases in the same period. The incidence actually observed was therefore only 0.89 of that anticipated (95% CI = 0.54, 1.48).

© 2006 Elsevier B.V. All rights reserved.

The numbers of women who had used clomiphene or human menopausal gonadotropin were too small to make more differentiated calculations, but the incidence of melanoma seemed to correspond to that in the general population.

On current evidence, there seems no reason to discourage fertility-promoting drug treatments because of any risk of melanoma; they may even reduce it to some extent. However, this does not alter the fact that the data are deficient in various ways. Quite apart from the small numbers of melanoma cases that have been recorded, all the work to date has been performed in relatively sunny parts of the world; it is not known what would happen in other climates. Within countries, there are sharp differences in melanoma figures; in the USA, where about 32 000 new cases of skin melanoma were projected for 1994 (35), the highest melanoma rates occur among light-skinned populations in areas of intense sunlight, for example Arizona; the same applies to Queensland, Australia. In the USA as a whole there is a melanoma incidence among whites of 12.4 per 100 000 (36), while mortality rates vary inversely with latitude (37). Furthermore, in whites there has been a recent increase in the incidence of melanoma, during the precise period that this type of treatment has become popular, but probably for entirely different reasons, which may be associated with lifestyles and holiday habits; the reported incidence in whites rose by no less than 102% from 1973 to 1991 (37). Finally, as the Australian authors themselves stressed, the fact that the Queensland clinic was a private institution specializing in IVF/GIFT therapy means that women with endocrine- or ovulation-associated infertility may not so readily have been referred to it.

All this makes it very difficult to find a baseline incidence for melanoma with which cases treated for infertility can be compared. It is to be hoped that data of this type will continue to arrive from other centers, so that a definitive judgement will become possible.

Ovarian cancer

The hypothesis that the use of fertility drugs, including human gonadotropins and clomiphene, which increase the endogenous secretion of gonadotropins, might increase the risk of ovarian cancer appears to have come first clearly into the open in 1996 (38). However one can distil similar suggestions from other work from 1992 onwards (39–41), and anecdotal reports of an association have accumulated. The hypothesis has emerged that the increased number of ovulations (or the high concentrations of estrogen and gonadotropin) induced by drugs given to treat infertility could promote the development of ovarian cancers.

Ovarian cancer is much less common in married women, and during the last 30 years a direct inverse association has been found between the number of pregnancies and the duration of use of oral contraception on the one hand and the occurrence of ovarian cancer on the other. In 1971 a Lancet reviewer suggested that incessant ovulation might be a causal factor for the development of cancer of the ovary, in that the repeated rupture of follicles involved a cycle of damage to the surface epithelium, alternating with repair involving mitogenic activity and thereby in turn a risk of mutations (42). On the other hand, as has been pointed out, no correlation has been found between the risk of ovarian cancer and the age at menarche and menopause, that is the length of the fertile period, which might be anticipated if the so-called "ovulation hypothesis" is correct.

An alternative suggestion has been that gonadotropins, by enhancing the transformation of ovarian epithelial cells, also increase the risk of malignant transformation in this tissue. This idea is compatible with the inverse relations between ovarian cancer and pregnancy or oral contraception, since the latter processes suppress the secretion of gonadotropins.

Both the hypothesis of ovarian injury and that of gonadotropic influence seem to provide tempting explanations for any relation that there may be between infertility treatment and ovarian cancer, since such treatment both induces further ovarian "injury" by ovulation (sometimes multiple) and increases circulating gonadotropin concentrations. However, the existence of a possible mechanism does not prove that there actually is an association.

The stumbling block in either proving or disproving a link between the drugs and the cancers is the fact that infertility itself proves to be a risk factor for ovarian cancer. Women who fail to become pregnant have a higher risk of ovarian malignancy than other women, irrespective of whether they are taking drugs or not. A study from Denmark in 1997 showed that among infertile women the overall risk of ovarian cancer was not influenced by the use (or otherwise) of treatment with antifertility drugs (43). There is also American work that shows that among infertile women with a high risk of ovarian cancer circulating gonadotropin concentrations are low, which is what one would expect in such a group, but which does not tally well with the theory of gonadotropic causation (44).

Given current evidence, and with anecdotal reports that add nothing to the discussion of a possible cause-and-effect relation, one can discern considerable polarization in the discussion. It is not irrelevant, nor is it uncharitable, to point out that whereas fully independent academic workers have been most vocal in expressing concern, the papers that seek to dismiss an association between the drugs and the cancers have tended to emerge from groups that acknowledge support from pharmaceutical companies that produce the drugs used in this field. That is natural, and it results in the sort of argument and counter-argument that may do something to promote the emergence of the truth. However, it is currently unhelpful to the physician who is treating women for infertility and who is anxious to know what to tell the concerned patient, as well as finding some way of reducing whatever risks treatment may carry. However, bearing in mind the fact that the use of high doses of fertility drugs certainly brings with it other risks (for example that of sometimes dangerous overstimulation), this could be a reason for applying some of the more restrained available dosage schemes, and for avoiding persisting with this inherently abrasive treatment when it has failed to produce results on two or more occasions.

Drug Administration

Drug formulations

The composition of different formulations of hCG is not entirely consistent, and could account for some discrepancies in clinical studies, as well as introducing risks. For example, previously, formulations of hCG have been shown to be toxic to Kaposi's sarcoma (KS) cells. However, clinical studies using commercial hCG formulations in the human sarcoma are highly contradictory (45). The apparent discrepancies between different studies may be because both pro- and anti-KS components are present in varying proportions in different hCG formulations. As certain hCG formulations may not only lack the ability to control Kaposi's sarcoma, but also contain contaminant KS growth factor(s), the authors suggested caution when using crude hCG for the treatment of Kaposi's sarcoma.

These findings point to the need to reconsider the international standards applicable to the standardization, formulation, and marketing of hCG products, whether of natural or recombinant origin.

Drug dosage regimens

The incidence of ovarian hyperstimulation is highly dependent on the therapeutic regimen. In one study (46) the following methods were compared:

- a conventional human menopausal gonadotropin + human chorionic gonadotropin (hMG + hCG) program;
- the hMG step-down method, in which the daily dose of hMG was reduced from 150 IU to 75 IU when the follicle diameter reached 11–13 mm;
- the sequential hMG + gonadotropin-releasing hormone (GnRH) method, in which hMG injection was switched to pulsatile GnRH administration (20 micrograms/120 minutes subcutaneously) when the follicle diameter reached 11–13 mm;
- a new, modified hMG + GnRH method, in which pulsatile GnRH was injected together with hMG; daily hMG was stopped and the GnRH dosage was changed from 10 to 20 micrograms when the follicle diameter reached 11–13 mm.

Initially, the established methods were used randomly to treat 34 cycles in 20 women; subsequently, five patients who failed to conceive after treatment with sequential hMG + GnRH were then treated by the new method. More than eight growing follicles and multiple pregnancies were observed during treatment by the conventional method. The incidence of ovarian hyperstimulation syndrome was 26% with the conventional method, 20% with the step-down method, and 0% with the sequential hMG + GnRH method; however, the rate of ovulation was only 50% with the sequential hMG + GnRH method. By contrast, with the new method fewer than three growing follicles occurred in 82% of patients, there was a 100% rate of ovulation, and there were no multiple pregnancies or ovarian hyperstimulation syndrome. Moreover, the new method induced pregnancy in three out of five patients. The authors considered their modified method suitable for the treatment of severe hypogonadotrophic amenorrhea. In view of the risks attached to ovarian hyperstimulation, this type of program certainly merits further evaluation.

Granulocyte colony-stimulating factor (G-CSF)

See also Myeloid colony stimulating factors

General Information

Granulocyte colony-stimulating factor (G-CSF) primarily increases the production and function of neutrophils by stimulating the proliferation of committed myeloid precursors, rather than pluripotential stem cells (1).

Recombinant human forms of G-CSF that have been developed include filgrastim (rINN), lenograstim (rINN), nartograstim (rINN), and pegfilgrastim (rINN) and peg-nartograstim (rINN), which are pegylated derivatives of filgrastim and nartograstim.

Besides common therapeutic indications, G-CSF has also been used in severe chronic neutropenic diseases (congenital, cyclic, idiopathic), aplastic anemia, and neonatal neutropenia. G-CSF is sometimes used in healthy volunteers to mobilize blood progenitor cells or granulocytes before infusion into neutropenic patients.

Observational studies

In all clinical studies carried out to date, G-CSF has been well tolerated, whether given subcutaneously or intravenously. At the recommended doses (5–10 micrograms/kg), generalized musculoskeletal and transient bone pains, headache, and mild rash are the commonest adverse effects (2). No additional adverse effects or delayed consequences have been so far reported in neonates treated at birth for presumed bacterial sepsis (SEDA-20, 337). An increase in the size of the spleen has been reported (3,4). Transient rises in alkaline phosphatase, lactate dehydrogenase, and uric acid are considered to be normal physiological consequences of the rise in the neutrophil count (5). Long-term G-CSF administration in patients with severe congenital neutropenia has also been considered to be relatively safe, with discontinuation or temporary withdrawal in only seven of 44 patients (6).

Two reviews have examined the available data on the effects of hemopoietic growth factors on the duration of neutropenia and mortality in drug-induced agranulocytosis, which mostly consists of isolated case reports or small series of patients (7,8). The authors reached contrasting opinions, suggesting that hemopoietic growth factors might or might not be of interest in patients with severe drug-induced agranulocytosis. Adverse effects were noted in 13 of 118 case reports (7). Although most of them were benign, pulmonary toxicity or acute respiratory distress syndrome have been noted in a few patients.

Comparative studies

Few studies have directly compared the safety of the various available colony-stimulating factors. The frequency and severity of adverse effects associated with the prophylactic use of filgrastim (a bacterial cell-derived G-CSF) or sargramostim (a yeast cell-derived GM-CSF) have been assessed in a retrospective review of the medical records of 490 cancer patients from 10 centers (9). Sargramostim-treated patients had significantly more frequent non-infectious fever, fatigue, diarrhea, injection site reactions, edema, and dermatological adverse effects, whereas skeletal pain was more frequent with filgrastim. In addition, switching to the alternative treatment was more frequent in the sargramostim group (18% of patients) than in the filgrastim group (none of the patients). The authors tried to minimize selection bias, but the strength of the results was limited by the retrospective nature of the study.

The effects and the safety of a 5-day regimen of G-CSF ($n = 9$) or GM-CSF ($n = 8$) have been compared (10). Most patients complained of flu-like symptoms in both groups (six and seven respectively), but rash at the injection site was observed only in four patients treated with GM-CSF. In the G-CSF group, there was a fall in platelet count (below 150×10^9/l) in five patients, raised serum lactic dehydrogenase activity, and raised uric acid concentrations; three patients required transient treatment with allopurinol.

Use in healthy volunteers

The G-CSF is sometimes used in healthy volunteers to mobilize blood progenitor cells or granulocytes before infusion into neutropenic patients (11).

The safety of filgrastim in healthy donors has been evaluated in a large prospective multicenter study (12). The interim results, obtained from the first 150 enrolled donors aged 18–64 years who received either 10 or 16 micrograms/kg/day, have shown that 99 patients had at least one adverse effect graded as mild (grade I) in 35% of cases, moderate (grade II) in 62%, and severe (grade III) in 3%. Bone pain and headaches were the most common acute adverse events, and all the patients completely recovered after withdrawal of filgrastim. There were no apparent differences in the proportion, the severity, or the type of adverse effects according to the administered regimen.

That the use of G-CSF in healthy donors of peripheral blood progenitor cells is reasonably safe has been confirmed in an analysis of adverse effects in 737 evaluable patients included in three independent databases from Spain, the USA, and Japan (13–15). In one study, the overall incidence of adverse effects was 67%. The most common adverse effects were bone pain (71–90%), headache (17–54%), fatigue (6–33%), insomnia (up to 14%), nausea/vomiting (3–13%), and low-grade fever (6%). Although most adverse effects were rated as moderate, about two-thirds of the patients required analgesics for bone pain or headache. Other adverse events, such as non-cardiac chest pain, paresthesia, itching, or minor injection site reactions, were rare. Very few patients discontinued G-CSF because of clinical toxicity. Doses higher than 8.8 micrograms/kg/day, patients younger than 35 years of age, and female sex were significant risk factors for bone pain, headache, and nausea/vomiting respectively (15).

Moderate thrombocytopenia was common after apheresis; there was more severe but asymptomatic and promptly reversible thrombocytopenia (below 50×10^{12}/l) in up to 3.9% of patients (14,15). However, the respective contributions of apheresis and G-CSF in

© 2006 Elsevier B.V. All rights reserved.

thrombocytopenia are difficult to assess. There was also a fall in the absolute neutrophil count to less than 1×10^9/l in 3% of patients 9–16 days after G-CSF withdrawal (15). Serum alkaline phosphatase and lactate dehydrogenase activities were increased about two-fold compared with pre-treatment, a finding that was explicable by G-CSF-induced neutrophilia (14,15). Symptoms of hypercoagulability have also been found in healthy donors.

However, more severe or unexpected consequences, including spontaneous splenic rupture, anaphylactoid reactions, deep necrotizing folliculitis, a psoriasiform eruption, acute gouty arthritis, iritis or episcleritis, and unexpectedly prolonged thrombocytopenia have been mentioned (SEDA-20, 337) (SEDA-21, 378) (SEDA-22, 407).

Among 90 healthy donors given 10 and 16 micrograms/kg/day of filgrastim for stem cell mobilization, severe adverse effects were mostly found in patients who had been given the higher dose (16), but one obese patient (body weight 170 kg) who received 10 micrograms/kg/day had a non-traumatic spleen rupture that resolved spontaneously.

Sufficient data on the potential long-term effects of G-CSF in healthy volunteers are still lacking. In one study, 101 healthy donors who had received filgrastim for a median of 6 days were questioned after a median of 43 (range 34–74) months to assess their current health; 70 donors also had a complete blood count (17). No unusual disease was detected and the blood counts were within the reference range. In 20 donors followed for 6–12 months after peripheral blood progenitor cell collection, there were no particular symptoms or hematological abnormalities (15).

The possible carcinogenic effects of G-CSF have also been discussed. There is as yet no indication of an increased risk of cancer, and no cases of acute or chronic leukemia were detected in a telephone interview study performed after a median of 39 months after peripheral blood progenitor cell donation in 281 donors (18).

Organs and Systems

Cardiovascular

Cardiovascular events have seldom been described in patients given colony-stimulating factors. However, possible excesses of cardiovascular events and unexpected deaths have been suggested (SED-13, 1115) (19), although the actual risk was not fully evaluated. In three isolated reports, acute arterial thrombosis or angina pectoris were deemed to have resulted from hypercoagulability with extreme leukocytosis and G-CSF-induced abnormalities in platelet aggregation (SEDA-20, 337) (SEDA-21, 377) (20). Increased platelet aggregation has also been found in healthy volunteers (21). Although the relevance of these findings is unclear, caution is warranted in patients predisposed to thromboembolic events.

- A 46-year-old donor denied pre-existing cardiac symptoms, but smoking and a family history of coronary artery disease were noted as possible risk factors (22). The pre-treatment electrocardiogram was normal. Six hours after the second and the third doses of G-CSF 10 micrograms/kg before peripheral blood progenitor cell collection, he developed symptoms and signs of cardiac ischemia, including palpitation, chest discomfort, trigeminy, and T wave inversion. However, troponin was unchanged. Cardiac catheterization showed severe coronary artery occlusion and he underwent percutaneous transluminal coronary angioplasty. He finally admitted mild exertional chest discomfort 2 weeks before the first dose of G-CSF.

Although not described during clinical trials, typical capillary leak syndrome has been anecdotally observed after G-CSF administration, illustrating the possible consequences of accelerated release of activated granulocytes (SEDA-22, 407) (23).

Microthrombotic necrotizing panniculitis has been reported (24).

- A 49-year-old woman received subcutaneous filgrastim 300 micrograms/day into the upper thighs for neutropenia prophylaxis after treatment of relapsing Hodgkin's disease with mitoguazone, etoposide, vinorelbine, and ifosfamide. After 3 days she suddenly developed fever, painful livedo, deeply infiltrated edema on the legs and thighs, and inflamed livedoid erythema on both soles. Deep biopsy specimens showed small vessel thrombosis with subcutaneous necrosis and hemorrhage. She recovered over the next 4 weeks after filgrastim withdrawal and prednisone treatment.

Although a causal relation was difficult to ascertain in the context of malignancy and cytotoxic chemotherapy, the short time to occurrence after G-CSF favored a causative role.

Respiratory

Pulmonary toxicity in patients receiving chemotherapy

Whether G-CSF can cause pulmonary toxicity or enhance chemotherapy-induced pulmonary toxicity is a matter of continuing debate (SED-13, 1115) (SEDA-21, 377). Some studies have suggested an increased risk of pulmonary complications in patients with hematological malignancies treated with various chemotherapeutic regimens who received G-CSF. In a review of 20 cases of interstitial pneumonia (including three that were fatal) observed during or within 10 days of G-CSF treatment, the chemotherapy regimen consisted of cyclophosphamide (95%), bleomycin (55%), methotrexate (25%), and etoposide (20%); most patients had non-Hodgkin's lymphoma (25). In another report, acute febrile interstitial pneumonitis occurred in five patients with non-Hodgkin's lymphoma who were receiving prophylactic G-CSF ($n = 3$) or GM-CSF ($n = 2$) within less than 48 hours after the second to fourth cycles of chemotherapy (doxorubicin, cyclophosphamide, bleomycin, methotrexate, plus methylprednisolone) (26). Lymphocytic alveolitis was confirmed in four of these patients, and all three patients tested had an increased number of CD8+ T cells. Even though all the patients received high-dose methylprednisolone, two died as a result of diffuse and extensive interstitial pulmonary fibrosis, identified at postmortem.

Several epidemiological studies have more accurately focused on this potential problem, but the results are

© 2006 Elsevier B.V. All rights reserved.

conflicting. Unfortunately, most of them were retrospective and involved historical controls. Interstitial pneumonia was identified in eight of 40 patients treated with antineoplastic drugs (mostly methotrexate and bleomycin) plus G-CSF, while no such cases were found before the use of G-CSF among 35 historical controls (27). Severe pulmonary toxicity was observed in four of 12 patients treated with BACOP (bleomycin, doxorubicin, cyclophosphamide, vincristine, plus prednisone) plus G-CSF compared with one of 24 historical controls who did not receive G-CSF (28). Of 52 patients treated with CHOP (cyclophosphamide, doxorubicin, vincristine, plus prednisolone), pulmonary symptoms were found in six who received G-CSF compared with none of 49 patients treated before the availability of G-CSF (29). This last study also raised the possibility that the intensified schedule of CHOP administration (every 2 weeks instead of every 3 weeks) allowed in patients undergoing G-CSF is a possible explanation for increased pulmonary toxicity. In contrast, other investigators failed to confirm that G-CSF increases the pulmonary toxicity of antineoplastic drugs, at least bleomycin (SEDA-21, 377). This was particularly exemplified by French authors who were unable to find an increased incidence of pulmonary complications in an analysis of two randomized controlled trials in 278 patients who received a bleomycin-containing regimen plus G-CSF or placebo (30).

Other predisposing factors have been suggested in five of 310 patients who developed acute adult respiratory distress syndrome (ARDS) after receiving G-CSF after allogeneic bone marrow transplantation or conventional chemotherapy (31). All had also been exposed to drugs or procedures with significant pulmonary toxicity. Respiratory symptoms developed suddenly, in conjunction with rapid recovery of the white blood cell count. Retrospective investigations showed that all five patients had the HLA-B51 or HLA-B52 antigens. In addition, plasma concentrations of tumor necrosis factor alfa and interleukin-8 were high at the onset of the ARDS. These effects did not occur in 45 patients who did not develop ARDS. The authors suggested that the risk of G-CSF-induced ARDS increases when the white blood cell count rises rapidly in patients who have the following conditions: HLA-B51 or HLA-B52 antigens, treatment with drugs with pulmonary toxicity, and a concomitant infection before recovery from granulocytopenia.

Whatever the truth of the matter, G-CSF should be regarded as a possible cause of pulmonary complications. The abrupt increase in the number of activated neutrophils after G-CSF may account for exacerbation of latent chemotherapy-induced pulmonary damage. Endothelial damage subsequent to increased neutrophil activity (that is, enhanced superoxide release and increased adhesion molecule expression and adherence) or the release of cytokines (IL-1, IL-6, TNF) has been advanced as possible mechanisms. In addition, transient slight hypoxia was found in G-CSF users, although no relation with specific cytotoxic drug treatment or previous radiotherapy was identified (32). A sudden increase in neutrophil count, a rise in LDH and C reactive protein, and the occurrence of dyspnea or fever in G-CSF-treated patients were proposed as possible early signs of the subsequent development of interstitial pneumonia.

Pulmonary toxicity in patients not receiving chemotherapy

The G-CSF can cause severe pulmonary toxicity in patients who are not receiving concomitant chemotherapy. For example, several reports have suggested that G-CSF administration for drug-induced agranulocytosis can play a role in the development or worsening of the adult respiratory distress syndrome (ARDS) (33).

- Fatal non-cardiac pulmonary edema has been reported in a 59-year-old man with renal amyloidosis who received G-CSF for 3 days for stem cell mobilization (34).

The authors extensively reviewed the available experimental and clinical data on the pulmonary toxicity of growth factors.

Another case suggested that G-CSF alone can cause severe pulmonary toxicity (35).

- A 72-year-old man with a normal chest X-ray was unnecessarily treated with G-CSF (5 micrograms/kg/day) for very moderate cytopenia. Five days later, he complained of dyspnea and fatigue, but without fever. His chest X-ray showed diffuse bilateral alveolar opacities and he had a low oxygen saturation. Blood cultures were negative, and infectious pneumonitis (with *Mycobacterium tuberculosis*, *Pneumocystis jiroveci*, *Herpes simplex*, and cytomegalovirus) was ruled out. Despite glucocorticoid and antibiotic treatment, he required mechanical ventilation and died 12 days after the onset of symptoms.

Nervous system

There is no clear evidence of specific central nervous system adverse effects due to G-CSF. In one patient, neurological symptoms, such as blurred vision, weakness, and headache, were attributed to G-CSF-induced extreme hyperleukocytosis with subsequent hyperviscosity (SEDA-21, 377). Encephalopathy, cortical blindness and seizures have also been mentioned in single case report (SEDA-21, 377).

Sensory systems

Severe retinal hemorrhage with a slowly reversible loss of visual acuity, and massive vitreous hemorrhage recurring after further G-CSF treatment and resulting in irreversible loss of vision in the affected eye have each been reported in single patients (SEDA-21, 378) (SEDA-22, 408). Concomitant hyperleukocytosis was suggested as a possible cause in the first patient, whereas G-CSF-induced reactivation of primary ocular inflammation (probably infectious in origin) was advanced as an explanation in the second case.

- A 61-year-old healthy donor developed marginal keratitis with associated mild uveitis after being given injections of filgrastim and sargramostim for 3 days (36). Topical prednisolone and withdrawal of sargramostim produced improvement within 24 hours, while filgrastim injections were continued.

Iritis and episcleritis have also been mentioned in healthy donors of blood progenitor cells.

Endocrine

Several studies have suggested that single or short-term administration of G-CSF did not produce significant changes in the serum concentrations of cortisol, growth hormone, prolactin, follicle-stimulating hormone, luteinizing hormone, or thyrotropin (SEDA-20, 337) (SEDA-21, 378).

Thyroid function and thyroid antibodies were not modified in 20 breast cancer patients (37), and only one case of hypothyroidism with increased thyroid antibodies has been reported (SEDA-20, 337). G-CSF had no effect on thyroid function in 33 patients with cancer, even in patients with pre-existing antibodies (38). Subclinical and spontaneously reversible hyperthyroidism occurred in eight patients without thyroid antibodies and with normal thyroid function before treatment, but this was felt to be related to stressful procedures.

Metabolism

Reductions in serum cholesterol concentrations have been sometimes noted in patients receiving G-CSF (2).

Hematologic

Erythrocytes

In a healthy woman, G-CSF was suggested to have transiently reactivated an alloantibody to an erythrocyte antigen (anti-Jka antibody) (39). This antibody was apparently passively transferred to the transplant recipient, who developed a high-titer of anti-Jka antibody during the first month after transplantation. This report raised the possibility that transplant recipients may develop hemolytic reactions to G-CSF subsequent to erythrocyte transfusion.

Leukocytes

The transient and moderate rises in leukocyte alkaline phosphatase and uric acid serum concentrations that are often observed after G-CSF treatment are considered to arise from an increased neutrophil count (SEDA-17, 396). Similarly, serum lactate dehydrogenase and alkaline phosphatase activities are often increased, and this should be interpreted as the consequence of enzyme release after growth factor-induced leukocyte recovery (SED-13, 1115).

Eosinophilia can occur in patients receiving long-term G-CSF for congenital neutropenia (6). Patients with congenital neutropenia or Felty's syndrome may also be susceptible to anemia and/or thrombocytopenia (6,40).

Platelets and clotting factors

There have been isolated reports of arterial thrombosis in patients or donors treated with G-CSF. In one study, there was more frequent and significantly more severe thrombocytopenia in patients who received G-CSF until 2 days before chemotherapy compared with controls, who had post-chemotherapy G-CSF only (41). This suggests that administration of G-CSF before chemotherapy can increase the bone marrow toxicity of the latter, a potentially relevant finding in patients undergoing intensification of chemotherapy with shortening treatment intervals. Isolated cases of thrombocytopenia have been reported in HIV-infected patients (SEDA-20, 337), and a reduced platelet count, sometimes associated with coagulation abnormalities, was retrospectively identified in nine of 28 patients who received prolonged G-CSF with antiretroviral drugs (42). Emperipolesis of neutrophils within megakaryocytes, an unusual feature of thrombocytopenia, was also reported in one patient receiving high-dose G-CSF (43).

Although abnormalities in platelet aggregation have been described in healthy volunteers (21), coagulation disorders are not typical features in patients who receive G-CSF. Only one HIV-infected patient treated with zidovudine and increasing G-CSF doses had a disseminated intravascular coagulopathy (42).

Hemostatic changes due to G-CSF have been investigated in 22 healthy donors (44). The patients received G-CSF 5 micrograms/kg bd for 5 days and underwent a series of laboratory tests before and 96 hours after G-CSF administration, that is, immediately before leukapheresis. The results suggested possible hypercoagulability, including significant increases in Von Willebrand factor and factor VIII and evidence of thrombin generation. The clinical relevance of these findings and of the previously reported effects of G-CSF on platelet aggregation (SED-14, 1270) is unknown.

Treatment with G-CSF in 26 healthy donors for 5–7 days produced transient changes in endothelial cell and clotting activation markers (45). Although these abnormalities may indicate a risk of thrombotic complications, their clinical relevance to healthy donors is unknown.

- A 53-year-old man with aplastic anemia had clinically asymptomatic and reversible hypercoagulability after the transfusion of granulocytes obtained from G-CSF-stimulated donors (46).

The authors stressed the recurrence of the disorder after each of the three granulocyte transfusions that the patient had received and suggested that adverse effects might occur after transfusion performed with G-CSF-mobilized granulocytes, even though the patient has not been given G-CSF.

The differential effects of G-CSF and GM-CSF on several coagulation parameters have been compared in 34 patients who received the colony-stimulating factors after bone marrow transplantation (47). The data suggested activation of the coagulation system in patients treated with GM-CSF, which resulted in a tendency to more frequent veno-occlusive disease of the liver and a significantly higher incidence of hemorrhage.

Hemopoietic tissues

Asymptomatic but significant increases in spleen volume (up to 150%) concomitant with neutrophilia have been reported in about 25% of patients treated with G-CSF for severe chronic neutropenia (6,48).

Of 13 patients with glycogen storage disease type 1b and neutropenia or neutrophil dysfunction treated with G-CSF, all developed splenomegaly, usually after 3 months of treatment (49). Hypersplenism, as defined by moderate thrombocytopenia on at least two consecutive blood counts, was found in five patients, but none required specific interventions. In one carefully

© 2006 Elsevier B.V. All rights reserved.

documented case, splenomegaly with extramedullary hemopoiesis was deemed to result from the mobilization of early hemopoietic progenitors from the marrow to the spleen (50). Experimental data suggested that reseeding of hemopoietic cells from the bone marrow may account for this phenomenon (51).

Splenic rupture has been reported in patients with cancer and in healthy donors, and should be anticipated by regular assessment of splenic size during prolonged treatment.

- Spontaneous splenic rupture, with histological evidence of massive extramedullary myelopoiesis after splenectomy, has been reported in a 33-year-old healthy donor who received G-CSF for 6 days (52).
- Life-threatening splenic rupture occurred in a 22-year-old woman with acute myeloid leukemia (53). The rupture was diagnosed in the presence of abdominal pain and signs of hypovolemic shock, 10 days after she started G-CSF treatment to support peripheral blood stem cell transplantation. Histology after splenectomy showed only small clusters of myeloblasts and no specific cause for the rupture. In particular, she was still pancytopenic at the time of splenic rupture.

One patient also had rapid and generalized lymph node enlargement and lymphopenia with recurrence of lymphadenopathy after a further course of G-CSF (54).

Liver

Clinical trials did not suggest G-CSF-induced hepatotoxicity, and very few cases of liver abnormalities have been reported (SED-13, 1116) (SEDA-19, 343). Although it may have been coincidental, the chronological features were in keeping with drug-induced hepatotoxicity in at least two patients, since increases in serum liver enzymes or acute hepatitis associated with pancreatitis recurred after renewed administration of G-CSF. One additional case of fatal fulminant hepatitis could have been due to alcohol abuse and the use of several concomitant drugs.

Urinary tract

No evidence of nephrotoxicity emerged from clinical trials, but a transient increase in serum creatinine concentration has been described (SEDA-20, 337).

- A 4-year-old girl was given filgrastim (30 micrograms/kg/day) for severe congenital neutropenia diagnosed at birth (55). Two months later she developed microscopic hematuria and recurrent episodes of macroscopic hematuria and proteinuria. Renal ultrasonography was normal and no obvious cause was found, but filgrastim was continued. Microscopic hematuria and multiple episodes of macroscopic hematuria with mild proteinuria persisted for 4 years. At this stage, she had an acute episode of macroscopic hematuria with more severe proteinuria and an increase in serum creatinine concentration (202 μmol/l). There were features of membranoproliferative glomerulonephritis type I on renal biopsy. Her renal function improved after filgrastim withdrawal and again deteriorated after reintroduction, with a persistent increase in serum creatinine concentration. Hematuria and proteinuria partially responded to glucocorticoids. Filgrastim was finally replaced by lenograstim when she was 13 years old, and this resulted in reduced proteinuria and improved renal function.

Although the girl also had hepatitis C virus infection during the course of her disease, renal dysfunction preceded this. The persistence of hematuria and proteinuria after the disappearance of hepatitis C virus RNA also argued against a role of hepatitis C infection.

Isolated and reversible hematuria was noted in several patients receiving long-term treatment for congenital neutropenia (6).

Although suggested in one report, G-CSF does not appear to increase the risk of renal allograft rejection (SEDA-20, 337).

Skin

A wide range of cutaneous reactions have been reported in patients receiving G-CSF. Most skin disorders were minor with a skin rash or itching in about 8% of patients (56).

Injection-site reactions

Localized cutaneous lesions were sometimes noted after subcutaneous injection and mimicked those described with GM-CSF. Injection-site subcutaneous nodules infiltrated by leukemic cells have been found in patients treated for acute leukemia (SEDA-19, 343), but in two other patients, inflammatory macrophages were misinterpreted as malignant cells (SEDA-20, 337).

The G-CSF can cause a lichenoid reaction at injection sites (57).

- A 40-year-old woman with metastatic breast cancer received cyclic subcutaneous G-CSF for chemotherapy-induced neutropenia. After 5 months she had a pruritic rash at injection sites. She did not change the injection sites and the lesions recurred after each injection. Biopsy showed a lichenoid reaction and the lesions healed with residual pigmentation after topical steroid application and G-CSF discontinuation. GM-CSF was well tolerated.
- Erythema exsudativum multiforme developed in a 40-year-old healthy donor 3 days after lenograstim was started for peripheral blood stem cell mobilization (58). The lesions were on the hips, apart from the site of lenograstim injection, and resolved 1 week after withdrawal.

Neutrophilic dermatitis

The possible role of G-CSF in inducing or exacerbating neutrophilic dermatitis (Sweet's syndrome) is in keeping with its stimulant effects on the production and functions of neutrophils. Although the ability of G-CSF to induce Sweet's syndrome (acute febrile neutrophilic dermatosis) is disputed, because the underlying malignant disease is a possible confounding factor, several reports of biopsy-proven Sweet's syndrome have been convincing; they have shown variously a close temporal relation between G-CSF treatment and the variations in neutrophil count or the recurrence of the lesions after G-CSF re-administration; one report concerned two patients with chronic neutropenia (SED-13, 1116) (SEDA-20, 338) (SEDA-21,

© 2006 Elsevier B.V. All rights reserved.

378). Localized Sweet's syndrome can also occur (SEDA-20, 338). The spectrum of forms of G-CSF-induced neutrophilic dermatitis is wide. In two children with painful erythematous lesions attributed to G-CSF, histology showed microscopic, sterile, neutrophilic abscesses in one and neutrophilic panniculitis in the other (59). Other forms of neutrophilic dermatitis mentioned in G-CSF-treated patients have included isolated cases of bullous pyoderma gangrenosum and neutrophilic eccrine hidradenitis (SEDA-21, 378) (SEDA-22, 408) (60). Sweet's syndrome has also been described in a case of hairy cell leukemia (61).

Other skin complications

Disseminated vesiculopustular lesions, generalized and indurated erythematous papules or plaques, severe exacerbation of acne, and lenograstim-induced erythema nodosum, with recurrence on filgrastim administration, were mentioned in isolated patients (SED-13, 1116) (SEDA-20, 337). Finally, several reports convincingly involved G-CSF in exacerbations of chronic psoriasis or psoriatic arthritis, suggesting that activated neutrophils play an important role in the occurrence and propagation of skin inflammation (SEDA-21, 378) (62).

Musculoskeletal

Transient bone and musculoskeletal pain preceding myeloid recovery by 2–3 days are the commonest adverse effects of G-CSF, and occur in up to 25% of patients. Bone pain usually disappears despite continued treatment, but severe, narcotic-resistant, generalized bone pain was attributed to bone marrow necrosis in one patient (63).

The G-CSF-induced exacerbation of pseudogout occurred in two patients (SEDA-20, 337) (SEDA-22, 408).

- A 69-year-old man with a non-small-cell lung cancer treated with paclitaxel and nedaplatin developed polyarthralgia and myalgia with rising fever after receiving G-CSF for 5 days (64). Similar symptoms recurred after the second cycle of chemotherapy and on retreatment with G-CSF. Synovial biopsy showed acute synovitis with a foreign body-type giant cell reaction.

Worsening of rheumatoid symptoms has been reported in patients receiving G-CSF, particularly in patients with neutropenia due to Felty's syndrome (SEDA-19, 344) (SEDA-20, 338). Although concern about the short-term safety of G-CSF has been raised in these patients, other investigators feel that G-CSF can be used for a prolonged period in most patients without a flare-up of rheumatoid symptoms (SEDA-22, 408). Similar conclusions were reached in patients with underlying rheumatoid arthritis (SEDA-21, 378). The mechanisms of rheumatological flare-up are unclear. G-CSF-induced localized neutrophil activation or G-CSF-mediated increases in local neutrophil responses to TNF-alfa have both been suggested as underlying processes.

Several investigators have diagnosed bone mineral loss, with features of osteopenia/osteoporosis on radiography, quantitative computed tomography, or absorptiometry, in patients receiving long-term G-CSF for severe congenital neutropenia (6,65). In one child there was significant improvement in bone mineral density with pamidronate (66). In another child, who had osteoporotic vertebral collapse, extensive investigations showed reduced bone mineral content, reduced concentrations of osteocalcin, and features of osteoporosis on bone biopsy (SEDA-19, 344). The role of G-CSF was unclear, because bone mineral loss is a possible complication of the underlying disease. Indeed, improvement or stabilization during G-CSF treatment was noted in several patients (6). Furthermore, there was no apparent effect on height, head circumference, or weight in patients under 18 years of age (6). In another study, there was bone mineral loss with features of osteopenia/osteoporosis in 15 of 30 patients treated with G-CSF for a mean of 5.8 years for severe chronic neutropenia (65). However, six of nine patients investigated before G-CSF treatment had evidence of osteopenia/osteoporosis.

These reports and the findings of G-CSF-induced mobilization of osteoclastic progenitors in healthy volunteers (67) support a possible role of G-CSF in bone changes.

Immunologic

Leukocytoclastic vasculitis is a well-described and confirmed adverse effect of G-CSF, as documented in several reports, with recurrence after renewed administration of G-CSF (SEDA-19, 343). Most cases were confined to the skin, and renal insufficiency with hematuria and proteinuria was noted in only very few patients. Based on 18 cases reported in the literature or to the manufacturers, vasculitis was thought to have occurred in 6% of patients with chronic benign neutropenia, but in only six of about 200 000 patients with malignant disease (68). Vasculitis usually developed when the neutrophil count rose above 800×10^6/l, suggesting that an increase in neutrophil count may play a role in necrotic vasculitis. Against this background, the occurrence of vasculitis is not considered as treatment-limiting and does not preclude further G-CSF administration if the absolute neutrophil count is lower than 1000×10^6/l.

Antibodies to rG-CSF have not so far been reported, even in patients on long-term treatment.

Exacerbation of lupus-like symptoms, with seizures, psychosis, and vasculitis, has been noted during three of 12 treatment courses in neutropenic patients with severe systemic lupus erythematosus (69).

Type I reactions

Although IgE-specific antibodies have not been yet detected, filgrastim is undoubtedly associated with type I allergic reactions. This has been illustrated in well-documented reports of anaphylactic reactions, urticaria, and angioedema, with positive intradermal tests in several patients (SEDA-20, 338) (70,71). However, anaphylaxis to G-CSF is supposedly rare and the manufacturer is aware of only two cases of anaphylactoid reactions among 20 000 patients treated with filgrastim (72). One report has suggested possible cross-reactivity between filgrastim and other products derived from *Escherichia coli* (73). Although one patient who developed an anaphylactic-like reaction, with dyspnea, hypotension, and a pruritic erythematous skin rash, within minutes of G-CSF

© 2006 Elsevier B.V. All rights reserved.

injection, later tolerated GM-CSF uneventfully (74), possible cross-reactivity between G-CSF and GM-CSF has been reported in at least one patient (75).

Long-Term Effects

Tumorigenicity

G-CSF-induced leukemia and myelodysplasia in patients with aplastic anemia or congenital neutropenia

Concerns have arisen over the prolonged use of G-CSF in patients with aplastic anemia, congenital neutropenia, or similar disorders and a possible increased or accelerated risk of myelodysplasia or acute leukemia (SED-14, 1274). Several investigators have noted reversible increases in circulating blasts during G-CSF treatment, and isolated reports have indicated a shortened delay in the occurrence of myelodysplasia and/or acute myeloid leukemia in this setting (SED-13, 1117) (SEDA-20, 338) (76). An abnormal karyotype (mostly monosomy 7) was sometimes found, and in vitro proliferation of myeloblasts by G-CSF was obtained in several patients. In addition, the potential role of point mutations on the G-CSF receptor has been also discussed as regards four of 28 patients with congenital neutropenia, two of whom developed acute myeloid leukemia (77). Myelodysplastic syndrome with monosomy 7 was also associated with G-CSF in another patient, with a reduction in the number of monosomy 7 positive cells after G-CSF withdrawal and a further increase after readministration (78).

This has been analysed in a number of epidemiological studies, most of which involved historical controls. The underlying predisposition of patients with aplastic anemia to develop myeloid malignancy has usually confounded attempts to determine whether growth factors are contributing factors.

In a retrospective study of 72 adults with aplastic anemia, of whom 18 received G-CSF and 23 received ciclosporin, five developed myelodysplastic syndrome (79). Four of them had received G-CSF + ciclosporin and all four had monosomy 7. The hematological disease was diagnosed within 16–31 months after the diagnosis of aplastic anemia and 12–20 months after the start of G-CSF treatment. Two died from acute leukemia. The incidence of myelodysplastic syndrome in this subgroup of patients was therefore 8.3% after 2 years and 39% after 3 years, whereas no case was observed over a 20-year period in patients not receiving this combined treatment. Univariate analysis showed that G-CSF + ciclosporin and G-CSF alone for more than 1 year were the most significant risk factors for the short-term development of monosomy 7 myelodysplastic syndrome.

In a prospective, multicenter, cohort study of 113 patients with aplastic anemia under 18 years of age, 12 developed myelodysplastic syndrome after a median of 37 months after the diagnosis of aplastic anemia and four others developed other cytogenetic clonal changes, of which the most common abnormality was monosomy 7 (80). From a multivariate analysis, G-CSF treatment duration and non-response to immunosuppressive therapy at 6 months were statistically significant risk factors for the development of myelodysplastic syndrome. The risk increased in proportion to the duration of G-CSF treatment, and the relative risks of the myelodysplastic syndrome were respectively 4.4 and 8.7 times higher in patients who received G-CSF for more than 120 and 180 days, compared with those who received it for less.

In contrast, a number of other studies did not confirm that the G-CSF increases the risk of myelodysplasia or acute leukemia, but the authors did not rule out a possible leukemogenic effect. In a study of patients with severe aplastic anemia the frequencies of cytogenetic abnormalities and myelodysplasia or leukemia were similar in 87 patients treated with G-CSF in addition to immunosuppressive treatment compared with 57 patients who did not receive G-CSF (81). Although the authors stated that a leukemogenic effect of G-CSF was unlikely, they mentioned that the median interval of appearance of cytogenetic abnormalities was shorter in the G-CSF group.

In another study the data from an international register of patients with severe chronic neutropenia were analysed (82). Of 352 patients treated with G-CSF for congenital neutropenia and followed for a mean of 6 years (maximum 11 years), 31 developed myelodysplasia or leukemia, whereas there were no cases in 344 patients with idiopathic or cyclic neutropenia. Associated cytogenetic clonal changes consisted of partial or complete loss of chromosome seven in 18 patients and abnormalities in chromosome 21 in nine. Isolated cytogenetic abnormalities were also found in nine other patients. None of the patients had abnormal marrow cytogenetic changes before G-CSF therapy. A more complete analysis failed to identify any correlation between G-CSF dose and treatment duration in patients who developed myelodysplasia or leukemia compared with those who were not affected. Although this argues against a role of G-CSF in the conversion of congenital neutropenia to myelodysplasia or leukemia, the authors recognized that a direct leukemogenic role of G-CSF could not be completely ruled out.

After a median follow-up of 43 months in 123 children treated with G-CSF, there was no difference in the incidence of secondary myelodysplasia or acute myeloid leukemia, in patients with aplastic anemia who survived longer than 2 years compared with the expected rate calculated before the use of G-CSF (83). Similarly, there was no evidence of an increased risk of myelodysplasia or acute myeloid leukemia in 54 patients treated with G-CSF for 4–6 years for severe congenital neutropenia (6).

Finally, in a randomized study in 102 patients of the safety and efficacy of lenograstim (5 micrograms/kg/day for 14 weeks) combined with standard immunosuppressants, there were no differences between the groups in survival, hematological response, or the occurrence of secondary leukemia (one case of myelodysplastic syndrome in each group) at a median follow-up of 5 years (84).

The role of G-CSF in leukemic transformation therefore remains unproven, primarily because these patients might be otherwise predisposed or have a previous history of immunosuppressive therapy. Although the clinical benefits of G-CSF probably outweigh any hazard of leukemogenesis, the possibility of an increased risk of myelodysplastic syndrome or acute myeloid leukemia under the influence of G-CSF should be borne in mind.

Careful monitoring of morphological bone marrow changes and cytogenetic studies are therefore recommended, and large randomized trials with long-term follow-up are still awaited to clarify these findings.

Stimulation of tumors or leukemic cells in patients with cancer

Because growth factor receptors are found on several tumor cell lines, there has been great concern that G-CSF may stimulate tumor progression (SED-13, 1117) (SEDA-20, 338) (SEDA-21, 378), with some anecdotal evidence of a temporal relation between G-CSF administration and the development or acceleration of malignancies, such as gastric cancer or Hodgkin's diseaseodgkin's disease (SED-13, 1117) (85–87). However, early clinical data and the results of several randomized controlled trials in patients with various malignancies provided no evidence for increased relapse rates (88,89).

With the demonstration of growth factor receptors on leukemic cells, the question has also been raised of whether there could be stimulation of leukemic cell growth with promotion of malignancies, or acceleration in the progression of myelodysplastic syndromes to acute myeloid leukemias. Although there has been some reluctance to use G-CSF in acute myeloid leukemia, no clear evidence of disease acceleration or recurrence was found in several trials (SED-13, 1117) (SEDA-21, 379). Based on an analysis of available in vitro data and published clinical trials, the risk of significant stimulation of leukemia or leukemic clone with an increased incidence of leukemia regrowth is currently estimated to be very low (90). Although clinical benefits are still debated in this setting, growth factors are considered to be safe in reducing the duration of neutropenia in patients with acute myeloid leukemia.

Although G-CSF is not believed to stimulate malignant lymphoid cells, G-CSF receptors have been found in patients with T cell leukemia, and this was associated with a significant increase in T cell leukemia cells in several patients (SEDA-21, 379). Other uncommon consequences of G-CSF have included blast mobilization with a phenotype change from common acute lymphoblastic leukemia to biphenotypic leukemia in one patient (87).

The risk of secondary cancer has been assessed in 412 children treated with etoposide and anthracyclines for acute lymphoblastic leukemia, 99 of whom also received G-CSF and 58 of whom received cranial irradiation (91). Overall, 20 children developed myeloid leukemia and myelodysplastic syndrome at a median of 2.3 years after treatment. The 6-year cumulative incidence of these secondary cancers was 11% among patients who received G-CSF, close to that observed in those who received cranial irradiation (12%), but significantly higher than in those who received neither irradiation nor G-CSF (2.7%).

Acceleration of myelodysplastic syndrome

A reversible increase in circulating blasts has been noted during G-CSF treatment in several patients with myelodysplastic syndrome, and other reports have documented a reversible secondary myelodysplastic syndrome or accelerated progression of a previous myelodysplastic syndrome (SEDA-21, 379) (89). In other instances, pseudoleukemia features or transient leukoerythroblastosis were evidenced on bone marrow biopsy (SEDA-19, 344) (SEDA-20, 338). Although there was no increased incidence of acute myeloblastic leukemia in G-CSF-treated patients with myelodysplastic syndrome, it has been considered that patients whose bone marrow contains more than 20% of blast cells should be regarded as being at higher risk of leukemic transformation (89).

Myeloma

The safety of growth factors in patients with myeloma is also of concern, as they can stimulate the proliferation of myeloma cells through IL-6 expression. Only isolated case reports, including accounts of the mobilization of clonal myeloma cells into the peripheral circulation, rapid progression of a multiple myeloma, or the new onset of a monoclonal gammopathy, directly or indirectly support the view that caution should be exercised in patients with multiple myeloma (SED-13, 1118) (92).

Susceptibility Factors

Renal disease

A hemodialysis patient developed refractory pleural effusion with prolonged leukopenia and thrombocytopenia, and another developed sudden cyanotic dyspnea with subsequent death after G-CSF administration for drug-induced neutropenia (93). The authors suggested that hemodialysis patients receiving G-CSF may have an increased risk of adverse effects.

Drug Administration

Drug formulations

Pegfilgrastim was developed by adding a polyethylene glycol molecule to the *N*-terminus of filgrastim. In a phase III study in 301 patients with advanced breast cancer who underwent myelosuppressive chemotherapy a single injection of pegfilgrastim had similar efficacy and safety profile to repeated injections of filgrastim (94).

Drug–Drug Interactions

Theophylline

A 30% increase in theophylline clearance occurred after the administration of G-CSF or GM-CSF (SEDA-20, 338).

Vincristine

In one study there was a synergistic effect of GM-CSF or G-CSF and cumulative doses of vincristine in causing severe atypical neuropathy (SEDA-20, 339).

Interference with Diagnostic Tests

Blood glucose analysis

Artifactual hypoglycemia occurred in patients taking G-CSF when blood glucose was analysed on the Ektachem 700 analyser (SEDA-20, 339).

© 2006 Elsevier B.V. All rights reserved.

Hepatitis B surface antigen

A single dose of G-CSF in a healthy donor produced a false positive test for hepatitis B surface antigen using an enzyme immunoassay (95).

Granulocyte–macrophage colony-stimulating factor (GM-CSF)

See also Myeloid colony stimulating factors

General Information

Granulocyte–macrophage colony-stimulating factor (GM-CSF) primarily increases the production and activity of neutrophils, and stimulates the proliferation of monocytes and eosinophils.

Recombinant human forms of GM-CSF that are in use include molgramostim and sargramostim. Based on a retrospective review and historical comparison, the safety of molgramostim has been thought to be less than that of sargramostim (1). However, there were no significant differences in the adverse effects profiles and severity of adverse effects with GM-CSF and G-CSF in 181 patients with cancers randomized to receive sargramostim (a yeast cell-derived GM-CSF) or filgrastim (a bacterial cell-derived G-CSF) for chemotherapy-induced myelosuppression (2).

Uses

The potential clinical applications of GM-CSF have been lengthily reviewed (3). It is used:

- to reduce chemotherapy-induced myelosuppression in patients with metastatic sarcoma, breast cancer, or melanoma.
- to facilitate the harvesting of peripheral blood stem cells for autologous bone marrow transplantation.
- in cyclic neutropenia.
- to aid recovery after high doses of ionizing radiation, and less successfully, for severe aplastic anemia.

GM-CSF has also been approved for the alleviation of neutropenia following myeloablative treatment with autologous bone marrow transplantation and ganciclovir-induced neutropenia in patients with AIDS (4).

General adverse effects

The adverse effects of GM-CSF are dose-related and have usually been tolerable. At the doses usually recommended, systemic adverse effects develop in 25–30% of patients, but they are rarely treatment-limiting (5). Doses over 250 micrograms/m^2 and the intravenous route are associated with more frequent adverse effects.

Bone pain and flu-like symptoms, with fever, myalgia, chills, and headache, are the most frequent adverse effects (5–7). These reactions occur in 40–60% of all treated patients (8) and are probably due to the activation of secondary cytokines (such as TNF-alfa and IL-1) (9). Other frequently reported adverse effects include erythematous eruptions at the injection site, thrombophlebitis, nausea, facial flushing, dyspnea, and gastrointestinal disorders with anorexia and weight loss. Severe fatigue and weakness are rare.

The first dose of GM-CSF can be followed within 3 hours by flushing, hypotension, tachycardia, dyspnea, musculoskeletal pain, and nausea and vomiting (6). At very high doses (generally over 16 micrograms/kg/day), erythroderma, weight gain, and edema with pleuropericardial effusions and ascites have been reported (10). Renal symptoms have also been described (11,12), as have various biochemical abnormalities, possibly due to secondary hyperaldosteronism (13–15).

Fever was observed in up to 50% of patients at doses over 3 micrograms/kg. The fact that the fever peaks at a constant time after GM-CSF injection, the lack of clinical and biological signs of infection, and a prompt response to paracetamol have been proposed as criteria to recognize GM-CSF-induced iatrogenic fever (16), but this concept is still disputed (17).

Organs and Systems

Cardiovascular

Mild local phlebitis sometimes occurs at intravenous sites of administration of GM-CSF. Central venous catheter site thrombosis, inferior vena cava thrombosis, and possible pulmonary embolism have sometimes been observed (5,18). Although chemotherapy for breast cancer is associated with a higher risk of developing vascular thrombosis, iliac artery thrombosis was attributed to GM-CSF in two patients (19).

Raynaud's phenomenon has been reported, but confounding factors including the use of high-dose antineoplastic drugs are possible (5).

A rapidly reversible first-dose syndrome (dyspnea, hypoxia, tachycardia, and hypotension) can occur within the first hour after the first continuous infusion in 15–30% of patients (5). A dose-limiting vascular leak syndrome was consistently described in patients receiving GM-CSF 30 micrograms/kg/day or more, but lower doses were also reported to induce a clinically relevant capillary leak syndrome (SEDA-22, 408) (20,21). Continuation of GM-CSF treatment at the same dose or lower and careful management was possible in some patients. Endothelial cell damage with an increase in the transcapillary escape rate of albumin and the possible role of IL-1 and TNF production by GM-CSF-activated monocytes were

© 2006 Elsevier B.V. All rights reserved.

suggested as possible mechanisms. This was consistent with the observation of marked hypoalbuminemia in some instances associated with edema and ascites after GM-CSF in four of nine patients treated for myelodysplastic syndrome or aplastic anemia (22).

Respiratory

It has been suggested that, as in the case of G-CSF, GM-CSF can increase the pulmonary toxicity of bleomycin and facilitate the development of the adult respiratory distress syndrome (ARDS), but evidence is still very sparse (SED-13, 1112) (SEDA-19, 342).

Acute febrile interstitial pneumonitis occurred within less than 48 hours after the second to fourth cycles of chemotherapy (doxorubicin, cyclophosphamide, bleomycin, methotrexate, plus methylprednisolone) in five patients with non-Hodgkin's lymphoma who were receiving prophylactic G-CSF ($n = 3$) or GM-CSF ($n = 2$) (23). Lymphocytic alveolitis was confirmed in four of these patients and all three patients tested had an increased number of CD8+ T cells. Even though all the patients received high-dose methylprednisolone, two died as a result of diffuse and extensive interstitial pulmonary fibrosis, demonstrated at postmortem. Although both G-CSF and GM-CSF can cause acute pneumonitis in patients with cancers, it is still unknown to what extent hemopoietic growth factors are involved in this complication.

In one patient, interstitial pulmonary edema with pulmonary failure was supposedly a first-dose reaction (24). Reversible eosinophilic pneumonia has also been reported (SEDA-19, 342).

One patient had acute bronchospasm after a subcutaneous injection of GM-CSF around a lower limb ulcer (25).

Nervous system

Very few neurological adverse effects have been associated with GM-CSF.

- Mania occurred in a 41-year-old woman taking GM-CSF who had previously tolerated G-CSF (SEDA-20, 339).
- A 49-year-old woman with chronic hepatitis C received filgrastim (G-CSF) for interferon-alfa-induced leukopenia (26). Filgrastim was withdrawn after 3 months, because of leg cramps and back pain. She later received sargramostim (GM-CSF) 500 micrograms twice weekly and she noticed gait unsteadiness and headaches within 2 weeks. During the next 3 months, she developed progressive confusion, forgetfulness, and lethargy, and both interferon alfa and sargramostim were withdrawn. She rapidly deteriorated and died from central hypoventilation 6 days later. Autopsy showed atypical, perivascular, lymphoid infiltrates in the white matter, basal ganglia, hypothalamus, brain stem, cerebellum, and spinal cord. Serum hepatitis C virus DNA sequences were not detected.

This case of fulminant perivascular lymphocytic proliferation suggests that some of the effects of GM-CSF on white blood cell proliferation can sometimes produce unexpected adverse effects.

Endocrine

Three patients with positive thyroid antibodies before GM-CSF treatment developed hypothyroidism or biphasic thyroiditis (27,28), whereas no similar thyroid dysfunction has been observed in patients without pre-existing thyroid antibodies (27). Based on these reports, GM-CSF has been thought to exacerbate underlying autoimmune thyroiditis.

Metabolism

Serum cholesterol concentrations have reportedly fallen in patients given GM-CSF (29).

Electrolyte balance

Severe symptomatic hypokalemia was thought to have resulted from increased intracellular potassium uptake linked to massive leukocytosis after GM-CSF (15).

Hematologic

Acute exacerbation of autoimmune thrombocytopenia (30) or hemolytic anemia has been linked to macrophage activation (31), and it has been suggested that patients with previous autoimmune blood disorders are at increased risk of hematological toxicity from GM-CSF.

A transient, moderate, and reversible rise in leukocyte alkaline phosphatase, lactate dehydrogenase (LDH) and serum uric acid concentrations is usually observed in cancer patients receiving supportive treatment with GM-CSF or G-CSF. Serum LDH increased from 37 to 85% and there was a linear relation between increased leukocyte production and the rise in serum LDH (32). Increases in serum LDH activity should therefore not be interpreted as indicative of disease progression, unless LDH activity remains high after growth factor withdrawal.

Erythrocytes

A typical vaso-occlusive crisis with increased hemolysis was noted within minutes after intracutaneous injection of GM-CSF in a patient with stable sickle cell disease (SEDA-19, 342). Topical GM-CSF was later uneventful.

Leukocytes

Dose-related and sometimes marked eosinophilia has been noted after GM-CSF (33). Although usually not associated with symptoms, excessive eosinophilia with fatal necrotizing pneumonia and Loeffler's endocarditis has been described (34).

Clotting factors

A marked reduction in vitamin K-dependent coagulation factors, which was prevented by vitamin K administration, has been described in patients with acute myeloid leukemia who were given GM-CSF (SEDA-19, 342).

The differential effects of G-CSF and GM-CSF on several coagulation parameters have been compared in 34 patients who received the colony-stimulating factors after bone marrow transplantation (35). The data suggested activation of the coagulation system in patients treated with GM-CSF, which resulted in a tendency to more frequent veno-occlusive disease of the liver and a significantly higher incidence of hemorrhage.

© 2006 Elsevier B.V. All rights reserved.

Hemopoietic tissues

Although GM-CSF acts primarily on neutrophils, stimulating effects on the myeloid lineage and other cells or cytokines of the immune system can be associated with deleterious consequences, as illustrated in several case reports. Splenomegaly with histologically documented splenic extramedullary hemopoiesis of all three lineages and histiocytic bone marrow proliferation have been described (36–38). More severe outcomes have been described, such as reactive hemophagic histiocytosis resulting in fatal pancytopenia in two bone marrow transplant patients (39). Extensive and persistent bone marrow histiocytosis was considered the likely cause of delayed bone marrow engraftment and subsequent death in both patients. These effects may have been the consequences of GM-CSF-induced proliferation and activation of the monocyte/macrophage system.

Liver

A moderate increase in serum transaminase activities sometimes occurs in patients receiving GM-CSF. More severe hepatotoxicity has been briefly reported in patients who received GM-CSF after autologous bone marrow transplantation (SEDA-19, 342). Hyperbilirubinemia was also found in 8% of bone marrow transplant patients and considered as possible ground for molgramostim withdrawal (1).

Urinary tract

There was no evidence of nephrotoxicity secondary to GM-CSF during clinical trials, but the possible occurrence of transient renal insufficiency has been discussed (1).

Skin

Cutaneous reactions to GM-CSF occur in about 50% of patients and have been reviewed (40); there is concern that autoimmune skin diseases, psoriasis, and other dermatoses might be exacerbated.

GM-CSF often causes erythema and itching at subcutaneous injection sites, with a particularly high incidence of relapsing macular pruritic infiltrates at sites of injection in patients with inflammatory breast cancer (SEDA-20, 339). Based on a retrospective review, molgramostim-induced rash was the most common treatment-limiting adverse event in bone marrow transplant patients, but further administration of sargramostim may be well tolerated (1).

Cutaneous reactions in 57 cancer patients given GM-CSF have been described in detail. They included localized immediate angioedema (8%), generalized cutaneous reactions (21%), or both (16%) (41). Generalized reactions consisted mostly of maculopapular, exfoliative, and urticarial eruptions, which resolved after topical treatment, dosage reduction, or treatment withdrawal. There was usually hyperkeratosis, mild spongiosis, lymphocytic exocytosis, and perivascular infiltration by lymphocytes, neutrophils, and eosinophils. Eosinophil activation was supposedly involved in the pathogenesis of these lesions, as was also suggested in the report of atopic dermatitis-like eruptions in two patients (42) or the acute revelation of an underlying epidermolysis bullosa acquisita in a previously asymptomatic patient (43).

As with G-CSF, GM-CSF-induced activation of neutrophils can play a critical role in the occurrence of neutrophilic dermatoses and other skin disorders. Other reports have described acute exacerbation of previous pyoderma gangrenosum (44) and subcorneal pustular dermatosis around injection sites (SEDA-19, 342).

Additional isolated reports suggesting an immunological response or inappropriate cytokine secretion subsequent to GM-CSF administration include accounts of erythema multiforme (SEDA-19, 342) and acutely generalized exacerbation of pre-existing psoriasis (45). The latter report is in keeping with the finding that GM-CSF is sometimes raised in patients with psoriasis.

Musculoskeletal

Transient bone pain is common with GM-CSF. Prompt reactivation or worsening of rheumatoid symptoms has been observed in several patients with Felty's syndrome and in one seropositive rheumatoid arthritic patient (SED-13, 1113) (46,47). GM-CSF-induced acute IL-6 release and an increase in acute phase proteins were thought to be involved.

Immunologic

Hypersensitivity reactions

Although anaphylactic reactions without any documented immune-mediated mechanism have been reported in about 8% of patients with testicular cancer given GM-CSF (48), GM-CSF has only otherwise rarely been associated with allergic reactions. Of two patients who had possible immune-mediated reactions (SEDA-19, 342) one had an immediate recurrent local reaction followed by systemic hypersensitivity reaction after sargramostim, and the other had a maculopapular pruritic eruption after molgramostim. Cross-reaction between the two recombinant forms of GM-CSF was suggested by the results of skin prick tests in one patient, but both patients thereafter tolerated filgrastim uneventfully.

However, cross-sensitivity and possible desensitization have been documented.

- A 42-year-old woman with defective immunological function had generalized pruritus, flushing, shortness of breath, and general discomfort within 30 minutes of her 16th intravenous injection of molgramostim (49). Her symptoms resolved with adrenaline, hydrocortisone, and promethazine. Despite the prophylactic use of glucocorticoids and antihistamines, she developed a similar reaction after molgramostim readministration and 4 hours after the fourth injection of filgrastim. Positive skin prick tests to molgramostim and filgrastim suggested IgE-mediated hypersensitivity. An acute desensitization protocol starting with molgramostim 0.0008 micrograms increasing to 320 micrograms was successful, and molgramostim was later continued uneventfully.

Vasculitis

GM-CSF can cause or exacerbate cutaneous leukocytoclastic vasculitis with possible renal or pulmonary involvement (SED-13, 1113). This adverse effect was substantiated by the prompt recurrence of vasculitis

© 2006 Elsevier B.V. All rights reserved.

after drug re-administration in several patients or the report of relapsing necrotizing vasculitis at all GM-CSF injection sites.

Antibodies to GM-CSF

Formation of antibodies to recombinant GM-CSF has been detected in 31% of patients treated with sargramostim and in 95% of patients treated with molgramostim derived from *Escherichia coli* (50,51). Although the clinical relevance of this is uncertain, a significant modification of exogenous GM-CSF pharmacokinetics, a reduction in the rise in leukocyte count, and a reduction in the frequency of GM-CSF-associated adverse effects have been suggested as possible consequences. Use of the subcutaneous route and repeated administration were deemed to increase the likelihood of antibody occurrence (51). However, the fact that most patients receiving growth factors are already likely to be immunocompromised as a result of intensive chemotherapy might also account for discrepancies between the widespread use of growth factors and the paucity of reports on antibodies against growth factors. In fact only one of eight potentially immunocompromised patients had anti-GM-CSF antibody titers and they were very low (51). Antibodies to GM-CSF have not been found after prolonged use in patients with AIDS (52).

Death

There were more frequent adverse effects and an increased death rate due to pulmonary complications, sepsis, or arterial thrombosis in lung cancer patients treated with chemotherapy plus radiotherapy and GM-CSF (SEDA-20, 339).

Long-Term Effects

Tumorigenicity

Previous fears that GM-CSF might give rise to progression of pre-leukemic conditions have not been substantiated (53).

The possibility that growth factors can stimulate the growth of malignant and leukemic cells, or accelerate the progression of myelodysplastic syndrome to acute myeloid leukemia has been discussed in the monograph on G-CSF section. At the moment, there is no indication from clinical trials that GM-CSF actually increases the risk of tumor growth or the relapse rate in patients with various malignancies (29,54–56). Isolated reports have referred to delayed occurrence of B cell non-Hodgkin's lymphoma after GM-CSF treatment for aplastic anemia and de novo occurrence of diffuse oligoclonal plasmocytosis after both GM-CSF and G-CSF for high-grade glioma (SEDA-19, 342).

Although reversible increases in circulating blasts during GM-CSF treatment are sometimes noted and have raised concern on the possible accelerated occurrence of acute leukemia, the progression of myelodysplastic syndromes to acute myeloid leukemia has been only anecdotally reported (SEDA-19, 342) (57). There was no evidence of significant leukemic cell proliferation in patients with acute myeloid leukemia, and no increased risk of graft failure, leukemogenesis, relapse, or death after a median follow-up of 36 months in 128 patients who underwent autologous bone marrow transplantation for lymphoid malignancies (29,58). Finally, one report has suggested that a GM-CSF-induced abrupt rise in peripheral blasts may have caused diffuse infiltration and proliferation of leukemic blast cells in the spleen, and subsequent fatal hemorrhagic spleen rupture (59).

Susceptibility Factors

Age

In a large, randomized, placebo-controlled trial in 264 very low birth weight neonates, treatment with GM-CSF for 28 days was not associated with specific toxic effects, but the incidence of nosocomial infections was not reduced (60).

Other features of the patient

Bone marrow transplantation

Because the production of cytokines (for example IL-1 or TNF-alfa) involved in the stimulation of cells responsible for graft-versus-host disease can be enhanced by hemopoietic growth factors, the use of growth factors after allogeneic transplantation is theoretically risky. However, in reviews of trials of G-CSF or GM-CSF in allogeneic bone marrow transplantation there were no increases in late engraftment failures, relapse rates, or exacerbation of graft-versus-host disease (54,61).

HIV infection

The safety and activity of subcutaneous GM-CSF (300 micrograms/day for 1 week and 150 micrograms twice weekly for 11 weeks) has been compared with no treatment in 244 leukopenic HIV-infected patients (62). Adverse effects were reported in most of the patients treated with GM-CSF and consisted of flu-like symptoms (98%), bone pain (42%), and injection site reactions (85%). There was a two-fold increase in serum transaminase and alkaline phosphatase activities in 5.7% of patients. There was a moderate, but not significant, increase in HIV p24 antigen concentration. The few relevant clinical trials have provided no convincing evidence that GM-CSF enhances HIV replication or accelerates HIV-associated diseases (for example infections or neoplasms) in patients with AIDS (63). Only one patient with AIDS and ultrasonographic confirmation of enhanced Kaposi's sarcoma lesions temporally related to GM-CSF used for interferon- and zidovudine-related severe neutropenia has been reported (SEDA-19, 343).

Drug–Drug Interactions

Theophylline

A 30% increase in theophylline clearance occurred after the administration of G-CSF or GM-CSF (SEDA-20, 338).

© 2006 Elsevier B.V. All rights reserved.

Vincristine

In one study there was a synergistic effect of GM-CSF or G-CSF and cumulative doses of vincristine in causing severe atypical neuropathy (SEDA-20, 339).

Grepafloxacin

See also Fluoroquinolones

General Information

Grepafloxacin is a synthetic fluoroquinolone antibiotic with extensive tissue distribution and strong antibacterial activity in vivo (1,2). However, it was withdrawn in 1999 because of its adverse cardiovascular effects, which included dysrhythmias (3–5).

Observational studies

In phase II and III trials of grepafloxacin in a total of more than 3000 patients, the most common adverse events with grepafloxacin 400 or 600 mg were gastrointestinal, such as nausea, vomiting, and diarrhea. Significantly more patients reported a mild unpleasant metallic taste with grepafloxacin than with ciprofloxacin, but under 1% of patients withdrew because of this. Headache occurred significantly more often with ciprofloxacin than grepafloxacin. In a study of more than 9000 patients, only 2.3% reported adverse events (nausea 0.8%; gastrointestinal symptoms 0.4%; dizziness 0.3%; photosensitization 0.04%). Rarely, an unpleasant taste has been reported as an adverse event in spontaneous reports (6).

Organs and Systems

Nervous system

Headache was recorded in patients taking grepafloxacin, at rates similar to those reported with ciprofloxacin and ofloxacin (8–9%), during short-course treatment of urinary tract infections (7).

Gastrointestinal

With grepafloxacin 600 mg/day the rates of the following adverse events were noticeably higher than with 400 mg/day: nausea (15 versus 11%), vomiting (6 versus 1%), and diarrhea (4 versus 3%) (8).

Griseofulvin

General Information

Griseofulvin was originally isolated in 1939 as a natural product of *Penicillium griseofulvum* (1). It interferes with fungal microtubule formation, disrupting the cell's mitotic spindle formation and arresting the metaphase of cell division. Griseofulvin is a fungistatic compound and is active against *Trichophyton*, *Microsporon*, and *Epidermophyton* species (2). With the development of newer safer azoles and the introduction of terbinafine, all of which are easy to administer, the indications for griseofulvin have dwindled (3).

Pharmacokinetics

Griseofulvin is commercially available for oral administration as griseofulvin microsize (4 μm particle size) and griseofulvin ultramicrosize (1 μm particle size). The oral availability of the micronized formulation is variable, 25–70%; ultramicronized griseofulvin, in contrast, is almost completely absorbed (4–6). Peak plasma concentrations occur about 4 hours after dosing. Griseofulvin distributes to keratin precursor cells and is concentrated in skin, hair, nails, liver, adipose tissue, and skeletal muscle. In skin, a concentration gradient is established over time, with the highest concentrations in the outermost stratum corneum (7,8). However, within 48–72 hours after withdrawal, plasma concentrations of griseofulvin are markedly reduced and it is no longer detectable in the stratum corneum (4–6). The half-life of griseofulvin is 9–21 hours (9). It is oxidatively demethylated and conjugated with glucuronic acid, primarily in the liver; its major metabolite, 6-desmethylgriseofulvin, is microbiologically inactive (10). Within 5 days, about one-third of a single dose of micronized griseofulvin is excreted in the feces, and 50% in the urine, predominantly as glucuronidated 6-desmethylgriseofulvin (10,11). The slow penetration rate of griseofulvin into tissues may explain difficulties and delays in eradication of infection in nails (SED-12, 676) (12).

General adverse effects

The more common adverse effects of griseofulvin include headache and a variety of gastrointestinal symptoms. Griseofulvin can cause photosensitivity and exacerbate lupus and porphyria. Cases of erythema multiforme-like reactions, toxic epidermal necrolysis, and a reaction resembling serum sickness have been reported. Proteinuria, nephrosis, hepatotoxicity, leukopenia, menstrual irregularities, estrogen-like effects, and reversible impairment of hearing have been reported rarely (4–6,13). Griseofulvin is teratogenic in animals and has mutagenic and carcinogenic potential, but the significance of these observations for humans is unclear (13).

Organs and Systems

Nervous system

Headache is the most common adverse effect of griseofulvin (14). It occurs in about 50% of patients and can be severe. Drowsiness, dizziness, fatigue, confusion, depression, irritability, and insomnia have also been observed (14). Impaired co-ordination and unsteadiness while walking have been reported in some cases when there was confusion (15). Peripheral neuritis has been attributed to griseofulvin, but with little proof of a causal relation (16).

Sensory systems

Eyes

Blurring of vision has been reported with griseofulvin (17).

Taste

Griseofulvin can cause dysgeusia; both taste and smell disturbances may occur more frequently than has been realized (SED-12, 676)(18).

Psychological, psychiatric

The psychiatric effects of griseofulvin can be very disturbing and are aggravated by alcohol (SED-12, 676) (14).

Endocrine

An estrogen-type effect has been reported in children, affecting the genitals and the breasts (SED-11, 567)(19).

Griseofulvin interferes with porphyrin metabolism. In man, transient increases in erythrocyte protoporphyrin concentrations have been demonstrated, and the production and excretion of porphyrins is increased. Acute intermittent porphyria is an absolute contraindication to griseofulvin. In patients with other forms of porphyria it should also be avoided, in view of the many alternatives (20–25).

Hematologic

There is no evidence that griseofulvin can cause serious blood disorders. However, leukopenia, neutropenia, and monocytosis have been reported (14,26).

Gastrointestinal

Anorexia, a feeling of bloating, mild nausea, and mild diarrhea are common (17). Vomiting, abdominal cramps, and more severe diarrhea are rare. Black, furry tongue, glossodynia, angular stomatitis, and taste disturbances have been described (18).

Liver

While there have been anecdotal reports of hepatitis (14) and cholestasis (27), a causal relation has never been shown.

Skin

Dermatological adverse effects are not uncommon with griseofulvin and are of considerable variety. The following have been described: urticaria (28,29), photosensitivity eruptions (30), erythema multiforme (31), morbilliform rashes (32), serum sickness-like reactions (33), fixed drug eruption (29,34,35), Stevens–Johnson syndrome (36), vasculitis (37), toxic epidermal necrolysis (38,39), and lupus erythematosus (40,41).

- A 40-year-old woman had a burning sensation and erythema of the lips, buccal mucosa, palate, and vulva, which recurred within 4 hours of oral rechallenge with griseofulvin 125 mg (42).

The risk of serious skin disorders has been estimated in 61 858 users, aged 20–79 years, of oral antifungal drugs identified in the UK General Practice Research Database (43). They had received at least one prescription for oral fluconazole, griseofulvin, itraconazole, ketoconazole, or terbinafine. The background rate of serious cutaneous adverse reactions (corresponding to non-use of oral antifungal drugs) was 3.9 per 10 000 person-years (95% CI = 2.9, 5.2). Incidence rates for current use were 15 per 10 000 person-years (1.9, 56) for itraconazole, 11.1 (3.0, 29) for terbinafine, 10 (1.3, 38) for fluconazole, and 4.6 (0.1, 26) for griseofulvin. Cutaneous disorders associated with the use of oral antifungal drugs in this study were all mild.

Immunologic

The triggering of a lupus-like syndrome by griseofulvin, by way of an allergic reaction, has been described, but is rare (44).

Second-Generation Effects

Pregnancy

Embryotoxicity and mutagenicity have been shown in animal experiments with high doses of griseofulvin. Although for this reason most handbooks and drug formularies warn against the use of griseofulvin during pregnancy, there are no reports of any adverse effects on the human fetus, despite the fact that griseofulvin has been on the market since the early 1960s and has been used extensively and, no doubt, during many pregnancies (SED-12, 676) (19,45–47).

© 2006 Elsevier B.V. All rights reserved.

Susceptibility Factors

Patients with porphyria are at risk; acute intermittent porphyria is an absolute contraindication to griseofulvin.

Exposure to intense natural or artificial sunlight should be avoided during treatment with griseofulvin.

Patients with pre-existing systemic lupus erythematosus may be more susceptible to the development of skin manifestations from griseofulvin (48).

Drug–Drug Interactions

Alcohol

The effects of alcohol are potentiated by griseofulvin, and the use of alcohol increases the risk and severity of psychiatric disturbances.

Ciclosporin

Ciclosporin blood concentrations halved in a patient who took griseofulvin 500 mg/day, despite an increase in ciclosporin dose by 70% (49). When griseofulvin was withdrawn, the ciclosporin concentration rose. This interaction is attributable to induction of cytochrome P450 by griseofulvin.

Coumarin anticoagulants

Griseofulvin is a potent inducer of cytochrome P450 and has a significant effect on P450 expression in hepatocytes (SEDA-12, 236). It therefore increases the rate of metabolism of coumarin anticoagulants (50). However, both increases and decreases in prothrombin time have been reported (SED-12, 676) (18).

Oral contraceptives

The combination of griseofulvin with oral contraceptives can lead to oligomenorrhea, amenorrhea, and breakthrough bleeding; unintended pregnancies have been reported (51). In a case of oligomenorrhea after treatment with griseofulvin, the use of a higher estrogen oral contraceptive restored regularity of the menstrual cycle (SEDA-12, 237) (51). The fact that griseofulvin has an estrogen-like effect in children suggests that it may affect the rate of estrogen metabolism (SED-12, 676) (52).

Phenobarbital

The concomitant use of phenobarbital reduces griseofulvin concentrations, an effect that has been attributed to induction of liver enzymes by phenobarbital (53).

Guanethidine

General Information

Guanethidine, an adrenergic neuron blocking drug, which was once used to treat hypertension, is obsolete for oral use and this indication. However, it has been used as eye-drops in cases of glaucoma, chemical sympathectomy, ptosis, and eyelid retraction (SEDA-1, 366). The reduction in intraocular pressure is small. In general, tissues treated topically with guanethidine become sensitized to sympathomimetic acting drugs. This is useful in glaucoma, for which adrenaline can be administered in low dosage in combination with guanethidine. After instillation of guanethidine-containing eye-drops, conjunctival hyperemia, ocular pain, and stinging have been described (1,2).

Guar gum

General Information

Guar gum is a low-viscosity water-soluble dietary fiber that has been used to treat diabetes because it slows the absorption of glucose from the gut. However, adverse effects such as regurgitation, obstipation, abdominal cramps, diarrhea, and itching are common (1). Partially hydrolysed guar gum has been added to enteral formulas and food products as a source of dietary fiber; it can reduce laxative use, diarrhea in septic patients receiving total enteral nutrition, and symptoms of irritable bowel syndrome (2).

In a systematic review of 11 trials of the use of guar gum to treat obesity, the most common adverse events were abdominal pain, flatulence, diarrhea, and cramps; 11 patients (3%) dropped out owing to adverse events (3).

© 2006 Elsevier B.V. All rights reserved.

Organs and Systems

Gastrointestinal

Of 26 reports of suspected adverse reactions to a diet formulation containing guar gum (Cal-Ban 3000), there were 18 cases of esophageal obstruction and seven of small bowel obstruction (4). There were pre-existing esophageal or gastric disorders in 50% of those with esophageal obstruction, including peptic stricture, pyrosis, hiatus hernia, esophagitis, gastric stapling, Schatzki ring, and muscular dystrophy. Fourteen patients with esophageal obstruction were treated successfully by endoscopy, although the tenacious gel-like material was often difficult to remove. One patient who developed a pulmonary embolism after surgical repair of an intraoperative esophageal tear died.

Immunologic

Guar gum can cause occupational rhinitis (5) and asthma (6). Of 162 employees at a carpet-manufacturing plant where guar gum was used to adhere dye to the fiber, 37 (23%) had a history suggestive of occupational asthma and 59 (36%) occupational rhinitis (7). Eight (5%) had immediate skin reactivity to guar gum and 11 (8.3%) had serum IgE antibodies to guar gum.

An employee of a pet food plant developed a severe cough, rhinitis, and conjunctivitis, and skin tests confirmed guar allergy. The symptoms resulted in obstructive sleep apnea which resolved after absence from work and recurred after rechallenge with guar gum dust (8).

Gum resins

General Information

Gum resins comprise a diverse variety of substances, including asafoetida (*Ferula*), colophony, frankincense (*Boswellia*), and myrrh (*Commiphora*).

Colophony

Colophony, a natural unmodified gum resin from *Pinus* species (terebinth), used in cosmetics such as mascara, lipsticks, creams, and hair removal products, is a known contact allergen. Modifications have been made to colophonium, resulting in a variety of ester gums.

Frankincense

Preparations from the gum resin of *Boswellia serrata* have been used as traditional remedies in Ayurvedic medicine in India for inflammatory diseases (1). The gum contains substances that have anti-inflammatory properties; they are pentacyclic triterpenes related to boswellic acid, which inhibit leukotriene biosynthesis in neutrophilic granulocytes by inhibiting 5-lipoxygenase. Certain boswellic acids also inhibit elastase in leukocytes, inhibit proliferation, induce apoptosis, and inhibit topoisomerases in cancer cell lines.

Use in asthma

In a double-blind, placebo-controlled study in 40 patients aged 18–75 years with bronchial asthma who were given *Boswellia serrata* 300 mg tds for 6 weeks, 28 had improved dyspnea, a reduced number of attacks, increases in FEV_1, FVC, and peak flow, and reduced eosinophil counts and ESR (2). Of 40 patients, aged 14–58 years, given lactose 300 mg tds for 6 weeks, only 11 improved.

Use in colitis

In patients with ulcerative colitis, *Boswellia serrata* 350 mg tds for 6 weeks produced improvements in stool properties, histopathology of rectal biopsies, hemoglobin, serum iron, calcium, phosphorus, proteins, and total leukocyte and eosinophil counts, with remission in 82% of patients (3). The corresponding figure with sulfasalazine 1 g tds was 75%.

In 30 patients aged 18–48 years with chronic colitis, characterized by vague lower abdominal pain, rectal bleeding, diarrhea, and palpable tender descending and sigmoid colons, *Boswellia serrata* (900 mg/day for 6 weeks) produced remission in 14 of 20 patients, and sulfasalazine (3 g/day for 6 weeks) in 4 of 10 patients (4). There were few adverse effects.

Myrrh

Myrrh is an oleo gum resin obtained from the stem of *Commiphora molmol*, a tree that grows in north-east Africa and the Arabian Peninsula. In mice, myrrh showed no mutagenic effects and was a potent cytotoxic drug against solid tumor cells (5). The antitumor potential of *C. molmol* was comparable to that of cyclophosphamide. Studies in hamsters suggested an antischistosomal activity of myrrh (6).

Use in schistosomiasis

The efficacy and adverse effects of myrrh and the most effective dosage schedule have been studied in 204 (169 men and 35 women) patients with schistosomiasis, aged 12–68, years and 20 healthy non-infected age- and sex-matched volunteers (6). The patients were divided into two groups: 86 patients with schistosomal colitis and 118 with hepatosplenic schistosomiasis, the latter being further divided into two subgroups: 77 patients with compensated disease and 41 with decompensated disease. All but 12 had received one or more courses of praziquantel. The dosage of myrrh was 10 mg/kg/day for 3 days on an empty stomach 1 hour before breakfast. A second course of 10 mg/kg/day for 6 days was given to patients who still had living ova in rectal or colonic biopsy specimens. The response rate to a single course of myrrh was 92% in 187 patients. The cure rates were 91%, 94%, and 90% in patients with schistosomal colitis, compensated hepatosplenic schistosomiasis and decompensated hepatosplenic schistosomiasis respectively. The cure rate was less in patients who had previously taken praziquantel and in patients with impaired liver function. *Schistosoma hematobium* infection was the most responsive ($n = 4$, cure rate 100%), followed by mixed infections ($n = 29$, cure rate 93%). Those infected with *Schistosoma mansoni* had the lowest cure rate ($n = 171$, cure rate 91%). There was no impairment of liver function after treatment with myrrh. In contrast, liver function tests significantly improved in patients with impaired liver function. There were no significant effects of myrrh on the electrocardiogram. Adverse effects of myrrh were reported in 24 of the 204 patients. Giddiness, somnolence, and mild fatigue were the most common (2.5%), and all other adverse effects were minor and less frequent. None of the healthy volunteers reported any adverse effects, nor were there any significant changes in liver or kidney function. A second course of myrrh resulted in a cure in 13 of the 17 patients who did not respond to a single course.

Use in fascioliasis

The efficacy of myrrh has been studied in seven patients aged 10–41 years (five men, two women) with fascioliasis and 10 age- and sex-matched healthy volunteers (7). Myrrh was given orally in the morning on an empty stomach in a dosage of 12 mg/kg/day for 6 days. All the patients were passing *Fasciola* eggs in their stools (mean 36 eggs per gram of stool). The symptoms and signs of fascioliasis resolved during treatment with myrrh, and *Fasciola* eggs could not be demonstrated in the stools 3 weeks and 3 months after treatment. Anti-fasciola antibody titers became negative in six of the seven patients. There were no adverse effects.

Organs and Systems

Immunologic

In a retrospective study, 1270 patients with leg ulcers were tested for contact allergy with colophonium and the modified ester gum: 31 patients were positive to colophonium alone, 41 to the ester gum alone, and 33 to both colophonium and the ester gum (8). The authors recommended that the patch test tray for patients with leg ulcers should include both colophonium and the ester gum resin.

Two other patients with cheilitis due to contact allergy to a lipstick reacted positively to glyceryl hydrogenated rosinate, an ester gum, and the main component of the rosinate, glyceryl abietate (both patchtested at 20% in petrolatum) (9).

Gusperimus

General Information

Gusperimus is a guanidine derivative with antitumor and immunosuppressive properties. Its mechanism of action is not well understood and may involve blockade of the maturation of B and T lymphocytes and monocytes, with inhibition of both cell-mediated and antibody-mediated immunity. In preliminary clinical trials in transplant patients, adverse effects at low doses included mild-to-moderate leukopenia, facial and perioral numbness, anorexia, gastrointestinal disturbances, facial flushing,

© 2006 Elsevier B.V. All rights reserved.

and weakness (1–3). Bone marrow suppression has been observed at high doses.

Haemophilus influenzae type b (Hib) vaccine

See also Vaccines

General Information

Haemophilus influenzae causes several infectious diseases in man, the most serious being meningitis. Most cases of *Haemophilus influenzae* infection are due to type b of the organism (Hib). Two types of Hib vaccines have been developed: Hib capsular polysaccharide (PRP) vaccines are first-generation Hib vaccines, while Hib conjugate vaccines are second-generation vaccines. The capsular polysaccharide vaccines do not protect infants and children under 18 months, whereas Hib conjugate vaccines have greater immunogenicity and induce a high rate of protection in children under 18 months. The latter have therefore completely replaced the first-generation polysaccharide vaccines.

Comparisons of adverse reactions to different vaccines are difficult, because vaccines are virtually always administered together with other vaccines. However, the general experience is that adverse reactions to Hib vaccine are mild. Most reactions develop when the vaccine is given simultaneously with DTP vaccine. There have been no deaths or permanent sequelae attributable to Hib immunization.

Four different types of conjugated vaccines are commercially available:

1. PRP-D Hib vaccine (a mutant polypeptide of diphtheria toxin covalently linked to PRP), for example ProHIBit (produced by Connaught Laboratories, Philadelphia).
2. HbOC vaccine (Hib oligosaccharides linked to the non-toxic diphtheria toxin variant CRM197), for example HibTITER (produced by Lederle-Praxis Biologicals, Pearl River, NY).
3. PRP-OMC (PRP conjugated to outer membrane protein of Neisseria meningitidis group B), for example PedvaxHIB (produced by Merck Sharp & Dohme Research Laboratories).
4. PRP-T Hib vaccine (tetanus toxoid linked to PRP), for example ActHIB or OmniHIB (produced by Pasteur Merieux, Lyon, France) and PRP-T (produced by Pasteur Mérieux Connaught and Glaxo SmithKline).

PRP-D-Hib has been almost completely replaced by different conjugated Hib vaccines (1–3). The four types of conjugated Hib vaccines have been reviewed (SED-12, 803) (SEDA-16, 377) (SEDA-17, 367) (SEDA-18, 330). More than 100 million doses of conjugated vaccines have now been administered worldwide, and no reports of deaths, anaphylaxis, or residual neurological damage have been causally connected with them.

In a study of the tolerability and immunogenicity of Hib vaccines, 30 volunteers aged 69–84 years were immunized with either Pedvax-Hib (a conjugate of Hib polysaccharide and an outer membrane protein complex of *Neisseria meningitidis*-PRP-OMP) or Hib TITER (a conjugate of Hib oligosaccharide and a non-toxic mutant diphtheria toxin, CRM 197-HbOC) (4). The volunteers received a pediatric dose. Before immunization, 40% of the volunteers had serum anti-PRP antibody concentrations below 1.0 μg/ml. Four weeks after immunization, all the volunteers had concentrations over 1.0 μg/ml, which is generally considered to be protective. Adverse effects of immunization were mild, except in one volunteer given HbOC, who developed extensive erythema and swelling at the injection site.

Different vaccines and immunization strategies have been evaluated in Denmark, Finland, Iceland, Norway, and Sweden (5). Few places outside Scandinavia have collected data on Hib immunization programs for so long (more than a decade has elapsed since universal Hib immunization was initiated in Scandinavia) and with similar accuracy. Phase 3 studies with PRP-D-Hib vaccine were done in Finland in the late 1980s, and PRP-D-Hib vaccine has been the only vaccine used in Iceland. HbOC vaccine was first compared with PRP-D-Hib vaccine in Finland and then reintroduced to the primary health-care system as the only Hib vaccine used. Finally, PRP-T-Hib vaccine was first temporarily used in Finland, and then as almost the only vaccine in Denmark, Norway, and Sweden. Besides the different conjugate vaccines, the immunization programs have differed in other aspects, such as immunization schedule and administration of vaccines (separate versus simultaneous administration with other vaccines, such as DT, DTP, DTaP, IPV, or MMR).

Experience with PRP-D derives from Finland and Iceland. In Finland, 14.1 adverse reactions per 100 000 doses were reported in all, consisting respectively of 5.3, 6.3, 4.4, and 2.9 per 100 000 doses of local reactions, fever, rash, and irritability. These rates probably underestimate the true rate. In Iceland, adverse effects have not been monitored, but no serious events have been reported. For PRP-CRM, there were 17.8 per 100 000 doses in all, of which 7.7 per 100 000 doses were due to local reactions, 8.9 to fever, and 8.3 to rash. PRP-T currently enjoys the largest use in Scandinavia, being the routine choice in three countries. Of 115 reactions reported in Denmark, none was of serious concern; most were local reactions, fever, or rash. In Norway, the incidence of systemic reactions was 1 in 550 doses; fever and other symptoms and signs similar to those after DTP vaccination were the most common complaints. However, two findings were characteristic of Norway, where local reactions were reported with an overall frequency of 1/1500 doses:

- immediate mild allergic reactions were more common than if DTP or IPV was given alone; their incidence was 1 in 35 000 doses of PRP-T;
- large swellings at the vaccination site, with edema and sometimes bluish or other discoloration of the legs, were reported in 18 children, suggesting an incidence of about 1 in 30 000 doses; this reaction developed within hours after vaccination and subsided within 24 hours; all the vaccinees recovered spontaneously without treatment or sequelae.

About 1.5 million doses of PRP-T have been used in Sweden. Similar concerns about adverse reactions have been raised as in Norway, and further elucidation has recently begun. In Finland (where PRP-T was used in

© 2006 Elsevier B.V. All rights reserved.

1990–93), there were 15.9 reports per 100 000 doses; 6.2 per 100 000 doses were local reactions, 5.9 fever, 2.8 rash, and 2.4 irritability (5).

Notwithstanding the different approaches taken in the various Scandinavian countries, the results are similar: before vaccination against invasive Hib diseases, first introduced in Finland in 1986, the incidence of cases in the five Scandinavian countries was 49 per 100 000 per year in 0- to 4-year olds and 3.5 per 100 000 overall. During the next decade, Hib conjugates given to young children had about 95% effectiveness, regardless of which conjugate was used, whether two or three primary doses were used, and at no matter what age in early infancy the first vaccination was given. Invasive diseases due to Hib have thus been nearly eliminated.

On the request of the French Drug Agency, the Regional Pharmacovigilance Center of Tours has analysed the adverse events that occurred in 1986–90 with the use of three different tetravalent DTwP-IPV vaccines produced by French vaccine manufacturers (6). The most frequent adverse events were local reactions (43% of the 631 events reported). Serious adverse events represented 25% of all reported events, including 23 reports of persistent crying, 12 febrile seizures, 14 apyretic seizures, and 3 reports of shock-like events.

Immunological interference, particularly to the Hib response, has been assessed in 135 infants at 2, 4, 6, and 18 months of age in studies of two different types of administration of DTaP and Hib vaccines: combined administration of the two vaccines mixed in the same syringe and simultaneous administration of separate injections at different sites (7). The vaccines were well tolerated and there were no differences in the rates of local and systemic reactions. Immune responses were also comparable between the two groups.

In 57 volunteers, 32 of whom had recently undergone splenectomy, who received Hib conjugate vaccine, antibodies to Hib were measured at 2, 6, 12, 24, and 36 months after immunization (8). All tolerated the vaccine well and reached protective antibody titers. The authors concluded that the vaccine is safe and protective in patients with thalassemia.

Combinations of vaccines

Since immunization against diphtheria, tetanus, and pertussis is recommended at the same age as immunization against *Haemophilus influenzae*, children must usually receive two intramuscular injections at separate sites during the same visit. Combined vaccines, for example DTP/Hib vaccines, requiring one injection, could be preferable and are commercially available. Results of clinical trials comparing the safety and efficacy of combined and simultaneously administrated vaccines (Hib, DTP, MMR, IPV) have been presented (SEDA-17, 369) (SEDA-18, 330). In general, the rates of local and systemic reactions and antibody responses did not differ significantly between the groups. The immunogenicity and safety of a diphtheria–tetanus–pertussis–Hib combination vaccine (tetanus-conjugated Hib vaccine) have been compared with those of the same combination obtained by the reconstitution of lyophilized Hib vaccine with liquid DTP vaccine in 262 healthy infants randomized to receive injections at 2, 4, and 6 months of age, a subgroup of 134 of whom received a booster dose at 12 months (9). Systemic and local reactions were generally mild and did not differ significantly between the two groups. With regard to Hib antibodies, the combination vaccine was at least as immunogenic as the lyophilized formulation.

Four-, five- and six-component combination vaccines based on DTaP or DTwP vaccine, and including other antigens such as hepatitis B or Hib or IPV, will play an important role in future worldwide immunization programs. The first hexavalent combination vaccines (DTaP-IPV-HB-Hib) were licensed in Germany; two hexavalent vaccines are available, manufactured by SmithKline Beecham and Aventis Pasteur.

The Hexavalent Study Group has compared the immunogenicity and safety of a new liquid hexavalent vaccine against diphtheria, tetanus, pertussis, poliomyelitis, hepatitis B, and Hib (DTP + IPV + HB + Hib vaccine, manufactured by Aventis Pasteur MSD, Lyon, France) with two reference vaccines, the pentavalent DTP + IPV + Hib vaccine and the monovalent hepatitis B vaccine, administrated separately at the same visit (10). Infants were randomized to receive either the hexavalent vaccine ($n = 423$) or (administered at different local sites) the pentavalent and the HB vaccine ($n = 425$) at 2, 4, and 6 months of age. The hexavalent vaccine was well tolerated (for details, see the monograph on Pertussis vaccines). At least one local reaction was reported in 20% of injections with hexavalent vaccine compared with 16% after the receipt of pentavalent vaccine or 3.8% after the receipt of hepatitis B vaccine. These reactions were generally mild and transient. At least one systemic reaction was reported in 46% of injections with hexavalent vaccine, whereas the respective rate for the recipients of pentavalent and HB vaccine was 42%. No vaccine-related serious adverse event occurred during the study. The hexavalent vaccine provided immune responses adequate for protection against the six diseases.

Regimens using different conjugated vaccines for primary series

Currently most advisory bodies for immunization practice recommend that the same Hib conjugate vaccine used to initiate a priming series should be continued for the entire series. However, interest in using different vaccines for sequential doses (mixed regimens) has been long-standing. Two- or three-dose mixed regimens of Hib conjugate vaccines have been compared in two randomized trials in 140 and 181 infants (11). In both trials, a group of infants received PRP-meningococcal protein conjugate vaccine (OMP, outer membrane protein) at 2 months of age, followed by either the same or another conjugate vaccine, oligosaccharide CRM197 Hib vaccine (HbOC, Hib oligosaccharides linked to the non-toxic diphtheria toxin variant CRM197) or PRP-tetanus toxoid Hib vaccine, either once (at 4 months of age) or twice (at 4 and 6 months of age). All the mixed regimens provided a mean anti-PRP antibody concentration that did not differ substantially compared with currently recommended regimens of proven or inferred efficacy. Recipients of a second dose of OMP vaccine had higher rates of swelling, erythema, and induration compared with the other recipients.

© 2006 Elsevier B.V. All rights reserved.

Organs and Systems

Nervous system

The neurological complications of conjugated Hib vaccines have been reviewed (12). A single convulsion occurred 12 hours after immunization in a 3-month-old child and a hyporesponsive episode occurred in another 3-month-old child.

Guillain–Barré syndrome has been reported after immunization with several different vaccines, including Hib conjugate vaccine (13,14). One patient had also received DTP and oral poliomyelitis vaccine.

Metabolism

The incidence of diabetes mellitus has been studied in Finnish children born between October 1983 and September 1985 compared with children born between October 1985 and 1987 (1). Of the children born in 1985–87, 50% received Hib vaccine (diphtheria conjugated PRP-D-Hib vaccine) at 3, 4, and 6 months as a primary course and a booster dose at 14–18 months; the other 50% received one dose of the same vaccine at the age of 24 months. Taking into account the documented increase in diabetes in Finnish children, the small difference between the incidence rate of diabetes in children born during the period 1985–87 and immunized at 18 months and the incidence rate of children born in 1983–85 and not immunized against Hib disease was expected, with a slightly higher non-significant incidence in immunized children. In children over 4 years of age primed during the first year of life the incidence rate of diabetes was also slightly but non-significantly higher than in children immunized at 18 months of age. The authors concluded that early PRP-D-Hib immunization does not increase the risk of diabetes during the first 10 years of life.

This study has been criticized on the grounds that the authors did not present data comparing the incidence rates of children born in 1985–87 and primed during the first year of life with children born in 1983–85 and not immunized (15). The critics presented significant differences in the incidence rate of diabetes between the two groups of children and concluded that immunization had increased the risk of diabetes. However, the relative risk of diabetes during the first 10 years of life in the immunized children born in 1985–87 was 1.19 compared with the non-immunized children born in 1983–85.

In another Finnish study, about 116 000 children born in Finland between 1 October 1985 and 31 August 1987 were randomized to receive four doses of Hib vaccine (PPR-D, Connaught) starting at 3 months of life or one dose starting after 24 months of life (16). A control cohort included all 128 500 children born in Finland in the 24 months before the study. The difference in cumulative incidence between those who received four doses of the vaccine and those who received none was 54 cases of diabetes per 100 000 at 7 years (relative risk = 1.26). Most of the extra cases of diabetes occurred in statistically significant clusters starting about 38 months after immunization and lasting about 6–8 months. The authors concluded that exposure to Hib immunization is associated with an increased risk of type 1 diabetes mellitus.

In 1997, US researchers suggested that immunization at 28 days after birth can cause type 1 diabetes mellitus in susceptible individuals. In May 1998, several institutions, including the National Institute of Allergy and Infectious Diseases, the Centers for Disease Control, the World Health Organization, and the UK's Department of Health, sponsored a workshop to assess the evidence of a possible link. Immunologists, diabetologists, epidemiologists, policymakers, and observers debated the available evidence and concluded that a causal link between immunization and type 1 diabetes is not supported. The results of a large, randomized, controlled trial of immunization against Hib carried out in Finland in 1985–87 (5) were also reanalysed and showed no association between the incidence of diabetes mellitus and the addition of another antigen to the schedule, irrespective of timing. Data reanalysis was made possible by prospective linking of individual information on exposure (in this case infant immunization or the administration of placebo) with the Finnish diabetes register (17).

Susceptibility Factors

Other features of the patient

Of 23 patients with Hodgkin's disease and splenectomy immunized with Hib conjugate vaccine, most responded, although the antibody response was significantly lower than in healthy people (18). There were adverse effects in three of the vaccinees: in one case nausea, vertigo, and weakness occurred 2–4 days after administration of the vaccine, myalgias occurred in another case, and fever and myalgias (after primary immunization, with milder symptoms after the booster) in a third.

Hair dyes

General Information

Hair dyes (for example henna, paraphenylenediamine, and paratoluenediamine) have been reviewed (1). They have moderate to low acute toxicity. Poisoning is rare and occurs only after oral ingestion. Contact sensitization usually occurs from unprotected professional exposure, but the prevalence has stabilized or fallen over the years. In vitro genotoxicity tests of hair dye ingredients have often been positive, but the relation to in vivo carcinogenicity is not clear and there is no in vivo evidence of genotoxicity. Despite the results of various studies that have suggested an association between the use of hair dyes and bladder cancer, a number of studies, including prospective investigations in large populations and systematic reviews, have shown no convincing associations with bladder cancer and other cancers. The results of direct toxicity studies and epidemiological studies suggest that hair dyes and their ingredients do not cause adverse reproductive effects.

Organs and Systems

Immunologic

Allergic reactions to constituents of hair dyes are not uncommon and are generally due to delayed hypersensitivity. Immediate hypersensitivity reactions have been described, but they are rare and seldom life-threatening.

Contact allergy to the paraphenylene group of hair dyes is well established (2). To test for cross-reactivity between these oxidative dyes and the new generation of hair dyes, 40 hairdressers allergic to paraphenylenediamine were selected; none reacted to any of the four acid dyes, two FD&C dyes, or four D&C dyes, suggesting that these newer hair dyes are safe alternatives to the paraphenylene-based hair dyes (3).

There is a risk of sensitization from paraphenylenediamine when it is applied to the skin in combination with henna (4–6). This can result in contact allergic reactions as well as persistent contact leukoderma, as illustrated in five patients with paint-on henna tattoos (7). All were positive on patch-testing with paraphenylenediamine. One developed erythema multiforme 4 weeks after the last application and the authors found no other causes of erythema multiforme.

The use of the combination of henna and paraphenylenediamine in 20 cases over 2 years in Khartoum (Sudan) resulted in severe toxicity (SEDA-9, 142). The initial symptoms were those of angioedema, with massive edema of the face, lips, glottis, pharynx, neck, and bronchi. These occurred within hours of the application of the dye-mix to the skin. In some the symptoms progressed on the second day to anuria and acute renal insufficiency, with death on the third day. Dialysis helped some patients, but others died from renal tubular necrosis.

The oxidation product of paratoluenediamine has been identified as a rare cause of a life-threatening immediate hypersensitivity reaction (8).

- A 45-year-old woman developed extensive urticarial lesions 30 minutes after the application of a hair dye, starting on the scalp and face, followed by abdominal cramps, watery diarrhea, vomiting, dysphonia, and loss of consciousness. A prick test with a 1/128 dilution of the hair dye showed a positive reaction, but individual dye constituents did not. Prick testing with the oxidation products of the individual dye constituents showed a strongly positive reaction to oxidized paratoluenediamine, which was weaker after addition of an antioxidant to the mixture.

Ten healthy controls had negative prick tests with the oxidized paratoluenediamine.

© 2006 Elsevier B.V. All rights reserved.

Long-Term Effects

Tumorigenicity

In a review of cohort and case-control studies of occupational exposure to hair dyes among hairdressers, barbers, and beauticians, the relative risk of bladder cancer was 1.4 from cohort studies, and somewhat over 1.0 from case-control studies; however, there were confounding factors, particularly since allowance for smoking was lacking or inadequate in most studies (9). In five case-control studies of personal use of hair dyes, there was no evidence of an increased risk of bladder cancer. In nine cohort studies the relative risk of lymphoid neoplasms overall was 1.2 (1.5 for non-Hodgkin's lymphomas and 1.1 for multiple myeloma). Of five case-control studies, three reported some association with lymphoid neoplasms, but the estimates of relative risk were only moderately above 1.0 and there was insufficient allowance for potential confounding factors, including social class and greying hair, which could correlate with both hair dye use and lymphoid neoplasms. No other neoplasms, including those of breast, skin, and lung were related to the use of hair dyes. In another study there was an increased risk of Hodgkin's disease among women who reported the use of hair coloring products before 1980 (OR = 1.3; CI = 1, 1.8) (10).

Drug Administration

Drug overdose

In one case deliberate ingestion of paraphenylenediamine with suicidal intent caused severe oropharyngeal edema, rhabdomyolysis, and cardiac death after 4 hours despite full supportive treatment (11).

Myocarditis has been attributed to paraphenylenediamine poisoning (12).

- An 18-year-old woman developed asphyxia and rhabdomyolysis after taking paraphenylenediamine 5 g. An electrocardiogram showed ventricular extra beats and inverted T waves. The serum CK activity was 28 020 μkat/l. Transthoracic echocardiography showed left and right ventricular hypokinesis and a left ventricular apical thrombus. Anticoagulation treatment with heparin was initiated. A follow-up echocardiogram performed on the 15th day showed normalization of ventricular function and disappearance of the thrombus.

In two patients acute oliguric renal insufficiency due to acute tubular necrosis followed paraphenylenediamine intoxication; there was associated vomiting, angioedema, cyanosis, and intravascular hemolysis (13). One patient recovered and the other died with septicemia. In four other cases acute renal insufficiency was due to rhabdomyolysis.

Halofantrine

General Information

Halofantrine is a phenanthrene-methanol derivative of an aminoalcohol, active against multidrug-resistant *Plasmodium falciparum* malaria. Halofantrine was known during World War II but was little used at that time. It is slowly and incompletely absorbed with peak concentrations 3.5–6 hours after dosing. Its absorption in its original formulation was unpredictable (SEDA-13, 820).

Dose-finding studies with halofantrine showed treatment failures with a single dose but cures with two doses, one of 1000 mg and one of 500 mg. A regimen of 500 mg at 6-hourly intervals was also effective. Three doses of 500 mg at 6-hourly intervals were also used in

© 2006 Elsevier B.V. All rights reserved.

a French study and treatment resulted in cure in semi-immune subjects. The dosage was insufficient in non-immune Caucasian patients.

Halofantrine is not indicated for prophylactic use. However, of 480 army personnel who took two doses of 1500 mg each on the third and the tenth days after they had returned to a non-malarial area, only one had *P. falciparum* malaria during the next 5 months (SEDA-13, 820) (1). There were no adverse effects, except for one case of morbilliform rash possibly due to the halofantrine.

General adverse effects

Adverse effects with the dosages originally recommended have in general been mild, no more than nausea, diarrhea, headache, and pruritus (SEDA-13, 820) (2–4). Pruritus occurred markedly less often with halofantrine than with chloroquine (SEDA-16, 306). A comparison between high-dose chloroquine (35 mg/kg total in three daily doses) and halofantrine in the standard dose (total 25 mg/kg given at 6-hour intervals) in patients 4–14 years old showed a fairly similar frequency of adverse effects. Itching was a common adverse effect of chloroquine (4).

Organs and Systems

Cardiovascular

In 1993, the sudden cardiac death of a 37-year-old woman after her ninth dose of halofantrine was reported. A subsequent prospective study showed that halofantrine was associated with a dose-related lengthening of the QT interval by more than 25% (SEDA-17, 328). Mefloquine did not cause such changes, but the combination of mefloquine with halofantrine had a more pronounced effect on the electrocardiogram. However, in the region where this investigation was carried out (on the Thai–Burmese border area) thiamine deficiency is common, and patients in this area have longer baseline QT intervals than are usually reported (SEDA-17, 328). Two patients, mother and son, both with congenital prolongation of the QT interval, suffered sustained episodes of torsade de pointes after a total dose of 1000 mg of halofantrine, and there have been other reports of dysrhythmias, including death in a patient who took mefloquine and halofantrine (SEDA-20, 260) (SEDA-21, 295). Dysrhythmias due to halofantrine may respond to propranolol (5).

African children who received halofantrine (three doses of 8 mg/kg 6-hourly) for uncomplicated *P. falciparum* malaria had increases in both the PR interval and the QT_c interval; out of 42 children in the study, two children developed first-degree heart block and one child second-degree heart block; the QT_c interval either increased by more than 125% of baseline value or by more than 0.44 seconds (an effect that persisted for at least 48 hours) (6).

There have been recent reports in the French medical press of cases of significant QT_c prolongation in children returning to France, and caution in its use has been urged (7). A small trial in non-immune adults in the Netherlands and France also showed increased QT_c dispersion with halofantrine but not artemether + lumefantrine (8).

- Death due to a dysrhythmia was reported in a woman who had taken halofantrine for malaria (9). She had a normal electrocardiogram before treatment and no family history of heart disease.

Prolongation of the QT interval occurred in 10 of 25 children treated with halofantrine (24 mg/kg oral suspension in three divided doses) for acute falciparum malaria (10).

Electrocardiographic monitoring is recommended for children and adults taking halofantrine.

Gastrointestinal

Gastrointestinal adverse effects are more common with halofantrine than with other antimalarial drugs (11).

Immunologic

Anaphylactic shock has been attributed to halofantrine (12).

Long-Term Effects

Drug tolerance

Early laboratory studies suggested cross-resistance of halofantrine with mefloquine. In rats, parasites that are resistant to mefloquine, quinine, chloroquine, and amodiaquine are also markedly resistant to halofantrine (13).

Susceptibility Factors

Pre-existing cardiac conduction abnormalities, including those induced by other drugs, are a definite risk. Due consideration should be given not only to the half-life of such drugs, but also to the tissue concentrations and total clearances of the agents involved.

Drug Administration

Drug formulations

Halofantrine is available in a micronized form. Early information suggested that this improved absorption, but two later studies provided conflicting evidence: there was a wide range of serum concentrations of halofantrine and its main metabolite *N*-desbutylhalofantrine after the administration of half of the standard dose (2) or the usual dose of 500 mg given three times with 6-hour intervals (3). In general, concentrations were similar to those obtained with the older formulation. Taking the drug with food is thought to increase absorption.

Food–Drug Interactions

Grapefruit juice

Since halofantrine is metabolized to *N*-debutyl-halofantrine by CYP3A4, grapefruit juice increases its systemic availability (14). Twelve healthy men and women took halofantrine 500 mg with water, orange juice, or grapefruit juice (250 ml/day for 3 days and once 12 hours before halofantrine) in a crossover study. Compared with water, grapefruit juice significantly increased halofantrine AUC

© 2006 Elsevier B.V. All rights reserved.

and C_{max} 2.8-fold and 3.2-fold respectively; there was no significant change in half-life. Maximum QT_c interval prolongation increased significantly from 17 ms when halofantrine was taken with water to 31 ms when it was taken with grapefruit juice. Grapefruit juice should be avoided by patients taking halofantrine.

Halogenated quinolines

General Information

The halogenated quinolines include clioquinol (iodochlorohydroxyquinoline), diiodohydroxyquinoline, broxyquinoline, and chlorquinaldol (all rINNs). Once regarded as a prophylactic and remedy for simple diarrhea, some of them remain in limited use for special purposes, notably for the treatment of amebiasis when no alternative is available.

A major epidemic of subacute myelo-optic neuropathy (SMON) in Japan during 1956–70 was identified as being due to clioquinol, which led to the withdrawal of halogenated quinolines in Japan itself and subsequently elsewhere. There is every reason to believe that the adverse effects seen with clioquinol can occur with the other hydroxyquinolines, but some of them are still sold freely in various parts of the world (1).

Organs and Systems

Nervous system

DoTS classification (BMJ 2003;327:1222–5)
- Adverse reaction: subacute myelo-optic neuropathy
- Dose-relation: collateral effect
- Time-course: intermediate
- Susceptibility factors: genetic (?Japanese more susceptible)

There was a major epidemic of subacute myelo-optic neuropathy (SMON) in Japan during 1956–70. In 1970 a clinical observation led to case-control and cohort studies, which identified clioquinol as the culprit. A few cases were also reported elsewhere in the world, in Australia (2), Denmark (3), the Netherlands (4), Sweden (5–7), Switzerland (8), the UK (9–11), and the USA (12); some cases involved halogenated quinolines other than clioquinol. Prolonged use of diiodohydroxyquinoline in high doses has been associated with loss of vision and optic atrophy (SED-11, 594) (13). Halogenated quinolines were withdrawn in Japan and the epidemic abated (14).

The main abdominal symptoms of SMON are diarrhea and abdominal pain, sometimes accompanied by nausea, vomiting, constipation, a bloated feeling in the abdomen, and meteorism. The neurological symptoms are acute or subacute in nature; sensory disturbances are characteristic and spread gradually from the feet up to the navel. Some 20–40% of cases have visual disturbances ranging from blurred vision to atrophy of the optic nerve and blindness. There is a wide range of mental symptoms.

© 2006 Elsevier B.V. All rights reserved.

The clearest proof of the cause-and-effect relation in Japan was the finding of clioquinol chelates in the green furring of the tongue and the greenish urine. There has been no clear explanation for the much higher incidence of cases in Japan than elsewhere, but several hypotheses have been suggested (15).

The risk is related to dose and duration of therapy (16):

- at a dose of 750 mg/day for less than 4 weeks there is little risk
- at a dose of 750–1500 mg/day for less than 2 weeks the risk is about 1%
- at a dose of 750–1500 mg/day for more than 2 weeks the risk is about 35%
- a dose of 1800 mg/day can cause symptoms within 5 days
- higher doses can cause symptoms within 24 hours.

The events in Japan, where the total of documented cases was some 10 000 (17), have been fully documented in earlier volumes from 1968 onwards (see for example SEDA-4, 253). Little further evidence has since accumulated, despite a major international conference at Kyoto, Japan, in April 1979 to examine the evidence. Since the withdrawal of such drugs in Japan descriptions of large numbers of new cases have ceased. The effect should now be largely of historical interest, but the condition continues to be reported very sporadically (SEDA-10, 326).

Endocrine

Diiodohydroxyquinoline can slightly enlarge the thyroid gland (18).

Hematologic

Thrombocytopenia has (unconvincingly) been ascribed to topical clioquinol (19).

Drug Administration

Drug administration route

Up to 40% of topically applied clioquinol can be absorbed percutaneously in man (20). Formulations that contain clioquinol are often used to treat diaper rash; in a child of 10 kg treated with 1 g of clioquinol 3% tds, the amount of drug applied would be 9 mg/kg/day. However, it is possible that in infants with diaper rashes the actual absorption of the drug would be over 40%, since absorption through inflamed skin occurs more readily than through intact skin, and infant skin is more permeable than adult skin (21).

In dogs treated with 5 g of a topical clioquinol 3% formulation twice daily over 28 days (about 17 mg/kg/day) there was significant toxicity (loss of weight, lethargy, paralysis, hepatotoxicity) (22).

uridine diphosphoglucose glucuronosyltransferase (1). It is mainly cleared by glucuronidation.

There has been a randomized, placebo-controlled comparison of haloperidol (mean dose 1.8 mg/day), trazodone (200 mg/day), and behavior management techniques in 149 patients with Alzheimer's disease (2). Although 34% of the subjects improved relative to baseline, there were no significant differences in outcomes among the four arms; there were significantly fewer cases of bradykinesia and parkinsonian gait in those given behavioral therapy. These results suggest that other treatments for agitation in dementia need to be considered and evaluated; likewise, they are consistent with the results of a meta-analysis (3) and a clinical trial (4).

Haloperidol 2–3 mg/day and 0.50–0.75 mg/day have been compared in 71 outpatients with Alzheimer's disease (5). After 12 weeks, there was a favorable therapeutic effect of haloperidol 2–3 mg/day, although 25% of the patients developed moderate to severe extrapyramidal signs.

A thorough review of the pharmacokinetics of haloperidol, with special emphasis on interactions, has been published (1).

Organs and Systems

Cardiovascular

Intravenous haloperidol is often prescribed to treat agitation, and torsade de pointes has on occasions occurred (SEDA-20, 36). In a cross-sectional cohort study QT_c intervals were measured before the intravenous administration of haloperidol plus flunitrazepam, and continuous electrocardiographic monitoring was performed for at least 8 hours after ($n = 34$) (6); patients who received only flunitrazepam served as controls. The mean QT_c interval after 8 hours in those who were given haloperidol was longer than in those who were given flunitrazepam alone; four patients given haloperidol had a QT_c interval of more than 500 ms after 8 hours. However, none developed ventricular tachydysrhythmias.

In a case-control study, haloperidol-induced QT_c prolongation was associated with torsade de pointes (7). The odds ratio of developing torsade de pointes in a patient with QT_c prolongation to over 550 ms compared with those with QT_c intervals shorter than 550 ms was 33 (95% CI = 6, 195). The sample consisted of all critically ill adult patients in medical, cardiac, and surgical intensive care units at a tertiary hospital who received intravenous haloperidol and had no metabolic, pharmacological, or neurological risk factors known to cause torsade de pointes, or if the dysrhythmia developed more than 24 hours after intravenous haloperidol. Of 223 patients who fulfilled the inclusion criteria, eight developed torsade de pointes. A group of 41 patients, randomly selected from the 215 without torsade de pointes, served as controls. The length of hospital stay after the development of haloperidol-associated torsade de pointes was significantly longer than that after the maximum dose of intravenous haloperidol in the control group. The overall incidence of torsade de pointes was 3.6% and 11% in patients who received intravenous haloperidol 35 mg or more over 24 hours.

Several cases of torsade de pointes have been reported with intravenous haloperidol used with low-dose oral haloperidol (8).

The effects of haloperidol dose and plasma concentration and CYP2D6 activity on the QT_c interval have been studied in 27 Caucasian patients taking oral haloperidol (aged 23–77 years, dosages 1.5–30 mg/day) (9). Three patients had a QT_c interval longer than 456 ms, which can be considered as the cut-off value for a risk of cardiac dysrhythmias. There was no correlation between QT_c interval and haloperidol dosage or plasma concentrations or CYP2D6 activity.

Asystolic cardiac arrest has been reported after intravenous haloperidol (10).

In one case, the use of carbamazepine and haloperidol led to prolongation of the QT_c interval and cardiac complications (11).

- A 75-year-old man developed ventricular fibrillation and cardiac arrest after intravenous haloperidol (12). His past history included coronary bypass surgery and coronary angioplasty. As he continued to have severe chest pain, emergency angioplasty was performed. On day 3 he received haloperidol by infusion 2 mg/hour, with 2 mg increments every 10 minutes (up to 20 mg in 6 hours) as needed for relief of agitation. Before haloperidol, his QT_c interval was normal; after haloperidol it increased to 570 ms. The next day he developed ventricular fibrillation. Subsequent electrocardiograms showed prolonged QT_c intervals of 579 and 615 ms, and haloperidol was withdrawn; the QT_c returned to normal.
- A 76-year-old man developed torsade de pointes while taking tiapride 300 mg/day; the QT_c interval 1 day after starting treatment was 600 ms; the dysrhythmia resolved when tiapride was withdrawn (13).
- A 39-year-old man died suddenly 1 hour after taking a single oral dose of haloperidol 5 mg (14). He had myasthenia, alcoholic hepatitis, and electrolyte abnormalities due to inadequate nutritional state. His electrocardiogram showed prolongation of the QT_c interval (460 ms). Autopsy showed a cardiomyopathy but no explanation for sudden death.

However, malignant dysrhythmias can occur without changes in the QT interval (SEDA-24, 54).

- A 64-year-old woman underwent coronary artery bypass surgery and was given intravenous haloperidol for agitation and to avoid postoperative delirium; she developed torsade de pointes (15).
- Asystolic cardiac arrest occurred in a 49-year-old woman after she had received haloperidol 10 mg intramuscularly for 2 days; no previous QT_c prolongation had been observed (16).

Respiratory

A single case of fatal pulmonary edema was reported in 1982 in association with haloperidol (17).

Nervous system

Three cases of radial nerve palsy were reported in demented elderly patients confined to wheelchairs who were treated with haloperidol. The combination of

© 2006 Elsevier B.V. All rights reserved.

extrapyramidal and sedative adverse effects, added to wheelchair confinement, may have resulted in pressure on the upper arm with subsequent neuropathy (18).

Extrapyramidal effects

- A 28-year-old woman simultaneously developed four types of tardive extrapyramidal symptoms (dystonia, dyskinesia, choreoathetotic movements, and myoclonus) while taking haloperidol; the symptoms were subsequently relieved by the use of low-dose risperidone (3 mg/day) (19).

Akathisia

A nocturnal eating/drinking syndrome secondary to neuroleptic drug-induced restless legs syndrome has been attributed to low-dose haloperidol in a 51-year-old schizophrenic woman (20).

Neuroleptic malignant syndrome

Neuroleptic malignant syndrome has been reported with haloperidol (21).

- A 21-year-old Turkish man with succinic semialdehyde dehydrogenase deficiency and mental retardation developed neuroleptic malignant syndrome after a single dose of haloperidol 10 mg for anxiety and agitation, having never received a neuroleptic drug before.

Several reports have suggested a higher incidence and severity of extrapyramidal symptoms during haloperidol treatment in congenitally poor metabolizers of substrates of CYP2D6 and a patient with a poor metabolizer polymorphism of the CYP2D6 gene developed neuroleptic malignant syndrome after receiving haloperidol (22). All frequent polymorphisms of CYP2D6 were therefore investigated in the second patient, who was a carrier of the wild-type genotype CYP2D6 *1/ *1, which is common in subjects of Caucasian origin. The authors concluded that a genetic defect of haloperidol metabolism via CYP2D6 was unlikely as a reason for the neuroleptic malignant syndrome in this case.

Endocrine

The relation of prolactin concentrations and certain adverse events has been explored in large randomized, double-blind studies. In 813 women and 1912 men, haloperidol produced dose-related increases in plasma prolactin concentrations in men and women, but they were not correlated with adverse events such as amenorrhea, galactorrhea, or reduced libido in women or with erectile dysfunction, ejaculatory dysfunction, gynecomastia, or reduced libido in men (23).

No further rise in plasma prolactin concentration was observed with dosages of haloperidol over 100 mg/day, which was explained as being related to saturation of the pituitary dopamine receptors by a modest amount of haloperidol (24).

The time-course of the prolactin increase has been examined in 17 subjects whose prolactin concentrations rose during the first 6–9 days of treatment with haloperidol (25). The increase was followed by a plateau that persisted, with minor fluctuations, throughout the 18 days of observation. Patients whose prolactin concentrations increased above 77 ng/ml ($n = 2$) had hypothyroidism, and it is known that TRH (thyrotropin) stimulates the release of prolactin (26).

The effects of haloperidol and quetiapine on serum prolactin concentrations have been compared in 35 patients with schizophrenia during a drug-free period for at least 2 weeks in a randomized study (27). There was no significant difference in prolactin concentration between the groups at the start of the study; control prolactin concentrations were significantly lower with quetiapine than with haloperidol. Two patients taking haloperidol had galactorrhea related to hyperprolactinemia.

Metabolism

Glucose metabolism has been studied in 10 patients taking haloperidol; none had impaired glucose tolerance and only one had a glycemic peak delay (28).

Liver

Occasional reports of cholestatic jaundice with haloperidol have been published (29,30).

Urinary tract

Retroperitoneal fibrosis has been attributed to haloperidol; since this condition affects the kidney, it should be differentiated from other causes of obstructive uropathy (31).

Skin

Haloperidol has been reported to have caused skin rashes.

- A 41-year-old man who had been taking weekly methotrexate 15 mg for 10 months for psoriasis started to take haloperidol 1.5 mg bd for a psychotic illness, and 2 weeks later developed sudden redness and swelling of the face and hands accompanied by redness and watering of both eyes (32). He had diffuse erythema, edema, scaling, and erosions over his face, the anterior aspect of the neck, and the backs of both hands. A skin biopsy showed parakeratosis, acanthosis, spongiosis, focal epidermal cell degeneration, and dermal edema, accompanied by a moderate lymphomononuclear infiltrate, consistent with subacute dermatitis. A diagnosis of pellagra-like photosensitivity dermatitis, caused by combined deficiency of niacin, riboflavin, and other water-soluble vitamins, probably precipitated by haloperidol, was therefore considered. Haloperidol was withdrawn, vitamins were administered, and the condition resolved in the next 5 days.
- A 55-year-old man who had been treated for a manic-depressive disorder for about 5 years developed toxic epidermal necrolysis after being given carbamazepine and haloperidol (33).

Sexual function

Sexual dysfunction can occur with neuroleptic drugs (SED-14, 149) (SEDA-22, 54) (34,35).

- A 49-year-old man with bipolar disorder had erectile dysfunction shortly after starting to take haloperidol 50 mg/day and lithium 1500 mg/day (36). Before this he had had normal sexual function. After 2 months, the dosage of haloperidol was reduced to 20 mg/day, but the sexual dysfunction persisted and did not

© 2006 Elsevier B.V. All rights reserved.

improve with sildenafil. He was then switched to olanzapine 10 mg/day and lithium 1200 mg/day and 1 week later his sexual dysfunction had disappeared.

Second-Generation Effects

Pregnancy

Although studies have failed to identify an increased rate of malformations with haloperidol, isolated cases have been reported (SED-14, 152) (37) (SEDA-22, 54) (38,39).

Teratogenicity

Several instances of limb reduction after the use of haloperidol during pregnancy suggest that it would be prudent not to use this drug during the first trimester, the period of limb development (37). There is also reason to argue that prenatally administered drugs of this class influence the offspring after the drug has been eliminated, and can produce behavioral teratogenicity; since neurotransmitter systems continue to develop long after birth, such drugs might influence behavior in an adverse way over a very long time (40).

Fetotoxicity

A neonate had severe hypothermia after antenatal exposure to haloperidol (41). He weighed 3710 g at birth and did not need resuscitation; his axillary temperature was 35°C and he had severe generalized hypotonia. His temperature rose to 36.5°C after 6 hours of rewarming with an overhead radiant heater.

Drug Administration

Drug additives

General allergic reactions have also been reported following injections of parabens-containing formulations of lidocaine and hydrocortisone and after oral use of barium sulfate contrast suspension, haloperidol syrup, and an antitussive syrup, all of which contained parabens (42).

Drug–Drug Interactions

General

Based on published data in humans, concomitant medications were classified as potential inhibitors (cimetidine, fluoxetine, levopromazine, paroxetine, and thioridazine) or inducers of haloperidol metabolism (carbamazepine, phenobarbital, and phenytoin).

Alcohol

Haloperidol increased blood alcohol concentrations (43).

Anticoagulants

Haloperidol has been reported to lower anticoagulant effectiveness through enzyme induction (44).

Buspirone

Buspirone increases haloperidol concentrations in some patients (SEDA-21, 39).

Carbamazepine

Haloperidol inhibits the metabolism of carbamazepine. In Japanese patients with schizophrenia, serum concentrations of carbamazepine were about 40% lower in the absence of haloperidol (45).

Chlorpromazine

- A 40-year-old man with schizophrenia developed a raised plasma concentration of haloperidol in combination with chlorpromazine and during overlap treatment with clozapine (46). Like haloperidol, chlorpromazine is a competitive inhibitor of CYP2D6; however, clozapine appears to be largely metabolized by CYP1A2.

Itraconazole

Adverse effects can result from increased plasma concentrations of haloperidol during itraconazole treatment. This has been observed in 13 schizophrenic patients treated with haloperidol 12 or 24 mg/day who took itraconazole 200 mg/day for 7 days (47). Plasma concentrations of haloperidol were significantly increased and neurological adverse effects were more common. Itraconazole is a potent inhibitor of CYP3A4.

Lithium

Persistent dysarthria with apraxia has been reported with a combination of lithium carbonate and haloperidol (48).

Lorazepam

Several cases of torsade de pointes have been reported with intravenous haloperidol used with lorazepam to treat delirium (SEDA-18, 30) (SEDA-18, 47). Acid mucopolysaccharide deposition may be associated with neuroleptic drug treatment as a possible mechanism contributing to rare cardiovascular adverse events (49).

Methyldopa

Dementia occurred when methyldopa was combined with haloperidol (50).

Nefazodone

Hepatic enzyme inhibition by nefazodone can significantly raise concentrations and toxicity of haloperidol (1).

Valproate

An interaction between valproate and haloperidol has been reported (51).

- A 30-year-old man with bipolar affective disorder was given intravenous sodium valproate 20 mg/kg/day without any major problem. Later, he was given oral haloperidol 10 mg bd for persistent aggressive behavior and manic symptoms. The next day he developed a sense of imbalance and started swaying. He was drowsy and had cerebellar ataxia. Haloperidol was withdrawn and

© 2006 Elsevier B.V. All rights reserved.

within 1 day his ataxia had disappeared completely in spite of continuing valproate.

Food–Drug Interactions

Grapefruit inhibits CYP3A4, but in one study there was no interaction with haloperidol (52).

Smoking

The extent to which smoking, the genotype for CYP2D6, and the concomitant use of enzyme inducers or inhibitors can explain variations in steady-state plasma concentrations of haloperidol has been evaluated in 92 patients (53). Smokers were treated with higher doses of haloperidol than non-smokers, supporting the view that smokers require larger doses of neuroleptic drugs than non-smokers to achieve therapeutic effects. Poor metabolizers had higher concentrations of haloperidol metabolites, but not of haloperidol, than extensive metabolizers. Altogether, the patients took about 150 different drugs; compared with the rest of the group, there was a tendency for patients taking inducers to be treated with slightly higher doses of haloperidol on average and to have lower dose-normalized plasma concentrations of haloperidol, although the differences were not significant.

Halothane

See also General anesthetics

General Information

Halothane is a non-inflammable hydrocarbon that induces anesthesia, with little tendency to excitement. Contrary to earlier assumptions, halothane is metabolized, the consequences of which are discussed below (1,2).

Organs and Systems

Cardiovascular

Halothane, isoflurane, and sevoflurane are potent coronary vasodilators, able to produce some degree of coronary steal in ischemic regions. Despite this, halothane may preferentially dilate large coronary arteries and/or interfere with platelet aggregation. If these experimental effects are confirmed, halothane may be the anesthetic of choice in the non-failing ischemic heart (3).

Halothane has a mild depressive effect on cardiac performance (4). In human ventricular myocardium, halothane interacted with L-type calcium channels by interfering with the dihydropyridine binding site; this may, at least in part, explain its negative inotropic effect (5).

Halothane depressed cardiovascular function significantly more than isoflurane in younger adults, but the falls in systolic and diastolic blood pressures in elderly patients were significantly greater with isoflurane (6).

Cardiac dysrhythmias

Halothane produces bradycardia, but dysrhythmias, most often ventricular in origin, also occur during maintenance of anesthesia. They were noted in 53% of 679 patients (7). Concomitant administration of catecholamines increases the risk of dysrhythmias.

Bundle branch block and aberrant conduction were noted in children during halothane anesthesia (8).

In a double-blind, randomized, controlled study of 77 children undergoing halothane anesthesia for adenoidectomy, the effects of atropine 0.02 mg/kg, glycopyrrolate 0.04 mg/kg, and physiological saline were compared (9). There was no difference in the incidence of ventricular dysrhythmias. Atropine prevented bradycardia but was associated with sinus tachycardia in most patients. The bradycardias that occurred in the groups that received glycopyrrolate or placebo were short-lived and resolved spontaneously.

Pulsus alternans in association with hypercapnia occurred in a study of 120 patients who breathed spontaneously during halothane anesthesia (10). End-tidal

© 2006 Elsevier B.V. All rights reserved.

carbon dioxide concentration was allowed to rise freely until pulsus alternans or other cardiac dysrhythmias occurred. Ten of the patients developed pulsus alternans, which was promptly relieved on institution of positive pressure ventilation and the return of end-tidal carbon dioxide concentration to normal. The mechanism and the significance of this phenomenon are not well understood.

Respiratory

Halothane is not irritant to the respiratory tract. Respiratory depression is a consequence only of high concentrations of halothane. A certain degree of bronchodilatation is observed, and may explain the fact that a beneficial effect of halothane was described in a 17-year-old woman with acute severe asthma who did not respond to conventional treatment (11).

Preterm infants can become apneic during the immediate postoperative period, even if the ventilatory response to CO_2 is not depressed after halothane anesthesia (12). In a prospective study in 167 preterm infants after inguinal herniorrhaphy with halothane/nitrous oxide anesthesia, only one had an episode of apnea up to 2 days postoperatively; however, the authors recommended careful monitoring until complete recovery from anesthesia has occurred (13).

Nervous system

In contrast to enflurane, cerebral irritability is very rare with halothane (14).

Halothane can cause an increase in intracranial pressure (15), as can other inhalational anesthetics, which can constitute a particular risk if the pressure is already raised before anesthesia. In neonates, the intracranial pressure may fall (16).

A child who underwent induction of anesthesia with halothane developed hiccups associated with pulmonary edema (17).

- An 8-year-old girl with a history of seizures and cerebral ischemic strokes secondary to moyamoya disease underwent anesthetic induction with halothane and 70% nitrous oxide. She had had three previous uneventful anesthetics. Hiccups started within seconds of induction of anesthesia and did not cease until 20 minutes later, when she was paralysed, intubated, and ventilated. During the next 20 minutes a period of hemodynamic instability ensued, with increasing oxygen requirements. The procedure was stopped and pulmonary edema was confirmed on chest X-ray. The child was transferred to the intensive care unit and ventilated overnight. Further recovery was uneventful.

Hiccups during anesthesia are often thought to be benign. Negative pressure pulmonary edema is usually associated with an obstructed airway, as occurs with laryngospasm, or other causes of upper airway obstruction, but was presumably the cause in this child.

The effect of increasing and decreasing concentrations of halothane on the cerebral circulation in 11 young children (aged 4 months to 3.5 years) undergoing minor urological surgery under general relaxant and caudal anesthesia has been studied (18). Cerebral blood flow velocity was measured in the middle cerebral artery using transcranial Doppler ultrasound. There was significantly increased cerebral blood flow velocity when the dose was increased from 0.5 to 1.0 minimum alveolar concentration (MAC) and from 0.5 to 1.5 MAC, but not when it was increased from 1.0 to 1.5 MAC. When the halothane concentration was reduced from 1.5 to 1.0 MAC, cerebral blood flow velocity fell significantly, whereas there was no effect when the concentration was reduced from 1.0 to 0.5 MAC. These results suggest that there is cerebrovascular hysteresis in response to increasing and decreasing concentrations of halothane.

Psychological, psychiatric

Slight depression of mood, lasting up to 30 days, along with a non-specific slowing of the electroencephalogram for 1–2 weeks, was observed after halothane. In 16 healthy young men, halothane anesthesia had negative effects on postoperative mood and intellectual function, the changes being greatest 2 days after anesthesia, with restoration of function after 8 days (19). In seven subjects, serial electroencephalography, serum bromide determinations, and psychological tests before and after halothane anesthesia showed that there was significant psychological impairment 2 days after anesthesia (20).

The effect of a single preoperative dose of the opioid oxycodone on emergence behavior has been studied in a randomized trial in 130 children (21). Oxycodone prophylaxis, compared with no premedication, significantly reduced the incidence of post-halothane agitation.

Mineral balance

Halothane can cause an increase in circulating concentrations of bromide and fluoride (20), which can be associated with impaired urine-concentrating ability in response to antidiuretic hormone (22).

Hematologic

Halothane produced inhibition of in vitro platelet aggregation and an increase in bleeding time (23).

Gastrointestinal

Postoperative nausea and vomiting can occur after halothane anesthesia (24). In one series, postoperative vomiting occurred in 13 of 29 patients who had received halothane for induction, but when dyxirazine was added during anesthesia the incidence of postoperative vomiting was significantly reduced (three of 29 patients) (25).

Liver

The greatest disadvantage of halothane is its ability to cause liver damage (26).

Incidence

The death rate due to halothane-induced liver damage was estimated in 1993 at one in 35 000 anesthetics (27), three times greater than the one in 110 000 incidence reported in 1976 (28). Both immune function and the metabolism of halothane play important roles in the pathophysiology of liver damage (29). Human hepatic microsomal carboxylesterase is a target antigen in halothane hepatitis, protein disulfide isomerase is an important factor in the mechanism of liver impairment, and an associated immune response

© 2006 Elsevier B.V. All rights reserved.

may be involved (SEDA-18, 116). So-called halothane-induced liver antigens are novel antigens found in the livers of some individuals who have been exposed to halothane, but not in the livers of unexposed individuals (30).

A retrospective review of the case-notes of 44 patients with drug-induced hepatotoxicity diagnosed in 1978–96 found only one case attributable to halothane (31). Antibiotics, non-steroidal anti-inflammatory drugs, and psychotropic drugs accounted for 73% of the cases.

Mechanisms

The mechanisms by which halothane causes hepatic toxicity have been reviewed (32). Oxidative metabolism of halothane to trifluoroacetate occurs in the liver, probably via CYP2E1. In rats, trifluoroacetylated CYP2E1 has been identified after exposure to halothane, as has antibody formation to this antigen (33). Covalent binding of halothane (34), after its activation to the trifluoroacetyl halide, to proteins in human liver microsomes has also been shown (35). It has been suggested that some genetic factor determines the risk of developing halothane hepatitis (36). A report of halothane hepatitis in three pairs of closely related women (37) raised the possibility of a pharmacogenetic defect in these patients, with increased production of hepatotoxic metabolites.

Most recorded cases of liver disorders occurred after either repeated exposure (38) or prolonged exposure (39) to halothane. In one case, hepatitis developed 3 weeks after a single halothane anesthetic in a 37-year-old renal transplant recipient who had previously been exposed to isoflurane (40); this report suggests that previous exposure to isoflurane may predispose to subsequent halothane toxicity.

Halothane also reduces liver blood flow during anesthesia, and this could increase the release of potentially hepatotoxic halothane metabolites. The role of reduced halothane metabolites and inorganic fluoride, which may covalently link to liver macromolecules, has been stressed; in keeping with this hypothesis is the observation of halothane hepatitis in patients who simultaneously take enzyme-inducing agents, for example barbiturates (41) or rifampicin (42).

It is therefore tempting to suggest that patients with one or several predisposing factors, for example a pharmacogenetic trait, hepatic hypoxia, or enzyme induction, are likely to produce large amounts of hepatotoxic halothane metabolites that covalently bind to liver macromolecules, rendering them immunogenic. The finding that repeated administration increases the risk of halothane jaundice (43,44) supports this hypothesis.

Presentation

Two patterns of liver damage associated with halothane have been observed (45). One pattern is a mild derangement of liver enzymes, which occurs in about one in four anesthetics. The other pattern is rare but is associated with severe hepatitis, often resulting in fulminant liver failure. This severe form occurs more often in middle-aged, obese women, usually after multiple anesthetics, and is known as halothane hepatitis. It is defined as unexplained severe liver damage occurring within 28 days of halothane exposure in a person with a previously normal liver, and it occurs in 1:35 000 halothane exposures. With repeated exposure to halothane within 1 month, the frequency of acute liver failure increases to 1:3700. The overall incidence of halothane hepatitis is falling, owing to reduced use of halothane. Survival after liver transplantation in patients with fulminant hepatic failure is lower than that after liver transplantation for other reasons.

A case of halothane hepatitis has been reported in a child (46).

- A 6-year-old boy sustained pelvic injuries and a femoral fracture. The first anesthetic he received consisted of thiopental, suxamethonium, isoflurane, and nitrous oxide. He also received two units of blood. He subsequently underwent four halothane anesthetics over 6 weeks for dilatation of a urethral stricture. Two days after the last anesthetic he was noted to be jaundiced. He had a negative viral screen but was positive for antitrifluoroacetyl IgG antibodies. He developed fulminant hepatic failure with grade 2 hepatic encephalopathy and underwent an auxiliary liver transplantation 24 days after his last exposure to halothane. He died of septicemia 18 days later. Both at autopsy and on a previous hepatobiliary scan he was noted to have had extensive native liver regeneration.

Halothane hepatitis in children is rare, and occurs in 1:82 000 to 1:200 000 exposures. Children as young as 11 months are not exempt from the risk, contrary to what was once thought and there is a growing number of reports of halothane hepatitis in children (47). It has been noted that sevoflurane is not metabolized to trifluoroacetic acid and may prove to be a better alternative for repeated anesthesia in children (48).

A retrospective review of the case-notes of 44 patients with drug-induced hepatotoxicity diagnosed in 1978–96 found only one case attributable to halothane (31). Antibiotics, non-steroidal anti-inflammatory drugs, and psychotropic drugs accounted for 73% of the cases.

Urinary tract

Renal blood flow, glomerular filtration rate, and urinary volume are sometimes mildly and reversibly reduced. In contrast, repeated massive polyuria has been reported in a 46-year-old man after two anesthetics with halothane (49). Acute renal insufficiency has been described (50) but is rare.

Skin

A young nurse complained of a skin rash with edema of the eyelids after repeated professional exposure to halothane (51).

Immunologic

Halothane can suppress host defence mechanisms; the clinical consequences are unclear (SED-11, 210) (SEDA-3, 101) (SEDA-4, 77) (SEDA-5, 121) (SEDA-11, 109).

Body temperature

Halothane reduces body temperature and can cause shivering, although active thermoregulation does not occur

© 2006 Elsevier B.V. All rights reserved.

until the core temperature is reduced by 2.5°C (52). The shivering can be attenuated by flumazenil, despite a lower core temperature (53).

Halothane in association with suxamethonium is the most frequent cause of malignant hyperthermia attributed to general anesthesia (54). Standard in vitro caffeine-halothane contracture testing was performed on 32 patients with a past history of malignant hyperthermia diagnosed on clinical grounds; they were compared with a matched control group of 120 subjects who were considered clinically to be at low risk of malignant hyperthermia (55). The sensitivity of the test was 97% and the specificity 78%.

Second-Generation Effects

Pregnancy

Halothane strongly reduces uterine contractility during labor (56).

Fetotoxicity

Halothane can be used as an anesthetic by maternal inhalation for fetal surgery and improves surgical exposure by relaxing the uterus. However, the effects of halothane on fetal cardiovascular homeostasis have been evaluated, and the authors concluded that halothane had a significant negative effect on the fetal heart and peripheral vasculature; it was therefore considered a poor anesthetic for this purpose (57).

Lactation

Halothane is readily excreted into breast milk (58).

Drug Administration

Drug administration route

In a randomized, double-blind, placebo-controlled comparison of intranasal and intramuscular atropine in 80 children, the intranasal route was equally effective at preventing halothane-induced bradycardia (59).

Drug overdose

Suicide attempts with halothane have sometimes succeeded, but in patients who recovered there was no residual damage. A 4-year-old boy was accidentally given halothane intravenously; he recovered fully within a few hours (60). Accidental intravenous injection and illicit inhalation have both caused pulmonary edema (61).

Drug–Drug Interactions

Disulfiram

Disulfiram is an inhibitor of CYP2E1. In 20 patients undergoing halothane-based maintenance of anesthesia at an end-tidal concentration of 1% for an average of 3 hours, disulfiram 500 mg taken the night before substantially attenuated trifluoroacetate production, as judged by its urinary excretion (62). It was suggested that a single dose of disulfiram may provide effective prophylaxis against halothane hepatitis.

Non-depolarizing muscle relaxants

Halothane potentiates the effects of non-depolarizing muscular relaxants (SED-11, 210) (63).

Helicobacter pylori eradication regimens

General Information

Drugs and regimens for *Helicobacter pylori* eradication have been reviewed (1,2). The major factor in choosing an antibiotic regimen is the pattern of antibiotic resistance in the community. Generally two antimicrobial drugs plus bismuth or ranitidine or a proton pump inhibitor such as omeprazole are required to achieve a cure rate of over 90% and avoid the resistance that occurs when clarithromycin or metronidazole is the single antimicrobial used. In regions where metronidazole and clarithromycin resistance is common initial quadruple therapy with bismuth, metronidazole, tetracycline, and a proton pump inhibitor is recommended. In general, higher doses and longer duration of therapy are associated with better outcomes. Although therapy for 1 week has become accepted in first-line regimens, therapy for 2 weeks is better when treating nitroimidazole-resistant or clarithromycin-susceptible strains.

Adverse effects of these regimens are related to the individual drugs used.

Comparative studies

The MACH-2 study has assessed the role of omeprazole in triple therapy in 539 patients with duodenal ulcers associated with *H. pylori* (3). The addition of omeprazole resulted in significantly higher eradication rates (over 90%) than antibiotics alone (amoxicillin plus clarithromycin about 25%; clarithromycin plus metronidazole 70%), and reduced the impact of primary resistance to metronidazole. About one-third of the patients who took amoxicillin reported diarrhea/loose stools. The frequency of taste disturbance was dose-dependent with clarithromycin. Increased liver enzymes were more commonly reported in those taking metronidazole. The addition of omeprazole did not increase the frequency of reported adverse effects.

The DU-MACH study assessed the efficacy of two omeprazole-based triple therapies (omeprazole, amoxicillin, clarithromycin versus omeprazole, metronidazole, clarithromycin) given for 1 week to 149 patients for eradicating *H. pylori*, healing duodenal ulcers, and preventing ulcer relapse over 6 months after treatment (4). Both regimens achieved high eradication rates (about 90%) and were well tolerated. Adverse effects were similar in the two groups, and included diarrhea, taste disturbance, headache, nausea, and dyspepsia.

Ranitidine 300 mg bd and omeprazole 20 mg bd have been compared as components of triple therapies (combining them with either amoxicillin plus clarithromycin or amoxicillin plus metronidazole) in 320 patients with *H. pylori* (5). Omeprazole and ranitidine combined with two antibiotics for 1 week were equally effective in eradicating *H. pylori*. This result questions the role of profound acid suppression in eradication. There was no difference in the reported adverse effects, which included nausea, vomiting, diarrhea, metallic taste, skin rashes, and headache.

In a similar study in 221 patients with peptic ulcer disease associated with *H. pylori*, rabeprazole has been compared with omeprazole and lansoprazole (combining them with amoxicillin plus clarithromycin for 1 week) (6). Rabeprazole was as effective as omeprazole and lansoprazole in eradicating *H. pylori* (84–88% each). There were no differences in reported adverse events. Common adverse effects were soft stools, glossitis, taste disturbances, and skin rashes.

Dual therapy (omeprazole plus clarithromycin) for 2 weeks has been compared with triple therapy (omeprazole plus amoxicillin and clarithromycin) for 1 week in the eradication of *H. pylori* in 145 patients with duodenal ulcers (7). Triple therapy was significantly more effective in eradicating *H. pylori* (71 versus 48%). There were no significant differences in compliance or adverse effects. The most frequent adverse effects were metallic taste and nausea in the dual-therapy group and metallic taste, mild abdominal pain, and diarrhea in the triple-therapy group.

Quadruple therapy (omeprazole, amoxicillin, roxithromycin, and metronidazole for 1 week) has been studied in an open trial in 169 patients with *H. pylori* (8). This regimen achieved an eradication rate of 92%. It was also beneficial in patients infected with pretreatment resistant strains to the antibiotics, in which cases the eradication rates achieved (over 90%) were similar to eradication rates in patients infected with sensitive strains. Compliance was good and there was only one serious adverse effect, anaphylaxis, probably due to amoxicillin. Frequent adverse effects were abdominal distension (10%), glossitis (9%), and diarrhea (8%).

Sucralfate 1 g tds in combination with amoxicillin 500 mg tds and clarithromycin 400 mg bd for 2 weeks was as effective as a combination of lansoprazole 30 mg bd plus amoxicillin 500 mg tds and clarithromycin 400 mg bd for 2 weeks for *H. pylori* eradication in a randomized, multicenter trial in 150 patients (9). There was no significant difference in adverse effects between the two groups. Diarrhea, abdominal pain, glossitis, and taste disturbance were the adverse effects commonly reported.

In an open trial, 7-day triple therapy with omeprazole 30 mg bd, amoxicillin 500 mg tds, and clarithromycin 400 mg bd was safe and effective in eradicating *H. pylori* in 12 of 13 patients undergoing hemodialysis (10). There were adverse effects in two patients (compared with three of 27 patients not undergoing hemodialysis) and treatment had to be discontinued in one, owing to severe nausea and vomiting.

Placebo-controlled studies

The effect of eradicating *H. pylori* in 20 patients with chronic idiopathic urticaria has been assessed in a

© 2006 Elsevier B.V. All rights reserved.

randomized, placebo-controlled trial (11). After 7 days of treatment with omeprazole 20 mg bd, amoxicillin 500 mg bd, and clarithromycin 500 mg bd *H. pylori* was eradicated in nine of 10 patients (compared with three of 10 in the placebo group) and there was a significant improvement in urticaria in four of these nine (compared with one of the seven in whom *H. pylori* was not eradicated). No serious adverse effects were reported in either treatment group.

In a randomized, controlled trial in 120 patients supplementation with inactivated *Lactobacillus acidophilus* tds significantly improved the efficacy of a standard 7-day regimen with rabeprazole 20 mg bd, clarithromycin 250 mg tds, and amoxicillin 500 mg tds (12). There was no significant difference in adverse effects between the two groups. Those reported were abdominal pain, nausea, and diarrhea.

In a randomized, placebo-controlled trial in 60 healthy, asymptomatic subjects who screened positive for *H. pylori*, supplementation with *Lactobacillus* GG twice daily for 14 days significantly reduced the adverse effects (diarrhea, nausea, taste disturbance) and improved the overall tolerability of a standard 7-day eradication regimen consisting of rabeprazole 20 mg bd, clarithromycin 500 mg bd, and tinidazole 500 mg bd (13).

Organs and Systems

Gastrointestinal

Pseudomembranous colitis has been reported in an 86-year-old woman with non-ulcer dyspepsia a few days after she had taken triple eradication therapy (omeprazole 20 mg bd, metronidazole 400 mg tds, and clarithromycin 500 mg bd); she recovered after treatment with oral vancomycin (14).

Susceptibility Factors

Age

The efficacy of triple therapy with bismuth plus amoxicillin and metronidazole has been assessed in an open trial in 26 children with duodenal ulcers associated with *H. pylori* (15). *Helicobacter pylori* was eradicated in 25 children and the ulcer was healed in 24. During a mean follow-up of nearly 2 years, the annual ulcer relapse rate was 9% (compared with 56% in historical controls, in whom the infection was not eradicated). Adverse events were reported by 13% of the children, and included diarrhea, dizziness, nausea, and vomiting.

Triple therapy with bismuth plus amoxicillin and metronidazole for 2 weeks has been compared with dual therapy with omeprazole plus amoxicillin for 2 weeks in 126 patients over the age of 60 years, who were *H. pylori* positive and had functional dyspepsia (16). Eradication rates were similar in the two groups 2 months after the end of therapy (66% with triple therapy and 64% with dual therapy), and there was a significant reduction in dyspeptic symptoms in patients in whom *H. pylori* was eradicated compared with those in whom infection persisted. Adverse effects were reported by 15% of patients who took triple therapy (nausea and metallic taste) compared with 4% of those who took dual therapy (nausea and headache). In all cases no adverse effect was severe enough to interrupt therapy.

Drug Administration

Drug dosage regimens

The effect of adding adherence-enhancing measures to triple therapy with omeprazole plus amoxicillin and metronidazole for 10 days has been studied in 119 Australian patients with *H. pylori* infection (17). The adherence-enhancing measures were:

- the provision of the medication in a dose-dispensing unit;
- the use of a medication chart;
- the provision of an information sheet about the treatment;
- a reminder by telephone 2 days after the start of therapy.

Ten days of triple therapy was effective for *H. pylori* eradication (85–90%) and patient adherence was excellent in both groups (97%). Attempts to improve adherence had no impact on outcome and adverse effects were common and were significantly associated with treatment failure and poor adherence to therapy in both groups. There were no significant differences in the adverse effects profiles. Female sex predicted more adverse effects. Two patients reported severe adverse effects, 19 reported moderate adverse effects, and 75 reported mild adverse effects. Common adverse effects included anorexia and nausea (35%), vomiting (7%), constipation (16%), diarrhea/flatulence (37%), abdominal pain/cramps (27%), a metallic taste (44%), headache/dizziness (48%), rash/itch (3%), lethargy/confusion (9%), and insomnia/agitation (4%). The authors attributed the unusually high prevalence of adverse effects to comprehensive reporting.

Hemin and heme arginate

General Information

Hemin (hematin), an exogenous source of heme, is used to treat acute intermittent porphyria and other hepatic porphyrias. It is generally well tolerated in the recommended doses, although thrombophlebitis, coagulation defects, circulatory collapse, and occasional renal insufficiency have been reported (1).

Thrombophlebitis is seen in up to 10% of patients, and this effect, as well as effects on coagulation (prolongation of the prothrombin and thromboplastin times, increased fibrin degradation products, and thrombocytopenia), may be caused by degradation products of hemin (2). There is evidence that slower infusion rates reduce the risk of adverse effects (3).

Heme arginate is more stable than hemin, but it is still not established whether its adverse effects (thrombophlebitis, anaphylaxis, and psychosis) (4) are fewer and whether its therapeutic effect is better than that of hemin (5).

Hemostatic compounds, miscellaneous

General Information

A number of compounds that have, or supposedly have, hemostatic activity are reviewed here. Some of them are obsolete and are included largely for historical interest. Others, such as fibrin glue, are still in use.

Aminaphtone

Experiments in the 1970s with aminaphtone (2-hydroxy-3-methyl-1,4-naphthohydroquinone-2-*p*-aminobenzoate) suggested that it could significantly shorten the bleeding time in both normal and heparinized rabbits and mice (1). Subsequent clinical experiments showed no adverse effects and toxicological studies in animals showed no evidence of

© 2006 Elsevier B.V. All rights reserved.

acute or long-term toxicity, even at quite high doses (1). No adverse effects were noted when patients who had initially been involved in an efficacy study of limited duration were treated with aminaphtone for a further year (2). No data are available on the absorption or metabolism of aminaphtone in humans. It has been claimed that aminaphtone may improve symptoms related to chronic venous insufficiency as well as lymphatic stasis (3).

Carbazochrome and carbazochrome salicylate

Adrenochrome, an oxidation product of adrenaline, is stabilized by binding to monosemicarbazone (adrenochrome monosemicarbazide). Its solubility is greatly enhanced by combination with sodium salicylate. The product, carbazochrome salicylate, can be given either by intramuscular injection or orally. The solution for intramuscular injection is hypertonic, and patients usually experience a brief stinging pain at the site of injection. Experiments in animals have shown a significant reduction in normal bleeding time when adrenochrome monosemicarbazide is given (4). This has been attributed to a direct effect on capillaries, as increased capillary resistance has been observed in experimental animals. Despite documentation of a transient reduction in bleeding time in humans in early experiments in the 1940s, subsequent double-blind controlled trials did not identify a useful reduction in blood loss after surgery (5–8). Despite the similarity to adrenaline, it is remarkably non-toxic and administration is not associated with the general systemic effects of sympathomimetic drugs (such as tachycardia, anxiety, or hypertension).

Fibrin glue

Fibrin glue is a topical biological adhesive, the effect of which imitates the final stages of coagulation. It contains two separate components, fibrinogen plus factor XIII, and thrombin plus calcium chloride. It is covered in a separate monograph.

5-Hydroxytryptamine creatinine sulfate

Platelets contain serotonin (5-hydroxytryptamine), which they take up from the plasma and store in dense granules. The serotonin is released when platelets are activated. Although serotonin was originally believed to play a vital part in platelet aggregation, it is now known that it does not, although it can contribute to local vasoconstriction. Treatment with reserpine induces depletion of serotonin in platelets, but this is not associated with any bleeding tendency (9). Nevertheless, belief in the importance of serotonin in hemostasis stimulated the search for analogues that might prove to be useful hemostatic agents, and 2-(5-hydroxy-3-indolyl) ethylamine creatinine sulfate was proposed as a hemostatic agent. However, subsequent clinical studies offered no evidence of benefit. Vertigo and tachycardia were reported in some patients who received the drug by rapid intravenous injection (10).

Naftazone

Naftazone (beta-naphthoquinone semicarbazone) is prepared by diazotization of sulfonic acid with beta-naphthol, and its properties are similar to those of adrenochrome. Naftazone significantly reduces the normal bleeding time as well as blood loss in rabbits and dogs. In many ways, this drug resembles adrenochrome, but it may in addition have certain effects at the cellular level. A double-blind, controlled study in patients undergoing prostatectomy reported significantly lower blood loss and transfusion requirements in the subjects receiving naftazone (11). No significant adverse effects were reported, but 4% of patients complained of transient and moderate nausea and gastric pain in a multicenter study of the efficacy and tolerance of naftazone in which two dosage regimens were compared (12).

Pectin

Pectin is a carbohydrate found in fruits, and is particularly rich in the rind of citrus fruits and in apples. It is a gelling agent and contributes to the solidification of jams. A formulation of pectin called Sangostop® was introduced as a hemostatic agent in 1935, and it was claimed that it could reduce bleeding in a variety of conditions. The active component consisted of colloidal polygalacturonic acid esters from apple pectin. It was given in a variety of ways: locally, orally, by subcutaneous or intravenous injection, or per rectum. The solution for local and oral use contained 5% pectin (3% for the preparation for intravenous administration). Several published reports from the 1930s claimed that pectin had a hemostatic effect, but these were based purely on subjective clinical judgement. Randomized controlled trials, with quantification of blood loss, have never been carried out.

It is clear that pectin, which has been given to a large number of patients in the past, rarely has adverse effects (13), although the toxicological investigations which would now be required by regulatory authorities have not been conducted. The largest study involved the use of Sangostop® in more than 400 patients undergoing surgery (14). Pectin was subsequently shown to have antifibrinolytic activity in vitro (15), which could explain its hemostatic effect. There has been one report of anaphylaxis in a patient given Sangostop® intravenously (16).

Sulfonaphtine

A number of claims were made in the 1950s that sodium 4-amino-1-naphthalene-1-sulphonate (sulfonaphtine glucoside, naphthionine glucoside) had hemostatic properties of clinical value. It was subjected to clinical evaluation because it is related to Congo Red dye, for which similar claims had been made in 1933. Thrombophlebitis was a common problem after intravenous administration of Congo Red, and so clinical trials with that dye were abandoned while other congeners were sought. Sulfonaphtine has been reported to enhance blood coagulation and to reduce the whole blood clotting time and bleeding time (17,18). However, no randomized, double-blinded clinical trials have been conducted. No adverse effects of sulfonaphtine, including thrombophlebitis, have been reported. It is no longer available commercially.

Thrombin and thromboplastin

Numerous tissue extracts, prepared from a variety of animal tissues, have been claimed to be effective

© 2006 Elsevier B.V. All rights reserved.

hemostatic agents. Examples of tissue extracts that are no longer available include thrombin extracts (such as Thrombinar and Thrombostat) and thromboplastin extracts (such as Clauden, Fibraccel, and Tachostyptan). Others include Coagulen, Clauden, Coazimol, Manetol, Thrombocytine, and Frénovex.

Thrombin is prepared from bovine plasma by reacting thrombin with thromboplastin in the presence of calcium. Thromboplastin is prepared as a micellar suspension of at least six phospholipids extracted from porcine brain and mixed in fixed proportions. It is stable at +4°C for several years (19).

Thromboplastin accelerates in-vitro coagulation, but only at certain concentrations and has been given intravenously by injection or infusion. Infusion shortens the bleeding time and normalizes both thrombin generation and prothrombin consumption in vitro for up to 3 hours in a small group of uremic patients (20). It has been used to treat postoperative hemorrhage in the oral cavity (21) and biliary tract (22). There were no adverse effects involving circulatory or cardiac function in healthy human subjects after intravenous injection of 10 ml, but rapid injection can reduce the blood pressure (23).

Heparins

General Information

Heparins are mucopolysaccharides whose molecules are of varying lengths. Unfractionated (standard) heparin contains molecules of average molecular weight of 12 000–15 000 Da. Low molecular weight heparins contain molecules whose average molecular weight is below 5000 Da. Each formulation of a low molecular weight

© 2006 Elsevier B.V. All rights reserved.

heparin contains a different range of sizes of molecules, but they have in common more activity against factor X than thrombin compared with standard heparin, a longer duration of action, and a lower risk of thrombocytopenia. They can be given subcutaneously once a day without the monitoring of activated partial thromboplastin time that is necessary for standard heparin. Low molecular weight heparins include bemiparin, certoparin, dalteparin, enoxaparin, nadroparin, reviparin, and tinzaparin.

Non-anticoagulant uses

A therapeutic role for heparin has been proposed in inflammatory bowel disease, particularly in ulcerative colitis (1). This beneficial response may result from mechanisms other than anticoagulation, including the restoration of high-affinity receptor binding by anti-ulcerogenic growth factors, such as basic fibroblast growth factor, that normally rely on the presence of heparian sulfate proteoglycans (2).

General adverse effects

The major adverse effect of heparin is bleeding. Thrombocytopenia occurs in some 5% of patients receiving standard heparin but is uncommon in those receiving low molecular weight heparins; bleeding as a result is rare. Long-term use can lead to osteoporosis. General vasospastic reactions have been reported and, exceptionally, skin necrosis can occur. Allergic reactions to heparin are well-known but rare. Tumor-inducing effects have not been described and the possibility of an anti-tumor effect has been raised.

Organs and Systems

Cardiovascular

Bolus administration of heparin causes vasodilatation and a fall in arterial blood pressure of 5–10 mmHg (3). Some convincing data have been reported concerning the role in these reactions of chlorbutol which has been used as a bactericidal and fungicidal ingredient in some heparin formulations (4).

Cardiogenic shock can occur in parallel with disseminated intravascular coagulation (5). In these circumstances heparin is thought to act as a hapten in a heparin–protein interaction that stimulates antibody production and an antigen–antibody reaction associated with release of platelet and vasoactive compounds.

General vasospastic reactions have been described in patients receiving heparin, exceptionally complicated by skin necrosis (6). Vasospastic reactions are probably part of the syndrome of thrombohemorrhagic complications considered above.

Nervous system

Effects of heparin on the nervous system, other than those due to bleeding, have not been reported.

Endocrine

Heparin-induced hypoaldosteronism is well documented, both in patients treated with standard heparin, even at low doses, and in patients treated with low molecular weight heparin (7,8). The most important mechanism of aldosterone inhibition appears to be a reduction in both the number and affinity of angiotensin II receptors in the zona glomerulosa (7). A direct effect of heparin on aldosterone synthesis, with inhibition of conversion of corticosterone to 18-hydroxycorticosterone, has also been suggested. This effect is believed to be responsible for the hyperkalemia that can occur in heparin-treated patients with impaired renal function and particularly in patients on chronic hemodialysis (9), or with diabetes mellitus, or who are taking other potentially hyperkalemic drugs.

Metabolism

Heparin has a strong clearing action on postprandial lipidemia by activating lipoprotein lipase. This has been thought to be associated with an increase in free fatty acid-induced dysrhythmias and death in patients with myocardial infarction.

- Substantial hypertriglyceridemia occurred in a pregnant woman who received long-term subcutaneous heparin treatment (10).

However, the risk of hyperlipidemia seems to have been exaggerated, since the extent of lipolysis is usually small (11).

Electrolyte balance

Hyperkalemia is an occasional complication of heparin therapy. It has been attributed to hypoaldosteronism, and fludrocortisone has been used to treat it (12). It has been suggested that marked hyperkalemia is only likely to occur in the presence of other factors that alter potassium balance (13).

Low molecular weight heparin is less likely to cause hyperkalemia than standard heparin. In 28 men, mean age 70 years, given low molecular weight heparin (40 mg subcutaneously every 12 hours) for deep venous thrombosis prophylaxis after an operation, the serum potassium concentration did not change significantly after 4 days of therapy (4.25 mmol/l before therapy and 4.35 mmol/l) (14).

However, in 85 patients enoxaparin therapy was associated with an increase in mean potassium concentration from 4.26 mmol/l at baseline to 4.43 mmol/l on the third day; potassium concentrations exceeded 5.0 mmol/l in 9% (15). There was no life-threatening or symptomatic hyperkalemia. Neither plasma renin activity nor aldosterone concentrations changed significantly and there was no correlation between the increase in potassium concentrations and the presence of diabetes mellitus or treatment with angiotensin converting enzymes inhibitors, angiotensin receptor blockers, beta-blockers, or potassium-wasting diuretics.

Hematologic

Hemorrhage

The major adverse effect of heparin is bleeding, and it can occur with low molecular weight heparins as well as with standard heparin (16).

© 2006 Elsevier B.V. All rights reserved.

DoTS classification (BMJ 2003;327:1222–5)
Dose-relation: toxic effect
Time-course: early
Susceptibility factors: treatment with antiplatelet drugs, sex, age, renal function

Frequency
An authoritative review of the relevant literature was published in 1993 and is still valid (17). Its authors concluded that the use of heparin in therapeutic dosages (over 15 000 IU/day) is typically marked by an average daily frequency of fatal, major, and major and minor bleeding episodes of 0.05, 0.8, and 2.0% respectively; these frequencies are about twice those expected without heparin therapy. In 2656 medical patients studied by the Boston Collaborative Drug Surveillance Program, the crude risk of bleeding from heparin (route unspecified) was 9% but varied with dose: 4.9% for doses below 50 IU/kg per dose, 8.1% for doses of 50–99 IU/kg per dose, and 17% for doses of 100 IU/kg per dose or more (18). The 7-day cumulative risk for any kind of bleeding was 9.1%. Melena, hematomas, and macrohematuria were the most frequent manifestations; intracranial bleeding and pulmonary bleeding were rare.

Presentation
In the Boston Collaborative Drug Surveillance Program study mentioned above (18), the localization of bleeding, expressed in percentages and broadly classified as major/minor, was as follows:

- gastrointestinal hemorrhage 49/11
- vaginal hemorrhage 11/8 (1/3 postpartum)
- bleeding from wounds and accidental soft-tissue trauma 11/28
- retroperitoneal bleeding 6/0
- genitourinary bleeding other than vaginal 6/35
- intracranial hemorrhage 5/0
- epistaxis 4/10
- other forms of blood loss 8/8.

An FDA Health Advisory warning was issued in December 1997 after 30 cases of spinal hematoma had been reported in patients undergoing spinal or epidural anesthesia while receiving low molecular weight heparin perioperatively. In the European literature, the risk of spinal hematoma in patients receiving low molecular weight heparin was not considered clinically significant. In Europe, low molecular weight heparin is given once a day and at a smaller total daily dose; this enables the placement (and removal) of needles and catheters during periods of reduced low molecular weight heparin activity. Identification of further risk factors is difficult, owing to the rarity of spinal hematoma. However, several possible risk factors have been suggested: about 75% of the patients were elderly women, in 22 patients an epidural catheter was used, and in 17 patients the first dose of low molecular weight heparin was administered while the catheter was indwelling; 12 patients received antiplatelet drugs and/or warfarin in addition to low molecular weight heparin (19). The authors formulated recommendations for minimizing the risk of spinal hematoma, including using the smallest effective dose of low molecular weight heparin perioperatively, delaying heparin therapy as long as possible postoperatively, and removing catheters when anticoagulant activity is low. Furthermore, they warned against combining low molecular weight heparin with antiplatelet drugs or oral anticoagulants.

Relation to dose
Subgroup analyses of randomized trials and prospective cohort studies point to an association, as one would expect, between the incidence of bleeding and the anticoagulant response as measured by a test of blood coagulation, for example the activated partial thromboplastin time (APTT). For instance, there were five major bleeding episodes in 10 patients whose APTT was prolonged to more than twice the upper limit of their therapeutic range but only one episode in 40 patients whose APTT remained in the therapeutic range (relative risk 20) (20). Furthermore, there is an increased rate of major bleeding with intermittent intravenous use compared with continuous intravenous heparin infusion. No differences in major bleeding are generally detected between continuous intravenous and subcutaneous heparin (21).

Time-course
In the Boston Collaborative Drug Surveillance Program study mentioned above, the peak incidence of bleeding was on the third day after the start of heparin therapy, which suggests a relatively safe initial 48-hour period in systemic heparinization (18). However, bleeding can be expected at any time during therapy, if the dosage becomes excessive or if susceptibility factors, such as trauma, intervene.

Susceptibility factors
In the Boston Collaborative Drug Surveillance Program study mentioned above, bleeding correlated with aspirin treatment, with sex, and probably with age and renal function (18). A meta-analysis of randomized trials reported that those aged over 70 are associated with the risk of major bleeding (22). Recent surgery or trauma also increase the risk.

Low molecular weight heparin
Because of its reduced activity on overall clotting, low molecular weight heparin is expected to cause less bleeding than standard heparin. However, several meta-analyses of randomized comparisons of low molecular weight heparin with standard heparin in the prevention of postoperative deep venous thrombosis showed no difference in the incidence of major bleeding (23,24). For low molecular weight heparin, the rates of major bleeding ranged from 0 to 3% and fatal bleeding from 0 to 0.8% (21). A later meta-analysis of randomized comparisons in the initial curative treatment of deep venous thrombosis showed a 35% reduction in major bleeding in patients treated with low molecular weight heparin, but this result was not significant (25).

Thrombocytopenia
Thrombocytopenia (100×10^9/l or lower) occurs in about 3–7% of patients, independent of the mode of administration or the dose and type of heparin (26,27). The incidence varies largely among published series, but the overall average may be some 5% (28). There was a higher incidence in some older studies (29), but this may have

© 2006 Elsevier B.V. All rights reserved.

been due to the presence of impurities in the heparin then available, and some of the studies clearly included cases of thrombocytopenia not attributable to heparin. Even the current incidence is to some extent uncertain, because of differences in methods of diagnosis and in the definitions used (30,31). Low molecular weight heparin is significantly less likely to cause thrombocytopenia than unfractionated heparin (27).

Two types of heparin-induced thrombocytopenia have been defined. Type I (mild) occurs within the first few days of heparin administration, while type II (severe), which is less common, is generally seen after a week or more of treatment and is often complicated by the recurrence of thromboembolic events.

A third variety, so-called "delayed-onset heparin-induced thrombocytopenia" has also been described in several reports. In 12 patients, recruited from secondary and tertiary care hospitals, thrombocytopenia and associated thrombosis occurred at a mean of 9.2 (range 5–19) days after the withdrawal of heparin; nine received additional heparin, with further falls in platelet counts (32). In a retrospective case series, 14 patients, seen over a 3-year period, developed thromboembolic complications a median of 14 days after treatment with heparin (33). The emboli were venous ($n = 10$), or arterial ($n = 2$), or both ($n = 2$); of the 12 patients with venous embolism, 7 had pulmonary embolism. Platelet counts were mildly reduced in all but two patients at the time of the second presentation. On readmission, 11 patients received therapeutic heparin, which worsened their clinical condition and further reduced the platelet count.

- A 44-year-old woman developed delayed-onset thrombocytopenia and cerebral thrombosis 7 days after a single dose of standard heparin 5000 units (34).

Type I heparin-induced thrombocytopenia

DoTS classification (BMJ 2003;327:1222–5)
Dose-relation: toxic effect
Time-course: early
Susceptibility factors: not known

Type I heparin-induced thrombocytopenia is common and is characterized by a mild transient thrombocytopenia (with platelet counts that usually do not fall below 50×10^9/l); the thrombocytopenia occurs on the first few days of heparin administration (usually 1–5 days) and requires careful monitoring but not usually withdrawal of heparin. Type I thrombocytopenia is generally harmless and very probably results from direct heparin-induced platelet aggregation. Thrombocytopenia is most common when large doses of heparin are used, or in some particular circumstances, such as after thrombolytic therapy (35) or in the early orthopedic postoperative period (36); it can abate in spite of continued therapy. Type I thrombocytopenia is a non-immune reaction, probably due to a direct activating effect of heparin on platelets.

Type II heparin-induced thrombocytopenia

DoTS classification (BMJ 2003;327:1222–5)
Dose-relation: hypersusceptibility effect
Time-course: delayed
Susceptibility factors: previous heparin therapy, co-administration of antiplatelet drugs or oral anticoagulants

Type II heparin-induced thrombocytopenia is less common than Type I but is often associated with severe thrombocytopenia. It is generally accepted that heparin-induced thrombocytopenia refers to platelet counts of less than 150×10^9/l or a reduction in platelet count of 30–50% to a previous count. In some cases, platelet counts that have fallen to 50% from a high normal previous count would remain apparently normal but should be considered as potentially heparin-induced thrombocytopenia.

Mechanism

Type II thrombocytopenia is probably an immune-mediated phenomenon, a fact that has been the subject of much specific investigation (27,37–42). It has been proposed that the diagnosis should depend on two criteria: the association of one or more clinical events and laboratory evidence of a heparin-dependent immunoglobulin (36).

Diagnosis

Laboratory diagnosis of heparin-induced thrombocytopenia can be made either using functional tests (demonstration of platelet activation of normal donor platelets in vitro by the patient's serum in the presence of heparin) or by screening for antibodies (27,43). The duration of the antibody response can vary from weeks to months up to 1 year. The two types of tests are complementary; both should be used when the reported results of either are inconsistent with the clinical problem.

Susceptibility factors

The risk of thrombocytopenia is increased in patients with a history of previous heparin therapy (44). Thrombocytopenia and/or thromboembolic complications can occur sooner in patients with a history of previous exposure to heparin, suggesting an anamnestic response (28,43).

The results of some prospective studies, including mainly transient benign thrombocytopenia (type I heparin-induced thrombocytopenia), have suggested that thrombocytopenia is more common in patients who have received the bovine lung type of heparin than in those who have received the porcine intestinal mucosa type (45–47). Type II thrombocytopenia is certainly more common in patients treated with standard heparin than in those treated with low molecular weight heparin (36), but there is usually cross-reactivity between standard heparin and low molecular weight heparin.

Heparin-coated catheters can sustain the thrombocytopenia in patients with heparin-associated antiplatelet antibodies (48,49) and therefore have to be removed from such patients.

Presentation

Heparin-induced thrombocytopenia usually occurs with a delayed onset (a week or more) and is often complicated by paradoxical recurrence of thromboembolic events, leading to life-threatening complications. The general term "heparin-induced thrombocytopenia" is as a rule used to designate this phenomenon.

© 2006 Elsevier B.V. All rights reserved.

Thrombosis can occur before the onset of overt thrombocytopenia (36). In some cases dramatic thrombotic events occur in association with antibodies without significant fall in platelet count (43). Thrombotic complications include new or recurrent arterial thromboembolism, often localized in the distal aorta and legs or presenting as myocardial infarction and hemiplegia (50), but also in the brachial artery (51), often requiring surgical treatment. In older reports there was a higher incidence of arterial than of venous thrombosis, but later reports documented that venous thrombosis is four times more common than arterial thrombosis (52). Heparin-induced thrombocytopenia can be associated with deep venous thrombosis and pulmonary embolism, but unusual forms of thrombosis, such as adrenal hemorrhagic infarction due to adrenal vein thrombosis, a complication that must be considered in patients who develop abdominal pain or unexplained hypotension during heparin therapy, are not uncommon.

Venous limb gangrene due to heparin-induced thrombocytopenia is characterized by distal tissue losses, with extensive venous thrombosis involving large veins and small venules (53). This reaction seems to be related to acquired deficiency of protein C induced by concomitant oral anticoagulants.

Patients with heparin-induced thrombocytopenia have a reported mortality of 25–30% and amputation rates of up to 25% (54). The development of the syndrome is not related to the dose of heparin in the therapeutic range (that is it is a hypersusceptibility reaction). This has been confirmed by the fact that thrombocytopenia with thromboembolic complications sometimes occurs after the limited exposure that is involved in "flushing" with heparin and saline to maintain the patency of venous catheters (55).

Management

In view of the severity of the Type II syndrome, it has been recommended that heparin therapy be monitored by twice-weekly platelet counts (56).

Heparin-induced thrombocytopenia demands immediate withdrawal of heparin (43), after which platelet counts usually return to normal within 2–3 days, that is much faster than after early-onset thrombocytopenia. Rechallenge with heparin leads to an abrupt fall in the number of platelets and to reappearance of the clinical signs and symptoms, sometimes leading to sudden death (57).

From the therapeutic point of view, prophylaxis of thrombosis must be continued after withdrawal of heparin, since even when there is no evidence of thrombosis in association with heparin-induced thrombocytopenia, thrombosis can follow after some days (52). Because of cross-reactivity, low molecular weight heparin should not be used when heparin has been withdrawn because of heparin-induced thrombocytopenia; nor should warfarin be used, because of the risk of venous gangrene, at least until the thrombocytopenia has resolved. Patients with life-threatening or limb-threatening thrombosis can be treated with thrombolytic drugs. Current views are that two antithrombotic drugs should be used, for example danaparoid plus lepirudin (58).

Eosinophilia

Eosinophilia has rarely been attributed to heparin, with positive rechallenge (52,59).

Liver

Minor increases in serum transaminases without evidence of liver dysfunction are common in patients receiving standard heparin or low molecular weight heparin given therapeutically or prophylactically (60,61). This rise is more pronounced for alanine transaminase than for aspartate transaminase and occurs after 5–10 days of heparin treatment (61). The source of heparin has no relation to the development of raised transaminases. After withdrawal of heparin and sometimes even in spite of continued treatment (60,61), the transaminases return to normal (62,63). The mechanism of these increases has not been elucidated. A concomitant increase in gamma-glutamyl transpeptidase activity has been described in some patients (64).

In one study of patients receiving heparin, the isoenzyme pattern of lactate dehydrogenase was studied; all had rises in the hepatic form of the enzyme, suggesting hepatocellular damage as the most likely source (60).

Heparin-associated hepatotoxicity has not been reported.

Skin

Erythematous nodules or infiltrated and sometimes eczema-like plaques at the site of injection are common adverse effects of subcutaneous standard heparin 3–21 days after starting heparin treatment. They are probably delayed-type hypersensitivity reactions and are also seen with low molecular weight heparin (65–69). There can be cross-reactivity between standard heparin and low molecular weight heparin (69).

Erythromelalgia has been described with enoxaparin (70).

In cases of local reactions, skin tests should not be performed, since they are rarely helpful in detecting potential cross-reactivity between low molecular weight heparin and heparin (65,71).

Two renal transplant recipients developed calcinosis cutis (tender erythematous subcutaneous nodules with induration, ulceration, and necrosis), confirmed by bone scan and biopsies, at the site of subcutaneous administration of nadroparin (72). Both had secondary hyperparathyroidism and a raised calcium-phosphate product at the time of administration. The authors suggested that the high concentration of calcium in nadroparin (220 mmol/l) had been an important factor, since in the same patients subcutaneous injections of nicomorphine or dalteparin did not cause subcutaneous nodules. Three more cases were found after retrospective examination of all 51 adult patients who underwent a renal transplantation in the same hospital during 7 months, and there were no other cases of calcinosis cutis at the injection sites of low molecular weight heparins after nadroparin was replaced by dalteparin.

Skin necrosis

Heparin-induced skin necrosis was first described in 1973 (73) and was later observed in patients with the

© 2006 Elsevier B.V. All rights reserved.

thrombohemorrhagic syndrome (74,75). The skin pathology develops 6–9 days after the start of subcutaneous heparin treatment and usually develops at the site of subcutaneous injection. However, it can also occur at sites distant from the site of injection (76) or after intravenous therapy (77). Vasculitis is likely to be present, perhaps with fever (78). There is an increased risk of thrombocytopenia and thrombotic complications in patients who have had previous heparin-associated skin necrosis episodes (79).

Various physiopathological mechanisms have been suggested (80), particularly heparin-induced thrombocytopenia, vasculitis caused by a type III hypersensitivity reaction, local trauma at the site of injection, and poor vascularization of adipose tissue resulting in reduced absorption of heparin, as seen in diabetic lipodystrophy. This form of skin necrosis must be distinguished from vasospastic skin necrosis and from skin necrosis induced by cholesterol embolization. Ergotism will be a differential diagnosis in patients who are receiving prophylaxis with the combination of low dose heparin and dihydroergotamine (81). In evaluating any necrotic skin reaction, one must always consider its infectious origin (particularly *Escherichia coli* or *Pseudomonas*) related to unsterile injections (82).

Several patients with heparin-induced skin necrosis were positive for HIT-IgG using the platelet ^{14}C-serotonin release assay, even though they did not develop thrombocytopenia (83). Skin necrosis has been particularly reported in patients receiving standard heparin but also occasionally with low molecular weight heparins, such as dalteparin (84) or enoxaparin (79).

The clinical and histological pictures of heparin-induced skin necrosis are similar to those found in so-called "coumarin necrosis." Laboratory examinations show inflammatory changes, with anemia, leukocytosis, eosinophilia, a raised erythrocyte sedimentation rate, and a positive capillary fragility test. The vasculitis can lead to organ involvement, such as glomerulonephritis (85).

Heparin-induced skin necrosis can be associated with high morbidity and occasional mortality. Heparin should be withdrawn when it occurs. The risk of recurrence if heparin is given again later is not known (86).

Musculoskeletal

Heparin-associated osteoporosis is observed with both standard heparin and low molecular weight heparin, although it is far less pronounced with the latter. The incidence of heparin-associated osteoporosis is not known, but it is probably less than 5% with standard heparin. The highest estimates are derived from studies of pregnant patients and should be interpreted cautiously, since pregnancy, even in the absence of heparin therapy, is sometimes itself associated with osteoporosis. Overall, it appears that osteoporosis can occur in patients given heparin for longer than 10 weeks and usually for a minimum of 4 months. The effect is rarely complicated by fractures. It has been suggested that during long-term heparin therapy, calcium supplements be given (87).

The processes involved are bone resorption and inhibition of bone deposition. Standard heparin may affect both phenomena, whereas low molecular weight heparin seems to affect only the rate of bone formation. Heparin-associated osteoporosis has been attributed to enhancement of collagenolysis or to enzyme inhibition by heparin. Other authors have stressed the resemblance to hyperparathyroid osteopathy. Further possibilities include deficiency of vitamin D analogues (88) and ascorbic acid deprivation at the site of osteoblast activity. Heparin-induced osteolysis may explain the metastatic calcification that can occur in patients with end-stage renal insufficiency treated by hemodialysis, which is sometimes associated with calcified subcutaneous nodules (89).

Sexual function

Heparin has been associated with priapism (90). The frequency and severity of iatrogenic priapism as a result of heparin therapy seems to be greater than with any other type of medical treatment (91). However, it is uncertain whether it is heparin or the underlying thrombotic condition that causes the complication.

Immunologic

A wide range of allergic reactions have been described in patients receiving heparin, including urticaria, conjunctivitis, rhinitis, asthma, cyanosis, tachypnea, a feeling of oppression, fever, chills, angioedema, and anaphylactic shock.

- A patient with end-stage renal disease developed recurrent anaphylaxis after receiving heparin during hemodialysis (92). There were raised concentrations of total and mature tryptase at 1 hour, but although the latter returned to normal by 24 hours the former did not. Prick tests were negative with heparin, enoxaparin, and danaparoid, but intradermal skin tests were positive with heparin and enoxaparin. Danaparoid was used as an anticoagulant during dialysis for the next 3 years without any adverse effects.

In some cases of allergy to a heparin formulation, the precipitating agent will prove to be a preservative, such as chlorocresol (93) or chlorbutol (94), rather than heparin itself.

Second-Generation Effects

Pregnancy

The maternal rate of bleeding complications during heparin treatment is about 2%. This is consistent with the reported rates of bleeding associated with heparin therapy in non-pregnant women, and in warfarin therapy when used for the treatment of venous thrombosis (95). Subcutaneous heparin given just before labor can also cause a persistent anticoagulant effect at the time of delivery; the mechanism of this prolonged effect is unclear (96).

Another pregnancy-associated hazard of long-term heparin administration is maternal osteoporosis, as clearly illustrated by several reports of pregnant women who developed severe osteoporosis after having received heparin, in some cases complicated by multiple vertebral fractures (97,98). Long-term heparin therapy during pregnancy results in changes in calcium homeostasis, which may be dose-related in the therapeutic range of doses (99). The incidence of osteoporotic fractures was 2.2% (four

© 2006 Elsevier B.V. All rights reserved.

patients) in 184 women receiving long-term subcutaneous prophylaxis with twice-daily heparin during pregnancy (100). In another study, the incidence of osteopenia in 70 pregnant women on long-term heparin was 17%; there was also a regression in the degree of osteopenia postpartum (101). It is difficult to distinguish between the mean bone loss that occurs in normal pregnancy and the additive effect on bone demineralization that results from heparin therapy; further prospective studies on bone demineralization during pregnancy are needed to clarify this point.

Fetotoxicity

An adverse fetal outcome occurs in about one-third of pregnancies after either oral anticoagulant or heparin treatment (102). However, the high rate of adverse fetal outcomes associated with heparin during pregnancy is in part a reflection of the severity of pre-existing maternal diseases (103). Moreover, some studies have suggested that unfractioned heparin is relatively safe for the fetus and is the anticoagulant therapy of choice during pregnancy, whereas oral anticoagulants may not be, particularly during the first trimester (95,104). Heparin does not cross the placenta, and therefore does not have the potential to cause fetal bleeding or teratogenicity (105). Low molecular weight heparins and heparinoids similarly do not cross the placenta (106,107).

Lactation

Heparin is not secreted into breast milk and can be given safely to nursing mothers (108).

Drug–Drug Interactions

Benzodiazepines

In healthy non-fasting subjects, 100–1000 IU of heparin given intravenously caused a rapid increase in the unbound fractions of diazepam, chlordiazepoxide, and oxazepam (109,110), but no change in the case of lorazepam (109). The clinical implications of this finding are not known.

Digitoxin

Reduced plasma protein binding of digitoxin has been reported after the administration of heparin (111). In 10 hemodialysed patients taking maintenance digitoxin therapy, there was reduced binding in vitro because of heparin-induced lipolysis, and not as a consequence of in vivo binding of digitoxin to plasma proteins.

Dobutamine hydrochloride

Dobutamine hydrochloride and heparin should not be mixed or infused through the same intravenous line, as this causes precipitation (112).

Glyceryl trinitrate

Resistance to heparin has been observed in patients in coronary care units receiving intravenous glyceryl trinitrate. Although this has been imputed to propylene glycol in glyceryl trinitrate formulations (113), resistance has also been described with propylene glycol-free formulations. The underlying mechanism might be a qualitative abnormality of antithrombin III induced by glyceryl trinitrate (114). It has also been reported that heparin concentrations can be markedly reduced by glyceryl trinitrate (115).

Interference with Diagnostic Tests

Acid phosphatase activity

Concentrations of heparin as low as 1 IU/ml give 80% inhibition of acid phosphatase activity in leukocytes (116).

Aminoglycosides

Heparin can interfere with the determination of aminoglycosides by enzyme-multiplied immunoassays, resulting in lower values than with the use of other assays (117,118). In the case of gentamicin, the lower values may be due to direct binding of gentamicin to heparin, as well as a more complex interaction involving heparin, gentamicin, and proteins (117). Blood samples for the determination of aminoglycosides by enzyme immunoassays should not be collected in heparinized tubes or from indwelling lines (118).

Arterial blood gases

Heparin can affect the analysis of arterial blood gases (119). Addition of excess heparin and acid mucopolysaccharide to the syringe can alter the Henderson–Hasselbalch equation, simulating metabolic acidosis. It is advisable to coat the syringe with heparin and remove all excess heparin before blood sampling.

Calcium

Pseudo-hypocalcemia can occur in hemodialysis patients, particularly in those who have chylomicronemia before administration of heparin (120). This spurious hypocalcemia is thought to result from lipolytic activity in vitro, sufficient to produce calcium soaps of fatty acid. This can be detected and eliminated by the analysis of blood samples immediately after venepuncture. During hemodialysis, there is a significant fall in plasma ionized calcium after intravenous administration of heparin (an average reduction of 0.03 mmol/l after 10 000 IU) (121).

Chromogenic lysate assay for endotoxin

Heparin has a dose-related inhibitory effect on the chromogenic lysate assay for endotoxin (122). There was a 90% reduction in detectable endotoxin at concentrations of heparin as low as 30 U/ml.

Ciclosporin

Measured ciclosporin concentrations differ according to the use of heparin or EDTA as anticoagulant (123).

Propranolol

Interference by heparin with the measurement of propranolol when the blood is collected from a heparinized cannula is well documented (124). There is no in vivo interaction, since the beta-blockade is unchanged (125).

© 2006 Elsevier B.V. All rights reserved.

Thyroid function tests

Artefactual increases of as much as 50% in total thyroxine, estimated by a competitive protein-binding assay, and of as much as 30% in triiodothyronine resin uptake are probably due to rapid and continuing lipolytic hydrolysis of triglycerides after blood has been drawn (126). Thyroid function tests should therefore always be performed on blood samples taken before (or a sufficient time after) heparin treatment (127). An increase in serum-free thyroxine concentrations has also been reported after low molecular weight heparin, by up to 171% in specimens taken 2–6 hours after injection. When specimens were obtained 10 hours after injection, the effects were smaller, but with concentrations still up to 40% above normal the results can still cause errors of interpretation (128).

Hepatitis vaccines

See also Vaccines

General Information

Hepatitis A

The successful propagation of hepatitis A virus in cell culture made the development of hepatitis A vaccines a realistic possibility. Various experimental hepatitis A vaccines have been tested in clinical trials. In December 1991, the first hepatitis A vaccine was licensed in Western European countries. Currently, two different hepatitis vaccines (prepared using different inactivation process) as well as vaccines for children (containing 720 enzyme-linked immunosorbent assay units per dose) and adults (containing 1440 units per dose) are commercially available and further products are under development. The results of safety and immunogenicity testing of hepatitis A vaccines developed by SmithKline-Beecham and by Merck Research Laboratories have been reviewed (SEDA-16, 384) (SEDA-17, 373) (SEDA-18, 333) (SEDA-21, 331). These vaccines were highly immunogenic. There were mild transient reactions at injection sites, but systemic reactions were minor and uncommon.

In a paper dealing mainly with indications for the use of hepatitis vaccine, the data on the hepatitis A vaccines most widely used, HAVRIX (manufactured by Glaxo SmithKline) and VAQTA (manufactured by Merck), have been summarized (1). The data are based on prelicensure clinical trials and worldwide follow-up reports. No serious adverse effects have been attributed to hepatitis A vaccines. In children who received HAVRIX, soreness (15%) and induration (4%) at the injection site, feeding problems (8%), and headaches (4%) have been the most frequently observed adverse effects. In children who received VAQTA, the most common adverse effects were pain (19%), tenderness (17%), and warmth (9%) at the injection site. The reported frequencies were similar to the frequencies reported with hepatitis B vaccines.

Hepatitis B

Two types of hepatitis B vaccine are commercially available: plasma-derived hepatitis B vaccine and yeast recombinant hepatitis B virus vaccine. The two vaccines are equally immunogenic, protective, and safe. However, in most countries the recombinant vaccine is considered the vaccine of choice.

Plasma-derived hepatitis B virus vaccine

Plasma-derived hepatitis B virus vaccine is prepared from the plasma of chronic HBsAg carriers, and consists of purified, inactivated 20-nm HBsAg particles adsorbed on to an aluminium adjuvant. The use of a vaccine produced with plasma derived from infected individuals represented a major departure from conventional approaches, and safety testing has therefore been designed to cover all possibilities of risk and to ensure freedom from transmission of residual HBV and other blood-borne agents. Various clinical trials (SEDA-10, 289) (SEDA-11, 289) have confirmed the safety of plasma-derived hepatitis B virus vaccines produced by different manufacturers. Fears that plasma-derived vaccine may transmit AIDS can be considered unfounded.

Subsequent to the identification of HIV and the growing knowledge of its relatively easy inactivation with procedures such as heat or triple-step chemical inactivation, the complete safety and suitability of plasma-derived vaccines that meet WHO requirements has now been generally accepted and their safety demonstrated (SEDA-12, 279). This type of hepatitis B vaccine is generally well tolerated. The most common adverse effect has been local soreness at the injection site. Less common local reactions include erythema, swelling, and induration; all usually subside within 48 hours. Transient low-grade fever has occurred occasionally; but malaise, fatigue, vomiting, dizziness, myalgia, and arthralgia have been infrequent. Individual reports of more severe suspected adverse effects (erythema multiforme, hepatitis-like changes in liver function, hypersensitivity, lichen planus, menstrual abnormality, myasthenia gravis, neurological disorders including transverse myelitis and Guillain–Barré syndrome, reactive arthritis, Takayasu's arteritis, urticaria, uveitis) are very rare and are no more than could be

© 2006 Elsevier B.V. All rights reserved.

expected by chance (SED-12, 804) (SEDA-16, 384) (SEDA-17, 373) (SEDA-18, 334). In one reported case with neurological symptoms, a preceding viral illness was the likely cause and in the patient with hepatitis-like symptoms mentioned above, the possibility of other causes was not excluded. In a case with urticaria, patch tests revealed a hypersensitivity to thiomersal, the preservative in the vaccine.

By 1988 it was possible to summarize the adverse effects reported after the distribution of over 1.8 million doses of plasma-derived hepatitis B vaccine (Table 1) (2). From 1982 onwards, the Centers for Disease Control, the Food and Drug Administration, and the manufacturers, Merck Sharp & Dohme, had supported a special surveillance system to monitor spontaneous reports of reactions to plasma-derived hepatitis vaccine. During the first 3 years, about 850 000 persons were immunized. In all, 41 reports were received for one of the following neurological adverse events: convulsion ($n = 5$), Bell's palsy ($n = 10$), Guillain–Barré syndrome ($n = 9$), lumbar radiculopathy ($n = 5$), brachial plexus neuropathy ($n = 3$), optic neuritis ($n = 5$), and transverse myelitis ($n = 4$). Half of these events occurred after the first vaccine dose. However, no conclusive causal association could be made between any neurological adverse event and the vaccine (3).

Yeast-derived recombinant hepatitis B vaccine

The yeast-derived recombinant vaccines first licensed in 1986 represented the first vaccine of any kind manufactured by recombinant technology. The vaccines are prepared using antigen produced by recombinant technology in yeast (*Saccharomyces cerevisiae*). The recombinant vaccine produced by Merck, Sharp & Dohme was as immunogenic and protective against hepatitis B as plasma-derived vaccine (4). Clinical reactions in this series were mild and transient. About 17% of all recipients had pain, soreness, and tenderness at the injection site. A smaller proportion reported headache, weakness, nausea, or malaise. Between February 1984 and August 1986, 33 investigators in 19 countries carried out clinical trials with the yeast-derived recombinant hepatitis B vaccine produced by SmithKline Biologicals. Among other risk groups, neonates, patients with thalassemia and sickle cell anemia, and hemodialysis patients have been vaccinated. All the results point to the safety and acceptability of a yeast-derived vaccine. The incidence of reported reactions varied widely in different studies depending on the scrupulousness with which minor signs were reported. No serious, severe, or anaphylactic reactions occurred. The incidence of local and systemic reactions reported in each study tended to decrease after successive doses, suggesting that immunization did not induce hypersensitivity (SEDA-12, 280).

Reports of studies of the efficacy and safety of recombinant hepatitis vaccines have been published (SED-12, 805) (SEDA-14, 282) (SEDA-15, 351) (SEDA-16, 385) (SEDA-17, 373) (SEDA-18, 334). Table 1 shows the adverse effects reported after the distribution of 205 000 doses of recombinant vaccine.

Third-generation hepatitis B vaccines

Between 5 and 15% of healthy immunocompetent individuals do not seroconvert after receipt of the currently licensed hepatitis B vaccines containing only the major surface protein HbsAg without pre-S epitopes. In a study of a hepatitis B vaccine containing pre-S1, pre-S2, and antigenic components of both viral subtypes adw and ayw, all three antigenic components were produced in a continuous mammalian cell line, after transfection of the cells with recombinant hepatitis B surface antigen DNA (5). The vaccine was manufactured as an aluminium hydroxide adjuvant formulation. The new vaccine (5, 10, 20, or 50 μg) was given to 68 individuals with HBs antibody titers below 10 IU/l. Seroconversion rates in the four groups were 60, 76, 64, and 80%. There were local or systemic reactions in 15%. No dose-related incidence was seen.

Surveillance of hepatitis B adverse events in the USA and Australia

Adverse events after hepatitis B vaccine reported between 1 January 1991 and 31 May 1995 to the US Vaccine Adverse Events Reporting System have been reviewed (6). The patients included 58 neonates and 192 infants who were immunized with hepatitis B

Table 1 Adverse effects after immunization with recombinant and plasma-derived hepatitis B vaccine

Adverse effect	Recombinant vaccine[a]		Plasma-derived vaccine[b]	
	Number of adverse effects	Rate per dose	Number of adverse effects	Rate per dose
Pruritus	2	1:103 000	38	1:48 000
Urticaria	2	1:103 000	23	1:79 000
Exanthems	6	1:103 000	58	1:30 000

vaccine alone and 1469 infants who had received hepatitis B vaccine in combination with DTP vaccine. The serious adverse events reported in neonates and infants included fever, agitation, and apnea. The events reported for infants who received hepatitis B vaccine and DTP vaccine simultaneously were compared with the events reported for infants who received either DTP vaccine or hepatitis B vaccine alone. The reports filed for the infants who received DTP vaccine alone or in combination with hepatitis B vaccine differed from the reports filed for infants who received hepatitis B vaccine alone, suggesting that these events may have been associated with the DTP vaccine. The reviewers concluded that no unexpected adverse events had occurred in neonates and infants given hepatitis B vaccine, despite the administration of at least 12 million doses.

Between 1988 and 1996, the Australian Drug Evaluation Committee received some 600 reports of suspected adverse events after hepatitis B immunization. There were no serious events, and the overwhelming majority were well-known mild-to-moderate local or systemic reactions (7). Musculoskeletal symptoms, such as arthralgia, arthritis, and myalgia, were mentioned in 106 reports.

General adverse effects

The reports of major adverse reactions that have been published since the introduction of recombinant hepatitis B vaccine have been reviewed (8). In the clinical trials with hepatitis B vaccine, the most frequent adverse effects were soreness at the injection site, sometimes accompanied by erythema (3–29%), fatigue (15%), headache (9%), and a temperature increase higher than 37.7°C. The postmarketing surveillance literature (4.5 million doses) showed an overall rate of one adverse effect per 15 500 doses. Of these, local reactions were reported at a rate of 1 in 85 000 doses. Systemic reactions included nausea, rash, headache, fever, malaise, fatigue, flu-like symptoms, diarrhea, urticaria, paresthesia, and somnolence, all of which resolved, generally within 24–48 hours of vaccine administration. Reactions were less frequent with subsequent doses. Major adverse effects have been published as case reports: anaphylaxis; urticaria, erythema nodosum, lichen planus; arthritis, Reiter's syndrome; pulmonary and cutaneous vasculitis; systemic lupus erythematosus; glomerulonephritis; Evan's syndrome, thrombocytopenic purpura; acute posterior multifocal placoid pigment epitheliopathy; Guillain–Barré syndrome, transverse myelitis, multiple sclerosis, acute cerebellar ataxia; chronic fatigue syndrome. Table 2 summarizes the reports. Discussing the cause of the reported major adverse effects and a possible causal relation with vaccine administration, the authors considered that apart from anaphylaxis and urticaria, most of the reactions described were not allergic in nature and that the symptoms were those of immune-complex disease due to autoimmune mechanisms. Because of the extreme rarity of such serious adverse events, coincidence seems the

Table 2 Summary of important adverse effects after recombinant hepatitis B vaccination

Adverse effect	Sex	Age (years)	Number	Time after immunization	Duration of symptoms
Nervous system					
Cerebellar ataxia	F	25	2	10 days	4 months
Demyelination	F	26	3	6 weeks	3 weeks
Demyelination	F	28	2	6 weeks	3 months

simplest explanation, but an immune-complex mediated pathogenesis should not be excluded, given the close temporal relation between immunization and the onset of disease. Apart from immune-complex mechanisms, there may be reactions to other components of the vaccine, such as thiomersal, aluminium, or small quantities of yeast proteins.

Hexavalent immunization, including hepatitis B

The Hexavalent Study Group has compared the immunogenicity and safety of a new liquid hexavalent vaccine against diphtheria, tetanus, pertussis, poliomyelitis, hepatitis B, and *Haemophilus influenzae* type b (DTP + IPV + HB + Hib vaccine, manufactured by Aventis Pasteur MSD, Lyon, France) with two reference vaccines, the pentavalent DTP + IPV + Hib vaccine and the monovalent hepatitis B vaccine, administrated separately at the same visit (9). Infants were randomized to receive either the hexavalent vaccine ($n = 423$) or (administered at different local sites) the pentavalent and the HB vaccine ($n = 425$) at 2, 4, and 6 months of age. The hexavalent vaccine was well tolerated (for details, see the monograph Pertussis vaccines). At least one local reaction was reported in 20% of injections with hexavalent vaccine compared with 16% after the receipt of pentavalent vaccine or 3.8% after the receipt of hepatitis B vaccine. These reactions were generally mild and transient. At least one systemic reaction was reported in 46% of injections with hexavalent vaccine, whereas the respective rate for the recipients of pentavalent and HB vaccine was 42%. No vaccine-related serious adverse event occurred during the study. The hexavalent vaccine provided immune responses adequate for protection against the six diseases.

Hepatitis E

Hepatitis E is an important cause of morbidity and mortality in young adults in developing countries, and is particularly dangerous in pregnant women. Through recombinant technology a hepatitis E vaccine has been developed; in its first clinical trials the vaccine was found to be safe and immunogenic (10).

Organs and Systems

Nervous system

Hepatitis A

Probable posthepatitis A immunization encephalopathy has been reported (11).

Hepatitis B

Neuralgic amyotrophy (12), febrile convulsions (13), and Guillain–Barré syndrome (14) have been attributed to hepatitis B vaccine. Fatal inflammatory polyradiculoneuropathy has been reported in temporal relation to hepatitis B administration (15).

Demyelination

Two patients developed neurological symptoms and signs of central nervous system demyelination 6 weeks after administration of recombinant hepatitis B vaccine (16). One was a known case of pre-existent multiple sclerosis but the other had no history of neurological diseases. Both had HLA haplotype DR2 and B7, which are associated with multiple sclerosis. A causal link between immunization and demyelination cannot be established from these two case reports, but the time interval would fit a proposed immunological mechanism. In addition, the Centers for Disease Control (CDC) in Atlanta, Georgia, received reports on four cases of "chronic demyelinating disease." Several other reports describe related conditions or other forms of neurological disorder.

- Acute myelitis occurred in a 56-year-old man 3 weeks after hepatitis B immunization (17).
- Optic neuritis has been attributed to hepatitis B vaccine (18).
- Transverse myelitis developed 3 weeks after the first dose of hepatitis B vaccine in an 11-year-old girl (19).

Guillain–Barré syndrome occurred in a 7-year-old girl after the administration of recombinant hepatitis vaccine (20). The author noted that several other such incidents had been reported after the use of recombinant vaccines, two involving optic neuritis and one Guillain–Barré syndrome.

Multiple sclerosis

Eight cases of nervous system diseases suspected to be either recurrent disseminated encephalitis or multiple sclerosis after hepatitis B immunization have been reported (21). Symptoms started in four cases at 4–14 days after vaccination, and in the other four cases 42–70 days after vaccination. There was a family history of multiple sclerosis in two patients, one of whom had had symptoms compatible with optic neuritis before immunization. In a third patient, there was a history of an episode compatible with Lhermitte's sign. The authors concluded that the risk of demyelinating diseases is unknown. They recommended avoiding hepatitis B immunization in individuals with a personal or familial history of symptoms suggestive of an inflammatory or demyelinating disease.

- A 45-year-old woman with a history of epilepsy developed a lumbosacral acute demyelinating polyneuropathy 1 month after her second hepatitis B immunization (22). She had an uncommon syndrome that combined demyelinating and axonal features confined to the lumbosacral roots whose relation to Guillain–Barré syndrome was unclear. Viral or bacterial causes of the disease could not be found.

The authors concluded that a relation between immunization and disease could not be excluded.

- A 44-year-old female health worker developed bilateral optic neuritis 7 days after immunization against poliomyelitis (OPV) and hepatitis B (23). All hematological, biochemical, bacterial, and virological investigations were normal, and there was no evidence of demyelination on MRI scanning.

Although the current hepatitis B vaccine seems to be one of the safest ever produced, concerns are still sometimes expressed (SEDA-22, 346) (24), particularly since 1996 when a French neurologist announced that he had seen

© 2006 Elsevier B.V. All rights reserved.

several cases of multiple sclerosis or demyelinating disease in women who had received hepatitis B vaccine. This report was taken up by the media and anti-immunization groups, resulting in further inquiry. In 1998 the French Health Authorities invited leading experts in the fields of immunization and possible adverse effects to meet in Paris and discuss scientific studies carried out in France on the possible relation between hepatitis B vaccine and multiple sclerosis. The conclusion of the meeting was that there was no evidence of a causal link between multiple sclerosis and hepatitis B vaccine. Nevertheless, the Minister of Health decided to stop hepatitis B immunization of schoolchildren aged 11–12 years, but to continue immunizing infants and adults at high risk. The rationale for this decision was the limited opportunity for the full discussion needed to attain informed consent during immunization sessions carried out in schools. It was recommended that immunization of school children and adolescents would in future be performed by general practitioners, who have a better opportunity to discuss the benefits and risks of immunization on an individual basis and to obtain informed consent.

The impact of this decision, or any other to curtail an immunization program, should not be underestimated. It raises concerns not only about the safety of the hepatitis B vaccine, but also about the safety of vaccines in general. In view of this, the WHO took strong action, and its Global Program on Immunization issued a statement in 1997 (after the French media had taken up the issue) that there was no evidence that hepatitis B vaccine causes multiple sclerosis (25). This conclusion was based on the following considerations:

- A comparison of the geographical incidence and prevalence of hepatitis B with that of multiple sclerosis, which shows large differences: Scandinavia and Northern Europe have the highest rates of multiple sclerosis and the lowest rates of hepatitis B infection, whereas in Africa and in Asia there are very low rates of multiple sclerosis and the highest rates of hepatitis B infection. If the virus does not cause multiple sclerosis, it is unlikely that the vaccine can do so.
- None of the postmarketing surveillance studies from the different vaccine manufacturers in North America showed any evidence of an increased risk of multiple sclerosis.
- Reanalysis by the WHO of the French data showed that the notification rate of demyelinating diseases following the administration of the hepatitis B vaccine was 0.6 cases/100 000 vaccinees, which is a lower rate than the expected incidence in the same population (estimated in France to be 1–3 cases/100 000 vaccinees).

The data and analyses were examined once more at a scientific conference organized by the Viral Hepatitis Prevention Board in collaboration with WHO, assisted by experts from many disciplines. Their final conclusion, published in a press release, was that the available scientific data did not demonstrate a causal association between hepatitis B vaccine and central nervous system diseases, including multiple sclerosis (26). It was pointed out moreover that since 1981 more than a billion doses of hepatitis B vaccine had been used worldwide, with an outstanding record of safety and efficacy. The WHO also warned of the consequences of stopping any immunization program on the basis of unfounded concerns, as had happened with pertussis vaccine in the UK, leading to major epidemics of natural pertussis in that country.

The National Multiple Sclerosis Society in the USA made a statement referring to anecdotal reports suggesting that immunization against hepatitis B may increase the risk of multiple sclerosis (27). They noted that:

- such reports had not been confirmed by any statistically significant scientific studies to date;
- because of the potential for public concern about this issue, further studies of the possibility of association of hepatitis B vaccine and demyelinating disease, including multiple sclerosis, were already under way in the USA and Europe;
- hepatitis B infection could result in serious, sometimes fatal, disease and immunization was effective in its prevention.

The official French position on hepatitis B immunization, expressed in January 1999, was that children should be vaccinated against hepatitis B, that adolescents should receive a dose of hepatitis B vaccine if they have not been vaccinated earlier, that adults at risk should be similarly vaccinated, and that the obligation is maintained for health professionals to be vaccinated against hepatitis B. The steps taken in 1998 had sought only to ensure that informed consent could be attained before children were vaccinated.

All available data that may throw light on the hypothesis that hepatitis B vaccine is causally linked to multiple sclerosis have been carefully reviewed (28). The authors concluded that the most plausible explanation for the observed temporal association between immunization and multiple sclerosis is coincidence.

A statement from the Viral Hepatitis Prevention Board (8 June 2000), working closely together with the WHO, is worth repeating: the data available to date do not show a causal association between hepatitis B immunization and central nervous system demyelinating disease, including multiple sclerosis. No evidence presented indicates a need to change public health policies with respect to hepatitis B immunization. Therefore, based on demonstrated important benefits (including prevention of liver cirrhosis and primary liver cancer) and a purely hypothetical risk, the Viral Hepatitis Prevention Board supports the recommendation of the WHO that all countries should have universal infant and/or adolescent immunization programs and should continue to immunize adults at increased risk of hepatitis B infection as appropriate (29).

However, the French Ministry of Health has already compensated 14 patients on the basis of a link between hepatitis B vaccine and neurological effects (multiple sclerosis, retrobulbar neuritis) or rheumatological symptoms. According to a press release from the French Ministry of Health, the decision was taken in the interest of the patients, and despite the fact that even the experts from the Agence française de securité sanitaire des produits, who were charged with regularly re-evaluating the safety profile of hepatitis B vaccine, have not yet been able to conclude whether there is an actual association between the vaccine and the development of

© 2006 Elsevier B.V. All rights reserved.

multiple sclerosis or autoimmune disorders. It also stated that the decision in no way challenges the benefit:harm evaluation of hepatitis B vaccine and recommendations with respect to national immunization policies (30).

In the USA, following public discussions on the safety of hepatitis B vaccine, health officials, testifying in 1999 before the Government Reform Subcommittee on Criminal Justice, Drug Policy, and Human Resources, said that use of the vaccine has been monitored for 15 years, that it has not been proven to be the cause of deaths, and is only rarely linked to serious adverse effects (31).

Further studies have confirmed that there is no scientific evidence of a causal link between hepatitis B vaccine and multiple sclerosis (32–35). A European-wide study should be particularly mentioned. In 643 patients in various European countries during 1993–97, 15% of whom received various immunizations within 1 year before relapse, there was no increase in the risk in immunized patients compared with patients who did not receive any vaccine (36).

The results of a hospital-based case-control study in 121 patients with a first episode of central nervous demyelination occurring within 180 days after either hepatitis B vaccine or other vaccines have been reported (37). The results were compared with age- and sex-matched controls seen during the same period. No conclusion regarding a causal relation between hepatitis B vaccine and a first MS episode could be drawn, but the authors were not able to exclude such an association with certainty.

In summary the international consensus is that hepatitis B vaccine is still among the safest and most powerful vaccines in immunization programs and that it should be used worldwide.

Leukoencephalitis

Two episodes of leukoencephalitis occurred in a previously healthy patient after a second dose of HB vaccine and rechallenge with a third dose (38).

- A 39-year-old woman developed a complete right homonymous hemianopia and severe dyslexia 4 weeks after receiving a second dose of HB vaccine. Brain MRI showed a large lesion that occupied most of the left occipital lobe and extended into the splenium of the corpus callosum. Histological examination with immunoperoxidase staining, although not pathognomonic, was consistent with demyelinating disease. She underwent surgery and 1 week later there was marked improvement in her condition. Three months later (4.5 months after the second dose), she received a third dose of HB vaccine and 11 days later developed a left hemiparesis and acute progressive deterioration in vision. Brain MRI showed a new large lesion in the right parieto-occipital region, with the characteristics associated with the previous lesion. In comparison with previous findings, there was significant improvement in the left occipital lobe, in which there remained a proencephalic cyst. She was treated with dexamethasone and markedly improved. At 1 year and 2.5 years after the first episode she had residual dyslexia and a complete right homonymous hemianopia. An MRI scan showed almost complete resolution of the previous findings, with the exception of the proencephalic cyst.

The authors considered that acute leukoencephalitis is a rare but possible complication of HB vaccine.

Sensory systems

Eyes

Three days after recombinant hepatitis B booster immunization, a 31-year-old man developed acute posterior multifocal placoid pigment epitheliopathy (visual loss) and eosinophilia (39,40).

Papillitis (41) and retinal vein occlusion (42) have been attributed to hepatitis B vaccine.

Optic neuritis has been attributed to immunization with hepatitis A and B (43).

- A 21-year-old woman developed acute irreversible loss of vision to 0.05 and a nasal visual field defect in the left eye 2 weeks after immunization with hepatitis A and B and yellow fever vaccine. An MRI scan showed hyperintense thickening of the optic nerve, and a diagnosis of optic neuritis was made. Vision acuity did not recover but the scotoma disappeared within 6 weeks.

Ears

Two cases of hearing loss have been reported in patients given hepatitis B immunization (39). Acute tinnitus with permanent audiovestibular damage has been reported in temporal relation to hepatitis B administration (44).

Hematologic

There have been reports of individual cases of thrombocytopenia purpura (45) and pancytopenia (46) in temporal relation with hepatitis B vaccination.

- A healthy 7-year-old girl developed thrombocytopenic purpura after hepatitis B immunization, three doses of vaccine every month followed by a booster (47).

Pancytopenia has been reported in temporal relation to hepatitis B administration (48).

Mouth

Oral lichenoid lesions have been reported in temporal relation to hepatitis B administration (49).

Urinary tract

Acute glomerulonephritis (50) and minimal-change nephrotic syndrome (51) have been attributed to hepatitis B vaccine.

Skin

Erythema multiforme (52) and pityriasis rosea (53) have been reported after hepatitis B vaccination.

Alopecia (54), anetoderma (a disorder characterized by loss of dermal substance clinically and loss of elastic substance histologically) (55), lichen planus (56), urticaria (57), and white dot syndrome (58) have been attributed to hepatitis B vaccine.

Four cases of urticaria and one case of angioedema have been reported after hepatitis B immunization (59). The results emphasize that urticaria can be due to

© 2006 Elsevier B.V. All rights reserved.

sensitization to the hepatitis Bs antigen itself, hyperimmunization, or a non-allergic reaction.

The first case of erythermalgia (paroxysmal attacks of bilateral pain in the extremities, with an acute increase in local heat in the affected parts, the production and aggravation of the distress by heat, relieved by cold) probably caused by hepatitis B vaccine has been reported (60).

- A 17-year-old boy developed the symptoms of erythermalgia two days after a third dose of hepatitis B vaccine. He was severely ill and recovered only 2 months after treatment with immunoglobulin and hypnotherapy. During hospitalization it was learned that he had had transient moderate pain of both feet for 3 nights after the second dose of vaccine.

The disease that followed the third dose of hepatitis B vaccine therefore met the criteria for positive rechallenge.

Musculoskeletal

In 31 cases of suspected chronic fatigue syndrome associated with hepatitis B immunization, no causal relation was determined (61).

Juvenile chronic polyarthropathy (62) and reactive arthritis (63) have been attributed to hepatitis B vaccine. Erythema nodosum and polyarthritis occurred the day after Engerix-B vaccine administration (64). The authors referred to reports of three other cases of polyarthritis in the literature.

Immunologic

Hepatitis A

Vasculitis suspected to be caused by the first dose of hepatitis A vaccine has been reported (SEDA-21, 331).

Hepatitis B

Polyarteritis nodosa (53), Sjögren's syndrome (65), lymphocytic vasculitis (66), vasculitis (67), and systemic lupus erythematosus (68) have been attributed to hepatitis B vaccine.

- After hepatitis B immunization, three doses of vaccine every month followed by a booster, a healthy 24-year-old woman lost weight and developed migratory arthralgia (47). Acute disseminated lupus erythematosus was diagnosed.

The authors discussed the possibility that immunization could have introduced an antigen that may have provoked an autoimmune reaction in genetically predisposed family members.

Churg–Strauss vasculitis (allergic angiitis and granulomatosis) has been attributed to hepatitis B immunization (69).

- A 20-year-old woman developed chronic rhinitis 1 month after the last dose of hepatitis B, followed about 1 year later by severe asthma, nasal polyposis, and petechial purpura in her fingernail beds and on her feet. A skin biopsy from the left leg showed infiltrates consistent with leukocytoclastic vasculitis.

The interval between immunization and the development of the vasculitis made it very difficult to establish a causal relation in this case.

Large artery vasculitis (two cases) (70) and polyarteritis nodosa (71) have been reported in temporal relation to hepatitis B administration.

A case of arthritis (72) and three cases of vasculitis (73) have been described 7–20 days after immunization with hepatitis B. A causal relation in such very rare cases is unclear, and probably they do not occur more than could be expected by chance.

Second-Generation Effects

Teratogenicity

In the children of 10 women who had received hepatitis B vaccine during the first trimester of pregnancy there were no congenital abnormalities; at 2–12 months the infants were physically and developmentally normal for their ages (74).

Drug Administration

Drug additives

To increase immunogenicity, the hepatitis A vaccines commercially available are coupled to adjuvant aluminium phosphate or aluminium hydroxide. However, alum precipitates provoke inflammatory responses at the injection site. Immunostimulating reconstituted influenza virosomes have therefore been used as an alternative adjuvant. In 1994, a hepatitis A vaccine using the new adjuvant was licensed in Switzerland, and it was later approved for use in other countries: the vaccine was well tolerated and highly immunogenic (SEDA-20, 290) (SEDA-22, 344). Nine people with a history of ocular sensitivity were immunized with hepatitis B, without untoward reactions. However, this result in such a small series should not be overestimated (75). There have been reports of three cases of inflammatory nodular reactions after hepatitis B immunization; aluminium allergy was confirmed (76–78).

Four cases of reactions to thiomersal in hepatitis B vaccines (both plasma-derived and recombinant) have been reported from two centers (79,80). Although thiomersal is present in these vaccines at a concentration of only 1:20 000, it can cause severe cutaneous reactions of the delayed hypersensitivity type, and sometimes the reactions can be very long lasting.

To interpret strictly the package insert for hepatitis B vaccines would preclude its administration to persons with a history of ocular sensitivity to thiomersal.

Drug dosage regimens

Revaccination is sometimes necessary because only 50–70% of immunocompromised persons, especially dialysis patients, develop antibodies, and the anti-HBs titers in these cases are low. In revaccinated non-responders to primary hepatitis immunization using either 20 μg of plasma-derived vaccine or 10 μg of recombinant vaccine, depending on the vaccine used for previous doses, the revaccinations were well tolerated (81,82). Only 6.6% of the vaccinees reported slight irritation at the injection site, tenderness, minimal pain, or swelling lasting for a few hours up to 2 days.

© 2006 Elsevier B.V. All rights reserved.

Drug administration route

Aiming at cost reduction of hepatitis B immunization programs, the administration of low doses (2 micrograms) of vaccine given intradermally had by 1987 been evaluated in clinical trials in health-care workers (83) and children (84). The resulting seroconversion rates were 96 and over 90%, respectively. A minimum of local side effects occurred. In a comparison of antibody responses and adverse effects after intradermal or subcutaneous administration of 2 micrograms of a plasma-derived hepatitis B vaccine and intramuscular administration of 20 μg, the intradermal and intramuscular routes gave the highest seroconversion rates (100 and 96%, respectively) and the highest mean titers of anti-HBs (85). The aluminium adjuvant in the vaccine was assumed to cause a substantial number of local reactions (37% discoloration, 17% itching, and 13% nodule formation) after intradermal administration; other routes of administration showed adverse effects only rarely. Correct intradermal deposition of the vaccine is crucial.

Drug–Drug Interactions

Other vaccines

When recombinant hepatitis B vaccine was given together with DTP vaccine and oral poliomyelitis vaccine, there was no evidence of increased reactogenicity after simultaneous administration compared with hepatitis B vaccine alone (86).

In 40 children born to HBsAg-positive mothers who had received second and third doses of hepatitis B vaccine simultaneously with DTP vaccine and inactivated poliomyelitis vaccine, immunogenicity and reactogenicity were comparable with non-simultaneous administration of the different vaccines (87).

Herbal medicines

See also Individual plant genera

General Information

In principle, herbal medicines have the potential to elicit the same types of adverse reactions as synthetic drugs; the body has no way of distinguishing between "natural" and man-made compounds. Herbal medicines consist of whole extracts of plant parts (for example roots, leaves) and contain numerous potentially active molecules. Synergy is normally assumed to play a part in the medicinal effects of plant extracts, and medical herbalists have always claimed that whole plant extracts have superior effects over single isolated constituents. Similarly, it is also claimed that combinations of herbs have synergistic effects. There is in vitro and/or in vivo evidence to support the occurrence of synergism between constituents in certain herbal extracts (1,2); however, clinical evidence is lacking, and it is in any case uncertain how far the principle extends. Synergy is also taken to mean an attenuation of undesirable effects, another key tenet of herbalism being that the toxicity of plant extracts is less than that of a single isolated constituent. However, theoretically, plant constituents could also interact to render a herbal preparation more toxic than a single chemical constituent. Virtually no evidence is available to substantiate either hypothesis. It is also important to determine whether herbal treatments that have been shown to be as effective as conventional drugs have a better safety profile. Contrary to the belief of most herbalists, long-standing experience is by no means a reliable yardstick when it comes to judging the risk of adverse reactions (3).

Herbal medicine continues to be a growth area. In the UK, retail sales of complementary medicines (licensed herbal medicines, homoeopathic remedies, essential oils used in aromatherapy) were estimated to be £72 million in 1996, an increase of 36% in real terms since 1991 (4). This, however, is likely to be a gross underestimate as popular products sold as food supplements, including *Ginkgo biloba* and garlic, were not included. According to a detailed analysis of the herbal medicines market in Germany and France, total sales of herbal products in those countries in 1997 were US$1.8 billion and US$1.1 billion respectively (5). In 1994, annual retail sales of botanical medicines in the USA were estimated to be around US$1.6 billion; in 1998, the figure was closer to US$4 billion (6).

Some of the most useful data on trends in the use of herbal medicines come from two surveys of US adults carried out in 1991 and 1997/98, which involved over 1500 and over 2000 individuals respectively (7,8). The use of at least one form of complementary therapy in the 12 months preceding the survey increased significantly from 34% in 1990 to 42% in 1997. Herbal medicine was one of the therapies showing the most increase over this time period: there was a statistically significant increase in self-medication with herbal medicine from 2.5% of the sample in 1990 to 13% in 1997 (8). Disclosure rates to physicians of complementary medicine use were below 40% in both surveys (8). Furthermore, 18% of prescription medicine users took

© 2006 Elsevier B.V. All rights reserved.

prescription medicines concurrently with herbal remedies and/or high-dose vitamins. These aspects of user behaviour clearly have implications for safety.

A hospital-based study from Oman has suggested that 15% of all cases of self-poisoning seen in this setting are with traditional medicines (9). A case series from Thailand has suggested that in patients with oral squamous cell carcinoma the use of herbal medicines before the first consultation with a healthcare professional increases the risk of an advanced stage almost six-fold (10) and survey data from the USA have suggested that herb–drug interactions may be a significant problem in a sizeable proportion of patients (11).

Several herbal medicines pose serious problems for surgical patients, for example through an increased bleeding tendency (12,13). Vulnerable populations also include children (14), and too few safety data are available to recommend herbal medicines during pregnancy or lactation (15). Several investigators have pointed out the potential of herbal medicines to harm certain organs, for example the liver (16) or the skin (17). Laxatives are often based on herbal extracts, and the risks of herbal laxatives have been emphasized (18). Many authors have reviewed the risks of herbal medicines in general terms (19,20).

The reasons for the popularity of herbal medicine are many and diverse. It appears that complementary medicine is not usually used because of an outright rejection of conventional medicine, but more because users desire to control their own health (5) and because they find complementary medicine to be more congruent with their own values, beliefs, and philosophical orientations toward health and life (21). Also, users may consult different practitioners for different reasons (5). An important reason for the increase in use is that consumers (often motivated by the lay press) consider complementary medicine to be "natural" and assume it is "safe". However, this notion is dangerously misleading; adverse effects have been associated with the use of complementary therapies (22). Furthermore, complementary therapies may not only be directly harmful (for example adverse effects of a herbal formulation), but like other medical treatments have the potential to be indirectly harmful (for example through being applied incompetently, by delaying appropriate effective treatment, or by causing needless expense) (23).

Incidence of adverse effects

Most of the data on adverse effects associated with herbal medicines is anecdotal, and assessment and classification of causality is often not possible. Likewise, there have been few attempts to determine systematically the incidence of adverse effects of non-orthodox therapies.

Of 1701 patients admitted to two general wards of a Hong Kong hospital, 3 (0.2%) had adverse reactions to Chinese herbal drugs; two of the three were serious (24). In a retrospective study of all 2695 patients admitted to a Taiwan department of medicine during 10 months 4% were admitted because of drug-related problems, and herbal remedies ranked third amongst the categories of medicines responsible (25). In an active surveillance adverse drug reaction reporting program conducted in a family medicine ward of the National Taiwan University Hospital, Chinese crude drugs were responsible for five hospital admissions (22% of the total) or 12% of all adverse reactions observed in the study (26). This is a part of the world where the herbal tradition is particularly strong; the figures do not apply elsewhere.

The incidence of contact sensitization associated with topical formulations containing plant extracts was significant when evaluated in 1032 consecutive or randomly selected patients visiting patch test clinics in The Netherlands (27).

In a 5-year toxicological study of traditional remedies and food supplements carried out by the Medical Toxicology Unit at Guy's and St. Thomas' Hospital, London, 1297 symptomatic enquiries by medical professionals were evaluated (28). Of these, an association was considered to have been confirmed, probable, or possible in 12, 35, and 738 cases respectively. Ten of the confirmed cases were related to Chinese or Indian herbal remedies. As a result of these findings, in October 1996 the UK Committee on Safety of Medicines extended its yellow card scheme for adverse drug reaction reporting to include unlicensed herbal remedies, which are marketed mostly as food supplements in the UK (the scheme had always applied to licensed herbal medicines) (29,30). This was an important milestone in herbal pharmacovigilance.

A report from the Uppsala Monitoring Centre of the WHO has summarized all suspected adverse reactions to herbal medicaments reported from 55 countries worldwide over 20 years (31). A total of 8985 case reports were on record. Most originated from Germany (20%), followed by France (17%), the USA (17%), and the UK (12%). Allergic reactions were the most frequent serious adverse events and there were 21 deaths. The authors pointed out that adverse reactions to herbal medicaments constitute only about 0.5% of all adverse reactions on record.

General adverse effects

Several reviews have focused on herbal medicines and have covered:

- the toxicity of medicinal plants (32–34);
- the safety of herbal products in general (35–46);
- adverse effects in specific countries, for example the USA (47) and Malaysia (48);
- adverse effects on specific organs (49), such as the cardiovascular system (50), the liver (51,52), and the skin (53,54);
- the safety of herbal medicines in vulnerable populations: elderly patients (55), pregnant women (56), and surgical patients (57,58);
- carcinogenicity (59);
- the adverse effects of herbal antidepressants (60);
- the adverse effects of Chinese herbal medicaments (61,62);
- the adverse effects of Ayurvedic medicines (63);
- herb–drug interactions (64–75);
- pharmacovigilance of herbal medicines (76).

Direct effects associated with herbal medicines can occur in several ways:

- hypersusceptibility reactions
- collateral reactions
- toxic reactions
- drug interactions
- contamination

© 2006 Elsevier B.V. All rights reserved.

- false authentication
- lack of quality control.

Some of these effects relate to product quality. While there are some data on certain of these aspects, information on other aspects is almost entirely lacking. For example, there are isolated case reports of interactions between conventional medicines and complementary (usually herbal) remedies (23,77,78), although further information is largely theoretical (79).

Even a perfectly safe remedy (mainstream or unorthodox) can become unsafe when used incompetently. Medical competence can be defined as doing everything in the best interest of the patient according to the best available evidence. There are numerous circumstances, both in orthodox and complementary medicine, when competence is jeopardized:

- missed diagnosis
- misdiagnosis
- disregarding contraindications
- preventing/delaying more effective treatments (for example misinformation about effective therapies; loss of herd immunity through a negative attitude toward immunization)
- clinical deterioration not diagnosed
- adverse reaction not diagnosed
- discontinuation of prescribed drugs
- self-medication.

The attitude of consumers toward herbal medicines can also constitute a risk. When 515 users of herbal remedies were interviewed about their behavior vis a vis adverse effects of herbal versus synthetic over-the-counter drugs, a clear difference emerged. While 26% would consult their doctor for a serious adverse effect of a synthetic medication, only 0.8% would do the same in relation to herbal remedies (80).

The only way to minimize incompetence is by proper education and training, combined with responsible regulatory control. While training and control are self-evident features of mainstream medicine they are often not fully incorporated in complementary medicine. Thus the issue of indirect health risk is particularly pertinent to complementary medicine. Whenever complementary practitioners take full responsibility for a patient, this should be matched with full medical competence; if on the other hand, competence is not demonstrably complete, the practitioner in question should not assume full responsibility (81).

Asian herbalism

Most reports of adverse effects associated with herbal remedies relate to Chinese herbal medicines (82). This is an issue of growing concern, particularly because in many Western countries the popularity of Chinese herbalism is increasing. This is happening in the almost complete absence of governmental control (83) or of systematic research into the potential hazards of Chinese herbal formulations (84).

There have been several reports of adverse effects associated with Asian herbal formulations (85–105). Most of the serious adverse effects of Chinese herbal remedies are associated with formulations containing aconitine, anticholinergic compounds, aristolochic acid, or podophyllin, contaminating substances (106). Problems with Chinese herbal formulations are intensified because of nomenclature, since common, botanical, and Chinese names exist side by side, making confusion likely.

In a German hospital specializing in Chinese herbalism of 145 patients who had been treated within 1 year 53% reported having had at least one adverse effect attributable to Chinese herbal medicines (107). Nausea, vomiting, and diarrhea were the most common complaints. It should be noted that causality in these cases can only be suspected and not proven. In the same institution about 1% of 1507 consecutive patients treated with Chinese herbal mixtures had clinically relevant rises in liver enzymes (108,109). *Glycyrrhiza* radix and *Atractylodis macrocephalae* rhizome were most consistently associated with such problems. In most of these cases there were no associated clinical signs and the abnormalities tended to normalize without specific therapy and in spite of continued treatment with the Chinese herbal mixtures.

When 1100 Australian practitioners of traditional Chinese medicine were asked to complete questionnaires about the adverse effects of Chinese herbal mixtures, they reported 860 adverse events, including 19 deaths (110). It was calculated that each practitioner had encountered an average of 1.4 adverse events during each year of full-time practice.

A physician prospectively monitored all 1265 patients taking traditional Chinese medicines at his clinic during 33 months (111). Liver enzymes were measured before the start of therapy and 3 and 10 weeks later. Alanine transaminase activity was raised in 107 patients (8.5%) who initially had normal values. Of these patients, about 25% reported symptoms such as abdominal discomfort, looseness of bowels, loss of appetite, or fatigue.

A retrospective analysis of all adverse events related to herbal medicines and dietary supplements reported to the California Poison Control System has given data on the risks of the adverse effects of herbal medicines (112). Between January 1997 and June 1998, 918 calls relating to such supplements were received. Exposures resulting in adverse reactions occurred most often at recommended doses. There were 233 adverse events, of which 29% occurred in children. The products most frequently implicated were zinc (38%), *Echinacea* (8%), witch hazel (6%), and chromium picolinate (6%). Most of the adverse events were not severe and required no treatment; hospitalization was required in only three cases.

Quality control and purity of herbal products

Quality control for herbal medicaments that are sold as dietary supplements in most countries is poor (113,114). Thus, considerable variations in the contents of active ingredients have been reported, with lot-to-lot variations of up to 1000% (115). In most countries, the sale and supply of herbal remedies is to a large extent uncontrolled and unregulated; most herbal remedies are sold as unlicensed food supplements and their safety, efficacy, and quality have therefore not been assessed by licensing authorities. Adulteration and contamination of herbal remedies with other plant material and conventional drugs have been documented (25,116) (Table 1).

© 2006 Elsevier B.V. All rights reserved.

Table 1 Potential adulterants that should be taken into account in the quality control of herbal medicines

Type of adulterant	Examples
Allopathic drugs	Analgesic and anti-inflammatory agents (for example aminophenazone, indometacin, phenylbutazone), benzodiazepines, glucocorticoids, sulfonylureas, thiazide diuretics, thyroid hormones
Botanicals	*Atropa belladonna*, *Digitalis* species, *Colchicum*, *Rauwolfia serpentina*, pyrrolizidine-containing plants (see separate monograph on pyrrolizidines)
Fumigation agents	Ethylene oxide, methyl bromide, phosphine
Heavy metals	Arsenic, cadmium, lead, mercury
Micro-organisms	*Escherichia coli* (certain strains), *Pseudomonas aeruginosa*, *Salmonella*, *Shigella*, *Staphylococcus aureus*
Microbial toxins	Aflatoxins, bacterial endotoxins
Pesticides	Carbamate insecticides and herbicides, chlorinated pesticides (for example aldrin, dieldrin, heptachlor, DDT, DDE, HCB, HCH isomers), dithiocarbamate fungicides, organic phosphates, triazine herbicides
Radionuclides	^{134}Cs, ^{137}Cs, ^{103}Ru, ^{131}I, ^{90}Sr

The authors of a survey of German importers of Chinese herbs concluded that "only rarely" had herbal drugs to be returned because of contamination (117). The authors also stated that "a 100% check for all possible contaminants is not possible." However, there have been many reports of adulteration and contamination relate to Chinese herbal remedies (118). Instances include adulteration/contamination with conventional drugs (119,120), heavy metals (121–127), and other substances (128,129).

When 27 samples of commercially available camomile formulations were tested in Brazil, it was found that all of them contained adulterants and only 50% had the essential oils needed to produce anti-inflammatory activity (130).

Concerns about the quality and safety of herbal remedies are justified, and there have been repeated calls for greater control and regulation (28,131,132).

Adulteration with allopathic drugs

Barbiturates

Phenobarbital has been reported as a contaminant in a Chinese patent medicine (133).

- A 10-year-old boy developed respiratory depression and became comatose after taking the Chinese patent medicine "Diankexing" for 6 months. His urine phenobarbital concentration was 95 μg/ml (target range 20–40 μg/ml). The remedy was withdrawn and he was successfully treated with activated charcoal.

Benzodiazepines

The Botanical Lab in the USA has manufactured the herbal medicines PC-SPES and SPES (134). These two products are marketed as "herbal dietary supplements" for "prostate health" and for "strengthening the immune system" respectively. They are sold through the internet, by mail order, by phone order, and through various distributors and health care professionals. An analytical report from the California Department of Health in 2002 showed that samples of PC-SPES and SPES have been contaminated with alprazolam and warfarin. The Canadian Medicines Regulatory Authority also reported similar contaminations. In view of these reports Health Canada, the Irish Medicines Board, and the State Health Director of California all warned consumers to stop using these two products immediately and to consult their healthcare practitioners. Botanic Lab also informed consumers of these laboratory findings and issued a product recall of all lots of PC-SPES, pending further reports from additional testing of PC-SPES in both commercial and academic laboratories.

In 2001 the California State Health Director warned consumers to stop using the herbal product Anso Comfort capsules immediately, because the product contains the undeclared prescription drug chlordiazepoxide. Chlordiazepoxide is a benzodiazepine that is used for anxiety and as a sedative and can be dangerous if not taken under medical supervision (135). Anso Comfort capsules, available by mail or telephone order from the distributor in 60-capsule bottles, were clear with dark green powder inside. The label was yellow with green English printing and a picture of a plant. An investigation by the California Department of Health Services Food and Drug Branch and Food and Drug Laboratory showed that the product contained chlordiazepoxide. The ingredients for the product were imported from China and the capsules were manufactured in California. Advertising for the product claimed that the capsules were useful for the treatment of a wide variety of illnesses, including high blood pressure and high cholesterol, in addition to claims that it was a natural herbal dietary supplement. The advertising also claimed that the product contained only Chinese herbal ingredients and that consumers could reduce or stop their need for prescribed medicines. No clear medical evidence supported any of these claims. The distributor, NuMeridian (formerly known as Top Line Project), voluntarily recalled the product nationwide.

A San Francisco woman with a history of diabetes and high blood pressure was hospitalized in January 2001 with life-threatening hypoglycemia after she consumed Anso Comfort capsules. This may have been due to an interaction of chlordiazepoxide with other unspecified medications that she was taking.

Glucocorticoids

Wau Wa cream is marketed in several countries as a herbal cream for eczema. After repeatedly observing surprising therapeutic successes, UK doctors analysed three samples of this cream given to them by three patients (136). The samples contained 0.013% clobetasol propionate, a powerful glucocorticoid that does not occur naturally.

Betamethasone, 0.1–0.3 mg per capsule, has been detected in Cheng Kum and Shen Loon, two herbal medicines that are popular for their benefits in joint pain, skin

© 2006 Elsevier B.V. All rights reserved.

problems, colds, menopausal symptoms, and dysmenorrhea (137). Over-exposure to betamethasone can result in typical signs of glucocorticoid excess, such as moon face, hypertension, easy bruising, purple abdominal striae, truncal obesity, and hirsutism. The recommended daily adult dose of Cheng Kum is 1–3 capsules per day, and there have been reports of glucocorticoid-induced adverse effects in patients taking Cheng Kum and Shen Loon, even in the absence of other exogenous corticosteroid consumption.

- Two patients, a 29-year-old woman and a 10-year-old girl, developed Cushingoid features after taking Shen Loon for 4 and 5 months respectively (138). Their morning plasma cortisol concentrations were increased and adrenal suppression was confirmed by a short Synacthen test. Both recovered after withdrawal of the remedy and treatment with prednisone.

The New Zealand Medicines and Medical Devices Safety Authority (Medsafe) has notified that the further importation of these herbal products into New Zealand will be stopped at Customs. However, because of the risk of adrenal suppression from glucocorticoid, consumers have been sent a letter advising them against abruptly discontinuing these products. They should continue with the treatment and see their general practitioner as soon as possible for instructions on how they can be safely weaned off the product. Medsafe has issued a letter to doctors advising them to determine whether patients taking Cheng Kum or Shen Loon are at risk of adrenal suppression by estimating the potential total dose of glucocorticoid (from Cheng Kum or Shen Loon plus any exogenous steroids) and the duration of use, by examining the patient for signs of glucocorticoid excess, and by ascertaining if other risk factors for adrenal suppression are present (such as Addison's disease and AIDS).

Hypoglycemic drugs

Herbal medicines, particularly Chinese ones, are sometimes contaminated with conventional synthetic drugs (139). In 2000 the California Department of Health Services Food and Drug Branch issued a warning to consumers that they should immediately stop using five herbal products because they contained two prescription drugs that were not listed as ingredients and that are unsafe without monitoring by a physician (140). The products were Diabetes Hypoglucose Capsules, Pearl Hypoglycemic Capsules, Tongyi Tang Diabetes Angel Pearl Hypoglycemic Capsules, Tongyi Tang Diabetes Angel Hypoglycemic Capsules, and Zhen Qi Capsules. The products were available by mail order and could be purchased by telephone or via the Internet. Their manufacturers claimed that they contained only natural Chinese herbal ingredients. However, after a diabetic patient in Northern California had had several episodes of hypoglycemia after taking Diabetes Hypoglucose Capsules, an investigation by the Department showed that they contain the antidiabetic drugs glibenclamide (glyburide) and phenformin.

Penicillamine

Penicillamine unexpectedly caused myasthenia gravis when present as an unrecognized additive in Chinese herbs (141).

Various

A systematic review included 18 case reports, two case series, and four analytical studies showing adulteration with various allopathic drugs (142). The adulterants included phenazone (aminopyrine), clobetasol propionate and other glucocorticoids, diazepam, diclofenac, glibenclamide, hydrochlorothiazide, indometacin, mefenamic acid, methylsalicylate, phenacetin, phenylbutazone, and phenytoin.

In 2002 the Medicines Safety Authority of the Ministry of Health in New Zealand (Medsafe) ordered the withdrawal of several traditional Chinese medicines sold as herbal remedies, since they contained scheduled medicines and toxic substances (143). The products included the following allopathic drugs:

- Wei Ge Wang tablets, which contained sildenafil
- Sang Ju Gan Mao Pian tablets, which contained diclofenac and chlorphenamine
- Yen Qiao Jie Du Pian capsules, which contained chlorphenamine, diclofenac, and paracetamol
- Xiaoke Wan pills, which contained glibenclamide
- Shuen Feng cream, which contained ketoconazole
- Dezhong Rhinitis drops, which contained ephedrine hydrochloride.

The New Zealand Director General of Health issued a Public Statement asking people to stop taking these products and to seek medical advice. Medsafe asked all importers and distributors of traditional Chinese medicines to cease all distribution and sale of these products, to withdraw them from retail outlets, and to ensure that other products they sell do not contain scheduled medicines.

Adulteration with botanicals

Two cases have been reported of contamination of plantain (a plant of the genus *Plantago*) by *Digitalis lanata* (144). Both patients suffered from serious overdose of cardiac glycosides with toxic serum digoxin concentrations as a result.

Adulteration with heavy metals

In 2002 the Medicines Safety Authority of the Ministry of Health in New Zealand (Medsafe) ordered the withdrawal of several traditional Chinese medicines sold as herbal remedies, since they contained scheduled medicines and toxic substances (143). The products included Niu Huang Jie Du Pian tablets, which contain 4% arsenic.

In Taipei, 319 children aged 1–7 years were screened for increased blood lead concentrations (145). The consumption of Chinese herbal medicines was significantly correlated with blood lead concentrations. In 2803 subjects from Taipei a history of herbal drug taking proved to be a major risk factor for increased blood lead concentrations (146).

- A 56-year-old woman developed the signs and symptoms of lead poisoning after taking an Indian herbal medicine for many years (147). Her blood and urine lead concentrations were 1530 ng/ml and 4785 μg/day. She also had raised liver enzymes. After withdrawal of the remedy and treatment with penicillamine, she made a full recovery.
- Czech doctors reported the case of a 26-year-old woman who had taken an Ayurvedic remedy (Astrum FE Femikalp) for sterility (148). It contained lead 113 mg/kg. Her blood lead concentration was raised and

© 2006 Elsevier B.V. All rights reserved.

normalized 1 month after withdrawal of the remedy. Lead poisoning was also confirmed by hair analysis.

Of 260 Asian patent medicines available in California, 7% contained undeclared pharmaceuticals. When 251 samples were tested for heavy metals, 24 products contained at least 10 parts per million of lead, 36 contained arsenic, and 35 contained mercury (149).

Three Singapore patients with chronic arsenic poisoning with characteristic skin changes had taken Chinese herbal remedies for many years to treat their asthma; two had cancers likely to be due to arsenic (150).

Cases of adulteration with the heavy metals mercury (151) and lead (152) have been reported.

- A 5-year-old Chinese boy developed motor and vocal tics. His parents had given him a Chinese herbal spray to treat mouth ulcers. The spray contained mercury 878 ppm. Mercury poisoning was confirmed by the blood mercury concentration (183 nmol/l, normal value for adults under 50 nmol/l).
- A 5-year-old boy of Indian origin with encephalopathy, seizures, and developmental delay developed persistent anemia. The more obvious causes were ruled out and his blood lead concentration was high (860 ng/ml). He was treated with chelation therapy and his blood lead concentration fell. For the previous 4 years his parents had given him "Tibetan Herbal Vitamins," produced in India, which contained large amounts of lead. The investigators calculated that over that time he had ingested around 63 g of lead.

A total of 54 samples of Asian remedies, purchased in Vietnam, Hong Kong, Florida, New York, and New Jersey, were analysed for heavy metal adulteration (153). They contained concentrations of arsenic, lead, and mercury that ranged from merely exceeding published guidelines (74%) to toxic (49%).

Ayurvedic medicines have also been reportedly adulterated and contaminated (154). For example, they have repeatedly been associated with arsenic poisoning, including hyperpigmentation and hyperkeratosis (155). Of 70 unique Ayurvedic products manufactured in India or Pakistan and sold in Boston, mostly for gastrointestinal disorders, 14 contained lead, mercury, and/or arsenic, in concentrations up to about 100 mg/g (156).

Adulteration with inorganic chemicals

There is a practice among urbanized South African blacks to replace traditional herbal ingredients of purgative enemas with sodium or potassium dichromate. This switch can result in serious toxicity, characterized by acute renal insufficiency, gastrointestinal hemorrhage, and hepatocellular dysfunction (157,158).

Contamination with micro-organisms

When 62 samples of medicinal plant material and 11 samples of herbal tea were examined in Croatia, fungal contamination was found to be abundant (159). *Aspergillus flavus*, a known producer of aflatoxins was present in 11 and one sample respectively. Mycotoxins were found in seven of the samples analysed.

Kombucha "mushroom" is a symbiotic yeast/bacteria aggregate surrounded by a permeable membrane. An outbreak of skin lesions affecting 20 patients from a village near Tehran has been reported (160). The lesions were painless and had a central black necrotic area, marginal erythema, and severe peripheral edema. These clinical signs led to the suspicion of anthrax infection. It turned out that all patients had applied Kombucha mushroom locally as a painkiller. The skin lesions had developed 5–7 days after the application of the material. Cultures from the skin lesions confirmed the presence of *Bacillus anthracis*. Cultures of the Kombucha mushrooms were inconclusive, owing to multiple bacterial contamination and overgrowth, but it was shown that anthrax would grow on uncontaminated material. The patients all recovered with antibiotic therapy.

Contamination with pesticides

Some herbal medicaments are contaminated with pesticides (161).

Drug overdose

In a retrospective study of 2764 poisoning cases admitted to eight urban hospitals in Zimbabwe between 1998 and 1999, 7% of all cases and 13% of all deaths were related to traditional medicines (162). The authors noted that these figures were markedly lower than those from a similar survey 10 years earlier.

Susceptibility factors

Owing to extensive modifications of drug formulations and chemical extracts from an expanding range of natural products, herbal formulations may contain ingredients that are particularly harmful to individuals with glucose-6-phosphate dehydrogenase (G6PD) deficiency. Extra vigilance is therefore required when herbal medicinal formulations, including topical applications, are used by patients with G6PD deficiency and even their carers (163).

Thallophytes

Liver damage has been attributed to *Spirulina*, a type of blue–green algae.

- A 52-year-old Japanese man was admitted with signs and symptoms consistent with toxic liver damage (164). His medical history relevant to liver disease was unremarkable; in particular, his liver enzymes had been normal. It turned out that 5 weeks before admission he had started taking a remedy containing *Spirulina*. A lymphocyte stimulation test for *Spirulina* was positive and infectious hepatitis was excluded. Liver biopsy was consistent with toxic liver injury. After withdrawal of *Spirulina* all his liver enzymes quickly returned to normal.

Proprietary herbal mixtures

Numerous herbal mixtures are promoted worldwide, for example through the Internet. In many cases their herbal ingredients are not disclosed.

Copaltra

Copaltra is a herbal tea sold in France as an adjuvant therapy for diabetes. It contains *Coutarea latiflora* (50 g) and *Centaurium erythreae* (50 g).

- A 49-year-old black woman was admitted with jaundice and raised liver enzymes 4 months after starting to take

© 2006 Elsevier B.V. All rights reserved.

Copaltra (165). She also took fenofibrate, polyunsaturated fatty acids, metformin, benfluorex, and veralipride. Liver biopsy confirmed the diagnosis of acute, severe, cytolytic hepatitis, most likely drug-induced. She made a full recovery after withdrawal of Copaltra.

The authors mentioned that five similar cases of Copaltra-induced hepatitis have been reported to the French authorities.

Essiac

Essiac is a Canadian herbal mixture promoted as a cancer cure. It has been reported to have caused fever (166).

- A 46-year-old woman with a squamous cell carcinoma of the cervix developed neutropenic fever during radiation therapy, 10 days after taking Essiac. The fever resolved after antibiotic therapy, but it delayed her radiation therapy for 9 days and required 4 days of hospitalization.

The authors felt that Essiac had caused this problem, but causality was uncertain, not least because she also took four other herbal medicaments.

Herbalife

Herbalife is a complex herbal formula that is promoted for weight loss. Acute mania has been attributed to it (167).

- A 39-year-old man developed classic symptoms of mania within 4–72 hours of taking Herbalife. He continued to take it and after several days became psychotic, paranoid, and out of control, culminating in a high-speed car chase with the police. Bipolar disorder was diagnosed and treated, including withdrawal of the Herbalife, and he remained free of symptoms 3 months later.

The author thought it likely that the herbal mixture had caused the psychotic illness in a man who had no previous history of mental disturbance.

Iberogast

Iberogast contains extracts of bitter candy tuft, chamomile flower, peppermint leaves, caraway fruit, licorice root, lemon balm leaves, angelica root, celandine, and milk thistle fruit, and has been used to treat dyspepsia (168). In a systematic review, adverse events were rare and similar to those found with placebo (169).

Isabgol

Isabgol is an Italian herbal mixture that is promoted for constipation.

- Syncytial giant cell hepatitis occurred in a 26-year-old woman who used Isabgol (170). Autoimmune disease and viral infections were excluded.

The authors felt that the causative role of the Isabgol was supported by the spontaneous and dramatic clinical, biochemical, and histological improvement that followed the withdrawal of Isabgol without any further therapy.

Jai Wey Guo Sao

- A 36-year-old woman was admitted to hospital because of general malaise (171). She had lost 5 kg within 6 months. She was found to have interstitial renal fibrosis and irreversible renal insufficiency. She had taken a Chinese herbal mixture Jai wey guo sao to treat irregular menses. The formulation contained *Angelica sinensis* root, *Rhemanniae* root and rhizome, *Ligustici* rhizome, *Paeoniae lactiflore* root, ginseng root, *Eucommiae* cortex, and honey.

The causative agent in this case could not be identified beyond doubt.

Kampo medicines

All admission records of patients suspected of having liver problems related to Kampo medicines between 1979 and 1999 in a Japanese Department of Oriental Medicine were reviewed (172). There were 30 cases that were suspected of being caused by Kampo medicines. On closer examination, nine seemed to be definitely unrelated, six were probably unrelated, nine were possibly related, and six were definitely or probably related to Kampo medicines. There were no deaths on record.

Sho-saiko-to is a so-called kampo medicine, a mixture of herbs, including Chinese date, ginger root, and licorice root. It is reportedly contraindicated in patients taking interferons, patients with liver cirrhosis or hepatoma, and patients with chronic hepatitis and a platelet count of 100×10^9/l (http://www.kamponews.com). Sho-saiko-to has repeatedly been implicated in interstitial or eosinophilic pneumonias.

- A 45-year-old woman developed a high fever, a non-productive cough, and severe dyspnea (173). Her chest X-ray showed bilateral alveolar infiltrates. Treatment with antibiotics was not successful and her condition deteriorated. She was finally put on mechanical ventilation and subsequently improved dramatically. It turned out that she had previously taken sho-saiko-to for liver dysfunction of unknown cause.

Based on a positive lymphocyte stimulation test, the authors were confident that this herbal remedy had caused pulmonary edema.

Corneal opacities causing photophobia have been attributed to a Kampo medicine (174).

- A 30-year-old Japanese woman developed bilateral photophobia. There were dust-like opacities in both corneae. She had a superficial keratectomy, and electron microscopy identified the opacities as lipid-like particles. She had intermittently taken a Kampo medicine composed of 18 different herbal ingredients. Her photophobia coincided with episodes of taking this medicine. The remedy was withdrawn and her symptoms subsequently subsided. She then abstained from the Kampo medicine without recurrence.

Severe liver damage has been attributed to a Kampo medicine (175).

- A 50-year-old Japanese woman with a 20-year history of asthma was taking steroids and bronchodilators when she started self-medicating with a Kampo mixture called Saiko-Keishi-Kankyo-To. Two months later, she developed acute severe liver damage. The Kampo mixture was withdrawn and she promptly recovered.

© 2006 Elsevier B.V. All rights reserved.

The authors attributed the liver damage to one ingredient of the mixture, *Trichosanthes* radix, a Chinese medicament that is prepared from the root of *Trichosanthes kirilowii maxim* (Tian-hua-fen).

Lipokinetix
The slimming aid "LipoKinetix" contains norephedrine hydrochloride, sodium usinate, 3,5-diiodothyronine, yohimbine hydrochloride, and caffeine. Seven patients all had the signs and symptoms of acute toxic hepatitis after taking this dietary supplement (176). Three patients had taken no other concomitant medications. All recovered spontaneously after "LipoKinetix" was withdrawn.

Rio Hair Naturalizer System
Rio Hair Naturalizer System is a complex mixture of metallic salts and botanical extracts promoted to straighten curled hair. The product has been popular with African Americans in the USA. A survey of 464 individuals who had complained to the FDA about this remedy showed that 95% had experienced hair breakage and hair loss (177). Three-quarters of those who had hair loss had lost 40% or more; regrowth took 8 months on average.

Ting kung teng
Cholinergic poisoning has been attributed to a Chinese herbal mixture, Ting kung teng.

- A 73-year-old man developed a cholinergic syndrome, with dizziness, sweating, chills, lacrimation, salivation, rhinorrhea, nausea, and vomiting after taking the Chinese patent medicine Ting kung teng for arthritis (178). The herbal mixture contained tropane alkaloids with cholinergic activity. After withdrawal of the remedy he made a swift and complete recovery.

Tsumura
Tsumura, a Japanese herbal mixture has been associated with hepatotoxicity (179).

- A 49-year-old Japanese woman had taken oral Tsumura for about 6 weeks to treat internal hemorrhoids when she felt unwell. Her liver enzymes were raised and a diagnosis of drug-induced hepatic damage caused by *Angelica radix* and *Bupleuri* radix contained in the mixture was made. The liver function tests normalized 4 months after withdrawal.

Monographs on herbal products

Each of the monographs on herbal products in this encyclopedia has the following structure:

- Family: each monograph is organized under a family of plants (for example Liliaceae).
- Genera: the various genera that are included under the family name are tabulated (for example the family Liliaceae contains 94 genera); the major source of information on families and genera is the Plants National Database (http://plants.usda.gov/index.html).
- Species: in each monograph some species are dealt with separately. For example, in the monograph on Liliaceae, four species are included under their Latin names and major common names—*Sassafras albidum* (sassafras), *Allium sativum* (garlic), *Colchicum autumnale* (autumn crocus), and *Ruscus aculeatus* (butcher's broom).

Each monograph includes the following information in varying amounts:

- Alternative common names; the major sources of this information are *A Modern Herbal* by Mrs M Grieve (1931; http://www.botanical.com/botanical/mgmh/mgmh.html) and *The Desktop Guide to Complementary and Alternative Medicine: an Evidence-Based Approach* by E Ernst, MH Pittler, C Stevenson, and A White (Mosby, 2001).
- Active ingredients; the major source of this information is the *Dictionary of Plants Containing Secondary Metabolites* by John S Glasby (Taylor & Francis, 1991).
- Uses, including traditional and modern uses.
- Adverse effects.

The families of plants and their species that are the subjects of monographs are listed in Table 2 by alphabetical order of family. The same data are listed in Table 3 by alphabetical order of species. Other monographs cover the Basidiomycetes (*Lentinus edodes*, shiitake) and algae. Table 4 gives the Latin equivalents of the common names. To locate a plant by its common name, convert the common name into the Latin name using Table 4 and then find out to which family it belongs by consulting Table 3.

Table 2 Families of plants and their species that are the subjects of monographs in this encyclopedia (by alphabetical order of family)

Family (common name)	Species (common name)
Acoraceae (calamus)	*Acorus calamus* (calamus root)
Aloeaceae (aloe)	*Aloe capensis* (aloe)
	Aloe vera (aloe)
Amaranthaceae (amaranth)	*Pfaffia paniculata* (Brazilian ginseng)
Anacardiaceae (sumac)	*Rhus species* (sumac)
Apiaceae (carrot)	*Ammi majus* (bishop's weed)
	Ammi visnaga (toothpick weed)
	Angelica sinensis (dong quai)
	Conium maculatum (hemlock)
	Coriandrum sativum (coriander)
	Ferula assa-foetida (asafetida)
Apocynaceae (dogbane)	*Rauwolfia serpentina* (snakeroot)
Araliaceae (ginseng)	*Eleutherococcus senticosus* (Siberian ginseng)
	Panax ginseng (Asian ginseng)
Arecaceae (palm)	*Areca catechu* (areca, betel)
	Serenoa repens (saw palmetto)
Aristolochiaceae (birthwort)	*Aristolochia* species (Dutchman's pipe)
	Asarum heterotropoides (Xu xin)
Asclepiadaceae (milkweed)	*Asclepias tuberosa* (pleurisy root)
	Xysmalobium undulatum (xysmalobium)

© 2006 Elsevier B.V. All rights reserved.

Family (common name)	Species (common name)
Asteraceae (aster)	*Achillea millefolium* (yarrow)
	Anthemis species *and Matricaria recutita* (chamomile)
	Arnica montana (arnica)
	Artemisia absinthium (wormwood)
	Artemisea annua (Qinghaosu)
	Artemisia cina (wormseed)
	Artemisia vulgaris (common wormwood)
	Calendula officinalis (marigold)
	Callilepis laureola (impila, ox-eye daisy)
	Chrysanthemum vulgaris (common tansy)
	Cynara scolymus (artichoke)
	Echinacea species (coneflower)
	Eupatorium species (thoroughwort)
	Inula helenium (elecampane)
	Petasites species (butterbur)
	Senecio species (ragwort)
	Silybum marianum (milk thistle)
	Tanacetum parthenium (feverfew)
	Tussilago farfara (coltsfoot)
Berberidaceae (barberry)	*Berberis vulgaris* (European barberry)
	Caulophyllum thalictroides (blue cohosh)
	Dysosma pleianthum (bajiaolian)
	Mahonia species (barberry)
Boraginaceae (borage)	*Cynoglossum officinale* (hound's tongue)
	Symphytum officinale (black wort)
	Heliotropium species (heliotrope)
Brassicaceae (mustard)	*Armoracia rusticana* (horseradish)
	Brassica nigra (black mustard)
	Raphanus sativus var. niger (black radish)
	Sinapis species (mustard)
Campanulaceae (bellflower)	*Lobelia inflata* (Indian tobacco)
Cannabaceae	*Humulus lupulus* (hop)
Capparaceae (caper)	*Capparis spinosa* (caper plant)
Celastraceae (bittersweet)	*Catha edulis* (khat, qat)
	Euonymus europaeus (spindle tree)
	Tripterygium wilfordii (Lei gong teng)
Chenopodiaceae (goosefoot)	*Chenopodium ambrosioides* (American wormseed)
Clusiaceae (mangosteen)	*Hypericum perforatum* (St John's wort)
Convolvulaceae (morning glory)	*Convolvulus scammonia* (Mexican scammony)
	Ipomoea purga (jalap)
Coriariaceae	*Coriaria arborea* (tutu)
Cucurbitaceae (cucumber)	*Bryonia alba* (white bryony)
	Citrullus colocynthis (colocynth)
	Ecballium elaterium (squirting cucumber)
	Momordica charantia (karela fruit, bitter melon)
	Sechium edule (chayote)
Cupressaceae (cypress)	*Juniperus communis* (juniper)
Cycadaceae (cycad)	*Cycas circinalis* (false sago palm)
Droseraceae (sundew)	*Dionaea muscipula* (Venus flytrap)
Dryopteraceae (wood fern)	*Dryopteris filix-mas* (male fern)
Ericaceae (heath)	*Arctostaphylos uva-ursi* (bearberry)
	Gaultheria procumbens (wintergreen)
	Ledum palustre (marsh Labrador tea)
	Vaccinium macrocarpon (cranberry)
Euphorbiaceae (spurge)	*Breynia officinalis* (Chi R Yun)
	Croton tiglium (croton)
	Ricinus communis (castor oil plant)
Fabaceae (pea)	*Cassia* species (senna)
	Crotalaria species (rattlebox)
	Cyamopsis tetragonoloba (cluster bean)
	Cytisus scoparius (Scotch broom)
	Dipteryx species (tonka beans)
	Genista tinctoria (dyer's broom)
	Glycyrrhiza glabra (liquorice)
	Lupinus species (lupin)
	Medicago sativa (alfalfa)
	Melilotus officinalis (sweet clover)
	Myroxylon species (balsam of Peru)
	Pithecollobium jiringa (jering fruit)
	Sophora falvescens (Ku shen)
	Trifolium pratense (red clover)
Gentianaceae (gentian)	*Gentiana* species (gentian)
	Swertia species (felwort)
Ginkgoaceae	*Ginkgo biloba* (maidenhair)
Hippocastanaceae (horse chestnut)	*Aesculus hippocastanum* (horse chestnut)
	Illicium species (star anise)
Illiciaceae (star anise)	*Crocus sativus* (Indian saffron)
Iridaceae (iris)	*Juglans regia* (English walnut)
Juglandaceae (walnut)	*Krameria* species (ratany)
Krameriaceae (Krameria)	*Hedeoma pulegoides* (pennyroyal)
Lamiaceae (mint)	*Lavandula angustifolia* (lavender)
	Mentha piperita (peppermint)
	Mentha pulegium (pennyroyal)
	Salvia miltiorrhiza (danshen)
	Salvia officinalis (sage)
	Scutellaria species (skullcap)
	Teucrium species (germander)
Lauraceae (laurel)	*Cinnamonum camphora* (camphor tree)
	Laurus nobilis (laurel)
	Sassafras albidum (sassafras)
Liliaceae (lily)	*Allium sativum* (garlic)
	Colchicum autumnale (autumn crocus)
	Ruscus aculeatus (butcher's broom)
	Veratrum species (hellebore)
Loganiaceae (Logania)	*Strychnos nux-vomica* (nux vomica)
Lycopodiaceae (club moss)	*Lycopodium serratum* (clubmoss)
Malvaceae (mallow)	*Gossypium* species (cotton)
	Psoralea corylifolia (bakuchi)
Meliaceae (mahogany)	*Azadirachta indica* (bead tree)
Menispermaceae (moonseed)	*Stephania* species (Jin bu huan)
Myristicaceae (nutmeg)	*Myristica fragrans* (nutmeg)
Myrtaceae (myrtle)	*Eucalyptus* species (eucalyptus)
	Melaleuca alternifolia (tea tree)
Onagraceae (evening primrose)	*Oenothera biennis* (evening primrose)
	Chelidonium majus (celandine)

Table 2 Continued

Family (common name)	Species (common name)
Papaveraceae (poppy)	*Papaver somniferum* (opium poppy)
	Passiflora incarnata (passion flower)
Passifloraceae (passion flower)	*Harpagophytum procumbens* (devil's claw)
Pedaliaceae (sesame)	*Phytolacca americana* (pokeweed)
Phytolaccaceae (pokeweed)	*Piper methysticum* (kava kava)
Piperaceae (pepper)	*Plantago* species (plantain)
Plantaginaceae (plantain)	*Anthoxanthum odoratum* (sweet vernal grass)
Poaceae (grass)	*Polygonum* (knotweed)
Polygonaceae (buckwheat)	*Rheum palmatum* (rhubarb)
	Aconitum napellus (monkshood)
Ranunculaceae (buttercup)	*Cimicifuga racemosa* (black cohosh)
	Delphinium species (delphinium)
	Hydrastis canadensis (golden seal)
	Pulsatilla species (pasque flower)
	Ranunculus damascenus (buttercup)
	Rhamnus purshianus (cascara sagrada)
Rhamnaceae (buckthorn)	*Ziziphus jujuba* (dazao)
	Crataegus species (hawthorn)
Rosaceae (rose)	*Prunus* species (plum)
	Zingiber officinale (ginger)
	Asperula odorata (sweet woodruff)
Rubiaceae (madder)	*Cephaelis ipecacuanha* (ipecac)
	Hintonia latiflora (copalchi bark)
	Morinda citrifolia (noni)
	Rubia tinctorum (madder)
	Uncaria tomentosa (cat's claw)
	Agathosma betulina (buchu)
Rutaceae (rue)	*Citrus auranticum* (bergamot)
	Citrus paradisi (grapefruit)
	Dictamnus dasycarpus (densefruit pittany)
	Pilocarpus species (pilocarpus)
	Ruta graveolens (rue)
	Salix species (willow)
Salicaceae (willow)	*Blighia sapida* (akee)
Sapindaceae (soapberry)	*Paullinia cupana* (guaraná)
	Selaginella doederleinii (spike moss)
Selaginellaceae (spike moss)	*Anisodus tanguticus* (Zangqie)
Solanaceae (potato)	*Capsicum annum* (chili pepper)
	Datura candida (angel's trumpet)
	Datura stramonium (Jimson weed)
	Datura suaveolens (angel's trumpet)
	Lycium barbarum (Chinese wolfberry)
	Mandragora species (mandrake)
	Nicotiana tabacum (tobacco)
	Scopolia species (scopola)
	Sterculia species (sterculia)
Sterculiaceae (cacao)	*Taxus* species (yew)
Taxaceae (yew)	*Camellia sinensis* (green tea)
Theaceae (tea)	*Urtica dioica* (stinging nettle)
Urticaceae (nettle)	*Valeriana* (valerian)
Valerianaceae (valerian)	*Vitex agnus-castus* (chaste tree)
Verbenaceae (verbena)	*Phoradendron flavescens* (American mistletoe)
Viscaceae (Christmas mistletoe)	*Viscum album* (mistletoe)

Table 3 Families of plants and their genera or species that are the subjects of monographs in this encyclopedia (by alphabetical order of genus or species)

Genus or species (common name)	Family (common name)
Achillea millefolium (yarrow)	Asteraceae (aster)
Aconitum napellus (monkshood)	Ranunculaceae (buttercup)
Acorus calamus (calamus root)	Acoraceae (calamus)
Aesculus hippocastanum (horse chestnut)	Hippocastanaceae (horse chestnut)
Agathosma betulina (buchu)	Rutaceae (rue)
Allium sativum (garlic)	Liliaceae (lily)
Aloe capensis (aloe)	Aloeaceae (aloe)
Aloe vera (aloe)	Aloeaceae (aloe)
Ammi majus (bishop's weed)	Apiaceae (carrot)
Ammi visnaga (toothpick weed)	Apiaceae (carrot)
Angelica sinensis (dong quai)	Apiaceae (carrot)
Anisodus tanguticus (zangqie),	Solanaceae (potato)
Anthemis species (chamomile)	Asteraceae (aster)
Anthoxanthum odoratum (sweet vernal grass)	Poaceae (grass)
Arctostaphylos uva-ursi (bearberry)	Ericaceae (heath)
Areca catechu (areca, betel)	Arecaceae (palm)
Aristolochia species (Dutchman's pipe)	Aristolochiaceae (birthwort)
Armoracia rusticana (horseradish)	Brassicaceae (mustard)
Arnica montana (arnica)	Asteraceae (aster)
Artemisea annua (qinghaosu)	Asteraceae (aster)
Artemisia absinthium (wormwood)	Asteraceae (aster)
Artemisia cina (wormseed)	Asteraceae (aster)
Artemisia vulgaris (common wormwood)	Asteraceae (aster)
Asarum heterotropoides (xu xin)	Aristolochiaceae (birthwort)
Asclepias tuberosa (pleurisy root)	Asclepiadaceae (milkweed)
Asperula odorata (sweet woodruff)	Rubiaceae (madder)
Azadirachta indica (bead tree)	Meliaceae (mahogany)
Berberis vulgaris (European barberry)	Berberidaceae (barberry)
Blighia sapida (akee)	Sapindaceae (soapberry)
Brassica nigra (black mustard)	Brassicaceae (mustard)
Breynia officinalis (chi r yun)	Euphorbiaceae (spurge)
Bryonia alba (white bryony)	Cucurbitaceae (cucumber)
Calendula officinalis (marigold)	Asteraceae (aster)
Callilepis laureola (impila, ox-eye daisy)	Asteraceae (aster)
Camellia sinensis (green tea)	Theaceae (tea)
Capparis spinosa (caper plant)	Capparaceae (caper)
Capsicum annum (chili pepper)	Solanaceae (potato)
Cassia species (senna)	Fabaceae (pea)
Catha edulis (khat, qat)	Celastraceae (bittersweet)
Caulophyllum thalictroides (blue cohosh)	Berberidaceae (barberry)
Cephaelis ipecacuanha (ipecac)	Rubiaceae (madder)
Chelidonium majus (celandine)	Papaveraceae (poppy)
Chenopodium ambrosioides (American wormseed)	Chenopodiaceae (goosefoot)
Chrysanthemum vulgaris (common tansy)	Asteraceae (aster)
Cimicifuga racemosa (black cohosh)	Ranunculaceae (buttercup)

Genus or species (common name)	Family (common name)
Cinnamonum camphora (camphor tree)	Lauraceae (laurel)
Citrullus colocynthis (colocynth)	Cucurbitaceae (cucumber)
Citrus auranticum (bergamot)	Rutaceae (rue)
Citrus paradisi (grapefruit)	Rutaceae (rue)
Colchicum autumnale (autumn crocus)	Liliaceae (lily)
Conium maculatum (hemlock)	Apiaceae (carrot)
Convolvulus scammonia (Mexican scammony)	Convolvulaceae (morning glory)
Coriandrum sativum (coriander)	Apiaceae (carrot)
Coriaria arborea (tutu)	Coriariaceae
Crataegus species (hawthorn)	Rosaceae (rose)
Crocus sativus (Indian saffron)	Iridaceae (iris)
Crotalaria species (rattlebox)	Fabaceae (pea)
Croton tiglium (croton)	Euphorbiaceae (spurge)
Cyamopsis tetragonoloba (cluster bean)	Fabaceae (pea)
Cycas circinalis (false sago palm)	Cycadaceae (cycad)
Cynara scolymus (artichoke)	Asteraceae (aster)
Cynoglossum officinale (hound's tongue)	Boraginaceae (borage)
Cytisus scoparius (Scotch broom)	Fabaceae (pea)
Datura candida (angel's trumpet)	Solanaceae (potato)
Datura stramonium (Jimson weed)	Solanaceae (potato)
Datura suaveolens (angel's trumpet)	Solanaceae (potato)
Delphinium species (delphinium)	Ranunculaceae (buttercup)
Dictamnus dasycarpus (densefruit pittany)	Rutaceae (rue)
Dionaea muscipula (Venus flytrap)	Droseraceae (sundew)
Dipteryx species (tonka beans)	Fabaceae (pea)
Dryopteris filix-mas (male fern)	Dryopteraceae (wood fern)
Dysosma pleianthum (bajiaolian)	Berberidaceae (barberry)
Ecballium elaterium (squirting cucumber)	Cucurbitaceae (cucumber)
Echinacea species (coneflower)	Asteraceae (aster)
Eleutherococcus senticosus (Siberian ginseng)	Araliaceae
Eucalyptus species (eucalyptus)	Myrtaceae (myrtle)
Euonymus europaeus (spindle tree)	Celastraceae (bittersweet)
Eupatorium species (thoroughwort)	Asteraceae (aster)
Ferula assa-foetida (asafetida)	Apiaceae (carrot)
Gaultheria procumbens (wintergreen)	Ericaceae (heath)
Genista tinctoria (dyer's broom)	Fabaceae (pea)
Gentiana species (gentian)	Gentianaceae (gentian)
Ginkgo biloba (maidenhair)	Ginkgoaceae
Glycyrrhiza glabra (liquorice)	Fabaceae (pea)
Gossypium (cotton)	Malvaceae (mallow)
Harpagophytum procumbens (devil's claw)	Pedaliaceae (sesame)
Hedeoma pulegoides (pennyroyal)	Lamiaceae (mint)
Heliotropium species (heliotrope)	Boraginaceae (borage)
Hintonia latiflora (copalchi bark)	Rubiaceae (madder)
Humulus lupulus (hop)	Cannabaceae
Hydrastis canadensis (golden seal)	Ranunculaceae (buttercup)
Hypericum perforatum (St John's wort)	Clusiaceae (mangosteen)
Illicium species (star anise)	Illiciaceae (star anise)
Inula helenium (elecampane)	Asteraceae (aster)
Ipomoea purga (jalap)	Convolvulaceae (morning glory)
Juglans regia (English walnut)	Juglandaceae (walnut)
Juniperus communis (juniper)	Cupressaceae (cypress)
Krameria species (ratany)	Krameriaceae (Krameria)
Laurus nobilis (laurel)	Lauraceae (laurel)
Lavandula angustifolia (lavender)	Lamiaceae
Ledum palustre (marsh Labrador tea)	Ericaceae (heath)
Lobelia inflata (Indian tobacco)	Campanulaceae (bellflower)
Lupinus species (lupin)	Fabaceae (pea)
Lycium barbarum (Chinese wolfberry)	Solanaceae (potato)
Lycopodium serratum (clubmoss)	Lycopodiaceae (club moss)
Mahonia species (barberry)	Berberidaceae (barberry)
Mandragora species (mandrake)	Solanaceae (potato)
Matricaria recutita (chamomile)	Asteraceae (aster)
Medicago sativa (alfalfa)	Fabaceae (pea)
Melaleuca alternifolia (tea tree)	Myrtaceae (myrtle)
Melilotus officinalis (sweet clover)	Fabaceae (pea)
Mentha piperita (peppermint)	Lamiaceae
Mentha pulegium (pennyroyal)	Lamiaceae (mint)
Momordica charantia (karela fruit, bitter melon)	Cucurbitaceae (cucumber)
Morinda citrifolia (noni)	Rubiaceae (madder)
Myristica fragrans (nutmeg)	Myristicaceae (nutmeg)
Myroxylon species (balsam of Peru)	Fabaceae (pea)
Nicotiana tabacum (tobacco)	Solanaceae (potato)
Oenothera biennis (evening primrose)	Onagraceae (evening primrose)
Panax ginseng (Asian ginseng)	Araliaceae (ginseng)
Papaver somniferum (opium poppy)	Papaveraceae (poppy)
Passiflora incarnata (passion flower)	Passifloraceae (passion flower)
Paullinia cupana (guaraná)	Sapindaceae (soapberry)
Petasites species (butterbur)	Asteraceae (aster)
Pfaffia paniculata (Brazilian ginseng)	Amaranthaceae (amaranth)
Phoradendron flavescens (American mistletoe)	Viscaceae (Christmas mistletoe)
Phytolacca americana (pokeweed)	Phytolaccaceae (pokeweed)
Pilocarpus species (pilocarpus)	Rutaceae (rue)
Piper methysticum (kava kava)	Piperaceae (pepper)
Pithecollobium jiringa (jering fruit)	Fabaceae (pea)
Plantago species (plantain)	Plantaginaceae (plantain)
Polygonum (knotweed)	Polygonaceae (buckwheat)
Prunus species (plum)	Rosaceae (rose)
Psoralea corylifolia (bakuchi)	Malvaceae (mallow)
Pulsatilla species (pasque flower)	Ranunculaceae (buttercup)
Ranunculus damascenus (buttercup)	Ranunculaceae (buttercup)
Raphanus sativus var. niger (black radish)	Brassicaceae (mustard)
Rauwolfia serpentina (snakeroot)	Apocynaceae (dogbane)
Rhamnus purshianus (cascara sagrada)	Rhamnaceae (buckthorn)

Table 3 Continued

Genus or species (common name)	Family (common name)
Rheum palmatum (rhubarb)	Polygonaceae (buckwheat)
Rhus species (sumac)	Anacardiaceae (sumac)
Ricinus communis (castor oil plant)	Euphorbiaceae (spurge)
Rubia tinctorum (madder)	Rubiaceae (madder)
Ruscus aculeatus (butcher's broom)	Liliaceae (lily)
Ruta graveolens (rue)	Rutaceae (rue)
Salix species (willow)	Salicaceae (willow)
Salvia miltiorrhiza (danshen)	Lamiaceae (mint)
Salvia officinalis (sage)	Lamiaceae (mint)
Sassafras albidum (sassafras)	Lauraceae (laurel)
Scopolia species (scopola)	Solanaceae (potato)
Scutellaria species (skullcap)	Lamiaceae (mint)
Sechium edule (chayote)	Cucurbitaceae (cucumber)
Selaginella doederleinii (spike moss)	Selaginellaceae (spike moss)
Senecio species (ragwort)	Asteraceae (aster)
Serenoa repens (saw palmetto)	Arecaceae (palm)
Silybum marianum (milk thistle)	Asteraceae (aster)
Sinapis species (mustard)	Brassicaceae (mustard)
Sophora falvescens (ku shen)	Fabaceae (pea)
Stephania species (jin bu huan)	Menispermaceae (moonseed)
Sterculia species (sterculia)	Sterculiaceae (cacao)
Strychnos nux-vomica (nux vomica)	Loganiaceae (Logania)
Swertia species (felwort)	Gentianaceae (gentian)
Symphytum officinale (black wort)	Boraginaceae (borage)
Tanacetum parthenium (feverfew)	Asteraceae (aster)
Taxus species (yew)	Taxaceae (yew)
Teucrium species (germander)	Lamiaceae (mint)
Trifolium pratense (red clover)	Fabaceae
Tripterygium wilfordii (lei gong teng)	Celastraceae (bittersweet)
Tussilago farfara (coltsfoot)	Asteraceae (aster)
Uncaria tomentosa (cat's claw)	Rubiaceae (madder)
Urtica dioica (stinging nettle)	Urticaceae (nettle)
Vaccinium macrocarpon (cranberry)	Ericaceae (heath)
Valeriana (valerian)	Valerianaceae (valerian)
Veratrum species (hellebore)	Liliaceae (lily)
Viscum album (mistletoe)	Viscaceae (Christmas mistletoe)
Vitex agnus-castus (chaste tree)	Verbenaceae (verbena)
Xysmalobium undulatum (xysmalobium)	Asclepiadaceae (milkweed)
Zingiber officinale (ginger)	Rosaceae
Ziziphus jujuba (dazao)	Rhamnaceae (buckthorn)

Table 4 Conversion of common names of plants to Latin names

Common name	Latin name (genus or species)
Akee	*Blighia sapida*
Alfalfa	*Medicago sativa*
Aloe	*Aloe capensis*
Aloe	*Aloe vera*
American mistletoe	*Phoradendron flavescens*
American wormseed	*Chenopodium ambrosioides*
Angel's trumpet	*Datura candida*
Angel's trumpet	*Datura suaveolens*
Areca, betel	*Areca catechu*
Arnica	*Arnica montana*
Artichoke	*Cynara scolymus*
Asafetida	*Ferula assa-foetida*
Asian ginseng	*Panax ginseng*
Autumn crocus	*Colchicum autumnale*
Bajiaolian	*Dysosma pleianthum*
Bakuchi	*Psoralea corylifolia*
Balsam of Peru	*Myroxylon* species
Barberry	*Mahonia* species
Bead tree	*Azadirachta indica*
Bearberry	*Arctostaphylos uva-ursi*
Bergamot	*Citrus auranticum*
Bishop's weed	*Ammi majus*
Black cohosh	*Cimicifuga racemosa*
Black mustard	*Brassica nigra*
Black radish	*Raphanus sativus* var. niger
Black wort	*Symphytum officinale*
Blue cohosh	*Caulophyllum thalictroides*
Brazilian ginseng	*Pfaffia paniculata*
Buchu	*Agathosma betulina*
Butcher's broom	*Ruscus aculeatus*
Butterbur	*Petasites* species
Buttercup	*Ranunculus damascenus*
Calamus root	*Acorus calamus*
Camphor tree	*Cinnamonum camphora*
Caper plant	*Capparis spinosa*
Cascara sagrada	*Rhamnus purshianus*
Castor oil plant	*Ricinus communis*
Cat's claw	*Uncaria tomentosa*
Celandine	*Chelidonium majus*
Chamomile	*Anthemis* species
Chamomile	*Matricaria recutita*
Chaste tree	*Vitex agnus-castus*
Chayote	*Sechium edule*
Chi r yun	*Breynia officinalis*
Chili pepper	*Capsicum annum*
Chinese wolfberry	*Lycium barbarum*
Clubmoss	*Lycopodium serratum*
Cluster bean	*Cyamopsis tetragonoloba*
Colocynth	*Citrullus colocynthis*
Coltsfoot	*Tussilago farfara*
Common tansy	*Chrysanthemum vulgaris*
Common wormwood	*Artemisia vulgaris*
Coneflower	*Echinacea* species
Copalchi bark	*Hintonia latiflora*
Coriander	*Coriandrum sativum*
Cotton	*Gossypium* species
Cranberry	*Vaccinium macrocarpon*
Croton	*Croton tiglium*
Danshen	*Salvia miltiorrhiza*
Dazao	*Ziziphus jujuba*
Delphinium	*Delphinium* species
Densefruit pittany	*Dictamnus dasycarpus*
Devil's claw	*Harpagophytum procumbens*
Dong quai	*Angelica sinensis*
Dutchman's pipe	*Aristolochia* species
Dyer's broom	*Genista tinctoria*
Elecampane	*Inula helenium*
English walnut	*Juglans regia*
Eucalyptus	*Eucalyptus* species
European barberry	*Berberis vulgaris*
Evening primrose	*Oenothera biennis*
False sago palm	*Cycas circinalis*
Felwort	*Swertia* species
Feverfew	*Tanacetum parthenium*
Garlic	*Allium sativum*

© 2006 Elsevier B.V. All rights reserved.

Common name	Latin name (genus or species)
Gentian	*Gentiana* species
Germander	*Teucrium* species
Ginger	*Zingiber officinale*
Golden seal	*Hydrastis canadensis*
Grapefruit	*Citrus paradisi*
Green tea	*Camellia sinensis*
Guaraná	*Paullinia cupana*
Guar gum	*Cyamopsis tetragonoloba*
Hawthorn	*Crataegus* species
Heliotrope	*Heliotropium* species
Hellebore	*Veratrum* species
Hemlock	*Conium maculatum*
Hop	*Humulus lupulus*
Horse chestnut	*Aesculus hippocastanum*
Horseradish	*Armoracia rusticana*
Hound's tongue	*Cynoglossum officinale*
Impila, ox-eye daisy	*Callilepis laureola*
Indian saffron	*Crocus sativus*
Indian tobacco	*Lobelia inflata*
Ipecac	*Cephaelis ipecacuanha*
Jalap	*Ipomoea purga*
Jering fruit	*Pithecollobium jiringa*
Jimson weed	*Datura stramonium*
Jin bu huan	*Stephania* species
Juniper	*Juniperus communis*
Karela fruit, bitter melon	*Momordica charantia*
Kava kava	*Piper methysticum*
Khat, qat	*Catha edulis*
Knotweed	*Polygonum*
Ku shen	*Sophora falvescens*
Laurel	*Laurus nobilis*
Lavender	*Lavandula angustifolia*
Lei gong teng	*Tripterygium wilfordii*
Liquorice	*Glycyrrhiza glabra*
Lupin	*Lupinus* species
Madder	*Rubia tinctorum*
Maidenhair	*Ginkgo biloba*
Male fern	*Dryopteris filix-mas*
Mandrake	*Mandragora* species
Marigold	*Calendula officinalis*
Marsh Labrador tea	*Ledum palustre*
Mexican scammony	*Convolvulus scammonia*
Milk thistle	*Silybum marianum*
Mistletoe	*Viscum album*
Monkshood	*Aconitum napellus*
Mustard	*Sinapis* species
Noni	*Morinda citrifolia*
Nutmeg	*Myristica fragrans*
Nux vomica	*Strychnos nux-vomica*
Opium poppy	*Papaver somniferum*
Pasque flower	*Pulsatilla* species
Passion flower	*Passiflora incarnata*
Pennyroyal	*Hedeoma pulegoides*
Pennyroyal	*Mentha pulegium*
Peppermint	*Mentha piperita*
Pilocarpus	*Pilocarpus* species
Plantain	*Plantago* species
Pleurisy root	*Asclepias tuberosa*
Plum	*Prunus* species
Pokeweed	*Phytolacca americana*
Qinghaosu	*Artemisea annua*
Ragwort	*Senecio* species
Ratany	*Krameria* species
Rattlebox	*Crotalaria* species
Red clover	*Trifolium pratense*
Rhubarb	*Rheum palmatum*
Rue	*Ruta graveolens*
Sage	*Salvia officinalis*
Sassafras	*Sassafras albidum*
Saw palmetto	*Serenoa repens*
Scopola	*Scopolia* species
Scotch broom	*Cytisus scoparius*
Senna	*Cassia* species
Siberian ginseng	*Eleutherococcus senticosus*
Skullcap	*Scutellaria* species
Snakeroot	*Rauwolfia serpentina*
Spike moss	*Selaginella doederleinii*
Spindle tree	*Euonymus europaeus*
Squirting cucumber	*Ecballium elaterium*
St John's wort	*Hypericum perforatum*
Star anise	*Illicium* species
Sterculia	*Sterculia* species
Stinging nettle	*Urtica dioica*
Sumac	*Rhus* species
Sweet clover	*Melilotus officinalis*
Sweet vernal grass	*Anthoxanthum odoratum*
Sweet woodruff	*Asperula odorata*
Tea tree	*Melaleuca alternifolia*
Thoroughwort	*Eupatorium* species
Tobacco	*Nicotiana tabacum*
Tonka beans	*Dipteryx* species
Toothpick weed	*Ammi visnaga*
Tutu	*Coriaria arborea*
Valerian	*Valeriana*
Venus flytrap	*Dionaea muscipula*
White bryony	*Bryonia alba*
Willow	*Salix* species
Wintergreen	*Gaultheria procumbens*
Wormseed	*Artemisia cina*
Wormwood	*Artemisia absinthium*
Xu xin	*Asarum heterotropoides*
Xysmalobium	*Xysmalobium undulatum*
Yarrow	*Achillea millefolium*
Yew	*Taxus* species
Zang qie	*Anisodus tanguticus*

Hexacarbacholine

General Information

Hexacarbacholine is obsolete. Accounts of its adverse effects will be found in earlier volumes in this series (SED-10, 213) (SEDA-6, 131).

© 2006 Elsevier B.V. All rights reserved.

Hexachloroparaxylene

General Information

Hexachloroparaxylene has been used in China and Russia as an antihelminthic drug, principally to treat the liver fluke infections (clonorchiasis due to *Clonorchis sinensis*, schistosomiasis due to *Schistosoma japonicum*, and opisthorchiasis due to *Opisthorchiidae* (1,2). However, other treatments are preferred. It is also used very extensively in the veterinary field in Russia.

Hexachloroparaxylene causes gastrointestinal reactions, cardiac dysrhythmias (perhaps in over 50% of cases), and nephrotoxicity. Hemolysis can occur both early and late, and death can occur from the hemolytic–uremic syndrome (SEDA-4, 219). Late-onset hemolysis after treatment is associated with beta-thalassemia, while early-onset hemolysis is associated with hemoglobin H disease.

Hexachlorophene

See also Disinfectants and antiseptics

General Information

Hexachlorophene has been extensively used as an ingredient of innumerable kinds of consumer goods and medical formulations. Since 1961, when it was reported that daily bathing of newborn infants with a 3% hexachlorophene suspension prevented colonization of the skin by coagulase-positive staphylococci, hexachlorophene has been widely used in hospital nurseries.

However, hexachlorophene readily penetrates excoriated or otherwise damaged skin and absorption through intact skin has also been described. The most dramatic complication reported was due to accidental use in talcum powder in neonates, with neurological and other features and many deaths (1). Since then there has been reticence to use hexachlorophene in young infants at all, and certainly the customary 3% emulsion is too strong (2).

As a result of investigations of the toxicity of hexachlorophene in animals and reports of accidental intoxication in France, the FDA in 1972 banned all nonprescription uses of this drug, restricting hexachlorophene to prescription use only, as a surgical scrub and hand-wash product for health-care personnel. Hexachlorophene was excluded from cosmetics, except as a preservative in concentrations not exceeding 0.1%. Other countries followed suit. An extensive critical review of hexachlorophene is given by Delcour-Firquet (3).

Organs and Systems

Respiratory

- Occupational asthma occurred in a pediatric nurse who had worked with hexachlorophene for 15 years (4). The initial symptom was rhinitis but at the time of diagnosis she was also suffering from attacks of asthma.

Nervous system

Neurotoxicity has been observed after dermal application of hexachlorophene to large areas of burned or otherwise excoriated skin, after accidental application of extremely high concentrations on intact skin, and after ingestion. If hexachlorophene is applied in high concentrations or at frequent intervals to the intact skin, excoriation will result, increasing the risk of systemic effects.

In animals, there is a clear relation between dosage, blood concentrations, duration of treatment, and morphological and functional disturbances of the nervous system. In the lower dose range, there is unequivocal histological evidence of neurotoxicity, but without symptoms of neurotoxicity (SEDA-9, 397) (SEDA-11, 486).

Five Chinese patients aged 14–39 years were treated for *Conorchiasis sinensis* infection with oral hexachlorophene 20 mg/kg for 5–6 days (5). They developed nausea, vomiting, diarrhea, abdominal pain, general muscle weakness, and soreness in the eyeballs and legs. Of eight children treated similarly, one became comatose on the fourth day, with temporary loss of light reflex, alternating dilatation and contraction of the pupils, and positive cerebrospinal tract signs (6). The fundus showed papillary edema. Recovery followed symptomatic treatment.

In experimental animals, hexachlorophene can cause cerebral edema (7), and occasional cases have also been reported in humans (8). It affects exclusively the white matter of the brain and spinal cord and produces a spongiform encephalopathy, transforming the white matter into an extensive network of cystic spaces lined by fragments of myelin. Electron microscopy shows intramyelinic edema, with splitting and separation of the myelin lamellae. Nerve damage due to hexachlorophene appears to be reversible, although it takes many weeks for all the holes in the white matter to disappear. However, extensive edema occurring within a rigid structure such as the spinal canal can result in infarction of nervous tissue. In one study of all premature infants who weighed under 1400 g at birth and who survived at least 4 days, there was a significant association between repeated whole-body bathing in 3% hexachlorophene soap (undiluted pHisoHex) and a vacuolar encephalopathy of the brainstem reticular formation (9).

Sensory systems

Optic atrophy has been described after oral or topical use of hexachlorophene (10).

© 2006 Elsevier B.V. All rights reserved.

Second-Generation Effects

Teratogenicity

Teratogenicity has been reported (11), but was not confirmed in an expert review (12). In a 1977 study of Swedish medical personnel it was suggested that repeated handwashing with hexachlorophene-containing detergents during the first trimester of pregnancy could be associated with a greatly increased incidence of both major and minor birth defects in the offspring (11). This publication was the subject of extensive discussion, but it had several serious methodological deficiencies, and the hypothesis that hexachlorophene was teratogenic has never been further examined or confirmed. One reason why it was initially taken seriously was the fact that hexachlorophene crosses the placenta and accumulates in fetal neural tissue in mice and rats; the administration of toxic doses in these species is associated with birth defects, including cleft palate, hydrocephalus, anophthalmia, and microphthalmia in rats.

Topical exposure of male neonatal rats to a commercial hexachlorophene formulation produced significantly reduced fertility, resulting in inability to ejaculate. It was possibly caused by dioxin, an "androgenic" contaminant of hexachlorophene, responsible for permanent disruption of the integrated ejaculatory reflex. However, in subneurotoxic concentrations, hexachlorophene did not seem to cause significant impairment of spermatogenesis in rats or dogs.

Lactation

Hexachlorophene is secreted into breast milk (13).

Susceptibility Factors

Age

The blood concentrations of hexachlorophene, determined during newborn skin care with hexachlorophene bathing, cover a range that varies between studies (14–17) but are similar to the concentrations associated with neurotoxicity in monkeys (18), rats (19), and mice (SEDA-9, 397). In interpreting hexachlorophene plasma concentrations, it must be remembered that most of the hexachlorophene is probably distributed very rapidly into lipophilic tissues and that low plasma concentrations may correspond to high tissue concentrations.

A critical review of the available data on the risk of hexachlorophene bathing or other kinds of hexachlorophene use in neonatal skin care has suggested that there is ample evidence of the toxic potential of this disinfectant. It is absolutely contraindicated in infants with a low birth weight (under 2000 g), excoriated areas of the skin, and raised serum bilirubin. The use of a dusting powder with a maximal concentration of 0.3–0.5% seems to be connected with a lower risk of toxicity, but there was marked absorption of hexachlorophene after the application of 0.33% hexachlorophene dusting powder (20) and further information is needed about the pharmacokinetics of hexachlorophene in neonates.

The view that a small degree of edematous change in the central nervous system caused by hexachlorophene use in neonates should be reversible and is very probably without influence on the further development of the child cannot be accepted, because these changes are certainly the first signs of central nervous system toxicity.

- In a neonate treated with a 3% hexachlorophene lotion which had not been rinsed off, the skin became excoriated 4 days later and there was muscular twitching, which progressed to convulsions (21). Four days after withdrawal of hexachlorophene, the convulsions disappeared; recovery was complete.

In assessing the use of hexachlorophene in the nursery, one also has to consider the fact that infections with highly infective strains of staphylococci, producing serious life-threatening diseases, do not appear to be prevented or aborted by hexachlorophene bathing, and the problem that reduced staphylococcal colonization of infants by hexachlorophene may lead to an increased number of infections with Gram-negative bacteria.

Other features of the patient

Owing to the high absorption rate of hexachlorophene through damaged skin and the risk of fatal intoxication, the use of hexachlorophene in the treatment of burns or on otherwise excoriated skin is strongly contraindicated.

- A 10-year-old boy who had sustained 25% first-degree and second-degree burns and was treated with frequent daily applications of a 3% hexachlorophene emulsion (diluted and undiluted) developed a fatal encephalopathy (7).

In six of eight burned children, including four with a history of convulsive seizures after hexachlorophene use, serum concentrations of hexachlorophene were 4–74 ng/ml (approximately equivalent to blood concentrations of 2–37 ng/ml) (22).

In 1972, six deaths related to the use of hexachlorophene in patients with burns were reported to the FDA (23).

In four children, two of whom were being treated with 3% hexachlorophene baths for burns and two for severe congenital ichthyosis, the interval between exposure and symptoms ranged from 6 hours to 10 days (24). All showed severe vacuolation of the white matter in different areas of the cerebrum and cerebellum.

Drug Administration

Drug administration route

Hexachlorophene in vaginal lubricants is variably absorbed from the vaginal mucosa, and hexachlorophene can be identified in maternal and cord serum in an appreciable number of women in whom vaginal examinations during labor were carried out with a hexachlorophene-containing antiseptic lubricant (25). Because of the potential for neonatal hexachlorophene toxicity, the use of alternative lubricants for pelvic examinations is recommended.

Drug overdose

In France, in 1972, 6% hexachlorophene was accidentally included in certain batches of a baby talcum powder. French law prohibited publication of the detailed report

© 2006 Elsevier B.V. All rights reserved.

on the consequences of this contamination, until litigation was concluded. In 1977, a detailed report of 18 children involved in this accidental poisoning appeared (26) and in 1982 a report described 204 children (SEDA-10, 433) (1). Follow-up investigations of 14 surviving children have also appeared (26). There were no obvious cerebral sequelae, but follow-up was not long enough to exclude the possibility of more subtle damage, which may be manifest by learning difficulties or behavior disorders.

In four cases of accidental ingestion of hexachlorophene in human subjects, anorexia, nausea, vomiting, abdominal cramps, and diarrhea occurred (27). No neurological symptoms were reported.

- Bilateral atrophy of the optic nerve occurred in a 31-year-old woman who had ingested 10–15 ml of a 3% hexachlorophene emulsion orally each day for 10–11 months. She had also applied large amounts of hexachlorophene solution to her face every day as self-treatment for pimples. She was depressed during this period, noted no headache, diplopia, or dizziness, but may have had intermittent numbness of the left foot.
- Acute bilateral optic nerve necrosis occurred in a 7-year-old boy who accidentally received 3% hexachlorophene emulsion (about 12 g) over 52 hours. After the last dose he complained of intermittent blindness. Peritoneal dialysis was ineffective, and he died 98 hours after the last dose.

Hexanetriol

General Information

1,2,6-hexanetriol is used as a humectant, solvent, and viscosity-controlling agent in medicaments and cosmetics.

Organs and Systems

Immunologic

- A 35-year-old woman had a 3-week history of pruritic erythema, edema, and linear vesiculation of the upper arms where she had applied fluocinonide cream (1). Patch tests with the cream were positive, but the active ingredient fluocinonide (0.05% in petrolatum) was negative, while 1,2,6-hexanetriol 5% showed strong positive reactions on days 3 and 7.

© 2006 Elsevier B.V. All rights reserved.

Hexetidine

See also Disinfectants and antiseptics

General Information

Hexetidine has been used as an oral cavity antiseptic. At the concentration normally used (1 mg/ml), it is effective in vitro against Gram-positive bacteria and *Candida albicans*, but insufficiently active against most Gram-negative bacteria. However, the duration of the reduction in germ count is not longer than 1 hour. When applied to mucosae it also appears to have a mild local anesthetic property. Very little critical work on hexetidine has been published (SEDA-11, 482).

Organs and Systems

Sensory systems

Of 61 patients in whom hexetidine was used as a buccal and pharyngeal antiseptic, a minority, generally those who had just undergone tonsillectomy, complained of a burning sensation and a salty taste (1).

Skin

Allergic contact dermatitis has been reported (SEDA-11, 482) (2).

Drug Administration

Drug administration route

It is not clear whether the use of hexetidine as a spray, of which some will certainly be inhaled, affects its clinical tolerance. Adverse effects were not recorded in 81 patients treated in this way, but the report was not sufficiently detailed for a full assessment (3).

Hippocastanaceae

See also Herbal medicines

General Information

The family of Hippocastanaceae contains the single genus *Aesculus* (buckeye, horse chestnut).

Aesculus species

Aescin is a complex mixture of triterpene saponins prepared from the seeds of the horse chestnut, *Aesculus hippocastanum*. It consists of a water-soluble fraction (alpha-aescin) and a water-insoluble fraction (beta-aescin).

Adverse effects

A systematic review of randomized trials of extracts of horse chestnut in chronic venous insufficiency showed that adverse effects are usually mild, for example pruritus, nausea, headache, dizziness, and gastrointestinal symptoms (1).

Urinary tract

Beta-aescin has been repeatedly associated with acute renal insufficiency when given intravenously in massive doses. Whether such effects can also occur after oral administration is unclear, as animal studies have shown poor absorption of beta-aescin from the gastrointestinal tract. (SEDA-3, 181) (SEDA-9, 190).

Skin

Contact dermatitis has been ascribed to aescin (2), as has contact urticaria (3).

Drug interactions

Beta-aescin can precipitate renal insufficiency when combined with aminoglycoside antibiotics (SEDA-3, 181) (SEDA-9, 190).

Histamine H_2 receptor antagonists

See also Individual agents

General Information

The histamine H_2 receptor antagonists are selective antagonists at histamine receptors in the stomach, reducing gastric acid secretion.

The overall safety record of the currently marketed agents, particularly cimetidine and ranitidine, which have had extensive worldwide use, is excellent, and in practice safety issues seldom affect drug choice (1), except perhaps when it is necessary to avoid interactions with phenytoin, theophylline, or warfarin. Surveillance studies, which have been going on for a quarter of a century (including 10-year studies in many patients, mainly involving cimetidine and ranitidine), have failed to detect any serious adverse effects other than those recognized by 1980, or any adverse effect on mortality (2).

The H_2 receptor antagonists do not prevent gastroduodenal ulceration by non-steroidal anti-inflammatory drugs, but they do prevent stress-induced ulceration and bleeding. In intensive care units there is evidence of a beneficial effect, but in patients with hematemesis and melena there is little evidence that H_2 receptor antagonists reduce rates of transfusion, surgical intervention, or mortality (SEDA-19, 326).

Observational studies

The use, efficacy, and adverse effects of non-prescription H_2 receptor antagonists and alginate-containing formulations obtained from community pharmacies have been evaluated in 767 customers with dyspepsia (3). Most obtained some or complete symptom relief (75%) and were completely satisfied with the product (78%). H_2 receptor antagonists were more likely to produce complete relief of symptoms than alginate-containing formulations. Only 3% reported adverse effects: diarrhea, constipation, bloating, and flatulence from alginate formulations, and dry mouth, altered bowel habit, diarrhea, and constipation from H_2 receptor antagonists.

Changes in healthcare utilization resulting from a formulary switch from nizatidine to cimetidine have been studied in 704 patients (4). There was no evidence of increased healthcare utilization during the 6 months after the formulary switch, which led to considerable pharmaceutical savings. During this period only four (0.004%) adverse drug reactions associated with cimetidine were reported; urticaria, nausea and vomiting, leg cramps, and impotence.

Comparative studies

Several treatments are available for promoting the healing of gastric and duodenal ulcers associated with the use of non-steroidal anti-inflammatory drugs (NSAIDs). They include histamine receptor antagonists, proton pump inhibitors, and prostaglandin analogues. Two large randomized, double-blind, multicenter trials in a total of 1456 patients have compared the efficacy of ranitidine 150 mg bd with omeprazole 20 or 40 mg/day (ASTRONAUT study) (5) and omeprazole 20 or 40 mg/day with misoprostol 200 micrograms qds (OMNIUM study) (6) in the treatment of NSAID-induced ulcers. The proportions of the patients with treatment success at 8 weeks were 77% with both doses of omeprazole, 63% with ranitidine, and 71% with misoprostol. The most frequent adverse effects were diarrhea in 11% and abdominal pain in 8% of patients taking misoprostol. Both these adverse effects were 2–4 times more frequent with misoprostol than with omeprazole. Withdrawal from the study owing to adverse effects was also more frequent in the misoprostol arm of the OMNIUM study.

Placebo-controlled studies

The effects of ranitidine 75 mg, famotidine 10 mg, and placebo, given 1 hour after a standard lunch, on intragastric acidity have been compared in 24 healthy volunteers (7). Low-dose ranitidine and famotidine reduced acidity significantly more than placebo during the daytime and nighttime. The effect of ranitidine was significantly greater than famotidine during the first 2.5 hours after dosing.

Organs and Systems

Cardiovascular

Rapid intravenous administration of ranitidine, cimetidine, or famotidine can precipitate cardiovascular complications, notably bradycardia, hypotension, and dysrhythmias (SEDA-20, 317).

Hematologic

H_2 receptor antagonists cause a significant reduction in the absorption of vitamin B_{12} from food. This is thought to be due to impaired release of the vitamin from food protein, which requires gastric acid and pepsin as the initial step in the absorption process. This can be sufficient to cause vitamin deficiency and anemia, notably in patients who have low body stores of vitamin B_{12} and are taking an H_2 receptor antagonist over a long period (8).

- Vitamin B_{12} deficiency has been reported in a 78-year-old non-vegetarian white woman with gastro-esophageal reflux who had taken H_2 receptor antagonists and omeprazole for 4.5 years (9).

Pancreas

The risk of acute pancreatitis associated with the use of acid-suppressing drugs has been assessed in a retrospective cohort study with a nested case-control design within the General Practice Research Database in the UK (10). The study included 180 178 people aged 20–74 years who had received at least one prescription for cimetidine, famotidine, nizatidine, ranitidine, lansoprazole, or omeprazole from January 1992 to September 1997, and who did not have major risk factors for pancreatic diseases. There were no cases of pancreatitis among users of famotidine, lansoprazole, or nizatidine. The relative risk compared with non-use, corrected for age, sex, calendar year, and use of medication known to be associated with pancreatitis was 1.3 (95% CI = 0.4, 4.1) for ranitidine, 2.1 (0.6,7.2) for cimetidine, and 1.1 (0.3,4.6) for omeprazole. The results do not support an association between acute pancreatitis and acid-suppressing drugs.

Musculoskeletal

In 33 patients taking cimetidine, ranitidine, or famotidine for more than 2 years there was little effect on the degree of bone mineral density (11).

© 2006 Elsevier B.V. All rights reserved.

Immunologic

Early studies suggested an increased risk of nosocomial pneumonia associated with H_2 receptor antagonists in critically ill patients. To investigate this further, two randomized studies have been performed. One compared ranitidine (0.25 mg/kg/hour intravenously) with sucralfate (1 g every 6 hours via nasogastric tube) for prophylaxis against stress-induced gastritis in 96 severely injured patients (12). Ranitidine was associated with a 1.5 times increased risk of developing any infection compared with sucralfate. Furthermore, of the 49 patients who received ranitidine, 14 developed 26 separate episodes of pneumonia, while of the 47 patients who received sucralfate, 10 developed 14 episodes of pneumonia. The other study, placebo-controlled, compared intravenous ranitidine (50 mg tds) and pirenzepine (10 mg tds) in 158 patients who were being mechanically ventilated; the pneumonia rates were similar in the three groups (13).

In another study of stress ulcer prophylaxis, 53 critically ill patients were randomized to receive sucralfate 1 g 6-hourly, cimetidine 300 mg 8-hourly, or cimetidine 900 mg/day by continuous intravenous infusion (14). Although bacterial colonization was increasingly likely in patients with a persistent alkaline gastric environment, gastric luminal pH and the degree of bacterial colonization of the stomach were similar in the three groups.

Long-Term Effects

Tumorigenicity

Tumor-inducing effects have been much discussed ever since the introduction of the H_2 receptor antagonists but their existence has not been clearly established. The discussion was seeded by:

- findings of intestinal metaplasia of the gastric epithelium in rats used for chronic toxicity studies, though only at extraordinarily high doses, followed by the appearance of intramucosal carcinomas in the pyloric region after 11 months of study;
- reports of patients taking cimetidine in whom gastric carcinoma was diagnosed; however, the drug has been widely (and sometimes without careful prior diagnosis) used in patients with a range of gastric disorders, and some of these are believed to have had early carcinomas at the time when cimetidine was started (15);
- the fact that cimetidine can undergo nitrosylation to form a mutagen;
- the structural resemblance of cimetidine to tiotidine, which can cause gastric carcinoma in animals.

In a retrospective case-control assessment of medical records of 56 patients who died of cardio-esophageal adenocarcinoma and 56 age- and sex-matched controls who died of myocardial infarction, subjects who died of cardio-esophageal adenocarcinoma were more likely to have consumed H_2 receptor antagonists (RR = 7.5; 95% CI = 1.3,42) (16).

However, there is still no valid reason for considering the H_2 receptor antagonists to be tumorigenic, and when studies have detected some excess incidence of gastric cancer in long-term users of H_2 receptor antagonists this was attributable to selection bias (17). The fact that drugs of this type have now been released for self-medication in many countries seems very likely to lead to an increase in the incidence of cases in which an H_2 receptor antagonist is used without prior exclusion of premalignant or malignant change, thus confusing the situation further.

Second-Generation Effects

Teratogenicity

In 178 women who took H_2 receptor antagonists during the first 3 months of pregnancy and 178 pregnant controls there was no evidence of teratogenicity (SEDA-21, 362).

Susceptibility Factors

Renal disease

In patients with renal insufficiency the elimination of H_2 receptor antagonists is subject to significant and clinically relevant alterations (18). Doses should be reduced, and ranitidine bismuth citrate should be avoided altogether in severe renal insufficiency.

Dialysis has no major effect on dosage schedules, because only negligible amounts of H_2 receptor antagonists are removed by this route (SEDA-19, 326).

Drug–Drug Interactions

Alcohol

A meta-analysis of 24 studies showed that cimetidine and ranitidine, but not famotidine or nizatidine, caused small increases in blood alcohol concentrations (19). The mechanism is unclear, but one possibility is inhibition of gastric alcohol dehydrogenase. However, relative to accepted legal definitions of intoxication the effect of any histamine receptor antagonist on blood alcohol concentrations is unlikely to be clinically significant.

HMG coenzyme-A reductase inhibitors

See also Individual agents

General Information

Statins inhibit HMG-CoA reductase and reduce cellular cholesterol synthesis (1). Lower intracellular cholesterol concentrations cause over-expression of the LDL receptor in the plasma membrane of hepatocytes. This overexpression increases the clearance of circulating LDL, reducing plasma concentrations of LDL cholesterol.

The statins include atorvastatin, bervastatin, cerivastatin, crilvastatin, dalvastatin, fluvastatin, glenvastatin, lovastatin, mevastatin, pitavastatin, pravastatin, rosuvastatin, simvastatin, and tenivastatin (all rINNs). Atorvastatin, cerivastatin, fluvastatin, lovastatin, pravastatin, and simvastatin are covered in separate monographs.

The adverse effects of the statins are mostly limited to slight increases in liver and muscle enzymes in the blood. Hypersensitivity reactions are very rare. There is no evidence of tumor-inducing effects. Second-generation effects are suspected, and statins should not be used during pregnancy.

Organs and Systems

Nervous system

Ratings on a depression scale rose in four out of six men given cholesterol-lowering drugs, in two of them to a degree that met the criteria for mild clinical depression (2).

Statins interfere with the production of isoprene which is somehow connected with sleep, but there have been neither changes in sleep EEG measures relevant to insomnia nor changes in the quality of sleep (SEDA-13, 1327) (3). However, there has been a report of sleep disturbances (4).

- Three months after starting to take metoprolol 100 mg bd and simvastatin 10 mg/day, a 55-year-old man reported restless nights and nightmares, which he had not previously experienced. The dose of metoprolol was reduced to 50 mg bd, with no observable benefit. Simvastatin was withdrawn 2 weeks later and pravastatin 20 mg/day was prescribed, with substantial improvement in the quality of sleep; however, some unpleasant nightmares still occurred. Four weeks later, metoprolol was also withdrawn and atenolol 100 mg/day was prescribed. Thereafter, the quality of sleep was significantly improved, and 6 months later the patient did not report any nightmares. Sleep disturbances recurred after a later attempt to reintroduce simvastatin in place of pravastatin. The same effect occurred when, during treatment with pravastatin, substitution of atenolol with metoprolol was attempted.

In this case, the statins may have interacted with metoprolol, and it may have been relevant that metoprolol is more lipid-soluble than atenolol.

Peripheral neuropathy occurs with statins, and perhaps with all cholesterol-lowering drugs, and may be related to reduced production of ubiquinone, as suggested in a review (5). Moreover, it appears that once a statin produces a neuropathy, rechallenge with any other statin is likely to cause a recurrence. This is reported to occur 1–3 weeks after rechallenge, whereas the resolution takes 4–6 weeks after withdrawal (5).

In a series of seven cases of neuropathy, all were axonal peripheral neuropathies and both thick and thin nerve fibers were affected (6). No cause of peripheral neuropathy other than statin treatment could be identified. In this

© 2006 Elsevier B.V. All rights reserved.

series at least four of the cases were irreversible, probably due to long exposure to statins (4–7 years versus 1–2 years in previous reports). Besides an effect on ubiquinone, interference with cholesterol synthesis may alter nerve membrane function, since cholesterol is a ubiquitous component of human cell membranes. Neuropathy has not been observed in extensive long-term trials of lipid-lowering drugs. It could be due to patient selection, a low frequency of the adverse effect, or lack of attention to symptoms of peripheral neuropathy. The observed association may also not be causal.

In a case-control study of 166 cases of idiopathic polyneuropathy, of which 35 had a definite diagnosis, the odds ratio for neuropathy was 14 for statin users compared with non-users (7).

With the current level of information, it is prudent to consider withdrawal of statins in patients with symptoms compatible with polyneuropathy.

Sensory systems

One should be alert to the possibility of color blindness due to statins (8), although the risk is uncertain.

Owing to the high cholesterol content of the human lens, ocular changes have been looked for during trials with statins. It has been concluded that cataract does not occur. Although the degree of lens opacities increases during treatment, the incidence does not differ from that seen in an untreated control population (9). With fenofibrate serving as control, lovastatin or simvastatin did not reduce visual acuity during treatment for 2 years (SEDA-13, 1328) (10). According to a review, there is no danger during long-term treatment and there should be no requirement for regular ophthalmological examination (11).

Psychological, psychiatric

Animal and cross-sectional studies have suggested that serum lipid concentrations can cause altered cognitive function, mood, and behavior (11).

Metabolism

Although the statins seem to be similar in their ability to lower LDL, there are also dissimilarities. For instance, simvastatin increases HDL cholesterol with increasing doses, whereas atorvastatin does not (12). The clinical significance of this is unknown.

Hematologic

Hematological adverse effects can occur during treatment with both simvastatin and atorvastatin, according to a brief review (13). They include thrombotic thrombocytopenic purpura and severe thrombocytopenic purpura.

Liver

HMG CoA reductase inhibitors can be associated with small rises in alanine transaminase activity, but have not been definitely associated with severe morbidity involving altered hepatic function. All cases of acute liver failure related to the use of lovastatin have been reviewed, and probably the frequency is similar to the background rate. This suggests that periodic monitoring of alanine transaminase in these patients would be burdensome and expensive (14).

The term "transaminitis" has been coined to describe a rise in the activities of serum transaminases without clinical symptoms. One author has suggested that in such cases one should switch from one statin to another, thereby preventing unnecessary withdrawal of statin treatment in dyslipidemic patients at high cardiovascular risk (15).

A return to normal or only slightly increased values of transaminases is often seen after a short period. The overall probability of having an increase in transaminase activity more than three times the top of the reference range is 0.7% (16). The probability may be increased in patients with pre-existing minor hepatic changes, as has been seen in one patient with systemic lupus erythematosus (17). There seems to be no difference between the various drugs in this respect (11), but when simvastatin and atorvastatin, each at a dose of 80 mg/day, were compared in 826 hypercholesterolemic patients there were fewer drug-related gastrointestinal symptoms and clinically significant transaminase rises with simvastatin (18). Frank hepatitis is rare. A cholestatic picture has also been reported (19). The mechanisms of these reactions are not known.

In one series, the frequency of liver toxicity was similar in patients taking pravastatin or simvastatin (20), while in another study there was a difference 6 months after the start of the study when the simvastatin group showed increases in liver enzymes (SEDA-13, 1327) (21).

In a comparison of atorvastatin with pravastatin, of 224 patients taking atorvastatin, two had clinically significant increases in alanine transaminase activity (22). They recovered during the next 4 months, one after withdrawal of atorvastatin and the other after a dosage reduction. Withdrawals due to adverse effects were similar in the two groups. One patient developed hepatitis while taking atorvastatin, but was able to tolerate simvastatin (23). The authors concluded that this adverse effect was not a class effect. Eosinophils in a liver-biopsy specimen pointed to an immunological mechanism.

Pancreas

Pancreatitis has been observed during treatment with simvastatin (q.v.).

- A 77-year-old woman taking rosuvastatin developed acute pancreatitis, which resolved on withdrawal (24). No other cause for the pancreatitis was found. She had had a similar episode 1 year before precipitated by atorvastatin, which resolved on withdrawal.

The authors suggested that pancreatitis may be a class effect of the statins.

Skin

Adverse effects of statins on the skin are rare, although statins can affect cutaneous lipid content. A series of skin reactions have been described in patients using statins (25).

Musculoskeletal

Rhabdomyolysis is a problem with several lipid-lowering drugs (SEDA-13, 1325) (SEDA-13, 1328) (SEDA-13,

© 2006 Elsevier B.V. All rights reserved.

1330) (SEDA-19, 409), especially when they are used in combination (26). In individuals with pre-existing renal insufficiency this can lead to an earlier need for chronic dialysis (27). Interactions between various hypolipidemic drugs and other drugs also sometimes cause rhabdomyolysis (SEDA-18, 426). For instance, itraconazole markedly increases plasma concentrations of lovastatin, and in one subject plasma creatine kinase was increased 10-fold within 24 hours of administration of this combination (28).

In four patients with muscle symptoms while taking statins, creatine kinase activity was normal, but they were subsequently able to distinguish from their symptoms whether they were taking drug or placebo; muscle biopsies showed evidence of mitochondrial dysfunction (29).

Hypothyroidism predisposes to rhabdomyolysis and screening thyroid function has been advocated before starting hypolipidemic drugs (SEDA-21, 458).

Myopathic symptoms, predominantly stiffness and tenderness of proximal limb muscles and difficulty in rising from a low chair, can develop within a month of starting therapy and most cases develop within 3 months. Most patients recover after withdrawal. Sometimes a glucocorticoid is needed to reverse the myopathy. In one patient, histological investigation of muscle biopsies suggested that the myopathy was due, at least in part, to an inflammatory reaction (30). The serum coenzyme Q concentration is reduced by about 30% during statin treatment, because the enzyme is carried by LDL particles, although the concentrations during long-term treatment are equal to those in healthy controls (SEDA-13, 1328) (31,32). Ubiquinone (coenzyme-Q) is part of the oxidative respiratory pathway generating ATP, and deficiency could impede the function of myocytes, leading to an increase in serum creatine kinase and even cell destruction, with release of myoglobin, which in its turn can block kidney tubules and thereby produce anuria.

- Simvastatin 5 mg/day caused rhabdomyolysis in a 61-year-old man who was not taking concomitant interacting drugs (33).
- An elderly lady with chronic renal insufficiency developed rhabdomyolysis during simvastatin therapy (34). Her symptoms of muscle pain, fatigue, myoglobulinuria, oliguria, and pulmonary edema occurred 48 hours after the first dose of simvastatin. Simvastatin was immediately withdrawn, and she was dialysed for 1 week.

Myopathy, defined as muscle symptoms with a rise in creatine kinase greater than 10 times the upper limit of the reference range, was found in one study in only one patient who was taking 40 mg od and in four patients taking 80 mg/day, out of a total of 8245 patients. The number of patients with rhabdomyolysis was, according to postmarketing reporting from the first million individuals taking lovastatin, 24 in all. Seventeen of those had taken other medications that are known to increase the risk (35). There is some evidence that patients with other concomitant illnesses may be at greater risk of myopathy than would be anticipated from experience in controlled trials.

Diplopia may be an early sign of generalized drug-induced muscle dysfunction. Altogether, 71 cases of diplopia, possibly related to various HMG-CoA inhibitors, have been collected from adverse drug reactions-reporting databases. The information was mostly too scanty to judge a causal relation, but improvement occurred in 33 on withdrawal, and two patients had positive rechallenge data (36).

- A 67-year-old woman had ocular myasthenia while taking various statins and also bezafibrate (37). Atorvastatin had the smallest effect.

The authors suggested that this was a variant of a generalized myopathy and was due to a low co-enzyme Q10 concentration.

Exercise-induced muscle pain, without myopathy and a rise in creatine kinase activity, can probably be caused by statins. This has been described in seven patients with heterozygous familial hypercholesterolemia and consisted of pain during exercise and cramps in the following hours (38).

Symptomatic rises in creatine kinase activity to over 10 times the upper end of the reference range occurred in 0, 1, and 0.9% of patients taking placebo, cerivastatin 0.4 mg, or cerivastatin 0.8 mg respectively (39), and rhabdomyolysis has been described in patients taking cerivastatin (40,41). However, in a review of the pharmacological properties and therapeutic efficacy of cerivastatin in hypercholesterolemia, it was stated that cerivastatin only infrequently causes rhabdomyolysis when given alone (42).

Four cases of tendinopathy have been reported in three men and one woman taking statins (43). The diagnoses were extensor tenosynovitis in the hands, tenosynovitis of the tibialis anterior tendon, and Achilles tendinopathy. Two patients were taking simvastatin and two atorvastatin. The tendinopathy developed 1–2 months after the start of treatment. The outcome was consistently favorable within 1–2 months after drug withdrawal.

Sexual function

Erectile dysfunction has been reported in 12% of 339 men treated with fibrate derivatives or statins, compared with 5.6% of similar patients not taking these drugs (44). The mechanism is unknown and should be confirmed in randomized studies. A class effect has been suggested by the case of a 57-year-old man who had impotence after taking lovastatin for 2 weeks and also when he later tried pravastatin (45).

Immunologic

Lupus-like symptoms have been reported in patients taking statins (46).

Long-Term Effects

Tumorigenicity

It has been suspected that low concentrations of serum cholesterol might be associated with an increased risk of cancer or overall mortality. All fibrates and statins cause cancer in rodents, but the relevance of this finding to man has been questioned (47). In an epidemiological study these risks were almost non-existent after adjusting for confounding factors. However, in the CARE study, breast cancer occurred in one patient in the control group and 12 in the pravastatin group (48). The incidence of cancers,

© 2006 Elsevier B.V. All rights reserved.

both during clinical studies and up to 9 years after, has been reassuring (49).

Drug–Drug Interactions

General

Many statins are metabolized by CYP3A4, and this and other mechanisms of drug interactions involving statins have been reviewed (50). Other drugs metabolized by CYP3A4 can greatly increase statin concentrations in the body and precipitate rhabdomyolysis. Although the statins are similar in their ability to lower cholesterol concentrations, there are dissimilarities in their interactions with other drugs.

With the exception of fluvastatin and pravastatin, the statins are metabolized by CYP3A4. Selective inhibition of CYP3A4 or of P-glycoprotein (50) in the small intestine probably increases the systemic availability of CYP3A4 substrates. Some drugs that are metabolized by this enzyme, such as the macrolide antibiotics and the antidepressant nefazodone, can greatly enhance the concentrations of statins in the body and thereby precipitate rhabdomyolysis. However, other drugs that are metabolized by CYP3A4, such as cimetidine, have not been reported to have this effect.

Antifungal azoles

The antifungal azoles inhibit CYP isozymes and can therefore interact with some statins.

Fluconazole

In a randomized, double-blind, crossover study in 12 healthy volunteers, fluconazole increased the plasma concentrations of fluvastatin and prolonged its elimination; the mechanism was probably inhibition of the CYP2C9-mediated metabolism of fluvastatin (51). Care should be taken if fluconazole or other potent inhibitors of CYP2C9 are given to patients using fluvastatin.

Itraconazole

The effects of itraconazole, a potent inhibitor of CYP3A4, on the pharmacokinetics of atorvastatin, cerivastatin, and pravastatin have been evaluated in an open, randomized, crossover study in 18 healthy subjects who took single doses of atorvastatin 20 mg, cerivastatin 0.8 mg, or pravastatin 40 mg, with and without itraconazole 200 mg (52). Itraconazole markedly raised atorvastatin plasma concentrations (2.5-fold) and produced modest rises in the plasma concentrations of cerivastatin (1.3-fold) and pravastatin (1.5-fold). These results suggest that in patients taking itraconazole, cerivastatin or pravastatin may be preferable to atorvastatin.

Physicians should check for lipid-lowering drugs before treating elderly individuals with itraconazole (53). Susceptibility to this interaction varies from statin to statin, in that simvastatin is more affected than pravastatin (54). Concomitant use of simvastatin with itraconazole should be avoided, and the same holds true for atorvastatin (55). In another study, the blood concentration of fluvastatin was not significantly increased, whereas that of lovastatin was (56).

Ketoconazole

Ketoconazole can also cause rhabdomyolysis when taken with both lovastatin and simvastatin (57).

Chlorzoxazone

- A 73-year-old woman had rhabdomyolysis, cholestatic hepatitis, and mild renal insufficiency 14 days after she started to take the centrally acting muscle relaxant chlorzoxazone while also taking simvastatin (58). Withdrawal of the causal medication and conservative therapy with volume substitution and forced diuresis was followed by almost complete resolution of the symptoms.

The authors believed that either the two drugs had interacted by metabolism through the same hepatic enzyme, or that chlorzoxazone had caused cholestasis which then increased the blood concentration of simvastatin.

Ciclosporin

Most drug interactions associated with rhabdomyolysis occur when ciclosporin is combined with simvastatin or lovastatin. It has been suggested that if a statin is to be combined with ciclosporin, pravastatin or fluvastatin should be chosen instead (59).

Coumarin anticoagulants

Interactions of statins with warfarin, resulting in an increased bleeding tendency, have been reported (35), including interactions of anticoagulants with both lovastatin (35) and fluvastatin (60).

Three patients taking fluvastatin 20 mg/day had raised international normalized ratios (INRs), with a risk of bleeding (61).

- A 67-year-old man receiving a stable maintenance dosage of warfarin experienced an increased INR without bleeding when his atorvastatin therapy was switched to fluvastatin. His warfarin dosage was reduced and his INR stabilized. The fluvastatin was switched back to atorvastatin, and the warfarin dosage was increased to maintain the patient's goal INR (62).

In 46 adults taking warfarin, a change from pravastatin to simvastatin caused a significant increase in INR from 2.42 to 2.74 without an overall change in the dose of warfarin; there were no unusual episodes of bleeding (63).

In three patients taking stable warfarin dosages with INRs in the target range, the INRs increased when fluvastatin was added (60). Although none had a bleeding episode, they did require a reduction in their weekly warfarin dosage to achieve an appropriate degree of anticoagulation.

In contrast, in 12 patients chronically maintained on warfarin, atorvastatin 80 mg/day for 2 weeks had no important effect on mean prothrombin time (63).

In 21 healthy men, cerivastatin 300 micrograms did not alter the pharmacokinetics of *R*- and *S*-warfarin, or the pharmacodynamics of a single oral dose of warfarin 25 mg (64).

In a patient given the anticoagulant acenocoumarol, the INR increased from the target range (2–3.5) to 9.0, 3 weeks after starting simvastatin 20 mg/day. It is

© 2006 Elsevier B.V. All rights reserved.

conceivable either that the two drugs competed for hepatic metabolism or that the oral anticoagulant was displaced from plasma albumin by simvastatin (65). The former mechanism is supported by the observation that pravastatin, which is only bound 50% to albumin, interacted with the anticoagulant fluindione and raised the INR (66).

Diltiazem

Diltiazem interacts with lovastatin but not with pravastatin (67). In 10 healthy volunteers given lovastatin orally with or without intravenous diltiazem in a randomized, two-way, crossover design, the interaction of diltiazem with lovastatin was primarily a first-pass effect, due to inhibition of CYP3A4 (68). Thus, drug interactions with diltiazem may become evident when a patient is switched from intravenous to oral dosing.

Fibrates

In a retrospective series, 4 (5%) out of 80 subjects taking lovastatin and gemfibrozil developed a myopathy. Based on this and on reports to US Food and Drug Administration the combined use of the two drugs is discouraged, especially in patients with compromised renal and/or hepatic function. Elderly women may be at special risk (69,70).

Some investigators have concluded that rare drug-induced reversible hepatotoxicity calls for close monitoring of liver enzymes in long-term treatment with statin-fibrate combinations (71).

Combination therapy with fluvastatin and bezafibrate 400 mg/day in 71 patients with persistent hypertriglyceridemia resulted in no significant increase in creatine kinase activity or in the frequency of myalgia (72).

- In contrast, although in vitro studies have not shown any evidence of pharmacokinetic interactions between cerivastatin and gemfibrozil (42), there was myalgia and a marked increase in creatine kinase in a 74-year-old woman with normal renal function who took gemfibrozil 1200 mg/day 3 weeks after she started to take cerivastatin 0.3 mg/day (41).

Since then several other cases have been described:

- a 64-year-old woman (73)
- a 63-year-old man with diabetes mellitus (74)
- a 75-year-old man (75)
- a 68-year-old man (76).

The last patient fared well on a combination of gemfibrozil and cerivastatin until he received influenza vaccination. Rhabdomyolysis has been reported with various viruses, including influenza A and B and inactivation of the virus does not totally prevent this.

Gemfibrozil also increased plasma concentrations of simvastatin and its active form, simvastatin acid, in a randomized, double-blind, crossover study in 10 healthy volunteers given gemfibrozil or placebo orally for 3 days before a single dose of simvastatin (77). This suggests that the increased risk of myopathy in combination treatment is at least partly pharmacokinetic in origin. Because gemfibrozil does not inhibit CYP3A4 in vitro, the mechanism of the pharmacokinetic interaction is probably inhibition of non-CYP3A4-mediated metabolism of simvastatin acid.

Grapefruit juice

Grapefruit juice inhibits CYP3A4, and serum concentrations of atorvastatin, but not of pravastatin, increased after administration of double-strength grapefruit juice 200 ml tds for 2 days (78).

When 10 healthy volunteers took simvastatin 24 hours after a large amount of grapefruit juice in a non-randomized, crossover study, the effect on the AUC of simvastatin was only about 10% of the effect observed when grapefruit juice and simvastatin were taken together (79). The interaction potential of even large amounts of grapefruit juice with CYP3A4 substrates dissipates within 3–7 days after ingestion of the last dose.

HIV protease inhibitors

Healthy volunteers were given protease inhibitors and statins, and the authors concluded that simvastatin should be avoided and that atorvastatin could be used with caution in people taking ritonavir and saquinavir (80). Dosage adjustment of pravastatin may be necessary with co-administration of ritonavir and saquinavir. Pravastatin does not alter the pharmacokinetics of nelfinavir, and thus appears to be safe for co-administration.

Macrolides

The macrolide antibiotic erythromycin together with statins enhances the risk of rhabdomyolysis (SED-13, 1328) (81), as do clarithromycin and azithromycin (82).

Nefazodone

The antidepressant nefazodone increases the risk of rhabdomyolysis from statins (83).

Red yeast rice

Rhabdomyolysis in a stable renal transplant recipient was attributed to the presence of red yeast rice (*Monascus purpureus*) in a herbal mixture (84). The condition resolved when he stopped taking the product. Rice fermented with red yeast contains several types of mevinic acids, including monacolin-K, which is identical to lovastatin. The authors postulated that the interaction of ciclosporin with these compounds through cytochrome P450 had resulted in the adverse effect. Transplant recipients must be cautioned against using herbal products to lower their lipid concentrations, in order to prevent such complications.

St John's wort

St John's wort induces CYP3A4 and reduces blood concentrations of CYP3A4 substrates. In one study, St John's wort reduced plasma concentrations of simvastatin but not pravastatin (85).

Troglitazone

When troglitazone was added in four men with diabetes using insulin and taking atorvastatin, serum LDL cholesterol and triglycerides increased by 23 and 21%

© 2006 Elsevier B.V. All rights reserved.

respectively (86). This suggests a drug interaction, but further studies are warranted to substantiate this.

Hormonal contraceptives—emergency contraception

See also Estrogens

General Information

For a complete account of the adverse effects of estrogens, readers should consult the following monographs as well as this one:

- Diethylstilbestrol
- Estrogens
- Hormonal contraceptives—oral
- Hormone replacement therapy—estrogens
- Hormone replacement therapy—estrogens + androgens
- Hormone replacement therapy—estrogens + progestogens

A review of the English language literature has shown that in the USA, the source of most of the evidence, the two most commonly used forms of emergency contraception are the Yuzpe regimen (high-dose ethinylestradiol + high-dose levonorgestrel) and "Plan B" (high-dose levonorgestrel alone) (1). Although both methods sometimes stop ovulation, they may also act by reducing the probability of implantation, through an effect on the endometrium (the "post-fertilization effect"). The available evidence for the latter mechanism is moderately strong. If this is the manner in which development of a zygote is prevented one would anticipate a certain proportion of failures, with the possibility of second-generation injury. This finding also has potential implications in such areas as informed consent, emergency department protocols, and conscience clauses, since it is more in the character of abortion than true contraception, making the term "emergency contraception" or "post-coital contraception" a slight misnomer.

Estrogens

Various estrogens and estrogen + progestogen combinations have been used in post-coital contraception. Courses of high-dose oral diethylstilbestrol, ethinylestradiol, conjugated estrogens, or combinations of estrogen and progestogen for 4–6 days are all effective. Estrogens are postovulatory rather than post-coital contraceptives, and so it is necessary to know the exact time of unprotected intercourse in relation to a woman's menstrual cycle (2). Depending on the frequency and timing of intercourse, a 5-day course of post-coital estrogen, introduced within 72 hours, gives a pregnancy rate of 0.03–0.3%.

Diethylstilbestrol has been widely used as a post-coital contraceptive. However, it is no longer in use in many countries for this purpose, because of the possible adverse effect on the development of a surviving fetus (see separate monograph).

Ethinylestradiol has been used in the past as a post-coital contraceptive, with a daily dose of 5 mg/day for 5 days. This method has a high incidence of adverse reactions, nausea, vomiting, and breast tenderness being the most frequent (3); the first menstrual cycle after treatment is likely to be abnormal.

Progestogens

Clinical trials of desogestrel implants showed that they were effective, but with bleeding irregularities and ovarian cysts as the primary adverse effects (4).

The "morning after" method of suppressing pregnancy is usually less well tolerated than normal hormonal contraception, and variants on the dosage schedule continue to be studied in an attempt to improve tolerability without undermining the reliability of the method.

Two regimens for emergency contraception started within 72 hours of unprotected coitus have been studied: (a) the progestogen levonorgestrel in two separate doses each of 0.75 mg; (b) the Yuzpe regimen of combined oral contraceptives—ethinylestradiol 100 micrograms + levonorgestrel 0.5 mg repeated 12 hours later (5). The relative risk of pregnancy for levonorgestrel compared with the Yuzpe regimen was 0.36 (95% C1 = 0.18, 0.70). Nausea and vomiting were significantly less frequent with the levonorgestrel regimen. Adverse effects of both regimens were nausea, vomiting, dizziness, fatigue, headache, breast tenderness, and low abdominal pain. However, all of these adverse effects were less frequent with levonorgestrel.

Estrogen + progestogen combinations

In recent years it has become common to use a combination of estrogen and progestogen for post-coital contraception. For example, a tablet containing ethinylestradiol 100 micrograms and levonorgestrel

© 2006 Elsevier B.V. All rights reserved.

0.5 mg (or norgestrel 1 mg) taken twice with an interval of 12 hours has been used (6). This treatment must begin within 72 hours of unprotected intercourse. The approach seems to be as effective as ethinylestradiol alone, while producing somewhat less nausea and vomiting (7). Apart from this the adverse effects most commonly experienced are as with estrogen alone. Overall failure rates are about 2–3%, with perhaps twice this failure rate when taken at mid-cycle. However, bearing in mind the rate of pregnancy after unprotected intercourse, the protective effect is not impressive; the chance of pregnancy is probably only halved.

It is probably impossible to define an ideal dose for this purpose. Essentially the aim is to provide a sufficient hormonal jolt to derange nidation and the development of the zygote, and this might be attained in various ways; the most acceptable dosage schemes will be those that are best tolerated. Because oral contraceptives are generally more readily available than specially formulated products, they have sometimes been used for this purpose in deliberate overdose. Even low-dose oral contraceptives, if taken in sufficient quantities, will prove effective post-coital contraception (8); progestogen-only tablets are also effective in a single dose, for example levonorgestrel 0.6 mg taken within 12 hours, but irregular bleeding, nausea, and dizziness are common adverse effects (SEDA-16, 466).

The FDA has approved a marketing application for the Prevent Emergency Contraceptive Kit (Gynetics), which contains tablets for post-coital emergency contraception, packaged with a urinary pregnancy test. The application is based on a regimen that consists of two tablets containing ethinylestradiol and levonorgestrel to be taken within 72 hours of unprotected intercourse and two tablets to be taken 12 hours later. This regimen is about 75% effective in preventing pregnancy. The most common adverse effects are nausea, vomiting, menstrual irregularities, breast tenderness, headache, abdominal pain and cramps, and dizziness (9).

Androgens

The synthetic androgen danazol has also been evaluated for post-coital use, but with inconsistent results (8); doses of twice 400 mg or twice 600 mg seem to be reliable while a single dose of 600 mg seems to be insufficient. A 10% incidence of vomiting, headache, and breast tenderness has been reported and a lower incidence (1–2%) of vomiting (10).

Antiprogesterones

The antiprogesterone mifepristone, almost exclusively used as an abortifacient, has also been tried as a post-coital contraceptive (11). In one randomized comparative trial, a single dose of mifepristone 600 mg was at least as effective as the usual hormonal method (12). Women who took mifepristone had lower rates of adverse effects, particularly nausea and vomiting, but their next menstrual period was more likely to be delayed. In another randomized trial, both methods were equally effective (SEDA-16, 466). The use of an estrogen + a progestogen had a higher total incidence of adverse effects, but mifepristone was associated with the greatest cycle disruption. If mifepristone was given in the follicular phase, 52% of women had a delay of 4 days or more in the onset of their next menstrual period (indicating that ovulation had been inhibited); when it was given in the luteal phase, 84% of women menstruated on time.

Physical methods

A non-hormonal approach to emergency contraception is insertion of an intrauterine contraceptive device up to 7 days after ovulation in a cycle during which unprotected intercourse has occurred (13).

Comparison of methods

The combined estradiol + levonorgestrel (Yuzpe regimen), the levonorgestrel-only regimen, and post-coital copper intrauterine devices have been compared by the Clinical Practice Gynaecology and Social and Sexual Issues Committees of the Society of Obstetricians and Gynaecologists of Canada. Sponsor: The Society of Obstetricians and Gynaecologists of Canada (13) and the following recommendations made:

1. Women who have had unprotected intercourse and want to prevent pregnancy should be offered hormonal emergency contraception up to 5 days after intercourse.
2. A copper IUCD can be used up to 7 days after intercourse in women who have no contraindications.
3. Women should be advised that the levonorgestrel regimen is more effective and causes fewer adverse effects than the Yuzpe regimen.
4. Either one double dose of the levonorgestrel regimen (1.5 mg) or the regular two-dose levonorgestrel regimen (0.75 mg each dose) can be used, as they have similar efficacy with no difference in adverse effects.
5. Hormonal emergency contraception should be started as soon as possible after unprotected sexual intercourse.
6. Women of reproductive age should be provided with a prescription for hormonal emergency contraception in advance of need.
7. The woman should be evaluated for pregnancy if menses have not begun within 21 days after emergency contraception.
8. A pelvic examination is not indicated for the provision of hormonal emergency contraception.

Second-Generation Effects

Pregnancy

In pregnancies that occur after failure of progestogen-only emergency oral contraception, the possibility of ectopic pregnancy should be considered, according to a Prescriber Update article recently posted on the New Zealand Medsafe website (14). This may occur by the same mechanism by which pregnancies in women using daily progestogen-only oral contraceptives are more likely to be ectopic than pregnancies in users of other contraceptive methods. The Centre for

© 2006 Elsevier B.V. All rights reserved.

Adverse Reaction Monitoring has received three reports of ectopic pregnancies after the use of progestogen-only emergency oral contraceptives, and prescribers are reminded to advise women about the possibility of ectopic pregnancy after failure of progestogen-only emergency oral contraceptives. Women should seek prompt medical attention if, after using a progestogen-only emergency oral contraceptive, amenorrhea or any other symptoms suggestive of pregnancy occur.

Susceptibility Factors

Post-coital contraception should not be used when there are absolute contraindications to estrogen; these include pregnancy, unstable angina, transient ischemic attacks, liver disease, undiagnosed genital bleeding, or a history of thromboembolism. Some absolute contraindications to long-term use, such as breast cancer and arterial disease, are not contraindications to short-term use (15).

Hormonal contraceptives—intracervical and intravaginal

See also Progestogens

General Information

The intracervical and intravaginal methods of contraception have not come into regular use, and experience with them has therefore been limited.

For a complete account of the adverse effects of progestogens, readers should consult the following monographs as well as this one:

- Hormonal contraceptives—progestogen implants
- Hormonal contraceptives—progestogen injections
- Hormonal contraceptives—oral
- Hormone replacement therapy—estrogens + progestogens
- Medroxyprogesterone
- Progestogens.

Intracervical contraceptives

When an intracervical device releasing levonorgestrel 20 mg/day was studied in 198 women over 2 years of use, a total of seven pregnancies occurred (1). All began during the first year and six occurred after the unnoticed expulsion of the device. One pregnancy occurred in an epileptic woman taking carbamazepine, while the intracervical device remained in place. In three cases the device was removed because of infection, in all three instances during the first year of use; in one case *Neisseria gonorrhoeae* was found and in another *Chlamydia trachomatis*. During the study, mean body weight increased, but remarkably there was a statistically significant reduction in the mean diastolic and systolic blood pressures after 1 and 2 years of use compared with the pre-insertion values.

Intravaginal contraceptives

As early as 1978, the vaginal administration of steroids for contraceptive purposes was attempted, at that time using vaginal rings containing medroxyprogesterone acetate or both norgestrel and estradiol. It was later found that complete inhibition of ovulation could as a rule be attained by the daily intravaginal application of a product containing norethisterone 1 mg and mestranol 50 micrograms (2).

Progestogen-only vaginal rings

Vaginal administration of steroid-containing polymer rings has been studied for at least 25 years as a means of

© 2006 Elsevier B.V. All rights reserved.

contraception, without gaining wide acceptance. In a large multicenter WHO trial with a levonorgestrel ring, releasing 20 micrograms/day, the 1-year pregnancy rate was 4.5% (3). The main reason for discontinuation was menstrual disturbances (17%), followed by frequent expulsion of the ring and vaginal symptoms.

The finding of erythematous lesions in the vagina in some women has led to the development of a more flexible device. The Population Council has also developed a vaginal ring containing Nestorone progestin (16-methylene-17α-acetoxy-19-norpregn-4-ene-3,20-dione) for 6 months of continuous use (4). Ovulation inhibition was achieved in over 97% of the segments studied, with rings releasing 50, 75, or 100 micrograms/day. No pregnancies occurred in women who used the low-dose ring, while one pregnancy each occurred with the intermediate-dose and high-dose rings, for 6-month cumulative pregnancy rates of 0.0, 1.9, and 2.1% respectively; it is not clear why the reported pregnancy rates were higher with the higher doses. However, bleeding irregularities were common, and this form of contraception still demands further development work.

A low-dose levonorgestrel vaginal ring has also been studied. Women using vaginal rings releasing levonorgestrel 20 mg/day had more bleeding or spotting days than women using other hormonal contraceptives, with menstrual patterns similar to those of progestogen-only tablet users (5). Irregular and infrequent bleeding was also recorded by some women. Analysis of menstrual calendar data from WHO phase III clinical trials showed that the percentage of women who experience bleeding patterns defined as "acceptable" increases steadily from 39% in the first 3 months to 56% during months 10–12 (6). Frequent and irregular bleeding were the most common problems. In another study in 108 women there were four pregnancies during 1 year of investigation, with a discontinuation rate of 71%. Menstrual disturbances were the main adverse effects and also the most common reason for discontinuation, occurring in 45% of cycles during the first month (7).

Hormonal contraceptives—male

General Information

The notion that an oral contraceptive closely similar to that used in women might be developed for men has been discussed for about 45 years, but the concept has not yet found wide acceptance. Delays in putting the concept into practice have related variously to difficulties in finding an effective combination, complaints of reduced libido or potency, and the long delay between the start of treatment and the attainment of azoospermia.

Of the many possible formulations tested all have proved to have unacceptable facets, generally including a very slow onset of action, uncertain reliability, and undesirable effects on biochemistry, body weight, or sexual function. However, some progress has been made with the combination of oral desogestrel and intramuscular testosterone.

In a study of the effects of various combinations of desogestrel and testosterone, including a sequential pattern, the optimal dosage to induce azoospermia seemed to be desogestrel 300 micrograms/day by mouth and testosterone enantate 50 mg weekly by intramuscular injection (1). Among 24 subjects, there were no withdrawals clearly related to the treatment. During weeks 1–3, adverse effects were reduced sex drive ($n = 4$), tiredness ($n = 1$), and a sensation of depression ($n = 1$); during weeks 4–24 they included mild acne ($n = 10$), increased sexual interest ($n = 3$), emotional lability ($n = 2$), tiredness ($n = 2$), night sweats ($n = 1$), and headache ($n = 1$). However, laboratory studies showed that desogestrel had clear effects on lipid metabolism in dosages of 150 micrograms/day or more, with reductions in HDL cholesterol, apolipoprotein, A1 lipoprotein, sex hormone binding globulin, and to some extent total cholesterol and LDL cholesterol. If this approach can be developed to provide a more convenient dosage scheme, these biochemical changes will be among those that need to be followed carefully.

A combination of oral desogestrel 150 or 300 micrograms + intramuscular testosterone 50 or 100 mg has been tested in 24 young men and compared with historical data from studies on a combination of oral levonorgestrel + intramuscular testosterone (2). All the doses tested achieved azoospermia. All the groups tended to gain weight compared with their baseline, but the weight gain was greatest (and statistically significant) in men who received the higher dose of testosterone. Adverse effects were acceptably low; acne occurred in occasional cases, but no one developed gynecomastia.

In a similar study limited to 8 weeks, the various formulations rapidly suppressed LH and FSH to a similar extent, irrespective of dosage, while testosterone concentrations fell slightly during treatment, with evidence of a linear dose-response relation (3). There were minor changes in plasma concentrations of inhibin B, but in seminal fluid it was suppressed, becoming undetectable in all the men who took desogestrel 300 micrograms/day. There were no significant changes in

© 2006 Elsevier B.V. All rights reserved.

lipoproteins, fibrinogen, or sexual behavior during treatment, and only minor falls in hematocrit and hemoglobin concentration.

Hormonal contraceptives—oral

General Information

For a complete account of the adverse effects of estrogens, readers should consult the following monographs as well as this one:

- Diethylstilbestrol
- Estrogens
- Hormonal contraceptives—emergency contraception
- Hormone replacement therapy—estrogens
- Hormone replacement therapy—estrogens + androgens
- Hormone replacement therapy—estrogens + progestogens.

For a complete account of the adverse effects of progestogens, readers should consult the following monographs as well as this one:

- Hormonal contraceptives—implants
- Hormonal contraceptives—progestogen injections
- Hormonal contraceptives—intracervical and intravaginal
- Hormone replacement therapy—estrogens + progestogens
- Medroxyprogesterone
- Progestogens.

Hormonal contraception relies on the actions of estrogens and progestogens, of which oral contraceptives contain a mixture. The adverse effects of the separate components are discussed in other monographs.

The commonly available combinations of oral contraceptives include (estrogen first):

- ethinylestradiol + desogestrel
- ethinylestradiol + levonorgestrel
- ethinylestradiol + norethisterone
- ethinylestradiol + norgestimate
- mestranol + norethisterone.

Other forms of administration include:

- implantation
- intracervical administration
- intramuscular injection
- intravaginal administration
- transdermal administration.

These forms of contraception are covered in other monographs.

Efficacy

Hormonal contraceptives based on combinations of estrogen + progestogen, administered cyclically each month, are among the most effective forms of contraception. During typical use, only some 3% of women using combined oral contraceptives become pregnant in the first year of use, despite the failures of compliance that inevitably occur (1). The pregnancy rate for progestogen-only oral contraceptives is somewhat higher, about 5% (2). Compared with the original high-dose combination products, the lower dosages now in current use offer a smaller margin for error if tablets are missed; the efficacy of progestogen-only contraceptives is even more dependent on correct use. The accidental pregnancy rates for injectable and implanted hormonal contraceptives are lower than for the oral products, primarily because they do not depend on the daily taking of a tablet. The 1-year pregnancy rate for depot medroxyprogesterone acetate (injectable) is 0.3% and for levonorgestrel implants 0.09%.

Mechanisms of action

Estrogen and progestogen together inhibit gonadotropin secretion and thus prevent ovulation. Estrogen also stabilizes the endometrium and potentiates the action of the progestogen. In addition, the progestogen has contraceptive effects on the cervical mucus (thickening the mucus to make it hostile to sperm penetration), the endometrium (interfering with implantation), and the fallopian tubes (altering ovum transport). The original fixed-dose combinations have given way to formulations that contain lower doses, as well as to variants on the principle. The estrogen dosage, originally 150 micrograms or more, today normally lies in the range of 30–35 micrograms ethinylestradiol; even lower doses have been investigated, but these result in an unsatisfactory bleeding pattern and have little effect on ovulation. Doses of progestogens have fallen from the 5 mg (or even 10 mg) originally in use in 1960 to 1 mg or less today. To calculate the dose of progestogen that offers the highest benefit-to-harm balance is not easy, particularly since the relative potency of any progestogen can be expressed in various ways (for example in terms of its effect on the human endometrium, its androgenic or corticosteroid potency, or its ability to inhibit ovulation); these do not run parallel to one another and it is not at all clear which of these activities are relevant to the various long-term safety issues.

Progestogen-only products do not have inhibition of ovulation as their main effect; up to half of all cycles are ovulatory, and the contraceptive potential relates largely to changes in the consistency of the cervical mucus and the creation of a hostile environment for the sperm, as

© 2006 Elsevier B.V. All rights reserved.

well as changes in tubal motility and ovum transport; after a period of treatment, endometrial atrophy occurs, rendering nidation unlikely.

Unusual combinations

Ethinylestradiol + chlormadinone acetate
In 19 650 women who had received six cycles of treatment with chlormadinone acetate 2 mg and ethinylestradiol 30 micrograms, cycle control was good, with beneficial reductions in intracyclic bleeding, severe withdrawal bleeding, dysmenorrhea, and amenorrhea (3). At baseline, 70% of the women had androgen-related skin disorders. After six cycles of chlormadinone acetate 2 mg + ethinylestradiol 30 micrograms, these disorders were improved in 87% of patients, including 29% who had complete resolution. The incidence of greasy or very greasy hair fell from 47 to 17%. There were two cases of venous thromboembolism. Breast pain (3.6%) and migraine or headache (2.6%) were the most frequently reported adverse events, but these symptoms disappeared in most women (85 and 80%) who had had them before treatment.

Ethinylestradiol + drospirenone
The effects of a monophasic oral contraceptive containing drospirenone 3 mg and ethinylestradiol 30 micrograms on pre-existing premenstrual symptoms has been studied in 326 women during 13 menstrual cycles (4). There were beneficial effects on water retention and appetite. Concentration was not significantly affected, and assessments of undesired hair changes and feelings of well-being did not change appreciably. There were no adverse effects of note.

Cyproterone acetate + a progestogen
There has been a single report of autoimmune hepatitis with the combination of cyproterone acetate and a progestogen (5). Similar events have been described very occasionally with other oral contraceptives and with diethylstilbestrol; they are not unique to cyproterone.

General adverse effects

The incidence of common adverse reactions to oral contraceptives varies with population and product. Many users have some mild reactions during the initial months of treatment, which disappear entirely as use continues; a small proportion of users withdraw at an early phase, because of individual intolerance, and turn to other methods of contraception. Relatively common adverse effects of combined oral contraceptives include intermenstrual bleeding, nausea or vomiting, breast tenderness, and headaches, although reactions are highly individual and problems can often be overcome by changing to a formulation with a greater or lesser content of active substances. Some women develop mild fever. Occasionally, oral contraceptive users report depression (or more usually a vague sensation of malaise), reduced libido, acne, or weight gain. Women taking combined oral contraceptives are also at greater risk of *Chlamydia* infection and of modest impairments of glucose and lipid metabolism. The most serious complications attributable to oral contraceptives are cardiovascular diseases, but these are extremely rare and are even less common now, with lower-dose formulations, than in earlier decades; these much discussed risks are reviewed separately above. Hypersensitivity reactions have been observed, but only very rarely.

Tumor-inducing effects are discussed in the monograph on estrogens. The risks of epithelial ovarian and endometrial cancer are reduced by combined oral contraceptives. Effects on other cancers are slight.

Overall benefit-to-harm balance of combined oral contraceptives

A comprehensive analysis by The Alan Guttmacher Institute in the USA in 1991 evaluated the health risks of various contraceptive methods, as well as the health risks of a normal female reproductive life without contraceptives (6). Because combined oral contraceptives are highly effective, they prevent pregnancy-related deaths, particularly those associated with ectopic pregnancy. This factor more than offsets the small increased risk of cardiovascular disease related to current use, resulting in averted deaths at all ages (ranging from 3.9 per 100 000 current users at ages 15–19 up to 19 per 100 000 at ages 40–44 in the USA). They also prevent future deaths from ovarian and endometrial cancers (from 23 per 100 000 at ages 15–19 to 10 per 100 000 at ages 40–44). Current oral contraceptive use also prevents 1614 hospitalizations per 100 000 users annually. Most of these avoided hospital admissions are because of prevention of the complications of pregnancy, but they also include a reduced rate of hospitalization due to ovarian cysts, benign breast disease, upper genital tract infection, urinary tract infection, and invasive cancers of the ovary and endometrium. The conditions for which hospitalization rates may be slightly increased among combined oral contraceptive users include: myocardial infarction; stroke; venous thrombosis and embolism; invasive cancers of the breast, cervix, and liver; cervical intraepithelial neoplasia; and gallbladder disease.

Data from the classic Nurses' Health Study, followed up in 1994, reflected no difference in all-cause mortality between women who had ever used oral contraceptives and those who had never used them (7). There was also no increase in mortality associated with duration of use and no relation with time since first use or time since last use. Similarly, in the OFPA (Oxford) study, the overall 20-year mortality risk for oral contraceptive users compared with women using diaphragms or IUCDs was 0.9, suggesting no effect (8). Although the number of deaths from each cause was small, the pattern is consistent with the risks found in other studies. Oral contraceptive users had somewhat higher death rates from ischemic heart disease and cervical cancer, but lower rates of ovarian cancer mortality. Breast cancer mortality was similar for oral contraceptive users and non-users.

In developing countries, wherever there is a high maternal mortality rate, the risk of oral contraception is low in comparison (9). For all women in developing countries below the age of 40, oral contraceptive use is substantially safer than no method at all or traditional methods, about as safe as IUCDs, but not as safe as

© 2006 Elsevier B.V. All rights reserved.

sterilization or as traditional methods backed by legal abortion performed by trained physicians.

Some of the risks have only become evaluable with much longer experience, for example those relating to the development of malignancies (covered in the monograph on estrogens). Data on these matters, too, seem reassuring; any cancer-promoting effect in one direction is at least counterbalanced by the reduction of risk in another.

Any consideration of major issues relating to the balance of benefit and harm, such as cancer or mortality rates, should be supplemented by a consideration of less prominent ones, for example, a reduction in disorders of the menstrual cycle (such as dysmenorrhea, menorrhagia, and the premenstrual syndrome) and the reduced risks of iron deficiency anemia, functional ovarian cysts, uterine fibroids, benign breast disease, pelvic inflammatory disease, and ectopic pregnancy (10,11).

Finally, since much of the work relates to high-dose products, it is important to stress that more recent work and reviews have confirmed the even greater relative safety of lower-dose products, although one must now express concern that the third-generation products may have increased certain risks once more. All the same, the broad picture of the safety of oral contraception is reassuring. Even at an earlier stage, such authoritative workers as Vessey and Doll (12) emphasized that the medical and social benefits of using oral contraceptives considerably outweighed the risks, while emphasizing the need to contain such risks as there are, that is by careful patient selection and supervision and by the use of oral contraceptives with the lowest possible dosages.

Progestogen-only oral contraceptives

Progestogen-only oral contraceptives are taken continuously and not cyclically. They not only lack the estrogen component of combined oral contraceptives but also have a lower dose of progestogen than even the current low-dose combined oral contraceptives. Progestogen-only contraceptives are therefore indicated for women who desire oral contraception but who have contraindications to or poor experience with the estrogen in combined oral contraceptives, who are breastfeeding, who are older (especially smokers), or who simply wish to keep their exogenous hormone doses to a minimum (11). The drawbacks of progestogen-only contraceptives are that menstrual irregularity is common and that careful compliance is necessary in order to achieve high efficacy.

The pharmacokinetics of progestogens in progestogen-only contraceptives are somewhat different from those in combined oral contraceptives, because of the interaction of estrogen and progestogen in the combination products. One of the major differences is that, as noted above, the plasma concentrations of progestogen rise over time in users of combined oral contraceptives; this does not happen in women taking progestogen-only contraceptives. The change is due in part to estrogen stimulation of serum hormone-binding globulin (SHBG) production, increased binding of progestogen to SHBG, and reduced progestogen clearance with combined oral contraceptives. In contrast, progestogen-only contraceptives cause reduced SHBG concentrations and modest falls in progestogen concentrations over time.

Organs and Systems

Cardiovascular

The cardiovascular complications of oral contraceptives include venous thrombosis and thromboembolism, arterial damage, and hypertension.

Venous thromboembolism

A central issue almost from the beginning of the oral contraceptive era has been the undoubted ability of these products to increase the risk of thromboembolic and allied complications. It was the dominant reason for the progressive reduction in hormonal content of these products during their first 20 years; it led at one point to a precipitate and poorly motivated replacement of mestranol by ethinylestradiol as the estrogenic component; and rightly or wrongly it has played a central role in the recent debate concerning modified products based on newer progestogens.

History

The fact that some women could develop thromboembolic complications as a result of taking oral contraceptives first emerged in 1961, although at that time the evidence was anecdotal and poorly quantified. The first reasonably quantified investigation conducted on a sufficient scale to merit conclusions was published in 1967 by the UK Medical Research Council (13). This and other large studies conducted during the early years (and considered in older volumes in this series) concluded that women using oral contraceptives ran a greater risk than non-users of developing deep venous thrombosis, pulmonary embolism, cerebral thrombosis, myocardial infarction, and retinal thrombosis. Later papers and case reports described deep venous thrombosis, portal venous thrombosis, and pulmonary embolism (14–16). The Boston Collaborative Drug Surveillance Program follow-up study of more than 65 000 healthy women in 1980–82 found a positive association between current oral contraceptive use and venous thromboembolism (rate ratio 2.8); there was also a positive association between current oral contraceptive use and stroke or myocardial infarction (17). A UK study using data from 1978, by which time lower-dose products were increasing in use, pointed to an approximate doubling of the risk of thromboembolism compared with controls (SEDA-7, 387). The early 1980s were nevertheless marked by a series of critical papers that sought to question the entire concept of there being a link.

Much of the work on both sides of the argument was less than watertight. Some studies failed to consider the confounding effects of other risk factors (notably smoking) or the likelihood of detection bias (particularly for venous thromboembolism, which is much more common in young women than myocardial infarction or stroke). The results of some studies were also confounded by uncertainties in the history of drug exposure. A landmark

© 2006 Elsevier B.V. All rights reserved.

paper to resolve the issue concluded that the link with venous thromboembolism in subjects without predisposition had been consistently observed in case-control and cohort studies (18). However, the evidence regarding myocardial infarction, various types of stroke, and cardiovascular mortality was less consistent. By 1990, an international Consensus Development Meeting reached agreement on the following statement regarding the relation between oral contraceptive use and cardiovascular disease (19):

> The majority of epidemiological studies strongly suggest an association between current oral contraceptive use and certain cardiovascular deaths. Although the relative risk is increased, the absolute risk is small. Because the risk of myocardial infarction is apparent in current users, disappears on cessation of use, and is not associated with duration of use, there is no epidemiologic support for the hypothesis that risk of cardiovascular diseases is of atherogenic origin .... Whether particular formulations or progestogens have qualitative advantages or disadvantages merits further study. Estrogens and progestogens interact at many levels, and in epidemiologic studies of users of combined oral contraceptives it is difficult to assign a risk to either component separately. Moreover, it is physiologically unsound to do so .... Alterations in plasma lipid, carbohydrate, and hemostasis variables are of major importance for the development of cardiovascular diseases, and their concentrations can be influenced by sex steroids, including artificial steroids contained in oral contraceptives. The pharmacodynamic responses ... are dependent on not only the type and dosage of sex steroids, but also on intra- and interindividual variability in pharmacokinetics.

Frequency

It has been confirmed that the incidence and mortality rates of thrombotic diseases among young women are low (20). However, the risk is increased by oral contraceptives and there is variation in the degree of risk, depending on the accompanying progestogen. The spontaneous incidence of venous thromboembolism in healthy nonpregnant women (not taking any oral contraceptive) is about five cases per 100 000 women per year of use. The incidence in users of third-generation formulations is about 15 per 100 000 women per year. The incidence in users of third-generation formulations is about 25 per 100 000 women per year: this excess incidence has not been satisfactorily explained by bias or confounding. The risks of venous thromboembolism increase with age and is likely to be increased in women with other known factors for venous thromboembolism, such as obesity. The risk in pregnancy has been estimated at 60 cases per 100 000 pregnancies.

The Medicines Commission of the UK has reviewed all currently available relevant data and has confirmed that the incidence of venous thromboembolism is about 25 per 100 000 women per year of use (21). The incidence of venous thrombembolism in users of second-generation combined oral contraceptives is about 15 per 100 000 women per year of use. This indicates a small excess risk of about 100 000 women-years for women using third-generation combined oral contraceptives containing desogestrel or gestodene, which has not been satisfactorily explained by bias or confounding. However, the absolute risk of venous thromboembolism in women taking combined oral contraceptives containing desogestrel or gestodene is very small and is much less than the risk of venous thromboembolism in pregnancy.

The incidence of venous thromboembolic disease in about 540 000 women born between 1941 and 1981 and taking oral contraceptives was 4.1–4.2 cases per 10 000 woman-years (22).

In another study, the figures ranged from 1895 events per 100 000 women-years when norgestimate was used to 3969 per 100 000 women-years when desogestrel was used (23). Although the authors did not find the difference statistically significant, it runs parallel to findings from other work regarding a higher risk when third-generation progestogens are used.

In women aged 15–29 years who used oral contraceptives containing third-generation progestogens, venous thromboembolism was twice as common as arterial complications. In women aged 30–44 years of age the number of arterial complications exceeded the number of venous complications by about 50%. However, in women under 30 years, deaths from arterial complications were 3.5 times more common than deaths from venous complications and in women aged 30–44 years 8.5 times more common. Women over 30 years of age who take oral contraceptives containing third-generation progestogens may have a lower risk of thrombotic morbidity, disability, and mortality than users of second-generation progestogens. However, a weighted analysis such as this does not result in any consistent recommendation of a particular progestogen type.

Nevertheless, some groups continue to produce data from their own systems that fail to confirm this. Some of these studies, including unpublished data circulated to experts for purposes of special pleading, have used selected material, and one can only consider them flawed. On the other hand, Jick et al. may be entirely right in their finding that, insofar as the special risk of idiopathic cerebral hemorrhage is concerned, no material difference in risk has been demonstrated between products of the second generation and those of the third generation (24).

And in another study it was found that users of oral contraceptives with second-generation progestogens have 30% greater increased risk of thrombotic diseases, a 260% greater increased risk of thrombotic deaths, and a 220% greater increased risk of post-thrombotic disability than users of oral contraceptives with third-generation progestogens (20).

Effects of dosage and formulation

As noted above, the early recognition of thromboembolic complications had repercussions for the formulation of the oral contraceptives; the progestogen and estrogen contents were both progressively reduced, and in 1969/70 mestranol was replaced by ethinylestradiol, on the grounds that the dose could thereby be halved (although it is not at all certain that this reduced the estrogenic

© 2006 Elsevier B.V. All rights reserved.

contribution to thromboembolic events). By the late 1980s, when a major cohort study based in Oxford examined the problem (8), products containing estrogen 50 micrograms accounted for about 70% of the woman-years of tablet use, most of the remainder being accounted for by lower doses.

By the mid-1990s it was reasonably well proven that progressive dose reduction had reduced the risk of thrombotic complications (25). Epidemiological studies showed that users of low-dose combined products had small, and often statistically non-significant, rises in the risks of myocardial infarction (SEDA-16, 465) (26,27), thrombotic stroke (28–30), venous thromboembolism (31), and subarachnoid hemorrhage (28,30,32). Several of these studies compared the risks presented by different doses and found somewhat higher rates for products containing more than 50 micrograms of estrogen but somewhat lower rates among women currently using the lower-dose formulations (26,28,29,33).

A group in The Netherlands has stressed the fact that even though the risk of venous thrombosis is small in absolute terms, oral contraceptives form the major cause of thrombotic disease in young women. The risk is higher during the first year of use (up to one per 1000 per year), among women with a prothrombotic predisposition, and with third-generation progestogens (34).

Presentation

The commonest presentation is deep venous thrombosis in the leg, which can lead to pulmonary embolism. Fatal pulmonary embolism has even been reported after intravenous injections of conjugated estrogens (35). Despite the improvement noted with reduced doses, incidental case reports of severe cardiovascular events during the use of low-dose products have continued to appear. They include incidents of cerebral venous thrombosis and subarachnoid hemorrhage, fatal central angiitis, sinus thrombosis, and cerebral ischemia. In one series of 22 cases of cerebral infarction involving either arteries or veins, all the oral contraceptives that had been used contained a low dose of ethinylestradiol (36). Thromboembolism in other veins, such as the hepatic vein, that is Budd–Chiari syndrome, has occasionally been reported (37); the first 10 such cases were reported as long ago as 1972 and the increasing number since then has at times raised some concern (SEDA-6, 344) (SEDA-7, 386). A case of renal vein thrombosis has also occurred (38). Incidental reports continue to appear of thrombotic incidents in relatively unusual forms, including a further case of mesenteric thrombosis leading to intestinal necrosis (39) and a report of fatal pulmonary embolism following intravenous injections of conjugated estrogens (35).

The incidence of hepatic veno-occlusive disease in 249 consecutive women treated with norethisterone who underwent allogenic hemopoietic stem cell transplantation was 27% compared with 3% in women without this treatment (40). One-year survival rates were 17% and 73% in patients with ($n = 24$) or without veno-occlusive disease ($n = 225$) respectively. Because of this adverse effect, norethisterone should not be used in patients undergoing bone-marrow transplantation. Heparin prophylaxis does not affect the risk of death from veno-occlusive disease.

Susceptibility factors

By 1980 it was considered clear that the risk of thromboembolic events was further increased under particular conditions. It was higher in smokers, in older women, and in the obese, and appropriate warnings were issued. The fact that these warnings to a large extent eliminated the high-risk individuals who had formed part of the early population of oral contraceptive users means that data from the early period cannot be used to provide a valid historical comparison with later findings (41,42).

Thrombotic diathesis

Early epidemiological data on the recurrence of thrombosis (43) indicated something of an inherited predisposition, and others found a low content of fibrinolytic activators in the vessel wall of women who 6–12 months earlier had experienced a thrombotic complication while using oral contraceptives (44); high doses of estrogen affected the concentrations of such activators (45). However, such lesions are apparently not exclusive to users of oral contraceptives (SEDA-8, 360) and examination of the vessel wall is not of predictive value in determining risk.

The risk of venous thrombosis among carriers of the factor V Leiden mutation is increased eight-fold overall and 30-fold among carriers who take an oral contraceptive (46,47). This mutation results in resistance to activated protein C and thereby potentiates the prothrombotic effect of oral contraceptives. Early work suggested a greater risk after major surgery (48,49). However, epidemiological studies of postoperative venous thromboembolism are limited and disputed (50). There is no documented excess risk of postoperative thrombosis associated with low-dose combined oral contraceptives among women without other risk factors (51). If it is correct that some effects on coagulation persist for several weeks, it is wise to withdraw these products a month before surgery (50). From a practical point of view, any decision regarding possible discontinuation of combined oral contraceptives before surgery should take into consideration the need for alternative and adequate contraception during the interim. If the woman chooses to stop taking combined oral contraceptives, progestogen-only formulations (as well as barrier methods) are deemed suitable (50). A recommended alternative to discontinuation of a combined oral contraceptive is heparin in low doses (51).

Age

The increase in risk with age is clear (6), although the underlying risk of cardiovascular disease also rises as age progresses. The US Food and Drug Administration has concluded that the benefits may outweigh the risks in healthy non-smoking women over age 40, and it has in most countries been common for over two decades to advise reticence in the use of oral contraceptives after the age of 35.

© 2006 Elsevier B.V. All rights reserved.

Obesity

Obesity has repeatedly been shown to play a role, and its relevance to particular types of complication has been demonstrated. The Oxford Family Planning Association's 1987 data showed that the risk of myocardial infarction or angina increased significantly with weight (52).

Smoking

Smoking has been very clearly incriminated as a susceptibility factor for thromboembolism and arterial thrombosis in women taking the oral contraceptive, and its apparently synergistic role has been well defined and quantified (53,54). The 1989 case-control analysis of the RCGP cohort study estimated the relative risk of myocardial infarct during current oral contraceptive use at only 0.9 for non-smokers, but at 3.5 for women smoking under 15 cigarettes per day, and as much as 21 for users of more than 15 cigarettes per day (55). Smoking increases not only the risk of myocardial infarction among oral contraceptive uses (27), but also the risk of angina pectoris (52), thrombotic stroke (28,29), and subarachnoid hemorrhage, and it can double or treble mortality (56–58). There has also been further confirmation that the effect is dose-related, light smokers having twice the risk of coronary heart disease and heavier smokers having up to four times the risk, compared with non-smokers; cessation of smoking is accompanied by a reduction in risk of coronary heart disease to the level prevalent among non-smokers within 3–5 years (54).

Smoking contributes to effects on the procoagulation process in young women (59). The effects of oral contraceptives on the coagulation system are much greater in smokers than non-smokers (44). Oral contraceptive users who were smokers generally have significantly lower fibrinolytic activity than non-smokers (60), but not consistently (61).

Others

Women of blood group O have less of a risk of thromboembolism (15). The risk of thromboembolic complications may be greater where there is a history of diabetes, hypertension, and pre-eclamptic toxemia. In some studies there has been an association with type II hyperlipoproteinemia, hypercholesterolemia, and atheroma (62–66). Hypertension may be an additional risk factor when considered in relation to oral contraceptive use.

Mechanisms

Study of the mechanisms that might underlie the link between oral contraceptives and thromboembolic events is of importance in developing safer formulations, but also in identifying, if possible, individuals at particular risk who should be advised to change to alternative contraceptive methods.

The 1990 international consensus statement cited above noted that: "Oral contraceptives induce alterations in hemostasis variables. There are changes in the concentrations of a large number of specific plasma components of the coagulation and fibrinolytic systems, although usually within the normal range .... It is conceivable that these effects are estrogen-mediated because they have not been demonstrated in progestogen-only preparations. There is a dose-dependent relationship in the case of estrogen, although in combination tablets, the progestogens might exert a modifying effect .... Further attention should be given to changes in factor VIIc and fibrinogen induced by oral contraceptives and also to the association between carbohydrate metabolism and fibrinolysis."

Quantification of coagulation factors is notoriously difficult, because of the interrelations among the various components of the coagulation cascade, the broad range of normal values, and considerable inter-laboratory variability (51). This variability is illustrated by a WHO study of users of combined oral contraceptives, conducted on several continents, which showed statistically significant differences among clinical centers in prothrombin time, fibrin plate lysis, plasminogen, and activated partial thromboplastin time (SEDA-16, 464). Effects also vary between different populations, users of different doses, users of different products, and tests performed at different periods of the medication cycle (61,67).

The term "hypercoagulability" has been used to describe a supposed pre-thrombotic state, identifiable by certain changes in the hemostatic system, but to date there is no broad-spectrum laboratory test for assessing the risk of thrombosis in a given individual, although coagulation changes in vitro have sometimes been regarded as proof of a thrombotic state. Deviations in laboratory data from patients with thromboses have often been interpreted as demonstrating the cause of the thrombosis, whereas they may simply be a consequence.

Despite the variations that are found, the overall conclusion is that oral contraceptives cause an increase in coagulation factors I (fibrinogen), II, VII, IX, X, and XII, and a reduction in antithrombin III concentrations, which would be expected to predispose to venous thromboembolism, especially if not counterbalanced by an increase either in fibrinolytic activity or of other inhibitory proteins of the coagulation, such as protein C (68).

There is also fairly strong evidence that immunological mechanisms play a role in thrombotic episodes associated with oral contraceptives, especially when they occur in the absence of risk factors for vascular disease (69), although this has been contested (70). In one series of reports on cerebral infarction, circulating immune complexes and/or specific antihormone antibodies were found in 15 of 20 patients (36). In a large series of women with venous or arterial thrombosis, anti-ethinylestradiol antibodies were absent in non-users but present in 72% of users; they were also present in 33% of healthy oral contraceptive users without thrombosis (SEDA-16, 465). In half of the cases there were both anti-ethinylestradiol antibodies and a history of smoking were found jointly in half of the cases.

There is a significant rise in fibrinogen concentrations during the early months of oral contraceptive use, and concentrations return to baseline after withdrawal (71). Prolonged use of oral contraception also seems to lower concentrations of antiaggregatory prostacyclin (72).

Some work that was considered to show severe acquired plasma resistance to activated protein C among users of third-generation (as opposed to second-generation)

© 2006 Elsevier B.V. All rights reserved.

products has been re-examined by a French group (73). In their view the technical measures used to demonstrate the effect of activated protein C introduced a bias of interpretation and hence false results; they have further argued that such a test cannot demonstrate the presence of a raised thromboembolic risk in asymptomatic women taking these contraceptives, since it is non-specific and subject to changes in the plasma concentrations of many coagulation factors that are themselves increased or decreased by estrogens and progestogens. They point, for example, to protein S (74), changes in which account for the differential effect of oral contraceptives on Rosing's assay (75), but which are in their view irrelevant to issues of thromboembolic risk with oral contraceptives; the androgenic potential of the progestogen may further counteract the effect of estrogens in the test. More generally, in such a complex situation in which there is a "modification of the modification," there is no hemostasis-related test that provides a risk indicator for thrombosis. This argument is sound, but it naturally remains theoretical; the question of thromboembolism with the third-generation products must, as pointed out above, be resolved on the basis of epidemiological data, and certainly those data now strongly point to an increased risk.

Relative roles of estrogens and progestogens

The risk of thrombosis is closely associated with the estrogen component (76) for both arterial and venous events and with the progestogen for arterial events; however, if a particular progestogen is metabolized to estrogen or raises estrogen concentrations, it will make a contribution to venous complications. Estrogen alone has after all been incriminated as a cause of thromboembolism when given to men (77); the risk of puerperal thromboembolism after estrogen inhibition of lactation has been shown in several studies (78); non-contraceptive estrogens clearly increase the risk of acute myocardial infarction in women under 46 years of age (79). Changes in coagulation factors appear to be related to the estrogen dose (44,45,80,81). Progestogen-only formulations do not have any significant effect on the coagulation system.

Third-generation oral contraceptives and thromboembolism

There are now reasons to doubt whether the third-generation oral contraceptives are indeed safer than their predecessors in respect to thromboembolism and substantial grounds for believing that they present greater risks.

The first reason is theoretical. The demonstrated effects of the new substances and combinations on lipids and carbohydrates do not have any major relevance to the thromboembolic process. The latter is linked primarily to changes in the hemostatic system and blood coagulation, involving platelet aggregation, coagulation factors, fibrinogen concentrations, and blood viscosity.

The second reason is kinetic. It is true that the dose of estrogen (probably the main instrument in inducing thromboembolism) has been kept to a minimum, but the new progestogen gestodene tends to accumulate in the system with continued use, and the concentrations of ethinylestradiol increase simultaneously; this increase is due to the ability of gestodene to inhibit cytochrome P450 and therefore to inhibit the breakdown of estrogen, as well as its own metabolism (82). Similar findings emerged with desogestrel, although they were somewhat less marked (83).

The third reason is hematological. The third-generation contraceptives have greater adverse effects on the clotting system than those of the second generation. In particular, women using the third-generation products have a greater resistance to activated protein C (84), a shift that is associated with a higher risk of thrombosis.

The fourth reason is epidemiological. During the period 1987–88, when the third-generation products were relatively new, anecdotal reports of thromboembolic events appeared, including at least one death, and partly for this reason a series of large controlled studies were set up. The findings of three such studies (British, European, and global) became available to the drug control authorities late in 1995 and were subsequently published. The UK Committee on Safety of Medicines, considering all three, concluded that the risk of venous thromboembolic events in these third-generation oral contraceptives was about double that in users of the previous generation of products using the older progestogens (30 as opposed to 15 per 100 000 woman-years, the risk in healthy women being only five per 100 000). Despite the different populations studied, the individual studies produced broadly consistent results. The global study on four continents found a relative risk of 2.6 when comparing the desogestrel/gestodene products with the older variety, while the European study found a relative risk of 1.5–1.6. Various later papers pointed in the same direction. In Denmark, there was an increase in hospital admissions for primary venous thromboembolism in young women coinciding with the introduction of the third-generation products (85). Papers from The Netherlands have confirmed the main trend (86,87).

Authoritative reviews and editorials have further confirmed the correctness of the above findings. There has been some criticism of the individual studies on various points of detail, but it is difficult to see that this in any way undermines what is now very consistent evidence that the third-generation oral contraceptives increase the risk of thromboembolic events to a substantially greater degree than previous products. Some work that has been advanced as pointing to the safety of third-generation products (88) proves to relate primarily to the second-generation combinations, with only a few late entrants using the more recent oral contraceptives, and other work was performed on a very small scale.

As a rule, the study of adverse reactions must relate to current and emergent issues. However, now and again it can be instructive to look back into recent history. When a drug problem has been fairly clearly defined, and particularly when it has for a time been the subject of debate and even frank controversy, one can learn something from the processes involved. How did the facts become known? Why did the controversy emerge? And could the risk have been detected and eliminated earlier?

Since their appearance in the late 1950s, oral contraceptives have gone through several stages of development. What are now in retrospect referred to as

© 2006 Elsevier B.V. All rights reserved.

first-generation oral contraceptives were high-dose combinations of progestogens (more particularly norethynodrel, norethisterone, and lynestrenol in doses of 2.5 mg or more) and the estrogen mestranol 75 micrograms. A decade later a second generation emerged, with substantially lower doses, commonly half of those used earlier and some new progestogens, notably the more potent levonorgestrel. Finally, in the early 1980s some manufacturers introduced so-called third-generation products, a particular characteristic of which was the use of entirely new, very potent progestogens, among them desogestrel and gestodene. Clinical studies of contraceptives that contained gestodene and desogestrel suggested that they are very similar to one another, although differences in dosage and potency could account for reports that products that contain gestodene provide better cycle control (89).

Almost from the earlier years, the risk of thromboembolic complications among users of "the pill" was recognized, and by the mid-1960s it was well documented (90,91). Progressive reductions in dosage, in particular that of the estrogenic component, during the period that first- and second-generation products held sway were widely regarded as having reduced this risk to manageable proportions, although it was not eliminated. The relative risk with first-generation products was highly variable (2–11), but the best work in the UK and the USA fairly consistently reached an estimate of 4–6 (92–94). With the second-generation products the relative risk of thromboembolic complications was again variously estimated, but a large cohort study published in 1991 set it at 1.5 with products containing the lowest doses of estrogen, and 1.7 with products containing intermediate doses of estrogen (33).

The fact that both prescribers and users of medicines are likely to anticipate that new drugs will be in some way better than those that have gone before means that both groups are in principle receptive to potentially spurious claims and suggestions. By the time the third-generation oral contraceptives were marketed, this type of contraception had been around for a quarter of a century; the risk of thromboembolism, the most widely publicized problem in the field, seemed by that time to have receded with progressive reductions in dosage. There was every reason to hope that it would recede further with the newest generation of products. That expectation was further nurtured by the even lower doses latterly attainable. It also seems to have been fostered by some of the suggestive promotion that appeared, although that in fact related as a rule merely to an improved lipid spectrum, which in turn raised the theoretical possibility, also discussed but not documented by some clinical investigators (95), that arterial and cardiac risks might be less.

What in fact happened was that by 1989 alarm bells began to ring in Germany, where the regulatory authorities were alerted to the submission of an unusually high number of spontaneous reports of thromboembolic complications thought to be associated with the new products. Cases continued to accumulate, long-term studies already begun were completed, and in 1995 Britain's Committee on Safety of Medicines made a public statement to the effect that the risk of thromboembolic complications among hitherto healthy users of third-generation products was approximately twice than that seen with second-generation products (SEDA-19, xix). The studies in question, including work by the World Health Organization and others (SED-14, 1410), were subsequently published and confirmed that conclusion, as did later work (96). It was further reinforced by others (97), who worked on a smaller scale but provided well-documented evidence that while a factor V Leiden mutation or a biased family history could increase the risk in individual cases, they did not explain the higher thrombosis risk seen with a product based on desogestrel than with contraceptives that incorporated levonorgestrel, norethisterone, or lynestrenol.

Currently one must ask why the particular risk of the third-generation contraceptives was identified so late. These third-generation products had been in development since the late 1970s and the first had been marketed in 1981–82, some 14 years before the Committee on Safety of Medicines issued its statement. Could society not have done better and thereby reduced the risks to which women were exposed? There are two principal answers, both of them at least partly in the affirmative.

The first is that products of this type could well have been entered at an earlier date into large studies of oral contraception and their effects. A series of university centers around the world, as well as bodies such as Britain's Royal College of Physicians and Royal College of General Practitioners, have throughout the oral contraceptive era either sponsored or participated in prolonged cohort and case-control studies of these products. Experience with data on thromboembolism suggests that significant data are likely to be obtainable in a cohort study of manageable size within some 5–7 years. The use of third-generation products may have been small in the early years, but they were aggressively promoted in major oral contraceptive markets to ensure rapid growth, in all probability sufficient to provide adequate recruitment. One would hesitate to argue that such studies should be a universal condition of the marketing of drugs, but when the products concerned have immense social significance and considerable potential for good and harm, as the oral contraceptives do, and when the compounds involved are entirely new, there is at least a sound medical reason for such work in every case. That work was performed with successive forms of the earlier oral contraceptive products, in which dosages were progressively reduced, and there was particular reason to set it in motion on the introduction of products that contained new chemical components with some significant structural and pharmacological differences from the older progestogens. A straightforward statistical calculation shows that an early cohort study involving some 30 000–50 000 women taking a third-generation product could within 2 years have shown the degree of increase in the thrombotic risk, which was actually not elicited until much later.

The second answer with respect to the earlier acquisition of risk data must come from the laboratory. Not from animal studies, which in this field are of very restricted value, but from biochemical and particularly hematological work. When during the 1990s various groups began to examine in detail the effects of the third-generation contraceptives on processes related to the clotting system, they identified a series of properties that could very well explain an increased incidence of thrombosis.

© 2006 Elsevier B.V. All rights reserved.

The first of these was an increase in circulating concentrations of factor VII produced by the desogestrel plus estrogen combination, which was some 20–30% higher than that seen with a second-generation product based on levonorgestrel (98). The methods used to carry out this work were available before 1988 (99), and it is not at all clear from the published material whether there was a failure to compare the two generations in this respect at an early date, or whether such work was performed and either overlooked or misinterpreted.

A second finding related to the effects of activated protein C on thrombin generation in low-platelet plasma via the intrinsic or extrinsic clotting pathways. Using a method developed on the basis of work first published in 1997 (100), a Dutch group in Maastricht found that all types of combined oral contraceptives induced acquired resistance to activated protein C. With the third-generation contraceptives, however, the effect was significantly more marked than with those of the second generation: in other words, these drugs significantly reduced the ability of activated protein C to down-regulate the formation of thrombin (84). However, this work only became feasible in the late 1990s.

A third underlying mechanism seems to involve a reduction in concentrations of free protein S, again more pronounced with third-generation products. When protein S falls, the antifibrinolytic effect of the so-called thrombin-activated fibrinolysis inhibitor is increased; in other words, fibrinolysis is impeded, with an increased risk of clotting problems (101). Again, however, these are recent methods, which were not available when the third-generation products were launched.

The laboratory findings therefore suggest that a greater thrombosis-inducing effect of the third-generation oral contraceptives can be explained and even anticipated on the basis of known mechanisms. Not all the relevant methods were available in the early years, but that relating to factor VII most certainly was. It is unfortunate, to say the least, that such work was either not performed or not properly interpreted.

All in all, had a combination of hematological methods and field studies been initiated sufficiently soon, the increased risk of thromboembolism with the third-generation oral contraceptives could have been detected some years earlier, sufficient for society to take decisions on the benefit-to-harm balance of these drugs before so much needless injury was incurred.

The third-generation oral contraceptives: a judicial assessment

It was extraordinary to find a major epidemiological dispute regarding drug safety being handled by the High Court in England in late July 2002, when the Court handed down its decision regarding thromboembolic events induced by the third-generation oral contraceptives (102). Essentially, a group of women who claimed to have been injured as a consequence of having using this latest version of "the pill," based on two new progestogens, had sought to reclaim extensive damages from the manufacturers, since in their view the product did not possess the degree of safety which, in the words of European law, the user was legitimately entitled to expect. Since the safety achieved with the widely used products of the second generation was so widely regarded as acceptable, the Court had to decide whether the newer products had significantly failed to meet that standard. Faced with a long procession of expert epidemiological witnesses from both sides, and with some flat contradictions, the judge was obliged to rule on their arguments.

However, that it was an English court in which the issue came to be debated was not surprising, for it was in England that the Committee on Safety of Medicines had written to prescribers in 1995 stating that three unpublished studies on the safety of combined oral contraceptives in relation to venous thromboembolism had indicated about "a two-fold increase in the risk of such conditions" compared with the preceding generation of products. This issue of a "two-fold increase" became crucial to the case. "For reasons of causation," as the Judge put it, the claimants had accepted the burden of proving that the increase in risk was not less than two-fold.

In fact, the English authorities, having rejected a vigorous defence of these products by the manufacturers, were by 1999 speaking more precisely of an increase in risk, as compared with the earlier products "of about 1.7–1.8 after adjustment," which was "not fully explained by bias or confounding"; appropriate label warnings were therefore imposed. These new warnings, summarized, said that an increased risk associated with combined oral contraceptives generally was well established, but was smaller than that associated with pregnancy (60 cases per 100 000 pregnancies). In healthy non-pregnant women who were not taking any combined contraceptive it was about five cases per 100 000 woman-years; in those taking the second-generation products it was about 15; and for third-generation products it was about 25. By September 2001, the European Union's Committee on Proprietary Pharmaceutical Products had formed its own view, and here too it was concluded that the "best estimate of the magnitude of the increased risk is in the range of 1.5–2.0."

In Court to support the claimants, Professor Alexander Walker assessed the relative risk of the third-generation products at 2.2, Dame Margaret Thorogood at 2.1, and Professor Klim McPherson at about 1.9. The experts for the defendants took the view that the relative risk was well below two, and could well be zero. As Mr Justice Mackay noted, having listened to these experts: " . . . the debate between them has been unyielding, at times almost rancorous in tone, and with a few honourable exceptions . . . devoid of willingness to countenance that there may be two sides to the question. So, science has failed to give women clear advice spoken with one voice."

There was also fundamental disagreement on confidence intervals when calculating relative risks in such matters: "The Defendants say that to establish causation in the individual, and therefore a relative risk which is greater than two, there must be seen not just a point estimate but also a lower confidence interval which is greater than two in order for the result to be significantly different from two."

The Court was faced with "a series of studies with different point estimates and largely overlapping confidence intervals. Time after time experts have had their attention drawn to point estimates from studies that appear, to the layman's eye, to be very different. Almost invariably they have dismissed those apparent differences

© 2006 Elsevier B.V. All rights reserved.

by reference to the overlapping confidence intervals, saying that the figures are statistically compatible and there is no significant difference." Confronted with such material, the Court chose to set aside as inexact and theoretical much of the statistical rhetoric. Having done that, the Judge felt himself in a position to emerge "from that forest into broader more open country where the simpler concept of the balance of probabilities rules." Constructing his judgement in that way, Mr Justice Mackay advanced in the course of 100 pages to the conclusion that the claimants had failed to demonstrate a doubling of the risk. In his view, "the most likely figure to represent the relative risk is around 1.7."

This extraordinary and wise judgement merits most careful reading by anyone anxious to understand the safety issues surrounding oral contraceptives. First, because of the insight that it demonstrates into the manner—not always edifying—in which evidence in this vital matter has been adduced, interpreted, and argued over in the course of more than a decade. Secondly, because it arrives, through a process of tight reasoning, at what is for the moment the most reliable conclusion we have. It seems beyond all possible doubt that the third generation of oral contraceptives is primarily characterized by an increased risk of thromboembolic complications. Whether that risk is great enough to warrant financial compensation is a matter for lawyers to decide. But given the lack of any tangible benefit to the user, the risk is clearly significant in human terms, and it is hard to see that there is any valid reason at all for continuing to use these products.

Arterial complications

Arterial disease and acute arterial disorders and their links to oral contraception have long been a matter of concern, partly because of actual reported instances of apparent complications, but largely because of the metabolic changes caused by the oral contraceptives. In particular, it has been thought that the effects of these products in raising blood pressure, affecting clotting, or changing the circulating concentrations of blood lipids and carbohydrates could result in cardiac and arterial risks, including an earlier onset of atherosclerosis and the occurrence of myocardial infarction and stroke. Basilar artery occlusion secondary to thrombosis (103), cerebral infarction (104,105), retinal vascular complications (106), and encephalopathy with renovascular hypertension (107) and acute myocardial infarction (108,109) have all been reported. There have been over 40 reports of intestinal ischemia and infarction in oral contraceptive users, with a high mortality rate (39,110).

The initial question must be whether the clinical data point to the emergence of complications of this type. The 1990 International Consensus Meeting found an increase in acute cardiovascular accidents during use of oral contraceptives, but not persisting after they had been discontinued. There is also a great deal of anecdotal evidence, although in view of the massive scale on which oral contraceptives have been used over 40 years, coincidence alone would lead to the accumulation of many reports of adverse events. Other evidence suggesting an increase in arterial thrombotic events has been noted incidentally in the discussion of venous events above. There is also evidence that the chance of unexpected cardiovascular death is lower in oral contraceptive users who have been taking a product based on one of the new progestogens in particular. In over 300 000 women there was a cardiovascular death rate of 4.3 per 100 000 women-years among users of combined oral contraceptives containing levonorgestrel, 1.5 per 100 000 among users of those based on desogestrel, and 4.8 per 100 000 among users of oral contraceptives containing gestodene (111). The relative risk estimates compared with levonorgestrel were 0.4 (95% CI = 0.1, 2.1) and 1.4 (0.5, 4.5) for desogestrel and gestodene respectively. However, it should be added that this is precisely one of the studies that concluded that the new progestogens substantially increased the incidence of venous thromboembolism.

However, a fatal flaw of most such studies was their failure to provide an adequate analysis of co-existent risk factors other than oral contraception. In fact, there is not a great deal of evidence of appreciable risks of this type among oral contraceptive users, unless other risk factors are present. The 1989 case-control analysis of the Royal College of General Practitioners cohort study showed that current oral contraception increased the risk of acute myocardial infarction, but only among smokers. The large cohort study from the Oxford Family Planning Association (OFPA) similarly found no significantly increased risk of myocardial infarction or angina pectoris among either current or former use of oral contraceptives, but a strong dose-related effect of current smoking. In an analogous manner, many studies have shown that the risk of coronary heart disease in oral contraceptive users or other women increases directly with body weight (52,54) and with age (6), but not clearly with oral contraceptive use alone. Nor does one find any published evidence that the risk of late arterial disease, notably atherosclerosis, is higher among users of oral contraceptives, despite the fact that with some 40 years of experience one would expect any such trend to have become evident by the end of the 20th century.

Alongside this clinical material one is faced with the biochemical evidence of changes in the oral contraceptive user. However, various findings make it impossible to draw clear pathogenetic conclusions from these biochemical data. As far as lipids are concerned, there is no doubt that oral contraceptives as a group increase low-density lipoprotein and reduce high-density lipoprotein and cholesterol; this shift is usually regarded as inducing a propensity to atherosclerosis, but here its significance is not so simple to assess. HDL cholesterol, for example, can be divided into subfractions, of which HDL2 seems to be more responsive to estrogens and progestogens; the concentration of HDL2 has been thought to correlate better with a reduced risk of cardiovascular disease than does total HDL cholesterol (112). The picture is further complicated by the fact that when estrogens are used in postmenopausal women they can raise HDL, a change that might be considered to have a favorable effect (113–115). What is more, the effects of these products on lipids change with time, rendering short-term studies useless as a basis for risk assessment. It could be that the older oral contraceptives raise the risk in the short term, as suggested above, but actually lower it in the long term.

© 2006 Elsevier B.V. All rights reserved.

It is by no means impossible that the overall effect of oral contraceptives on the arterial system is exercised through a complex of different mechanisms. In this respect it is worth recalling the "insulin resistance syndrome" or "metabolic syndrome," which comprises a set of metabolic risk factors for cardiovascular disease (specifically coronary heart disease and arterial disease) (116). These interrelated risk factors include hyperinsulinemia and impaired glucose tolerance, hypertriglyceridemia, reduced high-density lipoprotein (HDL) concentrations, and hypertension, with insulin resistance as a potential underlying factor. Hormonal contraceptives can variously affect these metabolic conditions, and the effect depends in part on steroid type and dose. Lower doses and newer formulations do not change HDL concentrations or increase blood pressure, but insulin resistance and hypertriglyceridemia still occur. These latter changes are caused primarily by the estrogen component of combined oral contraceptives, but the progestogen component can also modify these effects. The formulations with the least unfavorable metabolic effects are those that contain norethindrone or that are based on the newer progestogens, such as desogestrel, gestodene, or norgestimate. However, as noted elsewhere, it has yet to be determined whether the metabolic changes confer any clinical benefit.

Finally, it is fair to set the possible adverse effects of these hormonal products, and particularly of estrogen, against the fact that estrogen also has certain favorable effects on the arterial wall. It has been suggested that estrogen has a calcium channel blocking effect that relaxes the vessel walls, thus increasing blood flow (117). Others have documented in monkeys the fact that estrogens dilate the coronary arteries, an effect unrelated to plasma lipid concentrations, blood pressure, or heart rate (SED-13, 1217) (118). They have also found evidence in their animal studies that estrogen + progestogen administration to hypercholesterolemic animals reduces both their HDL cholesterol concentrations and their arterial lesions.

Frequency

West German data over the period 1955–80 showed no community-wide increase in the incidence of ischemic heart disease, cerebral vascular embolism, or pulmonary embolism, despite the rapid growth in oral contraceptive use (and the prevalence of high-dose products) during much of that period (119). The Oxford Family Planning Association's 1989 paper on its cohort study, which had followed up more than 17 000 women for an average of nearly 16 years, found no significant overall effect of oral contraceptive use on mortality, with a relative risk of 0.9 (8). Mortality from diseases of the circulatory system had slightly increased; the relative risk of death from ischemic heart disease in current or past oral contraceptive users was 3.3 (95% CI = 0.9–17.9), while data on fatal cerebrovascular disease were too few to be interpreted.

Similarly, a massive Finnish mortality study, covering 1 585 000 women-years of oral contraceptive use and two million women-years of copper-bearing intrauterine device use, showed no increase in relative risk among oral contraceptive users for myocardial infarction or cerebral hemorrhage deaths; however, there might have been an increased risk of death from pulmonary embolism among users of oral contraceptives (42).

An analysis of the cardiovascular mortality risk associated with low-dose oral contraceptives (under 50 micrograms of ethinylestradiol) in the USA showed that among non-smokers and light smokers the mortality among current oral contraceptive users was likely to be lower than the mortality due to pregnancy (25). Only among heavier smokers over 30 years old did the risk of oral contraceptive use exceed the risk of pregnancy. The researchers noted that in countries with higher maternal mortality rates than the USA, even older women who are both heavy smokers and oral contraceptive users would have a lower mortality risk than that associated with pregnancy.

A 5-year case-control study involving all Danish hospitals has once more quantified the thromboembolic risks associated with oral contraceptives as a whole; the risk with third-generation products was some 30% higher than with second-generation products (RR = 1.3; CI = 1.0, 1.8) (120). However, data on cerebral thrombosis from the same study showed that with third-generation products the mean risk was some 40% lower than with second-generation products (RR = 0.6; CI = 0.4, 0.9) (121).

Susceptibility factors

The effect of smoking has been investigated on a large scale in Denmark, where the incidence of smoking among women is much higher than in many other countries (122). Evidence has emerged that the combination of smoking with oral contraceptive use may have a synergistic effect on the risks of acute myocardial infarction and cerebral thromboembolism (but not of venous thromboembolism), particularly among users of high doses (50 micrograms). The authors therefore suggested that the very low-dose products, which in Denmark contain 20 micrograms of ethinylestradiol, should be preferred in smokers. While this conclusion is clear and defensible, the situation is somewhat complicated by the fact that in Denmark the only products that contain this low dose of estrogen are those in which it is combined with either desogestrel or gestodene, that is third-generation progestogens. It could well be that the safest combined oral contraceptives for smokers will prove to be those in which the 20 micrograms dose of estrogen is combined with a more traditional progestogen.

For current or potential users of oral contraceptives the question arises whether it is not wise to examine the individual's possible predisposition to thromboembolism (thrombophilia) before deciding for or against this form of birth control. It has been suggested that in teenage users who might prove to be carriers of the Factor V Leiden mutation, routine screening would not be economically justified (123). It was instead the author's view that clinicians can use thoughtful screening questions to identify potentially high-risk patients for thrombophilia and consider testing for inherited risk factors case by case.

Estrogens versus progestogens

As far as the estrogens are concerned, the original estrogen, mestranol, was abruptly replaced by ethinylestradiol in most or all products after a wide-scale panic relating to the thrombosis issue in 1969. The motive lay entirely in

© 2006 Elsevier B.V. All rights reserved.

the fact that the ethinylestradiol was about twice as potent, so that the dose could be halved. Whether this in fact led to any reduction in cardiovascular thromboembolic risk was never specifically examined. The choice of estrogen might still be relevant to the extent that (physiological) 17-β-estradiol in microcrystalline form later became available for oral use and in theory might prove safer in some respects than semisynthetic estrogens, since it seems to have less effect on the fibrinolytic system.

The question of the progestogens has come acutely to the fore as a result of the debate regarding the third-generation progestogens gestodene and desogestrel. At the time of marketing, no specific claim appears to have been made that they would present a lesser degree of risk of thromboembolism. However, emphasis was placed on experimental findings that might indicate a better cardiovascular prognosis. The older oral contraceptives produce an increase in low density lipoprotein and a reduction in high density lipoprotein and cholesterol; those changes may have some relevance to the occurrence of arterial disease. By avoiding them, and having the lowest possible estrogen content, the new combinations were expected to be safer, although this had in no sense been proven. However, the manner in which this information was presented could have introduced a degree of confusion in the minds of prescribers and users, and the belief appears to have arisen that these third-generation oral contraceptives might prove less likely than their predecessors to cause thromboembolic disorders. That this is not so in relation to venous thromboembolism is discussed above. The theoretical argument that the risk of atherosclerosis and its associated complications might in the long run be less is so far entirely unproven, and with the fall in use of these products following these unfavorable findings (124), it seems uncertain whether the data necessary to examine that hypothesis will ever be accumulated.

Persistence of risk after discontinuation

Most, but not all, studies have concluded that the effect of oral contraception on the risk of cardiovascular disorders disappears after withdrawal (6,41,54,125–127). The Nurses' Health Study found no differences in either incidence of or mortality from various cardiovascular diseases between never-users and past-users, regardless of the duration of use, or the time since last use (7). The nested case-control analysis of the RCGP study showed that, although stroke risk was higher among current oral contraceptive users regardless of smoking status, former users had an increased risk only if they were current smokers. Such conclusions are supported most strongly by a 1990 meta-analysis of published studies on the relation between past use of oral contraceptives and myocardial infarction, which produced an adjusted relative risk estimate of 1.01, suggesting no association (128). Thus, there does not appear to be a long-term mechanism at work, such as atherosclerosis, but rather an effect confined to current use, such as thrombosis (41,54). However, there have been only a few studies of stroke in relation to previous oral contraceptive use, and those studies have produced inconsistent results; thus, meta-analysis of stroke data is precluded.

With some of the newer drugs, the effects may (as seems to be the case with the older drugs) persist for a number of weeks and justify the withdrawal of these products some time before surgery or other risks. A study of changes in hemostasis after withdrawal of the newer combined oral contraceptives (ethinylestradiol 30 micrograms plus either desogestrel or gestodene) (41) showed that several weeks elapsed before plasma concentrations of fibrinogen, factor X, and antithrombin III returned to baseline.

It should be noted that a few studies have produced deviant conclusions, for reasons that are not clear. Some found that the risk of fatal myocardial infarction was similar for current and past users (26), whereas others actually reported a lower risk of cerebral thromboembolic attack in former users compared with never users (29).

In summary, the final chapter in the story of oral contraceptives and arterial lesions has not yet been written. However, in the light of long experience there is currently reason for optimism. There is no reasonable evidence that oral contraceptives, whatever their biochemical effects, actually do increase the risk of atherosclerosis; as to the occurrence of acute arterial events, these are explained largely or entirely by the presence of risk factors other than oral contraception.

Hypertension

The association between combined oral contraceptives and hypertension, noted and confirmed as early as 1961, has been explored in a multicenter clinical trial carried out by the WHO (129,130) and on a lesser scale in many other reports, yet the facts remain surprisingly puzzling. It has become clear that the use of oral contraceptives in any dose can cause a mean increase in blood pressure, the effect being much more marked in some individuals than others. With the current range of oral contraceptives a substantial proportion of users show some increase in blood pressure compared with their pre-treatment condition (131), but the rise is rarely of clinical significance. Clinical hypertension seems unlikely to occur in more than 1–5% of women (132). The incidence may have been higher with the older high-dose products, but that is not entirely clear. The figures have to be set against the incidence of hypertension in a population of otherwise healthy women of fertile age, which is about 2%. The rise in blood pressure can appear at any time during treatment and persists for at least as long as the drug is taken, sometimes for several months longer, but even then it generally returns to normal. In order to detect women who react poorly, blood pressure measurements should be an integral part of the follow-up care of all women taking oral contraceptives. Considerable research has shown no overall increase in blood pressure or in the prevalence of hypertension associated with use of progestogen-only contraceptives; nor does the available information point to any increase in other cardiovascular disorders.

It is not clear why many women remain normotensive while others have a rise in blood pressure. No confirmation has been obtained of early beliefs that hypertension during oral contraception was more likely to occur in black American women, or in women with a history of hypertension during pregnancy (56,133). However, there is clinical evidence that this can occur and that the women involved

© 2006 Elsevier B.V. All rights reserved.

may have a defect in dopaminergic transmission affecting blood pressure and prolactin secretion (134); pre-existent abnormalities of platelet function and fibrinolysis have also been linked with this complication (SEDA-6, 348).

Published studies, in which various doses have been used, show that there is no clear relation between blood pressure and estrogen intake. The progestogens seem to be involved, but here too most specific studies fail to detect a dose–response relation (131). However, some do: in a 1977 analysis of data from the large prospective study by the Royal College of General Practitioners (RCGP), with oral contraceptives containing ethinylestradiol 50 micrograms and norethisterone acetate 1, 3, or 4 mg, the risk of hypertension increased with increasing progestogen dose (135).

The rise in blood pressure might reflect water retention caused by the mineralocorticoid effect of progestogens, but that is probably not the complete explanation. These drugs have an effect on the renin-angiotensin system, but there actually seems to be some fall in responsiveness to plasma renin activity. Other possible pathophysiological mechanisms discussed so far include insufficient adaptation to increased production of angiotensin and aldosterone, an increase in cardiac output, and changes in the metabolism of catecholamines. The estrogenic component of oral contraceptives has been stated to be the more important factor in producing abnormalities in the renin system, but the progestogen may also play a role. Some workers have found higher estrogen concentrations in oral contraceptive users who develop hypertension (136).

As might be expected, the few women with severe hypertension during oral contraceptive use, whether or not they were hypertensive before that time, run a somewhat greater risk of acute secondary complications due to hypertension, such as subarachnoid hemorrhage. If the hypertension is severe and persistent one might anticipate long-term effects on the cardiovascular system and kidneys. Nested case-control studies using data from the RCGP study showed that hypertension was an independent risk factor for both stroke (28) and myocardial infarction (55); after controlling for other variables, including oral contraceptive use, the odds ratios (or estimated relative risks) associated with hypertension were 2.8 for stroke and 2.4 for myocardial infarction. In that study, oral contraceptive use did not further increase the risk associated with either hypertension or a history of toxemia of pregnancy. Nevertheless, hypertensive women who take oral contraceptives should be monitored carefully.

Respiratory

Oral contraception is not considered to be relevant to the induction or aggravation of respiratory disorders, although the fact that a very few women have allergic reactions to these formulations could in theory be relevant to the occurrence of asthma.

Nervous system

Headache has long been reported as a reaction to oral contraceptives, just as it occurs unpredictably with many other forms of drug treatment; it is probable that women who are susceptible to headaches at certain phases of the menstrual cycle are more likely to react to oral contraceptives in this way. However, it does not seem to be in any sense consistent; in a placebo-controlled trial conducted as long ago as 1971, when doses of estrogens were high, headache was not found to be associated with use of combined oral contraceptives containing mestranol either 50 or 100 mg (137). In many other studies of the adverse effects of oral contraceptives, it is not possible to ascertain whether the prevalence of specific complaints, such as headache, is actually increased, because there is no appropriate comparison group.

Because migraine headaches are of vascular origin and are sometimes linked to the menstrual cycle, it is pertinent to consider whether hormonal contraception is appropriate in women suffering from this condition (138). No association of migraine headache with stroke has been demonstrated. However, some women with migraine have an increase in the severity and frequency of headache when they take combined oral contraceptives, just as some other migraine sufferers describe a relation to the menstrual cycle. As a precaution, women who have migraine headaches with focal neurological symptoms should not take combined oral contraceptives.

Despite initial concern (SEDA-6, 349), combined oral contraceptives do not appear to worsen seizure control in most women with epilepsy, although seizure frequency should be carefully monitored. The primary consideration in selecting a contraceptive method for an epileptic woman is the need for dependability, but antiepileptic drugs that are enzyme inducers reduce the effectiveness of hormonal contraceptives. Women who wish to take combined oral contraceptives, but for whom enzyme-inducing drugs provide the best seizure control, should be given combined oral contraceptives with a relatively high dose of estrogen (for example ethinylestradiol 50 micrograms). Fewer seizures occur during the luteal phase (low estrogen) of the menstrual cycle, suggesting that estrogens (or oral contraceptives) may be epileptogenic.

Reversible electroencephalographic changes, probably due to progestogenic effects (139), have been observed in 25–60% of oral contraceptive users.

There are various reports of chorea (140,141), hemichorea (142), and paraballism (143). In one case, chorea was the first sign of lupus erythematosus (144).

Acute abdominal symptoms in users of hormonal contraceptives suggest embolism or infarction at some site, but there can be unusual explanations.

- Right-sided lower abdominal pain occurred in a 15-year-old girl, and had been present throughout the 3 months that she had used the product but it had now become so severe as to demand emergency care. The problem was traced to cutaneous nerve entrapment in the abdominal wall (145).

It is not clear how this could have resulted from the treatment, but it might have entailed fluid redistribution in or around an old appendicectomy scar. It may be noted that nerve entrapment is recognized as a possible adverse effect of oral contraceptives in the carpal tunnel syndrome.

Results from the Oxford Family Planning Association Study showed no relation between oral contraceptive use and the incidence of multiple sclerosis (146). Conversely, multiple sclerosis is no longer considered to be a contraindication to hormonal contraceptive use.

Sensory systems

Eyes

It is still difficult to judge whether there is a correlation between ocular pathology and the use of oral contraceptives, with the exception of thromboembolic incidents that affect the retinal circulation. Oral contraceptives have several times been reported to reduce the tolerability to contact lenses, but in any case this abates in some people as the years pass. However, pregnancy itself may result in loss of contact lens tolerance both for scleral and corneal lenses, lenses often having to be refitted after pregnancy; a similar effect of oral contraceptives is thus not entirely unlikely (147), even though other workers have failed to detect any such change (148). Similar doubts relate to the induction of macular hole with retinal detachment, but in one study 20 of 24 women with this complication were using oral contraceptives (SEDA-6, 348). Finally, there is one case report of retinal migraine linked to the end of oral contraceptive treatment cycles (149).

Ears

Aggravation of existing otosclerosis has been observed several times; in one series of five cases, withdrawal of the medication stabilized four cases while the fifth improved (150). There is no reason to expect a reduction in hearing except in cases of otosclerosis; indeed, in a study of several thousand American women, hearing was generally found to be better among current oral contraceptive users than in never-users, and was intermediate in past users (151). A long-term study of chronic oral contraceptive users, which included otological, audiological, and vestibular examinations, found no impairment of the function of the healthy internal ear (152).

Psychological, psychiatric

Psychiatric symptoms have been described in women taking oral contraceptives in isolated case reports (153,154), probably reflecting non-specific effects in susceptible individuals. As to psychological effects, many physicians have found that certain women react to oral contraceptives by becoming morose or unhappy (155), but this does not necessarily mean that they meet the clinical criteria of true depression, the incidence of which has not been found to be increased (156). Several possible biological mechanisms for mood changes have been suggested; however, when nervousness and depression among combined oral contraceptive users are carefully evaluated over time, the pattern is so inconsistent that it is difficult to study. If one looks for anything like consistent depression one is unlikely to find it (137).

Many women who change to an oral contraceptive after unsatisfactory experience with other forms of contraception find greater sexual satisfaction (156) because of relief from worry about pregnancy.

Endocrine

Both long-term and short-term progestational therapy can suppress pituitary ACTH production to some extent, as studied with the metyrapone test. Medroxyprogesterone and chlormadinone suppress the reaction to metyrapone almost completely. Recovery was rapid after withdrawal of therapy. However, no conclusion was drawn as to the relative effect of the ethinylestradiol that was also given. The cortisol secretion rate is depressed in women taking norethindrone and mestranol, and the suggestion has been made that the gluconeogenic effect of glucocorticoids is markedly potentiated in subjects taking estrogens or estrogen-like substances. Adrenal cortical insufficiency has been related to the use of ethinylestradiol and dimethisterone taken during 1 year. The ascorbic acid content of the anterior pituitary is reduced in the presence of estrogen-induced adenohypophyseal hypertrophy.

Fasting growth hormone concentrations are higher in women using a contraceptive agent than in controls (157).

Oral contraceptives can cause an increase in total thyroxine (158) and a fall in the percentage of free thyroxine (159). The uptake of radioactive iodine in the thyroid is usually normal; total uptake of radioactive iodine may be reduced (159). The effect of progestogens on thyroxine-binding globulin may possibly counteract the estrogenic action. The net result will be a rise in protein-bound iodine and a fall in resin triiodothyronine uptake (160). It has been suggested that oral contraceptives may actually have some protective effect against thyroid disease.

Metabolism

Lipid metabolism

The 1990 report of the International Consensus Development Meeting stated the following regarding the effects of oral contraceptives on carbohydrate and lipid metabolism (19): "All currently used oral contraceptives can cause deterioration in glucose tolerance accompanied by hyperinsulinemia. There is no evidence that the use of combined oral contraceptives is accompanied by overt symptoms of diabetes .... The progestogen component is mainly responsible for the effects of oral contraceptives on carbohydrate metabolism, but the estrogen component may modulate the influence. The magnitude of the impact on glucose metabolism depends on the type of progestogen and also on the doses of a given steroid."

As has become clear since that time, these effects do not run parallel for all oral contraceptives; the third-generation products, which contain either desogestrel or gestodene, have rather different effects, the significance of which is unclear.

Lipid changes seen with the most widely used combined oral contraceptives comprise an increase in low density lipoprotein and reductions in high density lipoprotein and cholesterol. The third-generation products have these effects to a much smaller extent, leading to claims that they would be less likely to have long-term adverse cardiovascular effects related to atherosclerosis. However, such a claim reflects an all too readily adopted belief that the lipid changes produced by the more traditional combined oral contraceptives are in this respect capable of causing this type of (primarily arterial) cardiovascular disease. This is of itself far from certain.

Changes in lipid metabolism among users of progestogen-only contraceptives are minimal. Some studies have shown very small falls in HDL and HDL2 cholesterol, but no effect on other parameters of lipid

© 2006 Elsevier B.V. All rights reserved.

metabolism. The androgenicity of progestogens parallels their effect on lipoprotein metabolism, but dosage must also be taken into account. For example, although levonorgestrel is more androgenic than norethindrone, its progestational potency is also greater, and levonorgestrel is therefore given in a lower dose for contraceptive purposes; the net result is that there is no clinical difference in lipid effects, as has been shown conclusively (161).

Adolescents with polycystic ovary syndrome are regarded as candidates for long-term combined hormonal treatment using a product of the oral contraceptive type, and there has been some concern about possible unfavorable late metabolic effects, notably on lipids. The risks with two combined products, one based on cyproterone acetate 2 mg and the other on desogestrel 0.15 mg, both with an estrogen, have been estimated in 24 women (95). After 12 months the hirsutism score was improved, but while triglycerides and HDL cholesterol were significantly increased by cyproterone, the only relevant effect of the desogestrel combination was a raised concentration of apolipoprotein A1. The authors concluded that the desogestrel combination was therefore to be preferred in such patients.

Carbohydrate metabolism

Carbohydrate metabolism was known at an early date to be affected by combined oral contraceptives. A mild to moderate degree of insulin resistance was found in some investigations (162,163). However, the considerably impaired glucose tolerance described in some users in the 1960s was directly dose-dependent. Although findings since then have not been entirely consistent (164), it is clear that the low-dose products introduced after the first decade of use had much less marked effects (165), as did the third-generation products based on newer progestogens. The clinical significance of these effects is limited. Even for the second-generation products, no difference was found across the board between ever users and never users in the incidence of diabetes mellitus. Prospective studies in England in 1979 and 1989 (166,167) showed no increased risk of diabetes in oral contraceptive users compared with controls or ex-users. These are, however, population-wide findings, and in some high-risk individuals, the effects on carbohydrate metabolism can be undesirable, with a significant deterioration in glucose tolerance (168); patients with serious or brittle diabetes should therefore not use these forms of contraception (169). It may also be wise to advise other contraceptive methods in women with a history of gestational diabetes, who might possibly be sensitive to these effects of the oral products (170). However, because of the increased risk of pregnancy complications in diabetic women, a highly effective contraceptive method such as the combined oral contraceptive is usually desirable, and it has been reasonably well demonstrated that there is no reason to avoid this type of formulation completely in a woman with stable and well-controlled diabetes. A clinical study of young women with insulin-dependent diabetes mellitus showed no significant differences between women using various combined oral contraceptives (containing up to 50 micrograms of ethinylestradiol) and non-users in hemoglobin A_{1c} concentrations, albumin excretion rates, and diabetic retinopathy (171). Possible very long-term consequences of changes in carbohydrate (and lipid) metabolism are considered further in this record and in connection with the cardiovascular system.

Most studies of carbohydrate metabolism have shown little effect of progestogen-only contraceptives, but there is a suggestion of slight deterioration in glucose tolerance and raised plasma insulin concentrations. Women with diabetes mellitus can generally take progestogen-only contraceptives without a change in insulin requirements.

Body weight

Body weight tends to increase in some women without a clear explanation, although it could be attributable in some individuals to improved appetite, water retention, or conceivably the anabolic effect of an androgenic progestogen. The increase is usually less than 2 kg and occurs during the first 6 months of use. Studies that record weight change over time have generally found similar fluctuations in oral contraceptive users and non-users (137). Cyclic weight gain purely due to fluid retention can also occur.

Nutrition

Alterations in plasma vitamin concentrations have been observed in oral contraceptive users, and attributed to reduced absorption and changes in plasma protein-binding capacity (172).

Vitamin A

While most vitamin concentrations in the blood fall (168), vitamin A concentrations increase, although carotene concentrations fall. Curiously, an isolated report of hypercarotenemia has been published (173).

Vitamin B_6

Alterations in vitamin B_6 metabolism have been discussed, particularly in connection with the suspicion that an oral contraceptive might cause depression. An additional daily intake of pyridoxine has long been suggested as a means of correcting the complex changes observed during use of oral contraceptives (174,175); there are no firm data proving that such medication has any useful effect in most women, but the approach may be tried empirically when mood changes are a problem (176).

Vitamin B_{12}

Vitamin B_{12} deficiency has been seen in healthy oral contraceptive users in whom serum vitamin B_{12} binding proteins were not altered.

Folate

Both sequential and non-sequential types of oral contraceptives impair the absorption of polyglutamic folate but not that of monoglutamic folate; the change can result in megaloblastic anemia in predisposed subjects, for example those with celiac disease or having a deficient diet (177).

Vitamin C

Some studies have suggested that ascorbic acid concentrations are lower in the leukocytes and platelets of oral contraceptive users (178); however, this has not been confirmed (179).

© 2006 Elsevier B.V. All rights reserved.

Vitamin D

Studies of the effects of oral contraceptives on serum concentrations of vitamin D derivatives have given variable results.

Wintertime concentrations of 25-hydroxycolecalciferol were measured in 66 young women aged 20–40 years who did and did not use oral contraceptives (180). The initial mean 25-hydroxycolecalciferol concentration in the 26 users was 41% higher than in the 40 non-users before adjustment for age and vitamin D intake (83 versus 59 nmol/l), and 39% higher after adjustment. In five women who stopped taking oral contraceptives during the year after the initial measurement the 25-hydroxycolecalciferol concentrations fell by an average of 26 nmol/l, whereas the concentrations in women whose use or non-use of oral contraceptives was constant did not change. The effect on 25-hydroxycolecalciferol concentrations was not related to the dosage of ethinylestradiol, the type of oral contraceptive, or the duration of use.

However, in another study there was no difference in the concentrations of 25-hydroxycolecalciferol between controls and women who took oral contraceptives containing ethinylestradiol 30–50 micrograms for more than 1 year (181).

The time of year and the point during the menstrual cycle during which vitamin D derivatives are measured may be important. In seven women there was a two-fold rise in the serum concentration of 1,25-dihydroxycolecalciferol on day 15 of the menstrual cycle compared with days 1 and 8, without a detectable change in the serum calcium concentration (182). This increase did not occur in five women taking oral contraceptives, and there was a small but significant fall in the serum calcium concentration.

Mineral balance

Users of oral contraceptives excrete significantly less calcium than non-users (183) and estrogen treatment prevents bone loss in postmenopausal women (184); it is thus likely that the diminished urinary calcium excretion observed in women using oral contraceptives results from suppression of bone resorption by exogenous estrogens. Long-term use of oral contraceptives may therefore affect skeletal bone stores and prevent the development of osteoporosis. In line with these findings is an investigation showing an increase in radio-opacities in the mandibles of women using oral contraceptives (185).

Metal metabolism

Sex hormones can cause changes in metal metabolism, including both increased and reduced plasma zinc concentrations and raised serum copper; however, serum magnesium is not affected (186). The clinical importance of these effects is not known.

Hematologic

Iron status is improved in most oral contraceptive users because of reduced menstrual blood loss; an important benefit of oral contraceptive use is therefore a reduction in the prevalence of iron deficiency anemia (187). Much of the relevant research has been with higher dosages than are currently used. However, a study of a low-dose combined oral contraceptive (ethinylestradiol 30 micrograms plus desogestrel 0.15 mg) documented significantly lower menstrual blood loss than at baseline (188). Most women had normal values of hemoglobin, hematocrit, erythrocyte index, and serum ferritin both before and during oral contraceptive administration, with no significant changes. However, two women who had menorrhagia (defined as menstrual blood loss greater than 80 ml) and low serum ferritin before oral contraceptive use experienced improvement in both of these parameters while taking oral contraceptives. The cyclic variation in serum iron during the menstrual cycle has also been found to be less pronounced during the use of anovulatory agents (189).

The binding capacity of serum proteins is altered by oral contraceptives (190) and leads to alterations in the serum concentrations of various substances, including thyroxine, cortisol, and serum iron (191), and in serum iron binding capacity, which are all increased.

Erythrocyte enzymopathies have rarely been observed during pregnancy and oral contraceptive treatment (192) and in these cases a cause and effect relation seems likely.

Hemostatic variables have been reviewed in women taking oral contraceptives containing desogestrel and gestodene in comparison with oral contraceptives containing levonorgestrel (193). The database of 17 comparative studies was homogeneous. There were no differential effects for coagulation and fibrinolysis parameters, except for factor VII, which was consistently increased by 20% among users of third-generation oral contraceptives than among users of second-generation oral contraceptives. Factor VII is not a risk marker for venous thrombotic disease.

Data from the Leiden Thrombophilia Study have been used to construct a case-control study, based on contraceptive users who had experienced a first episode of objectively proven deep vein thrombosis (97). Patients and controls were considered thrombophilic when they had protein C deficiency, protein S deficiency, antithrombin deficiency, factor V Leiden mutation, or a prothrombin 20210 A mutation. Among healthy women, the risk of developing deep vein thrombosis was trebled in the first 6 months and doubled in the first year of contraceptive use. Among women with thrombophilia, the risk of deep vein thrombosis was increased 19-fold during the first 6 months and 11-fold (95% CI = 2.1, 57) in the first year of use. Venous thrombosis during the first period of oral contraceptive use might actually point to the presence of an inherited clotting defect.

Coagulation factors in users of progestogen-only contraceptives have not been studied extensively using current laboratory methods, but there appears to be little effect. Perhaps the most informative study is a randomized clinical trial of two progestogen-only contraceptives (norethindrone 0.35 mg and levonorgestrel 0.03 mg) (161), which showed a reduction in several coagulation factors among women who switched from a combined oral contraceptive, but no change among women who had not previously been using a hormonal contraceptive. Thus progestogen-only contraceptives appear to be particularly suitable for women who desire oral contraception but who are at increased risk of thrombosis, including older women who are smokers.

© 2006 Elsevier B.V. All rights reserved.

Mouth and teeth

Gingivitis, of varying degrees of severity, is sometimes associated with oral contraceptive use, apparently because the steroids alter the microbial flora in the mouth (194). A case of gingival hyperplasia is described under "Reproductive system".

Even a low-dose oral contraceptive combination has an effect on the composition of saliva (195); although large individual variations were noted, protein, sialic acid, hexosamine, fucose, hydrogen ion concentration, and total electrolyte concentration fell, while the secretion rates increased. The sodium and hydrogen ion concentrations increased in parotid gland secretion and sodium in submandibular gland secretion. To what extent these changes might affect the dental status of the patient is unknown.

Oral pyogenic granulomata have been reported both in pregnant patients and in patients using oral contraceptives (196).

Progestogens, alone or together with estrogen, cause an increase in the width and tortuosity of peripheral blood vessels in the oral mucosa, which become more susceptible to local irritants and show increased permeability (197).

Gastrointestinal

Mild gastrointestinal complaints, such as nausea, vomiting and vague abdominal pain, were seen in 10–30% of patients in earlier studies when high-dose products were in use. A placebo-controlled clinical trial in 1971 documented a higher prevalence of nausea and vomiting among combined oral contraceptive users than among women taking either a placebo or a progestogen-only oral contraceptive; the prevalence was also higher for the combined oral contraceptive containing mestranol 100 micrograms than for the combination product containing mestranol 50 micrograms (137). Such effects are much less common with the low doses used today. Nausea, if it occurs, is associated with the estrogen component of combined oral contraceptives; its frequency and severity generally decline over time.

The relation between oral contraceptive use and inflammatory bowel disease was analysed in two case-control studies published in the 1990s (198,199). Both found a significantly increased risk among current users compared with never users for Crohn's disease, but only the former study detected an increased risk of ulcerative colitis; a dose–response effect was suggested for Crohn's disease. When the data were stratified by smoking status in the latter study, the increased risk was found only among current smokers.

Reversible ischemic colitis, an unusual condition in young people, has been described in 17 young women, with evidence for an association with oral contraceptives (200). Ischemic colitis occurs uncommonly in younger people. The median duration of illness was 2.1 days (range 1–4 days). All recovered with supportive care. Ten women (59%) were using low-dose estrogenic oral contraceptive agents, compared with the 1988 US average of 19% oral contraceptive users among women aged 15–44 years. The odds ratio showed a greater than 6-fold relative risk for the occurrence of ischemic colitis among oral contraceptive users.

Diarrhea, probably coincidental, is bound to occur on occasion in the very large population of oral contraceptive users; when it does so, the efficacy of the product is likely to be diminished and additional contraceptive methods may need to be used.

Liver

During the early years of oral contraception, with high-dose products in use, jaundice and other hepatic complications were a source of concern; with current products this is no longer the case. Most women experience no adverse effects on liver function, but occasional hepatic changes can occur, including intrahepatic cholestasis, cholelithiasis, vascular complications, and even tumors, which are discussed in the record on estrogens. It has been argued (37) that women with a history of liver disease whose liver function tests have returned to normal can take oral contraceptives with careful monitoring. However, it is widely considered that oral contraception should be avoided in women with a history of cholestatic jaundice of pregnancy; past or current benign or malignant hepatic tumors; active hepatitis; or familial defects of biliary excretion.

The most common change is a short-term rise in serum transaminases (201), which often abates if treatment is continued. An increase in serum alkaline phosphatase is usual, while serum transaminases can be normal to markedly increased (202). Long-term use leads to changes in hepatic ultrastructure, with involvement of the mitochondria, which develop crystalline inclusions. Furthermore, hypertrophy of the smooth endoplasmic reticulum and changes in the biliary canaliculi have been shown (203,204). These changes are not usually accompanied by any clinical symptoms. The Budd–Chiari syndrome can occur in connection with thromboembolism.

Benign liver tumors (hepatocellular adenoma and focal nodular hyperplasia) are extremely rare conditions that appear to be related to oral contraceptive use (205).

Jaundice as a result of oral contraceptive treatment has been repeatedly described. Whereas in the Swedish population figures between 1:100 and 1:4000 were published when the early high-dose formulations were still in use (206), the overall incidence was estimated in 1979 at about 1:10 000 (9), and the current incidence is certainly further reduced. When such hepatic symptoms occur, they usually do so within the first month of medication (207), and jaundice may be accompanied by anorexia, malaise, and pruritus. Very few cases arise after the third month of medication and those reported are regarded by some as unlikely to be due to oral contraceptives. Microscopic examination of the liver shows intrahepatic cholestasis. When medication is stopped, symptoms usually disappear rapidly and the reaction does not seem to leave any sequelae (208). Genetic components seem to be important for the development of the reaction; women who have experienced jaundice or severe pruritus in late pregnancy seem to be especially susceptible to jaundice or gallbladder disease when using oral contraceptives (209). Discussion of mechanisms has related mostly to estrogens (210), but cases have been described in individuals taking progestogens only (206); the explanation might be the conversion of the latter to estrogens in vivo (211). The cause of cholestasis is unknown, but animal data suggest that there is inhibition of bile flow and of the biliary excretion of bilirubin and bile salts.

© 2006 Elsevier B.V. All rights reserved.

Peliosis hepatis has been described in association with contraceptive-induced hepatic tumors and has sometimes developed in isolation, perhaps as a herald of more serious changes to follow, for example cirrhosis and portal hypertension; one such case ultimately required an orthotopic liver transplant (212).

Sinusoidal dilatation in the liver has been reported rarely.

- A 23-year-old woman developed an acute painful syndrome with cytolysis after 7 years of oral contraceptive use; she recovered promptly after oral contraceptive withdrawal (213).

Hepatic adenomatosis, which seems to have been reported only some 38 times, is a condition with a female preponderance; in earlier work it was noted that in 46% of the female patients oral contraception had been used. This means, however, that in the other 54% it had not, and it should be borne in mind that the condition can also occur in men.

- A 35-year-old woman, who had been fitted with Norplant 2 years before and had used oral contraceptives for some 20 years before that, developed epigastric and right upper quadrant abdominal pain (214). A liver mass was found and at surgery proved to consist of multiple adenomata; part of the liver had to be resected.

What is of potential concern is that in this case, as in a very few previously described, there was also evidence of hepatocellular dysplasia, which could be a pre-malignant condition. However, with widespread use of Norplant, some reported adverse events, such as this, may be purely coincidental.

Results in 1977 from the Boston Collaborative Drug Surveillance Program suggested that oral contraceptive users are more often diagnosed as having acute hepatitis than are non-users (215). There was no similar finding in the similarly early study by the UK Royal College of General Practitioners (135).

Biliary tract

The Boston Collaborative Drug Surveillance Program found in 1973 that of a large series of 212 patients with gallbladder disease 31% were using oral contraceptives, compared with only 20% of controls (216). In another study, the risk of gallbladder surgery was twice as high in oral contraceptive users as in non-users (217). A decade later, after dosages had fallen, a 1982 study from the UK Royal College of General Practitioners showed that there was no overall increased risk of gallbladder disease in the long term and that the previously demonstrated short-term increase in risk is due to acceleration of the onset of gallbladder disease in women already susceptible to it (135). The risk may also be age-related, the relative risk of gallstone disease being higher in young women using oral contraceptives than in older users (218–220).

- A 21-year-old woman developed increasing jaundice, with severe pruritus and weight loss, after a bout of dyspepsia (221). She had been taking contraceptives for 4 years (cyproterone acetate 2 mg, ethinylestradiol 0.035 mg). Laboratory tests at first suggested cholestatic hepatitis, but ultrasonography showed biliary sludge in the gallbladder and dilatation of the common bile duct and the smaller biliary passages. There was a space-occupying lesion near the papilla: it was not fixed and had no vascular supply. At endoscopic retrograde cholangiopancreatography the lesion was removed. It consisted of jelly-like viscous streaky bile without calculi. Within a few days the jaundice disappeared, the pruritus ceased, and liver function returned to normal.

A meta-analysis in 1993 of the relation between combined oral contraceptives and gallbladder disease yielded a small increased risk for women who had ever used oral contraceptives (pooled estimated RR = 1.38) (222). There was a dose-related effect in the therapeutic range of doses, suggesting that, although the risk is less with lower-dose combined oral contraceptives, there may still be a weak relation. The increased risk appears to be concentrated in the early years of oral contraceptive use, suggesting that oral contraceptives accelerate the development of the disease. On the other hand, the 1994 findings in the Nurses' Health Study II showed no substantial increase in risk associated with ever use of oral contraceptives, but relative risks of 1.6 for long-term use and for current use, after adjusting for body mass index and several other confounding variables (218). A 1994 report from the Oxford FPA study similarly suggested no relation with ever use of oral contraceptives (223).

The finding that oral contraceptive use causes an increase in the cholesterol concentration in bile and a shift in the chenodeoxycholic/cholic acid ratio suggests a biochemical basis for the increase in gallbladder disease among oral contraceptive users (224,225). Effects on gallstone formation may well be due to the estrogen content, for example since exogenous estrogens seem to increase the risk of gallbladder disease in men (226), while in women they can increase the cholesterol saturation of bile and hence the lithogenic index (227).

Pancreas

Acute pancreatitis has been reported as a very unusual complication of oral contraceptive treatment (228), as have increases in serum amylase (229).

Urinary tract

Over the years a few reports have suggested a higher incidence of urinary infections in users of oral contraceptives, but this probably reflected differing or altered patterns of sexual behavior.

Hemolytic–uremic syndrome seen in one very long-term user may have been due to antisteroid hormone antibodies (230).

Skin

Various types of skin reactions can occur during oral contraceptive treatment, but bearing in mind the vast number of women who take oral contraceptives, major skin reactions due to oral contraceptive treatment seem to be rare. The incidence, even including all minor complications, has been estimated at 5% (231), but field experience suggests that that is a generous figure. The figure

© 2006 Elsevier B.V. All rights reserved.

includes chloasma, seborrhea, hirsutism, pruritus, herpes gestationis, porphyria cutanea tarda, and allergic reactions such as urticaria.

Low-dose combined oral contraceptive use generally results in improvement of acne, although occasionally a user has worsening of acne owing to the androgenic potency of the progestin used. Use of a less androgenic progestogen, for example norgestimate (232) or desogestrel or the antiandrogen cyproterone acetate (233,234), can have a favorable effect in patients with pre-existing acne, reducing the severity of the condition; an oral contraceptive in which cyproterone acetate replaces the progestogen has proved helpful in women with pre-existing acne.

The efficacy and adverse effects of oral cyproterone acetate 2 mg in combination with ethinylestradiol 35 micrograms in facial acne tarda have been studied in 890 women aged 15–50 years, of whom 96 withdrew prematurely from the study (235). Of these 96 women, only 30 withdrew because of adverse events: menstrual problems ($n = 11$), headache ($n = 10$), increased body weight ($n = 3$), and thrombophlebitis ($n = 1$). Five women withdrew because of poor efficacy. In all, 260 patients had adverse events during treatment. The incidence fell as the study progressed. Of those events that first occurred during treatment, the most frequently cited were breast tension (12%), headache (8.9%), nausea (5.8%), nervousness (4.0%), and dizziness (2.6%). There were no serious adverse events. There were no clinical significant changes in body weight or blood pressure.

There is a possible association of oral contraceptives with erythema nodosum, which has been linked to the use of either estrogens or progestogens or a combination of the two; however, probably neither hormone directly causes the condition but merely creates a fertile background for its generation by other antigens.

Pre-existing condyloma acuminata have been stated to increase during oral contraception, with regression after withdrawal (236).

Increased pigmentation of areas exposed to sunlight, as well as photosensitivity, has been incidentally observed in some users, and is probably analogous to the pigment changes that can occur in pregnancy.

In one case, pityriasis lichenoides disappeared after withdrawal of oral contraceptives (237).

Sweet's syndrome (acute febrile neutrophilic dermatosis) has been attributed to an oral contraceptive (238). However, bearing in mind that the syndrome has a variable presentation and is thought to represent a form of hypersensitivity reaction, it is not at all clear that there was a true cause-and-effect relation.

Hair

Contraceptives induce a condition of pseudopregnancy, and alopecia during treatment and after withdrawal has been seen. Of five women who developed diffuse alopecia while taking oral contraceptives, three had male pattern baldness while they were taking the treatment; two began to lose their hair after having stopped taking treatment, and these resembled postpartum baldness (239). One woman did not regain her hair 20 months after having stopped taking the oral contraceptive. However, the incidence of alopecia among users of oral contraceptives is very low, and the association may be coincidental, since there are also case reports of improvement in the quality of the hair (240).

Musculoskeletal

Although some studies have shown that combined oral contraceptives increase bone mineral density, the available evidence suggests that any beneficial effect is rather small (241), and is presumably related to the dosage of estrogen. The effects may depend in part on the age of women being studied, as normally bone mass density continues to increase until it peaks in women in their 20s and 30s, and then remains constant until the premenopausal period, when it begins to fall. For example, a study of young women (aged 19–22 years) showed that those taking very low-dose combined oral contraceptives (with as little as 20 micrograms of ethinylestradiol) had no change in bone density over 5 years, whereas non-users had a significant increase (242).

There were some early reports of localized mandibular osteitis in women using oral contraceptives subsequent to surgery of the mandibular molar teeth (SEDA-2, 316). It has been suggested that changes in the hemostasis could be the cause.

It appears that oral contraceptive use reduces the prevalence of severe disabling rheumatoid arthritis. Although studies of this have produced discrepant results, a meta-analysis of studies that met specific methodological criteria produced an overall adjusted pooled odds ratio of 0.73 (243). The authors suggested that oral contraceptives do not actually prevent rheumatoid arthritis, but modify the disease process to prevent progression to severe disease. Pregnancy has similar effects. It is unclear whether it is the estrogen or the progestogen component of oral contraceptives that is responsible.

Sexual function

Occasionally, women report reduced libido, which may have a hormonal basis. One study showed that users of oral contraceptives had no rise in female-initiated sexual activity at the time when ovulation should have occurred, whereas non-users did show such an increase in sexual activity (244).

Reproductive system

Tumor-inducing effects of hormonal contraceptives are dealt with in the record on estrogens.

Breasts

Breast tenderness or pain can occur in some women (245,246), especially with estrogen-dominant formulations, although it is notable that other women with a history of breast discomfort experience improvement when they begin to take oral contraceptives.

- A woman with Wilson's disease treated with penicillamine developed severe hirsutism (247). After treatment with oral contraceptives, her breasts enlarged rapidly, and she had cyclic mastodynia. Around the same time she also developed gingival hyperplasia.

© 2006 Elsevier B.V. All rights reserved.

Benign breast disease (including fibroadenoma and cystic change) is less common among users of combined oral contraceptive than in the general population (205).

Ovaries

Women currently taking oral contraceptives are less likely than non-users to have functional ovarian cysts. This protective effect appears to be more modest with lower dose monophasic formulations than with those containing 35 micrograms or more of estrogen (248,249). Functional ovarian cysts (or persistent ovarian follicles) occur more often in users of progestogen-only contraceptives than in combined oral contraceptive users or in women using no hormonal contraceptive method. Follicular development is delayed and the follicle continues to grow for a period of time, but these enlarged follicles usually regress spontaneously and are not of clinical significance.

Uterus

Effects on menstrual function depend on the dose used and the sensitivity of the individual user; they may be welcome or unwelcome (188,250). Menses generally become more regular and predictable, and dysmenorrhea is less common and less severe. The number of days of blood loss in each menstrual period is often reduced, as is the amount of menstrual flow; thus women who previously had iron deficiency anemia associated with menorrhagia have increased iron stores. A comparison of women who kept menstrual diary records as part of WHO trials has confirmed that users of combined oral contraceptives in adequate dosages have more regular menstrual cycles than do users of other hormonal methods (251). None of the combined oral contraceptive users in these studies had amenorrhea (defined as the absence of bleeding throughout a 90-day reference period), although shorter periods of amenorrhea have occasionally been reported in other studies, particularly with very low-dosage formulations and with longer-term use.

Intermenstrual bleeding (breakthrough bleeding or spotting) often occurs, especially during the first few cycles of treatment, and is often the reason that women choose to stop taking an oral contraceptive. When using products based on newer progestogens it seems that better control may be offered by formulations that contain gestodene compared with desogestrel and by levonorgestrel compared with norethindrone (252), but the absence of standardized methods makes such conclusions tentative. Research on triphasic formulations is too sparse to allow firm conclusions on this point. One study confirmed the long-standing experience that intermenstrual bleeding rates vary inversely with both estrogen and progestogen dose (253). However, one finds no evidence that breakthrough bleeding is an indication of reduced contraceptive efficacy, despite speculation regarding a possible relation.

Dysmenorrhea is less common and less severe among women who use oral contraceptives of any type, provided that ovulation is inhibited; this emerges both from experience and from prospective studies; the effect seems to be maintained as long as the oral contraceptive is continued. There seem to be no significant differences in this respect between monophasic products with low or high progestogen doses, those with high progestogen doses, or triphasic products (250).

Since post-treatment amenorrhea of more than 6 months duration was first suggested as an adverse reaction in around 1965, much work has been devoted to delineating the risk and prognosis of menstrual changes after the withdrawal of hormonal contraception. It is now recognized that post-treatment amenorrhea occurs in 0.7–0.8% of women, but this is no different from the background rate of spontaneous secondary amenorrhea. No cause and effect relation between oral contraceptive use and subsequent amenorrhea has been documented.

Menstrual irregularities are common among women taking progestogen-only contraceptives and are often the reason a user chooses to discontinue the method (254,255). Users of progestogen-only contraceptives are more likely than users of other hormonal contraceptive methods to have frequent bleeding (251). Infrequent bleeding, amenorrhea, and irregular bleeding among progestogen-only contraceptive users are more likely than among combined oral contraceptive users, but less prominent than among women using levonorgestrel-releasing vaginal rings or DMPA.

There has been concern at various times that prolonged oral contraception might cause permanent changes in the genital system. When high-dose products were in use, various studies showed condensation of the superficial cortical layers of the ovary (SEDA-8, 863). Severe atrophy of the endometrium after a period of oral contraception has been described (256), but the report usually quoted is one that dates from a period when high doses were in use, and the incidence is not known, since the endometrium is not usually examined. Certainly, the endometrium will go into a resting phase in women who have amenorrhea, but there is no reason to believe that it will become permanently unresponsive.

Epidemiological studies of the relation between oral contraceptive use and pelvic endometriosis have variously shown an increased risk, a reduced risk, and no effect (257). For example, an Italian study showed an increased risk among ever users of oral contraceptives, but this increase occurred only among former users, not current users (258). Furthermore, the authors noted that a similar pattern had been shown in several large cohort studies (OFPA, RCGP, and Walnut Creek). There was no association in the Italian study with recency, latency, or duration of use, suggesting that any relation to oral contraceptive use is not a true biological relation but instead the result of selection and other biases.

Pelvic inflammatory disease, often resulting in infertility, ectopic pregnancy, or chronic pelvic pain, is a well-known pathological state that actually occurs at a somewhat lower incidence in oral contraceptive users and also tends to be less severe in these women compared with non-users (259–261). The biological mechanism for this protective effect may be the changes in cervical mucus or reduced menstrual bleeding (and thus reduced retrograde menstrual blood in the uterus). On the other hand, the relevant reviews have concluded that combined oral contraceptives provide no protection against lower reproductive tract infection (particularly cervical infections with *Chlamydia* or gonococcus) and may even have an adverse effect. This possible increased risk appears to be the result of an increase in the area of cervical ectropion associated with the estrogen in combined oral contraceptives.

© 2006 Elsevier B.V. All rights reserved.

Candidiasis of the vagina in oral contraceptive users without evidence of diabetes mellitus has often been reported.

Immunologic

There is a sex difference in immune responsiveness, but little attention has been paid to the possible role played by sex hormones in its regulation. This lack of insight has led to the question of whether the use of oral contraceptives might affect the immune response, for better or for worse. An authoritative review of the immunological effects of estrogens and progestogens has concluded that, although understanding of any effect is incomplete, it is not likely that the low doses used in oral contraceptives would have negative effects on the immune system (262).

If that is the case, there must be another explanation for periodic reports that suggest an increased risk of systemic infections in oral contraceptive users. In a 1974 study by the British Royal College of General Practitioners oral contraceptive users had a higher than average incidence of certain infectious diseases (135).

Support for the concept that oral contraceptives might increase the risk of infection has been presented in other studies, and workers in the tropics have remarked that pregnant women appear to be unduly sensitive to malarial infestation (WHO, unpublished data).

The antibody response to tetanus toxoid in women is considerably lower in oral contraceptive users than in controls (263).

A depressed lymphocyte response to phytohemagglutinin has been observed in a series of women taking oral contraceptives (264); the reduction in phytohemagglutinin response reflects impaired T cell function, and this finding is of interest in view of the fact that a deficiency of T cell function is important in certain autoimmune diseases. Another consequence of prolonged impairment of T cell function would be an increased susceptibility to infectious diseases.

There have been several studies of the effect of sex hormones on serum immunoglobulin titers. In a study of the effect of four different oral contraceptives on the serum concentration of IgA, IgG, and IgM, the concentrations of all three immunoglobulins fell during the first course of treatment and returned to normal during subsequent cycles (265). There was some evidence that the steroid-induced reduction in immunoglobulins was predominantly caused by the estrogenic component. Subsequently, a study was conducted in which plasma from women currently taking combined oral contraceptives, past users of such products, women who had never used them, and non-users with a history of venous thrombosis was examined for the presence of immunoglobulin G (IgG) that showed specific binding of ethinylestradiol (266). There was no increase in "specific" IgG and no evidence of ethinylestradiol binding in oral contraceptive users compared with non-users. This study therefore provided no support for the hypothesis that a significant percentage of oral contraceptive users develop a specific IgG with high binding affinity for ethinylestradiol, which might be causally linked to the development of thrombotic phenomena in oral contraceptive users.

Numerous case reports have suggested that combined oral contraceptives can cause systemic lupus erythematosus (144,267). However, systematic examination of this issue in a 1994 case-control study showed no association (268).

Aggravation of bronchial asthma, eczema, rashes, angioedema, and vasomotor rhinitis have been incidentally observed, and cold urticaria has been reported in women taking oral contraceptives (269). It is not known whether in any particular individual the hypersensitivity reaction is due to the hormones themselves or to other ingredients in the tablet. Nasal provocation tests with suspensions of contraceptive steroids in patients with allergic rhinitis or pollinosis who had been taking these products showed a positive response in one-third of cases; the same patients also reacted to topical estrogens (270). Life-threatening anaphylaxis with a positive rechallenge test occurred in a young woman using oral contraceptives, but this must be extraordinarily rare (271).

The immunological effects of two contraceptive combinations, namely Valette (ethinylestradiol 0.03 mg + dienogest 2.0 mg) and Lovelle (ethinylestradiol 0.02 mg + desogestrel 0.15 mg), have been examined during one treatment cycle (272). The latter significantly increased the numbers of lymphocytes, monocytes, and granulocytes. Valette reduced the CD4 lymphocyte count after 10 days and Lovelle did the opposite. Lovelle increased CD19 and CD23 cell counts after 21 days. Phagocytic activity was unaffected by either treatment. After 10 days, both contraceptives reduced the serum concentrations of IgA, IgG, and IgM, which remained low at day 21 with Lovelle but returned to baseline with Valette. Secretory IgA was unaffected by either contraceptive. Neither treatment affected concentrations of interleukins, except for a significant difference between the treatment groups in interleukin-6 after 10 days, which resolved after 21 days. Concentrations of non-immunoglobulin serum components fluctuated; macroglobulin was increased by Valette. However, total protein and albumin concentrations were reduced more by Lovelle than Valette. Complement factors also fluctuated. There was no evidence of sustained immunosuppression with either Valette or Lovelle.

Infection risk

Data on the risk of infection with HIV (human immunodeficiency virus) with combined oral contraceptives are sparse; some studies suggest an adverse effect and others show no association (259,273).

Body temperature

Body temperature tends to rise slightly in some users of oral contraceptives (274,275) Progesterone has a mild thermogenic effect, reflected in changes in body temperature during the normal menstrual cycle. Mild pyrexia in users of oral contraceptives may reflect this, but the patient should always be examined to exclude infection.

Long-Term Effects

Drug abuse

Children under 6 years who have accidentally ingested oral contraceptives have experienced nausea and

© 2006 Elsevier B.V. All rights reserved.

vomiting for 10–15 hours after ingestion (SEDA-1, 306). Occasionally, apathy, drowsiness, and slight increases in transaminase activities have been reported.

Drug withdrawal

Although it was originally believed that women who stopped taking oral contraceptives, particularly after a long period of use, were more likely to have amenorrhea, careful analysis has shown that that is not the case. The likelihood of conception is reduced during the first 1–2 months after discontinuation, but cumulative conception rates after several months are not affected.

Tumorigenicity

The carcinogenic effects of oral contraceptives are covered in the monograph on estrogens.

Second-Generation Effects

Fertility

The return of fertility after a period of oral contraception has been differently assessed at different times. Although there can be a delay of 1–2 months in the return of fertility after withdrawal of a combined oral contraceptive, within a few months conception rates are similar to those of women who stop using non-hormonal contraception (41,276,277). In 48 patients classified as having amenorrhea after oral contraceptive use the subsequent conception rate was no lower than in a control group not with amenorrhea (278). There appears to be a shorter delay with low-dose than high-dose products (279). Delay in the return of ovulation has on occasion led to the erroneous conclusion that the first pregnancy after oral contraceptive use might be unduly prolonged (SEDA-6, 351).

There does not appear to be any clinically significant delay in return of fertility after discontinuation of progestogen-only contraceptives. Although there have been no large studies, data from several small studies suggest no effect. Furthermore, because progestogen-only contraceptives prevent ovulation in only about half of cycles, and because the pregnancy prevention effects fall rapidly if a tablet is taken late, the normal reproductive physiology presumably returns quickly after tablet discontinuation.

Pregnancy

The likelihood of ectopic pregnancy in women taking oral contraceptives has to be set against the normal incidence in the population, taking care to use the same denominator; one can express it as the proportion of women who experience such an event, or as the proportion of pregnancies that occur and prove to be ectopic (280). The proportion of pregnancies that implant at an extrauterine site is 0.005 for both combined oral contraceptive users and women using no contraception, but, because oral contraceptive users are much less likely to conceive, their rate of ectopic pregnancy is much lower (0.005 per 1000 woman years, compared with 2.6 per 1000 woman years for women using no contraception). The incidence of ectopic pregnancies is also somewhat lower for combined oral contraceptives than for other contraceptive methods. In the past there was some concern about a possible increased risk of ectopic gestation after withdrawal of oral contraceptives (281), but this is no longer considered to be an issue.

Up to 10% of pregnancies among users of progestogen-only contraceptives implant outside the uterus; this is not greatly different to the ectopic pregnancy rate in unprotected women, but it is much higher than among users of adequate combined oral contraception (280). The reasons may relate to changes in tubal motility and delay in ovum transport.

Teratogenicity

Oral contraceptives are neither teratogenic nor mutagenic, and there is little concern about the risk of congenital anomalies if an oral contraceptive is accidentally taken during an early unrecognized pregnancy. The American College of Obstetrics and Gynecology concluded in 1993 that there was no causal link (282). Reviews have come to the same conclusion (283,284), as has a meta-analysis completed in 1995 (285). In theory the androgenicity of a progestogen could result in virilization, but it is most unlikely to be taken sufficiently late or in sufficiently high doses to have this effect.

Gene toxicity

The fear that oral contraceptives might prove to induce chromosomal abnormalities was expressed when they were relatively new, but has largely been laid to rest. When aborted fetuses from women who used oral contraceptives were compared with those from non-users, there was no difference in the frequency of abnormal karyotypes or in sex ratio between the two groups. Certainly, data have been presented showing a slightly raised frequency of minor chromosomal changes in children whose mothers had been exposed to oral contraceptives before pregnancy, but from a genetic point of view, these scattered findings are not alarming.

Sex of the offspring

There was early minor evidence that the use of oral contraceptives might result in a predominance of female births (286). However, later evidence has been indecisive (287,288). If there is any effect at all it must be extremely small.

Congenital anomalies

A number of early American studies appeared to show that children exposed in utero to oral contraceptives ran a slightly increased risk of being born with certain types of birth defects; in particular a syndrome was described comprising multiple malformations involving the vertebrae, anus, cardiac structures, trachea, esophagus, renal structures and limbs (abbreviated to VACTERL) (289). The entire VACTERL syndrome was in fact seldom or never encountered; clusters of defects falling within this group were seen, but the associations were very variable. Furthermore, virilization of the female fetus and some of the other elements in the VACTERL group have been described after exposure to certain progestogens, hormonal

© 2006 Elsevier B.V. All rights reserved.

pregnancy tests, or (rarely) to oral contraceptives taken in error in early pregnancy.

In a 1983 retrospective study of 155 children with congenital limb reductions 18 mothers (12%) were found to have taken oral contraceptives inadvertently during early pregnancy compared with only one mother in a control group, a relative risk of 24; adjustment for smoking hardly altered the figure (289). However, other work has suggested that smoking carries a higher risk of malformations than the use of oral contraceptives (SED-12, 1022) (290).

The results of such studies have led some reviewers to conclude that oral contraceptives are slightly teratogenic, but caution is needed. The conclusion of the 1980 WHO report cited above that such an effect is slight or absent probably remains valid for all widely used oral contraceptives; naturally, newer products might have other effects.

Congenital malformations may occur after the use of hormonal (estrogen + progestogen) pregnancy tests, now obsolete, since these high doses of a hormonal combination represented aggressive interference with any early pregnancy. A 1967 report suggested some association with meningomyelocele or hydrocephalus, and later retrospective studies provided some evidence of cardiac defects or limb reduction anomalies. Such studies always raise methodological doubts, but it is not unthinkable that these tests were harmful, since they sometimes induced bleeding even in early pregnancy; they could thus impair embryonic nutrition.

Lactation

The effects of combined oral contraceptives on lactation have been examined carefully (291,292), since estrogens are well-known inhibitors of ovulation in large doses. Even products containing 30 micrograms of ethinylestradiol reduce the volume of milk (293); the composition of the milk is also slightly altered, but again one has the impression that the effect is not important, except in a very poorly nourished population. Both progestogens and estrogens are excreted in the milk, their proportions correlating with those in plasma, but the absolute concentrations are lower. The plasma/milk ratio varies from compound to compound, probably owing to variations in the degree of protein binding and (for progestogens) also to the variable amount of fat in the milk. The amount of steroid transferred in 600 ml of milk is estimated at 0.1% or less of the daily dose taken. Although newborn infants might be relatively sensitive to these hormonal substances, because of the immaturity of their detoxification systems, no adverse effects have been found when they were looked for systematically; nevertheless, isolated cases of gynecomastia have been noted in babies when their mothers were taking oral contraceptives during lactation.

In an 8-year follow-up of Swedish children whose mothers used combined oral contraceptives while breastfeeding, there were no negative effects on health, growth, or development (294). It should be realized that the hormonal content of natural human milk and cows' milk is not negligible. If hormonal contraception is to be used during lactation, it would be sensible to prefer low-dose progestogens rather than combinations with estrogens; they are not the most effective contraceptives, but probably sufficient to supplement the contraceptive effect of lactation itself and they are unlikely to inhibit lactation.

There is much evidence that progestogen-only contraceptives (including tablets, injectables, and implants) have no adverse effects on milk production (295); they reach the milk in negligible amounts and have no adverse effects on the breast-fed infant (296).

Susceptibility Factors

There are no hard and fast rules about prescribing oral contraceptives in women at risk of complications; the degree of risk resulting from a particular factor has to be considered from case to case.

Absolute contraindications

Combined oral contraceptives should not be used by women with the following absolute contraindications:

1. thrombophlebitis or venous thromboembolic disorders (current or past)
2. cerebrovascular disease (current or past)
3. coronary artery or ischemic heart disease (current or past)
4. breast cancer (current or past)
5. endometrial cancer or other estrogen-dependent neoplasia (current or past)
6. hepatic adenoma or carcinoma (current or past)
7. impaired liver function (current)
8. less than 2 weeks postpartum
9. breastfeeding and less than 6 weeks postpartum
10. known or suspected pregnancy
11. use of enzyme-inducing drugs, specifically the antimicrobial drugs rifampicin and griseofulvin and many anticonvulsants.

Relative contraindications

Combined oral contraceptives should be used only with caution and careful monitoring by women with the following relative contraindications:

1. aged over 35 years and/or obese and/or currently smoking 15 or more cigarettes per day; when all three factors are present this can be regarded as an absolute contraindication
2. migraine, particularly with focal neurological symptoms
3. hypertension (current, controlled)
4. diabetes, particularly with retinopathy, neuropathy, or vascular disease
5. familial hyperlipidemia or current treatment for hyperlipidemia
6. gallbladder disease (current)
7. cholestatic jaundice of pregnancy or with prior oral contraceptive use
8. unexplained abnormal vaginal bleeding
9. breastfeeding, particularly if less than 6 months postpartum
10. major surgery, with prolonged immobility.

© 2006 Elsevier B.V. All rights reserved.

Although sickle cell disease is sometimes listed as a contraindication to oral contraceptive use, it has been suggested that this may not be justified (297). Women with sickle cell disease need highly effective contraception, because pregnancy is associated with increased morbidity and mortality to both mother and fetus, as well as the increased likelihood that the infant will have sickle cell disease. Theoretically, combined oral contraceptives should be given with caution, because of the increased risk of thrombosis associated with both sickle cell disease and combined oral contraceptives, but the limited available evidence indicates no change in hematological parameters among women using hormonal contraceptives. Progestogen-only formulations may be preferred, not only to avoid the potential risk of thrombosis but also because studies suggest that sickle cell crises may be inhibited.

The Oxford Family Planning Association's continuing study has shown convincingly that death from all causes is more than doubled in oral contraceptive users who smoke 15 or more cigarettes daily (298).

Drug Administration

Drug formulations

Low-dose oral contraceptives based on the older progestogens are relatively well tolerated in the short term, better so than the products that preceded them and those that came later. Two placebo-controlled studies with the combination of levonorgestrel 100 micrograms and ethinylestradiol in 704 patients over six cycles showed no differences in unwanted effects compared with placebo; in particular there was no evidence of weight gain (299).

Drug dosage regimens

Different schemes of administration have been studied and compared with one another without identifying any pattern of use that is ideal for all women. Various sequential programs of use, intended to mimic more closely the physiological changes in hormone secretion during the normal cycle rather than using a fixed combination throughout, have given better cycle control in some women, but others react better to the traditional pattern, in which the same combination is used throughout the 20-day period of use. The normophasic formulations use a popular sequential scheme; in these products the seven first tablets contain only estrogen and the next 14 tablets both estrogen and progestogen, giving an endometrium of a more normal secretory phase type; this in turn leads to more pronounced withdrawal bleeding. A further development of this principle, the triphasic type of product, involves administering a three-step regimen, in which the change from estrogenic to progestogenic dominance is more gradual; it appears to be helpful in avoiding excessive intermenstrual bleeding when this has been a problem, and it is apparently less likely than monophasic products to cause an unwanted reduction in HDL cholesterol (300). However, there is evidence that triphasic formulations based on norgestrel could carry the same increased risk of thromboembolic disorders as that seen with the third-generation oral contraceptives, because of a higher resistance to activated protein C than with the corresponding monophasic products (301).

In the "estrophasic" form of administration, ethinylestradiol 20 micrograms is given on days 1–5 of the cycle, 30 micrograms on days 6–12, and 35 micrograms on days 13–21. Norethisterone acetate 1 mg is also given throughout this period. The literature to date has not shown that this regimen, although claimed to be more "physiological" in its composition, is in fact better tolerated than a comparable combination in which ethinylestradiol is given in a dose of 30 micrograms throughout (302). However, the reduction in what may at some phases of the cycle be an unnecessarily high estrogen dose, that is more than is needed to maintain cycle control, is a healthy step, and it may be useful to have a further alternative product for women who do not find any existing formulation fully satisfactory.

There is continued interest in natural 17-β-estradiol in a form suitable for oral use, in view of the likelihood that it will produce fewer adverse effects than the synthetic estrogens used in most oral contraceptives. The particular problem has been to secure adequate cycle control with 17-β-estradiol, which is rapidly metabolized to estrone in the intestinal wall and liver; the degradation process is actually accelerated by progestogens. One approach under development in Germany involves combining this estrogen with dienogest, a progestogen that is reported to have no antiestrogenic activity (303). Preliminary work suggests that this can be successful, but one must be cautious in assuming that the end-product will be safer in all respects. There is evidence of a lesser effect of the natural estrogen on fibrinolysis, liver function, and lipid metabolism, but one must bear in mind that the true incidence of thromboembolic and other complications of the existing oral contraceptives is only now emerging after many years of worldwide use.

Drug–Drug Interactions

General

Two categories of drug interactions have been reported with oral contraceptives (304).

Interactions in which other drugs influence the effects of contraceptive steroids

The best known interactions are those in which another drug impairs the effect of the contraceptive steroids, leading to breakthrough bleeding and even pregnancy; such interactions are due primarily (but not exclusively) to enzyme induction, resulting in accelerated breakdown of the contraceptive steroids (305). This is a greater problem today than it was when higher-dose contraceptives with a larger reserve of contraceptive potency were in use. Many reported interactions of this type are single cases, and in some such instances it is likely that contraceptive failure was in fact due to poor adherence to therapy, diarrhea, or vomiting, rather than a direct interaction (306). However, with at least the enzyme-inducing anticonvulsants and rifampicin there are well-established major interactions.

© 2006 Elsevier B.V. All rights reserved.

In a few cases the activity of oral contraceptives is enhanced by other drugs; this is less likely to cause problems, but if the effect is very marked or prolonged one might suffer the consequences of hyperestrogenicity (306).

Interactions in which oral contraceptives interfere with the metabolism of other drugs

Studies in animals and in vitro studies in human liver microsomes have shown that oral contraceptives can inhibit the metabolism of other drugs that undergo various forms of oxidative metabolism. In contrast, oral contraceptives seem to induce glucuronidation. For example, oral contraceptives reduce the clearance of aminophenazone (aminopyrine) (307), phenazone (antipyrine) (308,309), and pethidine (310). It has been suggested that the estrogenic component of oral contraceptives is necessary for inhibition of drug oxidation, since women taking progestogens alone had a normal clearance of phenazone, whereas those taking a combination tablet had impaired elimination of phenazone (311). However, such interactions are rarely of clinical significance.

Alcohol

Women taking oral contraceptives have a significant fall in the absolute elimination rate of ethanol (105 mg/kg/hour) compared with controls (121 mg/kg/hour). The percentage elimination rate of ethanol is also significantly reduced in women taking oral contraceptives (0.015% per hour) compared with control subjects (0.019% per hour). These results are consistent during the three phases of the menstrual cycle and when body leanness is taken into consideration (312).

Antacids

Antacids apparently do not affect the systemic availability of oral contraceptives, but since magnesium-containing antacids can cause diarrhea, they might reduce absorption of contraceptive steroids.

Anticoagulants

Oral contraceptives have been reported to reduce the effect of anticoagulants, probably because oral contraceptives have an antagonistic effect on certain clotting factors, although they potentiate the action of acenocoumarol (SEDA-5, 371).

One study showed a significant increase in the clearance of phenprocoumon, owing to accelerated glucuronidation. As phenprocoumon is metabolized by hydroxylation as well as by direct glucuronidation, the increased clearance may mean that induction of the latter process over-rides inhibition of the former (313).

Antiepileptic drugs

Enzyme inducers

Failure of contraceptive therapy and breakthrough bleeding have been noted repeatedly in patients concurrently taking various enzyme-inducing anticonvulsant drugs (305,314). These include phenytoin, primidone, ethosuximide, phenobarbital, and carbamazepine. The specific isozyme responsible for metabolic 2-hydroxylation of ethinylestradiol is CYP3A4, which is induced by anticonvulsants (304). However, in addition to enzyme induction, the anticonvulsants can increase the binding of sex hormone- binding globulin. Since sex steroids bind with high affinity to sex hormone-binding globulin and since phenobarbital increases sex hormone-binding globulin capacity, unbound active steroid concentrations will tend to fall during treatment with phenobarbital (315). In addition, in animals, phenobarbital increases steroid metabolism in both the gut wall and liver (316).

The newer anticonvulsants have not been studied as intensively as the older drugs, but felbamate, oxcarbazepine, and topiramate have enzyme-inducing activity and reduce plasma steroid concentrations (317).

Non-enzyme inducers

Valproic acid, which is not an enzyme inducer, has no detectable effect on the pharmacokinetics of progestogens and estrogens (318).

The newer anticonvulsants have not been studied as intensively as the older drugs as regards the possibility of interference with the effects of oral contraceptives. The available data suggest that women taking oral contraceptives can also take gabapentin, lamotrigine, tiagabine, and vigabatrin without significant pharmacokinetic interactions; the effect of zonisamide is uncertain (313).

Management

The use of an alternative contraceptive method has long been advised in women taking antiepileptic drugs, unless they can be treated with the traditional high-dose oral products, for example containing 80–100 micrograms of estradiol (314); for effective protection they may also need a shortened tablet-free interval. A fair test is to see whether a woman taking oral contraceptives and anticonvulsants has adequate cycle control; if not, for example if there is mid-cycle spotting, this is a sign of interference and an alternative method will certainly be advisable.

Ascorbic acid

Ascorbic acid (vitamin C) is extensively sulfated in the gastrointestinal mucosa and competes with ethinylestradiol, which is also extensively sulfated. Plasma ethinylestradiol concentrations are increased by ascorbic acid in women, both after a single dose of ethinylestradiol and during long-term oral contraceptive use, but the results are not consistent. On one occasion it was claimed that this effectively transformed a low-dose oral contraceptive into a high-dose formulation (319). It seems very dubious whether ascorbic acid in fact interferes significantly with the effects of oral contraceptives.

Benzodiazepines

Oral contraceptives alter the metabolism of some benzodiazepines that undergo oxidation (chlordiazepoxide, alprazolam, diazepam) or nitroreduction (nitrazepam) (320). Oral contraceptives inhibit enzyme activity and reduce the clearances of these drugs. There is nevertheless no evidence that these interactions are of clinical importance. For other benzodiazepines that undergo oxidative metabolism, such as bromazepam and clotiazepam, no change has ever been found in oral contraceptive users.

© 2006 Elsevier B.V. All rights reserved.

Some other benzodiazepines are metabolized by glucuronic acid conjugation. Of these, the clearance of temazepam was increased when oral contraceptives were administered concomitantly, but the clearance of lorazepam and oxazepam was not (321). Again, it is unlikely that these are interactions of clinical importance.

Beta-blockers

Oral contraceptives increase the AUC and plasma concentrations of metoprolol, oxprenolol, and propranolol, but statistical significance is reached only with metoprolol. The changes are consistent with inhibition of hydroxylating enzymes, but are unlikely to be of clinical relevance (322).

Broad-spectrum antibiotics

There are sporadic, but well documented, reports of women using oral contraceptive steroids who became pregnant while taking a variety of antibiotics (323). However, there is much interindividual variation, which may explain the fact that some studies have shown no interference between oral contraceptives and antibiotics. Current suspicion focuses primarily on the broad-spectrum antibiotics (324), including ampicillin and the tetracyclines. The purported mechanism is apparently not enzyme induction but interference with the enterohepatic circulation of ethinylestradiol. Ethinylestradiol can be conjugated with both sulfate and glucuronic acid; sulfation occurs primarily in the small intestinal mucosa, while glucuronidation occurs mainly in the liver. These conjugates are excreted in the bile and then reach the colon, where they may be hydrolysed by gut bacteria to liberate unchanged ethinylestradiol, which can be reabsorbed (304). Broad-spectrum antibiotics may suppress this bacterial effect, resulting in reduced plasma hormone concentrations. The antibiotics doxycycline (325) and tetracycline (246) have been shown to have no effect on serum concentrations of exogenous estrogens and progestogens in women taking combined oral contraceptives containing ethinylestradiol 35 micrograms; however, in one of these studies endogenous progesterone was also assessed and there was no mid-cycle rise suggestive of ovulation.

Ciclosporin

Several case reports have suggested that the elimination of ciclosporin can be impaired by oral contraceptives, resulting in increased plasma ciclosporin concentrations. Ciclosporin undergoes hydroxylation and *N*-demethylation, in which cytochrome P450 is involved, so competitive enzyme inhibition probably explains the interaction. Dosages of ciclosporin should be reviewed carefully (326).

Clofibric acid

Oral contraceptives increase the plasma clearance of clofibric acid, which is mainly metabolized by glucuronidation (327,328).

Fluconazole

The effect of fluconazole 150 mg on circulating ethinylestradiol concentrations has been studied on day 6 of one of two cycles in women taking oral contraceptives (329). The serum concentrations of ethinylestradiol (C_{max} and AUC) were significantly increased by fluconazole, but t_{max} was not affected. These findings suggest that there is a potential for a clinically significant interaction between fluconazole and ethinylestradiol, by inhibition of estrogen metabolism.

Since oral contraceptive users sometimes need to be treated for vaginal candidiasis, the question arises which of the available treatments can be used without risk of impairing contraception. In a crossover placebo-controlled study, fluconazole 300 mg weekly for two cycles has been studied in 21 healthy women using Ortho-Novum 7/7/7 as a contraceptive (330). Fluconazole in this dose, which is twice that ordinarily recommended, produced small but statistically significant increases in the $AUC_{0–24}$ for both ethinylestradiol (mean 24% increase) and norethindrone (mean 13%). The C_{max} of ethinylestradiol was slightly, but just significantly, higher with fluconazole than placebo. The C_{max} for norethindrone was not different between the two groups. There were no adverse events related to fluconazole. These changes are such that one should not anticipate any increased risk of contraceptive failure when fluconazole is given simultaneously.

Glucocorticoids

In standard reference works, oral contraceptives are commonly listed as increasing the circulating concentrations of glucocorticoids (80), but variable effects have been reported with different glucocorticoids.

In oral contraceptive users there is a 30–50% reduction in the clearance of prednisolone and a prolonged half-life (331). These alterations result from changes in both protein binding, which is increased, presumably owing to increased concentrations of glucocorticoid-binding globulin, and unbound drug clearance, which is reduced, presumably owing to inhibition of metabolism. It has therefore been suggested that lower doses of prednisolone should be used in oral contraceptive users.

In 40 healthy women oral contraceptives had a greater effect on prednisolone than on budesonide (44). In oral contraceptive users, the average plasma concentration of simultaneously administered prednisolone was 131% higher than in a control group, whereas the average plasma concentration of budesonide was only 22% higher. Mean plasma cortisol concentrations were suppressed by 90% and 82% with prednisolone and by 22% and 28% with budesonide in oral contraceptive users and controls, respectively. Ethinylestradiol plasma concentrations were not affected by either glucocorticoid. The authors concluded that the oral contraceptive made no difference to the plasma concentrations of budesonide or cortisol suppression after the administration of budesonide capsules. These findings suggest that oral budesonide can be used in the usual doses without problems in women using oral contraceptives.

Griseofulvin

Griseofulvin modifies hepatic enzyme activity in mice, and although there is no good evidence of a major enzyme-inducing effect in humans, several case reports of pregnancies in women taking both oral contraceptives and griseofulvin suggest an interaction; the authorities in

© 2006 Elsevier B.V. All rights reserved.

several countries have warned that the contraceptive effect may be diminished (332).

Methylxanthines

The clearances of both theophylline and caffeine are reduced in oral contraceptive users and half-lives are increased, probably because of inhibition of hepatic metabolism by cytochrome P450 (333). Caution in dosage is advisable.

Neuroleptic drugs

A single case of neuroleptic malignant syndrome has been described in a woman taking haloperidol and thioridazine, 12 hours after she started to take an oral contraceptive. The authors suggested that this could have been a pharmacodynamic interaction involving dopaminergic neurotransmission (334).

A kinetic study in which ziprasidone (40 mg/day) or placebo were co-administered with a second-generation oral contraceptive has provided evidence that ziprasidone is unlikely to interfere with oral contraception (335).

Opioid analgesics

Increased glucuronidation may explain the fact that oral contraceptives enhance morphine clearance (336).

Paracetamol

Paracetamol might have a similar effect to ascorbic acid, that is competition with ethinylestradiol for sulfation capacity in the gut. Paracetamol significantly reduced the AUC of ethinylestradiol sulfate but had no effect on plasma levonorgestrel concentrations

In six healthy women, a single dose of paracetamol 1 g significantly increased the AUC of ethinylestradiol by 22% and reduced the AUC of ethinylestradiol sulfate (337). Plasma concentrations of levonorgestrel were unaltered. This interaction could be of clinical significance in women taking oral contraceptives who take paracetamol regularly or suddenly stop taking it, but it is doubtful whether it has any practical repercussions.

The clearance of paracetamol was 22% greater in men than women, entirely because of increased glucuronidation, there being no sex-related differences in the sulfation or oxidative metabolism of paracetamol (338). Paracetamol clearance in women using oral contraceptive steroids was 49% greater than in the control women. Glucuronidation and oxidative metabolism were both induced in contraceptive users (by 78% and 36% respectively) but sulfation was not altered. Although sex-related differences in paracetamol metabolism are unlikely to be of clinical importance, induction of paracetamol metabolism by oral contraceptive steroids may have clinical and toxicological consequences.

Rifamycins

Increased intermenstrual or breakthrough bleeding and pregnancy have been reported in women taking rifampicin in conjunction with contraceptive steroids (339). There is evidence that rifampicin increases the rate of metabolism of both the estrogenic and progestogenic components of oral contraceptives through hepatic microsomal enzyme induction (340) involving the same CYP isozyme as that induced by anticonvulsants, CYP3A. A four-fold increase in the rate of steroid metabolism has been shown; it is therefore unwise for women taking rifampicin to rely on steroid contraception and an alternative method should be used.

Roxithromycin

Roxithromycin does not interfere with the pharmacokinetics of oral contraceptives (341).

Salicylates

In a small study, the degree of erythrocyte aggregation during oral contraception was, at least in the short term, partly reversed by treatment with acetylsalicylic acid 100 mg/day (342).

Salicylic acid clearance is higher in users of oral contraceptives, owing to increases in the glycine and glucuronic acid conjugation pathways. In eight men, eight women, and eight women taking oral contraceptive steroids, the clearance of salicylic acid after an oral dose of aspirin 900 mg was 61% higher in the men than in the control women, largely because of increased activity of the glycine conjugation pathway (salicyluric acid formation) (343). Salicylic acid clearance was 41% higher in contraceptive users than in the control women, because of increases in both the glycine and glucuronic acid conjugation pathways. These data confirm the importance of hormonal factors in the regulation of drug conjugation reactions and suggest that sex-related differences in the disposition of salicylic acid and aspirin may be of clinical importance.

Tricyclic antidepressants

Oral contraceptives reduce the clearance of imipramine, probably by reducing hepatic oxidation, and thus increase its half-life. Hydroxylation of amitriptyline is inhibited by contraceptive steroids. The clinical significance is uncertain, but there is at least anecdotal evidence of an increase in antidepressant adverse effects (344). Caution should be exercised when tricyclic antidepressants are used long term in women taking oral contraceptives.

Troleandomycin

There have been several reports of hepatic cholestasis in women taking both troleandomycin and oral contraceptives (345). Oxidation of troleandomycin by CYP3A4 produces a derivative (probably a nitrosylated derivative) that binds tightly to the enzyme and thereby causes inactivation. This inhibition is highly selective for CYP3A4, and hepatic accumulation of ethinylestradiol is possible.

Smoking

The polycyclic hydrocarbons in cigarette smoke are potent inducers of certain cytochrome P450 isozymes. There is a marked increase in the 2-hydroxylation of natural estradiol in smokers, but not of ethinylestradiol, suggesting that the two estrogens are metabolized by different P450 enzymes. There is thus probably no pharmacokinetic interaction between smoking and oral

© 2006 Elsevier B.V. All rights reserved.

contraceptives, but women taking oral contraception should be encouraged to avoid heavy smoking because of the risks to the cardiovascular system.

Hormonal contraceptives—progestogen implants

See also Progestogens

General Information

Hormonal formulations for implantation contain progestogens, including the following:

- levonorgestrel
- etonogestrel
- desogestrel
- megestrol
- norethisterone.

For a complete account of the adverse effects of progestogens, readers are urged to consult the following monographs as well as this one:

- Hormonal contraceptives—progestogen injections
- Hormonal contraceptives—intracervical and intravaginal
- Hormonal contraceptives—oral
- Hormone replacement therapy—estrogens + progestogens
- Medroxyprogesterone
- Progestogens.

Levonorgestrel

Subdermal implanted silastic rods containing levonorgestrel (Norplant) have been widely studied and used with the support of the Population Council, but have fallen out of favor in a number of industrialized countries, because of complications. Six rods are inserted subdermally into the arm using a special device; each contains 35 mg of levonorgestrel, which is released into the circulation over 5 years. The total amount of levonorgestrel released daily during the first 500 days averages about 60 micrograms, falling to a plateau of 30 micrograms/day for the remainder of the 5-year period during which the product remains effective. It then has to be removed and replaced. The contraceptive effect of the implant does not seem to be caused primarily by ovulation inhibition, since after about the first year of use the hormone concentrations are too low to have this effect (1,2).

A product similar in approach to Norplant is the biodegradable subdermal capsular implant Capronor, which releases levonorgestrel over 12–18 months. Doses of 12 and 21.6 mg in capsules of differing size have been compared (3). Ovulation occurred in all cycles at the lower dose and in a quarter of cycles at the higher dose, so it is likely that the contraceptive

© 2006 Elsevier B.V. All rights reserved.

effect results essentially from other progestogen-induced changes. Several users had local swelling or itching of the skin at the capsule insertion site, relieved by topical glucocorticoids.

The effectiveness, adverse events, and acceptability of the FDA-approved variant of levonorgestrel capsule implants in the USA over 5 years and the determinants of these outcomes have been studied (4). There were three pregnancies, yielding a 5-year cumulative rate of 1.3 per 100 users, an average annual rate of three per 1000 women. Ectopic pregnancy occurred at a rate of 0.6 per 1000 woman-years. There were no pregnancies in women who weighed less than 79 kg. Medical conditions that most often led to removal of the implant were prolonged or irregular menstrual bleeding, followed by headache, weight gain, and mood changes. Weight gain averaged 1 kg/year.

Etonogestrel

Implanon, which became available in 1999, is a subdermal implant that contains 68 mg of etonogestrel, the active metabolite of desogestrel. The product and field experience is therefore still limited. During the first 2 years after implantation, there is no ovulation; ovulation occurs occasionally in the third year, and it is recommended that the implant be removed after this time. As with Norplant, the principal problem is the occurrence of irregular bleeding (5), which leads some 25–30% of users to ask that the implant be removed. After some time, amenorrhea occurs in some 20% of users. There was a clinically significant increase in bodyweight in 20% of women carrying the implant (6). There may also be some local irritation from the implant, and minor scarring at the implantation site (7,8). In clinical trials the implant had no effect on coagulation measures, hemostasis, fat metabolism, or hepatic function, but according to the approved product information sheet the possibility of a slight increase in insulin resistance cannot be excluded.

Desogestrel

In clinical trials, implants containing desogestrel were effective, but with bleeding irregularities and ovarian cysts as the primary adverse effects (9).

Megestrol

Implants filled with megestrol acetate gave an unexpectedly high incidence of tubal pregnancies, while the absolute number of ectopic pregnancies was clearly greater than that expected for the general population (10). This finding reflects the same type of effect as has been described from time to time with oral progestogen-only products.

Norethisterone

A biodegradable delivery system using subcutaneous implants of fused pellets made from norethisterone and pure cholesterol has been tested (11).

General adverse effects

Generally speaking, the systemic effects of progestogen implants are very similar to those of low-dose oral progestogen-only contraception, except for variations due to the progressive change in the amount of hormone released. Many studies using various metabolic measures have shown no significant pattern of deviation from normal values (12,13), either during use of the implant or after removal (14).

Acceptability

As in the case of injectable depot contraceptives (SED-14, 1433) subdermal contraceptive implants are more likely to be used in developing countries, in order to overcome social and compliance problems, and that this can in principle involve risks to which underprivileged populations may be especially subject. All the same, acceptance is strikingly good (15). In a survey of data from eight developing countries, information was available on 7977 women starting Norplant, of whom 6625 used intrauterine devices and 1419 had been sterilized; most of the participants were followed for 5 years. All of the methods produced satisfactory degrees of contraception and, with a few exceptions, no characteristic morbidity was detected among Norplant users compared with the other groups. The two principal exceptions concerned gallbladder disease, which was 50% more common in women who used Norplant, and hypertension and borderline hypertension, the incidence of which was markedly raised in current implant users (RR = 1.81; 95% CI = 1.12, 2.92). Other unexpected findings were increased rates of respiratory disease and reduced risks of inflammatory disease of the genital tract in users of Norplant compared with sterilized women and those who used an intrauterine device (16).

In Burkina Faso, experience in 1660 women over 4 years has been critically reviewed (17). There were 247 withdrawals before the fourth year, for various reasons, including cycle disorders (60 withdrawals), unspecified medical reasons ($n = 53$), personal objections ($n = 47$), weight gain ($n = 14$), and contraceptive failure ($n = 2$). Menstrual disorders, including amenorrhea, spotting, and hypermenorrhea, occurred in 51% of the cases. The investigators stressed the need for a good information and sensitization campaign to reduce the number of implant withdrawals before the fourth year of use, since the product often seems to be withdrawn for insufficient reasons.

A study in Senegal produced similar findings over 5 years; the method was safe and effective, but dissatisfaction with cycle control was again a prominent reason for requesting removal of the implant (18).

A Thai study in 88 asymptomatic, young, HIV-1-positive women immediately after delivery has similarly confirmed the good acceptability of Norplant in a developing country, despite the high incidence of irregular bleeding and some instances of headache and hair loss (19).

In 10 718 women in China, Norplant was reliable and no serious or fatal effects were reported (20). When pregnancies did occur, only 3.1 per 100 were ectopic, which is higher than for the general population in Beijing but much lower than in US studies of Norplant (presumably

© 2006 Elsevier B.V. All rights reserved.

because of lower rates of pelvic inflammatory disease in China). The 5-year continuation rate was 72 per 100 acceptors. Hemoglobin concentrations increased during the first year of use and remained high, presumably because of a reduction in menstrual blood loss. Although early findings suggested a reduction in platelet counts, follow-up work showed that in this population these were already low on admission to the study. Insertion-related complications necessitated removal in only 21 users.

In a study in Greece the method was well accepted by adolescents, although the study was small (13 subjects) (21). No significant problems arose during the 24-month follow-up period.

On the other hand, Norplant has been criticized in some Western countries, primarily because of adverse effects at the implantation site. An overview of adverse events reported to the FDA over 3 years, during which more than 700 000 implants were estimated to be in place, cited reports of 24 women hospitalized for infections at the insertion site and 14 who were either hospitalized or disabled because of difficulties associated with capsule removal (22). Fourteen women (two per 100 000) were reportedly hospitalized because of strokes. Three women developed thrombotic thrombocytopenic purpura and six developed thrombocytopenia. Finally, 39 Norplant users developed pseudotumor cerebri (benign intracranial hypertension), an incidence of 5.5 per 100 000; this condition is associated with obesity or recent weight gain, conditions that were present in most of the women for whom data were given. Although the rates of stroke and pseudotumor cerebri were slightly less than the expected rates in the general population of women of reproductive age, one has to take into account the well-known underreporting of adverse events to agencies such as the FDA; the figures could therefore mean that Norplant users are actually at increased risk.

Reviewing the overall scene in Britain, Hannaford has pointed to the considerable difference in acceptance rates for Norplant in the industrialized world and developing countries and has stressed the fact that the adverse reaction incidence is, according to the best evidence, low (23).

Rapid rejection of implantable progestogen-based contraceptives by some users, because of discomfort and local complications (for example because of breakage or migration of the device, or less than expert placement and removal), has attracted much attention in past reviews.

Organs and Systems

Cardiovascular

Norplant does not alter the blood pressure (24).

Nervous system

Headache is fairly common in women using progestogen implants (25).

Psychological, psychiatric

Two cases of major depression and panic disorder, developing soon after insertion of Norplant and resolving after removal, have been reported, but a causal association was not proven (26).

Five women using the Norplant system developed major depression, two of whom also developed obsessive-compulsive disorder and one of whom also developed agoraphobia (27). They had no prior psychiatric history but developed major depression within 1–3 months after insertion of Norplant. The depression worsened over time and in all cases resolved within 1–2 months after removal of Norplant. There was no recurrence of depression after 7–8 months in four cases available for follow-up. In addition to major depression, obsessive-compulsive disorder developed in two women and symptoms of agoraphobia developed in one woman during Norplant treatment, which resolved after removal.

Metabolism

Norplant does not alter body weight (28).

Hematologic

Research on blood coagulation has produced inconsistent results, usually showing little effect, as one would expect from a progestogen-based method without an estrogen component (29).

During 1 year of observation of 23 healthy fertile African women, beginning at the time that a Norplant device was inserted, the mean packed cell volume rose slightly but significantly from 40.5 to 42.2, but the mean total leukocyte, neutrophil, and lymphocyte counts all fell significantly, as did the mean platelet count (30). In four patients, the platelet counts were only 50–80 $\times$ 10^9/l. The rise in packed cell volume might, according to the authors, help to counter anemia in people in developing countries. However, the fall in the platelet count is hard to explain.

Skin

Some women who use progestogen implants develop acne, because of the androgenic activity of levonorgestrel. Three women developed severe acne vulgaris within several weeks to a few months after either insertion of a levonorgestrel IUCD (two women, 27 and 33 years of age) or subcutaneous implantation of etonogestrel (a 26-year-old woman) (31).

Reproductive system

The most frequent adverse effect of progestogen implants is irregular menstrual bleeding (32), which in some countries has reduced the acceptability of the treatment (33). It is common during the first year of use but tends to become much less marked thereafter (12,28,34). In one study, the incidence of menstrual irregularity in Norplant users was 73% compared with only 5% in a comparable population using oral contraceptives (35). There is also a fairly high incidence of breakthrough bleeding or amenorrhea (36). The cause of the irregular bleeding is not fully understood, but there is evidence that an increase in endometrial vascular fragility might precipitate vessel breakdown and hence breakthrough bleeding (37).

© 2006 Elsevier B.V. All rights reserved.

It is not clear why some women are more susceptible to this complication than others. In a Thai study in a large number of Norplant users irregular bleeding was characterized by low estradiol concentrations, absence of luteal activity, and a thin hyperechoic pattern in the endometrium (38). The possible role of cellular apoptosis in the endometrial response to Norplant has been investigated using immunohistochemistry, but with negative results (39). However, among Norplant users the superficial endometrial blood vessels are more fragile than in controls and even more fragile than in untreated women with dysfunctional uterine bleeding (40).

An unusual approach to dealing with this irregular bleeding has been to give an antiprogestogen simultaneously. In 50 Chinese women with implants, mifepristone 50 mg once every 4 weeks has been compared with placebo (41). In all the women, regardless of treatment, the frequency of bleeding fell significantly over 1 year of observation, as it commonly does. However, women who took mifepristone had significantly shorter episodes of bleeding during treatment than during the 90 days before treatment started; the duration of bleeding episodes fell more gradually in the controls. Women who used mifepristone were more likely to find the treatment acceptable than the women who used placebo. Despite concerns that antiprogestogenic effects may jeopardize contraception, there were no pregnancies. In the view of the investigators, this approach may offer a useful strategy to relieve unwanted adverse effects of implants until bleeding patterns improve spontaneously with time.

A second unusual approach to the bleeding problem has been to give vitamin E. There is evidence that there is a poor angiogenic response in the endometrium of users of Norplant, and it has been hypothesized that this might be caused by an imbalance of pro-oxidant and antioxidant processes. A placebo-controlled study has suggested that vitamin E (200 mg/day for 10 days monthly) significantly reduces the number of monthly bleeding days (42). However, there was also some reduction in bleeding days with placebo, and this approach would need further study before the results could be accepted as clinically useful.

Amenorrhea is uncommon in women with progestogen implants, but the monthly blood loss is usually reduced rather than increased (43). Menstrual irregularity does not appear to be correlated with body mass index.

The appearance of enlarged ovarian follicles is a recognized complication of Norplant, but the reported incidence varies, probably because different methods are used to recognize them. Serial ultrasonography produces much higher figures than clinical methods and has led to exaggerated concern; the enlarged follicles are transient and do not require intervention (44).

Breast discharge has been reported in some women with progestogen implants (45).

Infection risk

Insertion-related complications include infection, hematoma formation, local irritation, scar formation, early implant expulsions, and allergic reactions to the dressing. A pooled analysis of insertion site complications in multicountry studies showed that 0.8% of women develop infection after insertion of Norplant, generally within the first week, but sometimes several months later (46). Implant expulsion occurred at some stage in 0.4% of users, often because of infection but sometimes because of poor placement. Two-thirds of expulsions were reported more than 2 months after insertion. The rates of such complications vary widely between practices and between countries.

Second-Generation Effects

Fertility

As with other progestogen-based contraceptive methods, the return of fertility after withdrawal is rapid: serum levonorgestrel concentrations are undetectable within a week after implant removal, and normal cycles usually resume during the first month.

Teratogenicity

Because the pregnancy rate among users of Norplant is quite low, the rate of ectopic pregnancy is also very low. There is no evidence that infants conceived during Norplant use are at higher risk of birth defects.

Lactation

One particular advantage of progestogen-only contraception is its suitability for use during breastfeeding, since there are no estrogens to impede lactation. The infant's intake of steroids is low and appears to be acceptable; its daily intake of steroids (estimated from concentrations in maternal milk during the first month of use) has been estimated to be 90–100 nanograms of levonorgestrel (Norplant), 75–120 nanograms of etonogestrel (Implanon), and 50 and 110 nanograms of nestorone (Nestorone and Elcometrine implants respectively) (47). However, it is still considered advisable to defer the implantation of these devices until 6 weeks after delivery, in view of the theoretical possibility of an adverse influence on the neonate.

Drug Administration

Drug formulations

The practical problems associated with Norplant have related to its physical form rather than its pharmacological profile. Practitioners specially trained in the insertion and removal of the device usually handle it without major problems, but without this special instruction it can be difficult to ensure that the rods are properly placed and that they are removed without scarring or other complications. Even given appropriate handling, the rods can cause problems as a result of migration or breakage in situ.

An implant can usually be removed in under a quarter of an hour under local anesthesia, but removal can be more difficult if the clinician is inexperienced, if the rods were not positioned properly at insertion, or if fibrous tissue has grown around them.

© 2006 Elsevier B.V. All rights reserved.

If removal is not expertly handled in problematic cases, considerable scarring can result, and some users have proceeded to litigation as a consequence of such complications. Complications in the removal of Norplant capsules have been evaluated in 3416 cases from 11 countries (48). Complications were reported in 4.5% of removals, usually attributable to implants being broken during removal (1.7%) or being embedded below the subdermal plane (1.2%). Logistic regression analysis showed that the most important risk factors for complicated removals were complications at insertion and an infection at the implant site (before or at the time or removal). For women without complications, the mean removal time was 12 minutes, but for those with complications the mean increased to 30 minutes. These results illustrate the necessity of proper insertion technique, under aseptic conditions. Capsules become surrounded by a fibrous sheath within 3 months after implantation; beyond a few months, there is no difference in complication rate by duration of use.

Modified Norplant

A modified system, Norplant-2, requires only two instead of six rods. In 140 women using the Norplant-2 contraceptive subdermal implant system there were no accidental pregnancies over 3 years (49). Adverse effects that caused withdrawal from the study were acne, headache, and pain at the implant site. The termination rate for these medical reasons in year 3 of the study was 4.6%. The other main reason for termination was prolonged menstrual flow; the 3-year cumulative termination rate for menstrual irregularities was 3.8%.

Hormonal contraceptives—progestogen injections

See also Progestogens

General Information

For a complete account of the adverse effects of progestogens, readers should consult the following monographs as well as this one:

- Hormonal contraceptives—intracervical and intravaginal
- Hormonal contraceptives—oral
- Hormonal contraceptives—progesterone implants
- Hormone replacement therapy—estrogens + progestogens
- Medroxyprogesterone
- Progestogens.

Injectable hormonal contraceptives, which are normally composed of long-acting esters of progestogens, have obvious practical advantages over oral products when user compliance is poor, for example in illiterate or mentally subnormal women or in some populations in developing countries. However, the fact that they are used in this type of patient has led to some social protest against their use, as if they were intended to undermine free will or provide cheap but unpleasant contraception for the underprivileged. This may in turn explain some unbalanced criticism of these products in terms of efficacy and safety. Their sometimes incomplete cycle control is indeed a practical disadvantage, but not a risk, and the fact that they contain no estrogen actually means that they are safer in those respects when risks of hormonal contraception are due mainly to estrogenic effects, particularly thromboembolic complications. All in all, the injectable hormonal contraceptives provide effective, reversible, and relatively safe contraception, which can well be used not only in the populations named above but also, for example, in some women who smoke or when an estrogen is contraindicated (1,2).

General adverse effects

The degree to which women tolerate the adverse effects of long-acting injectable contraceptives seems to vary from one population to another, and it can be important to examine the frequency and severity of complaints in different environments. Particularly in developed countries, these products are often stated to cause mood changes, weight gain, and demineralization, but in developing countries they are very widely used. A worldwide review has surveyed the incidence of these conditions in users and has compared some of the figures with those found with an implantable product (Norplant; see the monograph on Hormonal contraceptives–progestogen injections) (3). Perhaps surprisingly, a consensus seems to be emerging that depot medroxyprogesterone acetate implants do not in fact result in an increase in the incidence of depression or in the severity of pre-existing depression, even after 1 or 2 years, nor do they cause significant weight gain. Similarly, Norplant did not cause depression.

© 2006 Elsevier B.V. All rights reserved.

Subgroups of users of depot medroxyprogesterone acetate may have reduced spinal bone density, but this seems to be reversible after withdrawal, even after several years of drug exposure (4). Bone mineral density in one cross-sectional study was lower among users of depot medroxyprogesterone acetate, but withdrawal was followed by complete recovery of normal bone density (4). A current study in the USA is expected to provide further data on this matter in women who have used medroxyprogesterone acetate for as long as 10 years.

Norethisterone enantate

The adverse effects of norethisterone enantate when used as a 2-monthly injectable contraceptive have been compared in various populations with those of depot medroxyprogesterone acetate and were found to be closely similar (5,6).

The largest single trial conducted with norethisterone enantate, covering some 9000 women-months of use, provided a fair picture of its adverse effects. Menstrual irregularity (prolonged bleeding, spotting, or amenorrhea) was the main complaint. Other adverse effects were periodic abdominal bloating and tender breasts, both of which were thought to be due to water retention and were relieved by diuretics. There was no associated weight gain. More than 50 of the women had pre-existing hypertension, and in these users the injections did not significantly affect blood pressure, which generally remained below 140/90 mmHg. Blood clotting was also not affected. High density lipoprotein cholesterol concentrations in the women treated were significantly lower than in the controls. The results of glucose tolerance tests did not differ significantly (7).

Three studies carried out in Bangladesh (8), Pakistan (9), and China (10) showed similar adverse reactions patterns. In the Bangladeshi study, nine of 254 women had a rise in both systolic and diastolic blood pressures, but five had a reduction of the same magnitude. In the Chinese women there were no significant changes in blood pressure. However, five Chinese women developed abnormal liver function tests and three of these women had liver enlargement after treatment for more than 2 years.

Other compounds and combinations

Other progestogen-only injectables have been tested, but those examined so far appear to have similar properties to the formulations that are already available.

Combined estrogen + progestogen injectables have been the subject of much experimentation. Administered monthly, they were developed in order to provide more dependable patterns of vaginal bleeding. Many formulations have been evaluated, and two of these have undergone phase III clinical trials by the WHO: one contains medroxyprogesterone acetate 25 mg with estradiol cipionate 5 mg and the other norethisterone enantate 50 mg plus estradiol valerate 5 mg. Analysis of daily menstrual diary record cards for women using these methods, compared with several other contraceptive methods and no method, showed that bleeding patterns for women receiving monthly injections were more regular, but not entirely normal (11). Although the median experience was similar to that of women not using contraception, the range of menstrual patterns was much wider. The outcome in this respect was found to be acceptable in only 70% of cycles during the first year of use, but later this figure rose to 85–90%. Under 10% of women discontinued use during the first year because of bleeding irregularities or amenorrhea, a rate that is presumably related in part to thorough counselling.

Hormonal replacement therapy—estrogens + androgens

See also Estrogens *and* Androgens

General Information

For a complete account of the adverse effects of estrogens, readers should consult the following monographs as well as this one:

- Diethylstilbestrol
- Estrogens
- Hormonal contraceptives—emergency contraception
- Hormonal contraceptives—oral
- Hormone replacement therapy—estrogens
- Hormone replacement therapy—estrogens + progestogens.

An estrogen + an androgen

This variant on the theme of estrogen replacement therapy has been propagated from various centers for different reasons (1,2).

© 2006 Elsevier B.V. All rights reserved.

The theoretical starting point is the observation that (particularly after oophorectomy) there are deficiencies of both testosterone and androstenedione (3) and from the observation that estrogens alone do not relieve all menopausal symptoms. While there may well be justification for androgen replacement after oophorectomy, it is not clear that most of the claims made for use of this approach following a natural menopause are sufficiently well founded to justify the risks involved.

Adding an androgen to estrogen replacement therapy in the menopause has been thought to provide supplementary benefit with respect to climacteric symptoms, fatigue, and impaired libido, as well as favorably affecting muscle mass, skin quality, and bone density. It is also stated that androgens improve relief of vasomotor symptoms and relieve depression and anxiety when they occur after the menopause in this group of patients. Some workers have concluded that in women who respond to conjugated estrogens with a rise in blood pressure (not a common response by any means), this effect could be avoided by the addition of an androgen. Yet others have asserted that when the hematocrit falls during estrogen therapy, the effect can be prevented by an androgen.

The main reason for caution with the use of androgens is the susceptibility of menopausal women to their virilizing effects, which can sometimes prove irreversible. Deepening of the voice, hirsutism, and acne can occur in many patients at an early stage of treatment and can prove distressing. There may be enlargement of the clitoris, although not consistently.

However, there are other reasons for caution. Statements with respect to the effect of estrogen + androgen combinations on blood lipids are, for example, contradictory, depending on the combinations used. If androgens are to be used, the effect on lipoproteins should at all events be monitored (1).

It is doubtful whether one can avoid unwanted androgenic effects by cautious dosing. For example, the published data seem to show that a desired effect on libido is only likely to occur at androgen doses sufficient to produce serum testosterone concentrations in the virilizing range (over 2 ng/ml), and that even after withdrawal of such doses virilizing concentrations of testosterone are maintained for many months.

Finally, androgens actually appear in some respects to counter the desired effects of estrogens in this patient group. Doppler flowmetry has been used to study the cardiovascular effects of adding an androgen to an estrogen in an open, randomized study in 40 patients over 8 months, all of whom were using transdermal estradiol (50 micrograms/day) and cyclic medroxyprogesterone acetate (10 mg/day) (4). Half of the subjects then received additional testosterone undecanoate (40 mg/day). The investigators concluded that while the androgen improved sexual desire and satisfaction and had no effect on endometrial thickness, it did in part counteract the beneficial effects of the estrogens on cerebral vascular activity and lipids. The most notable change was a significant increase in the pulsatility index of the middle cerebral artery. The androgen also resulted in a 10% reduction in HDL cholesterol concentration within 8 months. The authors therefore urged caution in using androgens, at least in the manner used in this study.

There are naturally some groups that have worked together with manufacturers to profile the supposed advantages of particular estrogen + androgen regimens, especially when these are available in the form of fixed combination formulations.

The adverse effects of estrogen + androgen therapy include mild hirsutism and acne (5). One group of workers, who examined the use of "Estratest" (an esterified combination of estrogen and methyltestosterone), concluded that in their experience under 5% of women developed acne or facial hirsutism, a frequency similar to that experienced when using conjugated estrogens 0.625 mg/day. Women had significantly less nausea with the estrogen + androgen treatment than with conjugated estrogen therapy. Cancers, cardiovascular disease, thromboembolism, and liver disease were stated to be rare among users of the combination. The only adverse events exceeding 4% of total reports were alopecia, acne, weight gain, and hirsutism (6). However, much higher rates of complications with such combinations have been reported from other centres (1).

The evident disadvantage of a fixed combination is that it renders it impossible to carry out any fine adjustment of dosages, such as might be called for in the light of the clinical response and adverse effects in a given individual.

All in all, it seems very doubtful whether any of the supposed benefits of androgen therapy justify the risks involved, except possibly as a transitional measure in those recently oophorectomized women who have acute symptoms of sudden androgen withdrawal.

An estrogen + an androgen + a progestogen

Another variant on hormone replacement therapy involves using all three types of sex steroid in parallel, starting from the argument that during the fertile period all three are synthesized by the ovary (7). A "natural" version of this therapy uses estradiol, testosterone (with or without dehydroepiandrosterone), and progesterone in an appropriate pharmaceutical form (for example micronized), so that absorption is attained without the need for 17-substitution. This approach naturally avoids some of the undesirable effects of the synthetic steroids, and has been stated to improve menopausal depression and anxiety. However, the adverse effects of all three types of component can be experienced.

Hormone replacement therapy—estrogens

See also Estrogens

General Information

For a complete account of the adverse effects of estrogens, readers should consult the following monographs as well as this one:

- Diethylstilbestrol
- Estrogens
- Hormonal contraceptives—emergency contraception
- Hormonal contraceptives—oral
- Hormone replacement therapy—estrogens + androgens
- Hormone replacement therapy—estrogens + progestogens.

Estrogen replacement therapy was until recently widely recommended for the prevention of osteoporosis in middle-aged and older women (1). Long-term estrogen therapy also reduces the incidence of ischemic heart disease in such women (2). However, it has always been difficult to know in which women such prophylactic use is likely to be needed, and this dilemma is compounded by the prospect of adverse reactions, which can include any of the acute effects listed in the estrogen monograph, but also in some cases long-term effects such as tumors.

The multiplicity of hormone replacement therapy regimens in use (involving one or two drugs, continuous or intermittent treatment, and various forms of administration) makes it difficult to express any general conclusion about the benefit-to-harm balance, and there has been a thoughtful review of the obstacles to assessing these matters objectively and scientifically, including questions of both ethics and trial design (3). Even the ultimate effect of hormone replacement therapy on the incidence of ischemic heart disease remains subject to dispute (4), and incidental reports of cardiac complications, sometimes in women with entirely healthy coronary vessels, continue to cause concern (5). For such reasons, much work has been devoted to determining the lowest effective dose of estrogen needed to achieve particular results.

An extraordinarily thorough review of all significant controlled studies of estrogen replacement therapy has been published by the Cochrane Collaboration (6). The participants totalled 2511 and the trials lasted 0.25–3 years. The primary purpose was to confirm efficacy, but data on adverse effects were also collected. Withdrawal because of adverse events, commonly breast tenderness, edema, joint pains, and psychological symptoms, was not significantly higher with HRT than placebo (OR = 1.38; 95% CI = 0.87, 2.21). Breast tenderness and withdrawal bleeding were the only significant problems in terms of frequency. The studies did not justify the conclusion that there are serious adverse effects, such as thrombosis and malignancies.

Carefully assessed data like these illustrate the delicacy of the balance in the debate regarding the benefit-to-harm balance of long-term HRT; extreme statements have been made in both directions, and clearly most are not justified. A reasoned critical review, stressing how inadequate many of the data still are on both efficacy and safety issues, has been published (7).

Observational studies

A Japanese study of the use of estriol 2 mg/day for 12 months in 68 postmenopausal women with climacteric symptoms showed a significant effect in relieving hot flushes, night sweats, and insomnia (8,9). There were significant falls in serum follicle stimulating hormone (FSH) and luteinizing hormone (LH) concentrations, but no effect on lipids, bone demineralization, or blood pressure. There was slight vaginal bleeding in 14% of women treated during a natural menopause, but histological and ultrasound evaluation showed no changes in the endometrium or breasts. It is evident, however, that higher doses might be needed when treating women of other races with a higher body weight. Other workers have found that when given with a progestogen over long periods, estriol 2.0 mg/day seems much less likely to cause undesirable lipid changes than are equine conjugated estrogens, which can cause increased HDL cholesterol and triglyceride concentrations (10).

Comparative studies

In a randomized, multicenter study in Denmark 376 perimenopausal women with climacteric symptoms were randomly allocated to oral sequential combined treatment with regimens based on estrogen plus either desogestrel or medroxyprogesterone acetate (11). Both treatments effectively alleviated menopausal complaints within 6 months and gave good cycle control. Bleeding pattern and mood disturbances were more favorably affected by desogestrel, but overall the differences in adverse effects (irregular bleeding and a slight tendency to hypotension) were not large. It should be noted, however, that with cyclic combined hormone replacement therapy treatment, the bleeding pattern alone does not seem to be a reliable means of distinguishing cases in which the endometrium is atrophic or inactive from those in which it is proliferative or hyperplastic (12).

Organs and Systems

Cardiovascular

One of the most serious aspects of the thromboembolic complications now widely acknowledged as being associated with HRT is that their emergence coincides with the development of the conclusion that the role of HRT in reducing the risk of coronary heart disease is at best unproven. A form of treatment that was originally viewed

© 2006 Elsevier B.V. All rights reserved.

as potentially beneficial to the cardiovascular system is at present on balance perhaps harmful (13).

A US group examined potential risk factors for venous thromboembolic events in women assigned to HRT in the Postmenopausal Estrogen/Progestin Interventions (PEPI) study, a 3-year double-blind study in 875 postmenopausal women designed to assess the effects of HRT on heart disease risk factors (HDL cholesterol, fibrinogen, blood pressure, and insulin) (14). Women with a history of estrogen-associated venous thromboembolic events were excluded. Ten women, all assigned to HRT, had a venous thromboembolic event during the study. Only baseline fibrinogen varied significantly between those who had a venous thromboembolic event while assigned to HRT event (mean 2.49 g/l) and those who did not have an event (mean 2.81 g/l). Adjusting for covariates did not affect this finding. As the authors remarked, the lower fibrinogen concentrations among women who subsequently reported venous thromboembolic events may be a marker for a specific, but as yet undefined, coagulopathy that is magnified in the presence of exogenous hormones. However, larger studies are needed to confirm this hypothesis.

Since much of the evidence of thromboembolic complications with HRT relates to the use of conjugated equine estrogens, the degree of risk when natural 17-beta-estradiol was used instead has been examined in Norway in a population-based case-control study involving consecutive women, aged 44–70 years, discharged from a University Hospital between 1990 and 1996 with a diagnosis of deep venous thrombosis or pulmonary embolism (15). Women with cancer-associated thrombosis were excluded. Random controls were used. The material comprised 176 cases and 352 controls, that is two controls for each case. All the women who received HRT had been given estradiol. The frequency of HRT use was 28% (50/176) in cases and 26% (93/352) in controls. The estimated matched crude odds ratio was 1.13 (CI = 0.71, 1.78), which shows no significant association of overall use of estradiol-based HRT and thromboembolism. However, when the duration of exposure to HRT was taken into account by stratification, there was an increased risk of thromboembolism during the first year of use, with a crude odds ratio of 3.54 (CI = 1.54, 5.2). This effect was reduced by extended use to a crude odds ratio of 0.66 (CI = 0.39, 1.10) after the first year of use. The authors concluded that the use of estradiol for HRT was associated with a three-fold increase in the risk of venous thromboembolism, but that this increased risk was restricted to the first year of use. One is bound to wonder whether this shift in risk was genuine or reflects only the limitations of the study.

Among the less common forms of thromboembolism that have been reported is occlusion of the retinal vein, familiar with the oral contraceptives but unusual with HRT (16).

Ear, nose, throat

Visual hallucinations have been associated with estrogen in a patient with Charles Bonnet syndrome (17).

- An 84-year-old woman with poor visual acuity secondary to bilateral, non-exudative, age-related macular degeneration had non-threatening visual hallucinations 2 weeks after starting oral estrogen for osteoporosis. The estrogen was withdrawn and the hallucinations subsided. She was given estrogen twice more and each time the hallucinations recurred.

In this patient estrogen may have promoted release phenomena and triggered the hallucinatory episodes.

Nervous system

Over the years there have been reports that headache or classical migraine is either alleviated or exacerbated by HRT. This has been studied in 50 menopausal women with headaches who were randomized to either transdermal estradiol 50 micrograms for 7 days a month or oral conjugated estrogens 0.625 mg/day for 28 days, both regimens being supplemented with medroxyprogesterone acetate 10 mg/day during the latter half of each month (18). In patients with episodic tension headache there was no significant change in headache pattern. However, in women with migraine without aura the frequency and duration of the attacks increased significantly during HRT in the subgroup using the oral formulation; the transdermal formulation had no effect on the migraine pattern.

Sensory systems

The possibility that estrogen replacement therapy might cause dryness of the eyes has been reviewed in the light of data from the large Women's Health Study in the USA (19), and this work has been further reviewed (20). Questionnaires were sent to 25 665 participants. For every 3-year increase in the duration of replacement therapy there was a 15% increase in the incidence of dry eye syndrome. The risk was greater in women who used estrogen alone than in those who used combined estrogen + progestogen regimens. The evidence was not statistically strong, but it suggests that there is some correlation and that users and prescribers should be aware of it.

Metabolism

Lipids

Changes in lipids have been observed with both HRT and oral contraceptives and have sometimes been promoted as potentially advantageous, but it is not clear how significant such changes are, at least in biochemical terms. A review and pooled analysis of 248 prospective studies available up to the year 2000 has provided data on this issue in postmenopausal women (21). All estrogen-only regimens raised HDL cholesterol and lowered LDL and total cholesterol. Oral estrogens raised triglycerides. Transdermal 17-beta-estradiol lowered triglycerides.

Weight

Weight gain is widely believed to be a common consequence of HRT, and the desire to avoid obesity is a major reason why some women decline treatment. However, the potential effects of HRT need to be distinguished from effects that could be due to changing lifestyle or ageing. The effects of short-term hormone replacement and age on alterations in weight, body composition, and energy balance have therefore been studied in a prospective

© 2006 Elsevier B.V. All rights reserved.

study in 18 healthy women aged 45–55 years and in 15 aged 70–80 years, with measurements at baseline, repeated after 1 month of transdermal estrogen (Estraderm 50 micrograms/day), and again after a further month of transdermal estrogen with vaginal progesterone (100 mg bd) added for the final 7 days (22). In neither age group did estrogen treatment correlate with anthropometric changes. Resting energy expenditure and activity were positively correlated with fat-free mass, while energy intake was not. Resting energy expenditure, energy intake, and activity were lower in older women when adjusted for fat-free mass. Changes in weight during treatment were not statistically significant. In addition, there was no difference between the groups in body mass index, fat mass, fat-free mass, total body water, or waist-to-hip ratio. This work has confirmed the reduction in energy expenditure that occurs with ageing, and it suggests that there is no effect of HRT on resting energy expenditure or body weight.

Hematologic

There has been a randomized, placebo-controlled study in 25 postmenopausal women to investigate the mechanisms that could underlie the induction of thrombosis by unopposed estrogens (23). Fasting and fat-load-stimulated plasma concentrations of clotting factor VII were measured after 8 weeks of oral 17-beta-estradiol (2 mg/day). Estradiol increased the mean fasting and postprandial plasma concentrations of total factor VII by 17 and 21% respectively, but did not affect the fasting and/or postprandial plasma concentrations of active factor VII. These findings argue against the idea that raised concentrations of total factor VII underlie the increased risk of arterial thromboembolism in these women.

It has been firmly concluded, in the light of prior evidence, that HRT increases the risk of venous thrombosis, this risk not being outweighed by any demonstrable benefit in terms of arterial cardiovascular disease (24). This conclusion is now being increasingly accepted, and the effects of postmenopausal HRT on blood coagulation have been intensively studied and documented over the years. However, the effects in older women, who have the highest risk of thromboembolism, are not well defined, and a US group has studied the association between HRT and concentrations of natural anticoagulant proteins in this subpopulation in a cross-sectional study in women of 65 years or older participating in the Cardiovascular Health Study (25). Protein C antigen and antithrombin were measured in HRT users (230 taking an unopposed estrogen and 60 taking an estrogen with a progestogen) and a comparison group of 196 non-users. Estrogen use was associated with significantly higher protein C concentrations (4.80 versus 4.30 micrograms/ml); the results were similar with estrogen/progestogen. In both user groups, antithrombin was significantly lower than in non-users (109% for each treatment group versus 115% in non-users). Adjustment for factors related to prescription of HRT and to anticoagulant protein concentrations had little impact on the results. For antithrombin, the association with HRT was larger for thinner Caucasian women and black women. The authors concluded that venous thrombosis from HRT may be partly mediated by alterations in antithrombin, but not by protein C concentrations.

Although the thrombogenic potential of oral estrogen in postmenopausal women is well documented, it has been argued that direct studies of the effect of estrogen replacement on hemostasis are largely lacking and not well known (26). A review of a series of randomized trials has shown that the treatment has no significant effect on concentrations of fibrinogen and factor VII. Plasma concentrations of antithrombin and protein S fell with oral estrogen but not with transdermal estrogen. No form of replacement affected protein C concentrations, but there was activation of coagulation in the presence of oral estrogen, as reflected by a rise in the concentration of prothrombin fragment 1 + 2. As far as fibrinolysis is concerned, oral estrogen reduces plasma PAI-1 and tPA, leading to an increase in fibrinolytic potential. The absence of an effect of transdermal estrogen on coagulation and fibrinolysis suggests that the route of estrogen administration is important, but it has not to date been convincingly shown that transdermal estrogen in equieffective doses is less thrombogenic than the oral form.

Urinary tract

Since microalbuminuria can be regarded as being associated with renal and cardiovascular disease, evidence that the incidence of microalbuminuria is higher during treatment with oral contraceptives or hormone replacement therapy deserves to be taken seriously. A Dutch group has performed a case-control study of baseline and dispensing data relating to 4301 women participating in a study on the prevention of renal and vascular disease; the main outcome measure was microalbuminuria (30–300 mg/day) (27). After adjusting for age, hypertension, diabetes, obesity, hyperlipidemia, and smoking, the odds ratio for microalbuminuria was 1.90 (CI = 1.23, 2.93) for premenopausal oral contraceptive users and 2.05 (1.12, 3.77) for postmenopausal hormone replacement therapy users. The point estimate increased dose-dependently, albeit insignificantly, according to the estrogen content of the oral contraceptives (30–50 micrograms) and was greater in oral contraceptives with a second-generation progestogen (OR = 2.04) than those using a third-generation progestogen (OR = 1.39; CI = 0.63, 3.06). In the case of HRT, the odds ratio increased with the duration of HRT, that in women who had used the product for more than 5 years being double that in others.

Skin

- A 54-year-old woman developed melasma, macular hyperpigmentation associated with increased estrogen states, in atypical sites after starting to take HRT; on withdrawal it began to fade (28).

Musculoskeletal

Despite the evidence that estrogens can be of value in countering osteoporosis, some studies have suggested that women who use them are more likely to have back pain than those who do not; the possible causal link has remained unclear, and continues so despite recent confirmation of the phenomenon. Baseline information on

© 2006 Elsevier B.V. All rights reserved.

estrogen replacement therapy, functional status, back pain and function, and other variables has been obtained in 7209 elderly white American women (mean age 71 years) enrolled in a study of osteoporotic fractures; X-rays were also taken at baseline and an average of 3.7 years later (29). A total of 1039 women were using estrogen replacement therapy at baseline, 2016 reported former use, and 4154 had never used estrogen replacement therapy. Compared with never-users, a significantly higher percentage of current estrogen users reported clinical back pain (53 versus 43%) and back impairment (12 versus 9.2%) at baseline and at the follow-up visit (pain 51 versus 41; impairment 16 versus 12%). This occurred despite a higher prevalence of vertebral fractures in never-users of estrogen at the baseline visit. The increased likelihood of back pain and impairment of function in current and former estrogen users remained in evidence, despite statistical adjustment for possibly interfering factors. The relative risks for impaired back function in former and current users at follow-up were 1.1 (0.9, 1.3) and 1.6 (1.3, 2.0) respectively (30).

Reproductive system

Breasts

Two doses of transdermal estrogen, 50 and 100 micrograms/day, have been compared with placebo in preventing bone loss in postmenopausal women over 24 months (31). Bone mineral density in the lumbar spine was only marginally better with the higher dose; the slightly better effect was largely offset by a higher incidence of breast pain, reported by 8% of women on placebo, by 6% of those who took 50 micrograms/day, and by 17% of women who took 100 micrograms/day.

Uterus

It has long been recognized that periodic or irregular uterine bleeding will occur in some women using HRT. While it is simple to dismiss this merely as a reactivation of endometrial proliferation and shedding, some workers have sought to examine the precise mechanism of this unwanted complication, particularly because it might prove to be the harbinger of more serious events involving the endometrium. From recent work in the UK it has been concluded that estrogen treatment appears to alter the endometrial expression of matrix metalloprotease 9 (MMP-9) and the tissue inhibitor of metalloproteases (TIMP-1) as well as the local balance between these molecules (32). This alteration may promote breakdown of the endometrial extracellular matrix and blood vessels and hence bleeding.

There could be fairly simple ways of screening for endometrial disorders in women using HRT. A study in 93 such women has confirmed the earlier finding that if a Papanicolaou smear is taken from the vagina the presence of endometrial cells in the smear gives some (non-specific) indication that there are endometrial changes, which may range from hyperplasia or polyps to endometrial carcinoma (33).

Immunologic

Two healthy young women took estrogen supplements for some 3 years and then developed classic Sjögren's syndrome (34). The syndrome was most severe in the woman who had taken the higher dose. These cases seem to have confirmed earlier reports that estrogens can play a role in the pathogenesis of Sjögren's syndrome in susceptible patients.

Long-Term Effects

Drug dependence

While the effects of estrogen treatment on mental function and mood are generally assessed as positive, work in Britain has raised the possibility of some form of psychological dependence. The starting point was the finding in various studies that a proportion of women in whom hormone replacement therapy was terminated had a return of psychological symptoms, such as low mood and tiredness, despite the fact that their circulating estrogen concentrations were high. A questionnaire-based study was therefore carried out in 600 women, mean age 46 years; in most of them, HRT with implants had been undertaken after hysterectomy, and the mean duration of use was 5 years. Among those with high circulating estradiol concentrations (more than 500 pmol/l) 40% reported a need to use top-up doses of HRT to cope with daily activities, 78% spoke of low mood and tiredness (apparently when estrogen concentrations were falling), 80% experienced a "buzz" (which was undefined) 1–2 weeks after receiving a new implant, and 75% claimed that life without an implant would be "terrible." These effects, interpreted as evidence of dependence, were almost absent in women with lower circulating estrogen concentrations. The authors were of the opinion that circulating concentrations of some 300 pmol/l, which are sufficient to maintain bone mass, should be the therapeutic aim, and that there will then be much less of a dependence problem than when higher concentrations are attained (35,36).

Mutagenicity

A finding that needs further study is that when estrogens are used for the treatment of osteoporosis they may have some genotoxic potential, as evidenced by their ability to cause an increased frequency of sister chromatid exchange (37).

Tumorigenicity

The associations between hormone replacement therapy and breast, endometrial, and ovarian cancers are discussed in the monograph on estrogens.

Susceptibility Factors

Age

When a young woman undergoes a surgical menopause it is clear that estrogen replacement treatment, if given at all, is likely to be needed for many years, and in the present state of knowledge this is probably justifiable, provided that the effects are monitored. The dilemma that the physician faces in such cases has been discussed in the light of a patient in whom gross obesity compounded the possible risk of thrombosis; the patient was

© 2006 Elsevier B.V. All rights reserved.

nevertheless treated with an implant and remained well for 4 years (38).

Renal disease

Estrogen replacement therapy may have untoward effects in patients with renal disease, including an increased risk of thrombosis of dialysis access and potentially worsening of coronary artery disease, probably because the excretion of estrogens is impaired (39).

Drug Administration

Drug dosage regimens

The amount of estrogen taken during estrogen replacement is usually about one quarter of that found in oral contraceptives, and is intended to be sufficient to restore physiological amounts of endogenous estrogens. During the physiological cycle, menstrual discomfort of all types is at its mildest (and usually absent) during the mid-follicular phase when plasma estradiol concentrations are 60–150 pg/ml (40). In replacement therapy some workers seek to titrate the dose of estrogen individually in order to maintain this level, hoping thereby not only to avoid adverse effects associated with hyper- or hypo-estrogenicity but also to optimize the therapeutic effect. Strictly speaking this individualized treatment is called for because of the variability of estrogen clearance, but in normal women plasma levels are rarely measured, an approximate adaptation of dosage being undertaken purely on the basis of subjective reactions.

There is no benefit and sometimes a disadvantage to giving estrogen alone for only 25 days a month; in particular, estrogen withdrawal symptoms such as decreased well being, headaches, and hot flushes can occur each time the treatment is interrupted.

It is widely recommended that estrogen replacement therapy, if it is to be used at all, should be initiated at the time of menopause or within 3 years of it, since it is at this time that bone loss can be most severe. Many physicians go on to argue that once it has been started hormonal replacement therapy should continue for at least 20 years and perhaps indefinitely, in view of evidence that withdrawal may be followed by accelerated bone loss, at least comparable to that observed after the menopause. Later use of estrogen, once bone has already been lost, does not result in appreciable recovery of bone, although further loss can still be prevented. Large comparative studies have suggested that a series of alternative regimens for hormone replacement therapy should be available, so that for each individual woman the most appropriate form of treatment can be chosen; no one regimen is ideal for all, and finding the best approach for a given patient may be a matter of trial and error (41).

For the acute treatment of climacteric vasomotor symptoms it seems clear that micronized 17-beta-estradiol in a dose as low as 0.25 mg can be sufficient; however, a starting dose of 1 mg is advisable, with subsequent adjustments as necessary. At a dose of 2 mg the proportion of women who withdraw from treatment with the active product because of adverse effects was twice that seen with placebo (42). To provide longer-term protection against early postmenopausal bone loss, treatment with estradiol in a dose of 1 mg/day, balanced by a progestogen, is adequate (43). Most workers believe that the estrogen is best counterbalanced by a progestogen when used in the long term, but here there is still some disagreement about the doses needed.

Drug administration route

If it is indeed true that transdermal estrogens have certain advantages over oral estrogens in terms of safety, this needs to be better documented than hitherto; as in so many instances, the evidence is confusing, because of the multiplicity of products and doses. In 35 postmenopausal women who had been amenorrheic for at least 1 year, two consecutive 2-month courses of transdermal estrogen (estradiol patches 25 micrograms and 50 micrograms) were randomly followed by a 2-month course of treatment with either an estradiol patch 100 micrograms/day or an estradiol patch 50 micrograms/day combined with either progesterone 300 mg/day or medroxyprogesterone acetate 5 mg/day during the last 14 days (44). Neither transdermal estradiol alone nor transdermal estradiol plus progestogen altered the lipoprotein profile, LDL resistance to oxidation, or LDL particle size. However, all treatments similarly reduced myeloperoxidase protein concentrations.

In a case-control study 155 postmenopausal women who had had venous thromboembolism were compared with 381 matched controls (45). In all, 32 cases and 27 controls were current users of oral replacement therapy, whereas 30 cases and 93 controls were current users of transdermal products. After adjustment for potential confounding variables, the estimated risk ratio for venous thromboembolism in current users of the oral products compared with the transdermal users was 4.0 (1.9–8.3). This is strong evidence that the transdermal route was considerably safer. However, the conclusions of different studies continue to conflict with one another, no doubt in part because of variations in the formulations and patterns of use of the products.

Drug–Drug Interactions

Dexamfetamine

Preclinical studies (as well as anecdotal clinical reports in the course of the years) seem to show that estrogens, through their effects on the central nervous system, can affect behavioral responses to psychoactive drugs. In an unusual crossover study, the subjective and physiological effects of oral dexamfetamine 10 mg have been assessed after pretreatment with estradiol (46). One group of healthy young women used estradiol patches (Estraderm TTS, total dose 0.8 mg), which raised plasma estradiol concentrations to about 750 pg/ml, and a control group used placebo patches. Most of the subjective and physiological effects of dexamfetamine were not affected by acute estradiol treatment, but the estrogen did increase the magnitude of the effect of dexamfetamine on subjective ratings of "pleasant stimulation" and reduced ratings of "want more." Estradiol also produced some subjective effects

© 2006 Elsevier B.V. All rights reserved.

when used alone, raising ratings of "feel drug," "energy and intellectual efficiency," and "pleasant stimulation."

Hormone replacement therapy—estrogens + progestogens

See also Estrogens *and* Progestogens

General Information

For a complete account of the adverse effects of estrogens, readers should consult the following monographs as well as this one:

- Diethylstilbestrol
- Estrogens
- Hormonal contraceptives—emergency contraception
- Hormonal contraceptives—oral
- Hormone replacement therapy—estrogens
- Hormone replacement therapy—estrogens + androgens.

For a complete account of the adverse effects of progestogens, readers should consult the following monographs as well as this one:

- Hormonal contraceptives—intracervical and intravaginal
- Hormonal contraceptives—oral
- Hormonal contraceptives—progestogen implants
- Hormonal contraceptives—progestogen injections
- Medroxyprogesterone
- Progestogens.

Two alternatives to long-term estrogen therapy have been proposed, because of the fear of certain risks (particularly malignancy) that might result in postmenopausal women:

- combined estrogen + progestogen regimens with a monthly interruption to allow for withdrawal bleeding
- long-term therapy with estrogens alone periodically interrupted by a cycle of combined treatment.

In those few countries in which hysterectomy is still endemic it has been argued that in the residual minority of women with an intact uterus combination therapy should be the normal form of HRT. Therapeutic benefits have also been claimed from using the combination. Unfortunately, some of the publications that have made claims for the therapeutic advantages of adding progestogens to estrogens in HRT have not provided exact comparative data, and the beneficial effects which are described are not clearly different from those claimed for estrogen alone.

The dispute about the benefit to harm balance of the various competing forms of HRT for use in the climacteric or postmenopausally is becoming increasingly intense, with a sharp division of opinion between protagonists and critics of the individual patterns of treatment. The view was often defended by earlier workers that, at least for certain classes of users, some form of combined estrogen + progestogen treatment is likely to be more appropriate and perhaps more physiological than estrogen replacement alone. Many variants have been used and none is likely to be ideal for all subjects. Some have argued that in the climacteric there are sound reasons for using estrogen with intermittent progestogen and that it is much underused, despite the fact that uterine bleeding and other adverse progestogenic effects are, with some combined formulations (but not all), major reasons for patient noncompliance and early withdrawal (1).

Observational studies

In 104 women with established postmenopausal osteoporosis, continuous estrogen + progestogen therapy resulted in increases in bone mineral density of the femoral neck and a fall in systolic blood pressure; the most common adverse effects were mastalgia (44%) and vaginal bleeding (29%) (2).

The combined use of estradiol and dydrogesterone reduce both diastolic and systolic blood pressures in postmenopausal women in whom the diastolic pressure had been raised (3). Evidence is also advanced from various quarters that adding a progestogen to adequate dosages of an estrogen promotes new bone formation, restores bone that has been lost and reduces the risk of carcinoma of the breast.

When 16 diabetic and hypertensive postmenopausal women aged 47–57 years were treated cyclically with estradiol plus norgestrel, existing proteinuria and even creatinine clearance often improved (4). The effects were unrelated to conventional risk factors for vascular complications, such as raised blood pressure, plasma glucose, or serum cholesterol.

General adverse effects

Of 206 postmenopausal women who took the oral combination of estradiol valerate plus norethisterone (5) eight withdrew because of bleeding during year 1; during years 2 and 3 there were no withdrawals because of bleeding. By the end of year 3, 133 patients had completed the study. There were serious adverse effects in 24, but there was no definite relation to therapy. The numbers of adverse events reported each year by the patients who completed the study are shown in Table 1. The authors concluded that this combination was effective in the majority of patients and was well tolerated.

Distinguishing adverse effects due to estrogens or progestogens

When patients have adverse effects during combined hormone replacement therapy it is necessary to determine whether the progestogen or the estrogen is causing the problem. If heavy bleeding or breast tenderness is the primary complaint, the estrogen component is probably the problem and therefore the dose should be reduced. If the patient complains of irritability, depression, water retention, or headaches, the problems are probably due to the progestogen component and the latter should in that case be changed or the dose adjusted; since several different progestogens are in use (particularly norethindrone, norethindrone acetate, medroxyprogesterone acetate, and micronized progesterone) there is a degree of choice.

Benefit to harm balance

With increasing concern over the long-term safety of hormone replacement therapy, the benefit to harm balance has to be continually reassessed, and conclusions as to its prophylactic or therapeutic value need to be adjusted as experience accumulates. Not all the promises held out for the benefits of this therapy have been confirmed. For example, while estrogens prevent peripheral bone loss they do not prevent vertebral fractures (6) and in a 2-year placebo-controlled, crossover study in 34 healthy postmenopausal women, treatment with transdermal estrogen alone (Menorest 50 micrograms/day) did not improve lipid profiles or any indices of arterial function (7).

Table 1 The numbers of adverse events in 3 successive years in patients taking estradiol valerate + norethisterone (5)

Adverse event	Year 1 ($n = 164$)	Year 2 ($n = 144$)	Year 3 ($n = 133$)
Cardiovascular			
Hypertension	5	3	—
Palpitation	4	4	3
Phlebitis	3	—	—
Respiratory			
Breathlessness	3	0	1
Metabolism			
Weight gain	10	5	2
Gastrointestinal			
Abdominal pain	2	2	—
Musculoskeletal			
Fractures	7	1	1
Joint/bone pain	6	3	6
Reproductive system			
Menopausal symptoms	4	1	5
Breast tenderness	63	4	3
Breast lumps	2	4	2
Bleeding/spotting	91	60	24
Abnormal smear	—	2	—
Ovarian cysts	1	1	4
Other adverse events	105	53	34
Total	306	143	85

It is remarkable that, despite decades of accumulated observational evidence, the balance of benefits and harms for hormone use in healthy postmenopausal women remains uncertain (8). Quite apart from the constantly changing spectrum of the available data, one explanation for the confusion is the relatively high proportion of poor-quality clinical work, particularly studies that are designed to promote particular commercialized forms of treatment from among the many alternatives available.

A study that cannot be faulted on that score is the Women's Health Initiative, a randomized, controlled, primary prevention trial (planned to last for 8.5 years), in which 16 608 postmenopausal women aged 50–79 years with an intact uterus at baseline were recruited at 40 US clinical centers over the period 1993–98 (9). In one part of this study, 8506 participants received conjugated equine estrogens 0.625 mg/day plus medroxyprogesterone acetate 2.5 mg/day; 8102 were given placebo. The primary desired outcome was reduction of coronary heart disease (non-fatal myocardial infarction and death), with invasive breast cancer as the primary anticipated adverse outcome. After a mean of 5.2 years, the data and safety monitoring board recommended stopping the trial of estrogen plus progestogen versus placebo because the test statistic for invasive breast cancer exceeded the stopping boundary for this adverse effect and the global index statistic supported harms exceeding benefits. The estimated hazard ratios (and 95% confidence intervals) were:

- coronary disease 1.29 (1.02, 1.63; $n = 286$)
- breast cancer 1.26 (1.00, 1.59; $n = 290$)
- stroke 1.41 (1.07, 1.85; $n = 212$)
- pulmonary embolism 2.13 (1.39, 3.25; $n = 101$)
- colorectal cancer 0.63 (0.43, 0.92; $n = 112$)
- endometrial cancer 0.83 (0.47, 1.47; $n = 47$)
- hip fracture 0.66 (0.45, 0.98; $n = 106$)
- death due to other causes 0.92 (0.74, 1.14; $n = 331$).

What the above amounts to is that the absolute excess risks per 10 000 woman-years attributable to the use of an estrogen plus a progestogen were seven more coronary heart disease events, eight more strokes, eight more pulmonary embolisms, and eight more invasive breast cancers, while the risk reductions per 10 000 woman-years were six fewer colorectal cancers and five fewer hip fractures. The absolute excess risk of events included in the global index was 19 per 10 000 woman-years. The overall harms in this study thus clearly exceeded the benefits. All-cause mortality was not affected.

Other published studies, many of which are of limited scope, do not run closely parallel to the above findings

© 2006 Elsevier B.V. All rights reserved.

from the Women's Health Initiative, and the data on cardiovascular effects remain particularly confusing. However, Beral and colleagues have pointed out optimistically that "substantial new data should soon be available from randomized trials of estrogen-alone hormonal replacement therapy versus placebo," although they added that "few additional trial data on combined hormone replacement therapy are expected for about a decade" (10). They also pointed out that existing randomized trials are too small to provide reliable evidence on some basic matters, including the relative risks of the various compounds in use.

Organs and Systems

Cardiovascular

Despite biologically plausible mechanisms whereby estrogens might be expected to confer cardioprotection in postmenopausal women, as well as observational data suggesting cardiovascular benefit, the literature continues to provide contradictory outcomes on this. Electrocardiographic work has suggested that not only the estrogen but also the progestogen component of HRT can have some impact on the electrophysiological properties of the heart (11), the clinical significance of which, if any, is not understood. The picture is further confused by evidence that a particular regimen may initially increase the risk, yet confer long-term benefit, as in the Heart and Estrogen/progestin Replacement Study (HERS), while in other well-planned work, such as the recent Estrogen Replacement and Atherosclerosis trial (ERA), there was no benefit (12).

There has been a randomized trial in 270 postmenopausal women to evaluate the effects on cardiovascular risk markers of two continuous combined estrogen + progestogen replacement products (17-beta-estradiol 1 mg with or without norethindrone acetate 0.25 or 0.5 mg) compared with unopposed estrogen or placebo (13). LDL cholesterol was reduced to a similar extent in all those who took the active treatment (10–14% from baseline). Compared with unopposed 17-beta-estradiol, 17-beta-estradiol plus norethindrone acetate 0.5 mg enhanced the reductions in total cholesterol and apolipoprotein B concentrations. The combination of 17-beta-estradiol plus norethindrone blunted or reversed the increases in concentrations of high-density lipoprotein cholesterol, apolipoprotein A-I, and triglycerides produced by 17-beta-estradiol alone. The effects of 17-beta-estradiol plus norethindrone on hemostatic variables were similar to those of 17-beta-estradiol alone, except for factor VII activity, which was significantly reduced by 17-beta-estradiol plus norethindrone acetate 0.25 and 0.5 mg. The combination of 17-beta-estradiol plus norethindrone blunted reductions in C peptide and insulin concentrations produced by unopposed 17-beta-estradiol, but did not affect them compared with placebo. The authors concluded that 17-beta-estradiol plus norethindrone produced favorable changes in most cardiovascular risk markers and had a profile distinct from that of unopposed estrogen.

The findings of the randomized HERS suggested that in women with clinically recognized heart disease, HRT might be associated with early harm but late benefit in terms of coronary events. The findings of that study seem in the meantime to have been confirmed by some further US work. In one study the histories and subsequent course of 981 postmenopausal women who had survived a first myocardial infarct and had thereafter used estrogen or estrogen + progestogen were examined (14). Relative to the risk in a parallel group of women not currently using hormones there was a suggestion of increased risk during the first 60 days after starting hormone therapy (RR = 2.16; CI = 0.94, 4.95) but of reduced risk with current hormone use for longer than 1 year (RR = 0.76), although the confidence intervals were wide.

However, in a second study, data on 1857 women from the Coumadin Aspirin Reinfarction Study were used to assess the incidence of cardiac deaths or unstable angina as related to the use of HRT. Of the population studied, 524 (28%) had used HRT at some point and 111 of the latter (21%) had started HRT after suffering a myocardial infarct ("new users"). Women who began HRT after their first myocardial infarct had a significantly higher subsequent incidence of unstable angina than women who had never used hormones (39 versus 20%); however, these new hormone users suffered death or recurrence of myocardial infarct at a much lower rate than never-users (4 versus 15%). These differences are striking. Prior/current users had no excess risk of the composite end-point after adjustment. Users of estrogen plus progestogen had a lower incidence of death, infarct, or unstable angina during follow-up than users of estrogen only (RR = 0.56) (15). As Grady and Hulley have commented in an editorial, current data seem to make it clear that "postmenopausal hormone therapy should not be used for the purpose of preventing coronary disease unless future data from well-designed randomized trials document such benefit" (16).

The thrombotic complications of combined HRT in a potentially high-risk group have been assessed in a randomized, multicenter study in the USA in 2763 women, average age 67 years (17). All had some degree of pre-existing coronary heart disease but no previous venous thromboembolism, and none had undergone hysterectomy. They took either conjugated equine estrogens 0.625 mg + medroxyprogesterone acetate 2.5 mg or a placebo. During an average 4.1 years of follow-up, 34 women in the hormone therapy group and 13 in the placebo group had venous thromboembolism (relative risk = 2.7, excess risk = 3.9 per 1000 woman-years). The mean risk for venous thromboembolism was increased among women who had leg fractures (RR = 18) or cancer (RR = 4) and it was also raised several-fold for 3 months after in-patient surgery or non-surgical hospitalization. The risk was approximately halved by the use of aspirin or statins.

Metabolism

Hyperlipidemic postmenopausal women taking combined sequential estrogen + progestogen replacement therapy have large fluctuations in lipid and lipoprotein

© 2006 Elsevier B.V. All rights reserved.

concentrations. These fluctuations depend on the hormonal phase, that is estrogen alone or combined with progestogen. Progestogens blunt or even overwhelm the estrogenic effects on lipoproteins (18).

Progestogen has also been claimed to produce more favorable concentrations of HDL cholesterol (19), but this is a questionable conclusion; most work seems to show that whereas estrogen alone increases HDL concentrations (for example by some 7%), combined treatment weakens this favorable effect and actually can reduce HDL concentrations by some 16%.

Changes in lipids have been observed with both HRT and oral contraceptives and have sometimes been promoted as potentially advantageous, but it is not clear how significant such changes are, at least in biochemical terms. A review and pooled analysis of 248 prospective studies available up to the year 2000 has provided data on this issue in postmenopausal women (20). All estrogen-only regimens raised HDL cholesterol and lowered LDL and total cholesterol. Oral estrogens raised triglycerides. Transdermal 17-beta-estradiol lowered triglycerides. Progestogens had little effect on estrogen-induced reductions in LDL and total cholesterol. Estrogen-induced increases in HDL and triglycerides were opposed according to the type of progestogen in the following order (from least to greatest effect): dydrogesterone and medrogestone, progesterone, cyproterone acetate, medroxyprogesterone acetate, transdermal norethindrone acetate, norgestrel, and oral norethindrone acetate. Tibolone reduced HDL cholesterol and triglyceride concentrations. Raloxifene reduced LDL cholesterol concentrations. In 41 studies of 20 different formulations, HRT generally lowered lipoprotein (a). Thus, the route of estrogen administration and the type of progestogen used determine the effects of HRT on lipid and lipoprotein concentrations.

In another study an estrogen + progestogen combination produced no adverse effects on serum lipids or lipoproteins (21), but this again may depend very much on the exact combination and duration of treatment.

Whatever the truth, the question arises whether the modifications in lipid effects resulting from the addition of progestogen will not interfere with the favorable impact of estrogen on coronary artery disease; there has been some earlier evidence that the combined therapy is rather less effective than plain estrogen in preventing cardiac disorders (SEDA-16, 459).

Female sex hormones can also have effects on lipids when they are given transdermally, and this has been studied retrospectively in 159 women who used transdermal or oral replacement therapy (22). All used either transdermal estradiol 0.05 mg twice weekly or oral conjugated estrogen 0.625 mg/day, each combined with oral medroxyprogesterone acetate 2.5 mg/day. The mean increases in HDL cholesterol in the first year and second year averaged 10 and 31% with oral treatment, the corresponding figures for transdermal therapy being 14 and 34%. With oral therapy the mean reductions in total cholesterol in the first and second years were 2.9 and 15%, and with transdermal treatment 5.6 and 5.7%. With oral treatment, the mean falls in LDL cholesterol in the first and second years were 6.2 and 18% and with transdermal treatment 7.9 and 16% respectively. Transdermal treatment reduced triglyceride concentrations by 34%, whereas oral estrogen treatment increased them by 19% at the end of 2 years. Both treatments changed serum lipids favorably. Nevertheless, triglycerides were increased by oral estrogen but reduced by transdermal treatment at 2 years.

It has been hypothetically suggested that the use of HRT could slow the progression of atherosclerosis by an effect on lipids. In a 1-year study of 321 women with increased thickness of the carotid intima media who were using either various forms of HRT or none at all, there was no slowing in the progression of subclinical atherosclerosis and no unfavorable effect on the process (23). HRT significantly reduced LDL cholesterol, fibrinogen, and FSH.

Reproductive system

Adding a progestogen to estrogen therapy means that regular withdrawal bleeding occurs, probably in some 97% of users up to the age of 60 years. This could explain why such combinations, although increasingly advocated, have not been used on a wider scale; few women relish the prospect of regular "menstrual" bleeding persisting for many years after the menopause, and it might introduce new and unforeseen risks, particularly to the aging uterus. However, on theoretical and practical grounds, such combinations have been developed and used for relatively short periods of treatment during the climacteric itself to regularize bleeding and to relieve menopausal symptoms. The pattern of short-term adverse effects of these products is very similar to that of the combined oral contraceptives.

Some cases have underlined the need to use an estrogen in combination with a progestogen, rather than unopposed estrogen, when treating women who have undergone radical surgery (removal of both the ovaries and uterus) for endometriosis. If unopposed estrogen replacement is given, any residual area of endometriosis will rapidly expand (24).

Continuous administration of an estrogen + progestogen combination is effective in achieving amenorrhea with prolonged use (75% at 6 months). An adverse effect of such a regimen is a high incidence of unpredictable break-through bleeding, particularly during the initial months of treatment (25).

Mammary tension and mastodynia are adverse effects related to the action of estrogens (26). In postmenopausal women estrogen + progestogen replacement therapy can be associated with an increase in mammographic density and with the onset or worsening of mastodynia. Tibolone, a steroid with estrogenic, progestogenic, and some androgenic activity, does not seem to affect breasts of normal structure and can be considered a first-rate replacement therapy in women whose breasts are rather dense or who have benign mastopathy (26).

Various companies and investigational groups continue to examine the relative efficacy and safety of different forms of combined postmenopausal treatment. In a randomized, placebo-controlled trial 579 women were treated for 26 cycles with sequential combinations of 17-beta-estradiol 1 mg plus dydrogesterone 5 or 10 mg or 17-beta-estradiol 2 mg with dydrogesterone 10 or 20 mg (27). The effects of these treatments in the 442 women who underwent biopsy were considered satisfactory in terms of

© 2006 Elsevier B.V. All rights reserved.

cycle control and endometrial response, but the 1 mg dose of 17-beta-estradiol was associated with more intermittent uterine bleeding than the 2 mg dose. Higher doses of dydrogesterone were associated with a higher incidence of cyclical bleeds and a later time of onset.

Long-Term Effects

Tumorigenicity

Breast cancer

The complexity of the relation between hormonal replacement therapy and breast cancer has been stressed in previous volumes (SED-14, 1454) (SEDA-22, 465), and much depends on the type of replacement therapy given and the class of tumor studied. This latter point has been underscored by a US study that provided evidence that the use of combined hormonal replacement therapy increases the risk of lobular, but not ductal, breast carcinoma in middle-aged women (28).

An American cohort study designed to determine whether increases in risk associated with an estrogen + progestogen regimen are greater than those associated with estrogen alone has been carried out based on follow-up data for 1980–1995 from the National Breast Cancer Detection Demonstration Project (29). From 46 355 postmenopausal women, mean age at the start of follow-up was 58 years, 2082 cases of breast cancer were identified. Increases in risk with estrogen only and estrogen + progestogen were restricted to use within the previous 4 years, the relative risks being 1.2 and 1.4 respectively. The relative risk increased by 0.01 with each year of estrogen use and by 0.08 with each year of estrogen + progestogen use. Among women with a BMI of 24.4 kg/m^2 or less, the mean increases in relative risk were 0.03 and 0.12 with each year of estrogen use and estrogen + progestogen use respectively. These associations were evident for the majority of invasive tumors with ductal histology and regardless of the extent of invasive disease. The risk in heavier women did not increase with the use of estrogen only or estrogen + progestogen. These data suggest that estrogen + progestogen increases the risk of breast cancer beyond that associated with estrogen alone.

Endometrial cancer

Because sequential combined hormone replacement therapy with estrogen + progestogen for 10–24 days per month can increase the risk of endometrial cancer in the long run, attention has been devoted to the possibility of giving the two types of hormone continuously. In one retrospective case-control study in the USA it was concluded that the risk of endometrial cancer among users of continuous combined treatment, relative to women who had never used hormone replacement therapy, was 0.6 (95% CI = 0.3, 1.3); the risk relative to women who used intermittent combined therapy was 0.4 (CI = 0.2, 1.1) (30). The authors' conclusions were cautious, since most continuous combined hormonal therapy had been fairly short-term (under 72 months), but the figures suggested that women taking continuous combined hormone replacement therapy for several years were not at an increased risk of endometrial cancer compared with women who had never taken hormone replacement therapy and might in fact be at reduced risk of endometrial cancer.

In the meantime, others have concluded that the risk of endometrial cancer is present, but is less with combined therapy than with unopposed estrogen. However, the picture is not simple; the contradictions could be explained by the fact that risks appear to vary both by usage patterns and by patient characteristics, such as body weight and a history of diabetes (31).

Susceptibility Factors

Genetic factors

In a population-based, case-control study in 232 postmenopausal women who had had a non-fatal myocardial infarct during the previous 3 years, a stratified random sample of 723 postmenopausal women without a history of infarction acted as controls (32). Among hypertensive women, the presence of the prothrombin 20210 G→A variant was a significant risk factor for infarct (OR = 4.32; 95% CI = 1.52, 12) and in this group there was also a significant interaction between the use of HRT and the presence of the prothrombin variant in increasing the risk of infarction. Compared with non-users of HRT with the wild-type genotype, women who were current users and who had the prothrombin variant ($n = 8$) had a nearly 11-fold increase in the risk of a non-fatal myocardial infarct. The interaction was absent among non-hypertensive women. No interaction with HRT was found for factor V Leiden in either hypertensive or non-hypertensive women. These findings suggest that screening for the prothrombin variant may allow a better assessment of the risks and benefits associated with HRT in individual postmenopausal women.

Other features of the patient

While the extent of vaginal bleeding when using estrogens plus progestogens varies somewhat with the exact formulation and dose, another determining factor is the pretreatment state of the endometrium: a thick endometrium at the start of treatment results in significantly more bleeding days than a thin endometrium (33). This might be a helpful predictor of the extent to which a particular woman will find this type of HRT acceptable.

Drug Administration

Drug formulations

The impact of a new formulation of low-dose micronized medroxyprogesterone plus 17-beta-estradiol on lipid profiles in menopausal women has been studied for 12 months. Total cholesterol concentrations fell 8.4%, low-density lipoprotein cholesterol fell 18%, and high-density lipoprotein cholesterol increased 6.9%; total triglycerides increased 12%. The most frequently reported adverse events were menorrhagia, breast tenderness, cervical polyps or cysts, bloating, fatigue or lethargy,

© 2006 Elsevier B.V. All rights reserved.

influenza or a flu-like syndrome, back pain, headaches, irritability, and depression (34).

Drug dosage regimens

In 438 postmenopausal women, randomly assigned to either constant 17-beta-estradiol (1 mg/day) plus inter mittent norgestimate 90 micrograms (3 days off, 3 days on) or a fixed combination of 17-beta-estradiol (2 mg/day) with norethisterone acetate (1 mg), the two regimens had similar bleeding profiles and provided comparable relief from vasomotor symptoms (1). However, breast discomfort and edema were experienced by twice as many subjects who used the fixed combination. The intermittent regimen was notably free of endometrial hyperplasia.

Drug administration route

In an open, non-comparative study, the efficacy of a low dose transdermal estrogen (Oesclim 25 transdermal patches, releasing 17-beta-estradiol 25 micrograms/day) was tested in 60 women with postmenopausal symptoms over 8 weeks (35). The dosage could be doubled if required and sequential treatment with an oral progestogen was also given for 12 days or more each month in all non-hysterectomized women. Of the 60 patients, 53 reacted satisfactorily to the basic dose and all the various treatments were said to be well tolerated. One could cite a dozen similar papers from the recent past in which the findings were so amorphous that they have not made a serious contribution to the evolution of knowledge.

In two multicenter, double-blind, randomized, controlled trials of three once-a-week transdermal systems delivering continuous combined 17-beta-estradiol + levonorgestrel (estrogen 45 micrograms/day + progestogen 15, 30, or 40 micrograms/day) to treat vasomotor symptoms and prevent estrogen-induced endometrial hyperplasia in 1138 women, all were highly effective (36). Reactions at the site of application, vaginal hemorrhage, and breast pain were the most common adverse events, and the proportion of women with amenorrhea increased over time in all the treatment groups.

Drug–Drug Interactions

Statins

With growing interest in the use of statins in women, the question naturally arises whether hormonal replacement could have any effect on their efficacy or safety. Data from the HERS (conducted in women with cardiac disorders) seem to have shown that there is no interaction (37). Estrogen replacement itself resulted in a significant increase in the early risk of primary events in women who did not use statins but not in statin users. Adjustment for statin use after randomization showed no adverse effect of estrogen on the efficacy of statins, in terms of either cardiovascular events or mortality.

Human immunodeficiency virus (HIV) vaccine

See also Vaccines

General Information

The difficult problems connected with clinical trials that have not been approved by independent authorities were highlighted in 1991 when Zagury published the first reports of immunization of humans using *Vaccinia* vaccine expressing HIV glycoprotein gp-160 (1,2). The first HIV vaccine approved for clinical trial status (1989) by the US Food and Drug Administration (FDA) was a recombinant gp-160 vaccine produced in a baculovirus-insect cell expression system by MicroGeneSys (3). Since then, various clinical trials using different HIV vaccines have been carried out. However, all HIV vaccines are still experimental. An overview of the current status of HIV vaccine development, with emphasis on efficacy and safety, has been provided by the AIDS Division of the National Institute of Allergy and Infectious Diseases (4).

Human papilloma virus (HPV) vaccine

See also Vaccines

General Information

Cervical cancer is the second most common cause of cancer deaths in women worldwide and the number one cause in the developing world. It is almost invariably associated with HPV infection. HPV type 16 is found in about 50% of cervical cancers. About 70% of cervical cancers are associated with HPV types 16, 18, and 8 other HPV types. Types 18, 31, and 45 account for 25% of HVP-positive tumors. HPV types 6 and 11 can cause genital warts. The development of a safe and effective HPV vaccine could prevent pre-malignant and malignant disease associated with HPV infection. Various HPV vaccines are under development or are undergoing clinical trials. Among others, GlaxoSmithKline (bivalent HPV types 16 and 18) and Merck (HPV types 6, 11, 16, 18) are both conducting expanded phase III trials and the researchers say the results so far have been promising. Merck plans to apply for approval to the US Food and Drug Administration in late 2005.

Clinical studies with a recombinant vaccine (using *Vaccinia* virus expressing HPV 16, 18, E6, and E7 proteins) in patients with preinvasive and invasive cancer have been reviewed (1).

Observational studies

There has been a trial of a papilloma (HPV-16) virus-like particle vaccine in 72 healthy volunteers, aged 18–27 years (2). The vaccine was well tolerated and highly immunogenic.

Placebo-controlled studies

In a double-blind study in 2392 young women (aged 16–23 years) randomly assigned to either three doses of placebo or HPV-16 vaccine at day 0, month 2, and month 6, the vaccine reduced the incidence of both HPV-16 infection (3.8 per 100 woman-years at risk in the placebo group versus 0 per 100 woman-years at risk in the vaccine group) and HPV-16-related cervical intraepithelial neoplasia (all nine cases of neoplasia occurred among the placebo recipients) (3).

Hyaluronic acid

General Information

Hyaluronic acid is a naturally occurring polysaccharide that is widely distributed in body tissues and intracellular fluids, including the aqueous and vitreous humour, synovial fluid, and in the ground substance that surrounds cells (1). It is a high-molecular weight substance originally developed for use as a vitreous replacement. Although 98% of the product consists of water, it is very viscoelastic.

Uses

Hyaluronic acid is considered to have low inflammatory and antigenic potential, and has been used in various intraocular procedures. In addition to filtration bleb formation, it has been used to protect the corneal endothelium during intraocular lens implantation and keratoplasty, to reform the anterior chamber, to push back a bulging vitreous face, and in retinal detachment surgery as a vitreous replacement.

Hyaluronate sodium is also combined with sodium chondroitin sulfate (in Viscoat) as a corneal transplant preservation medium. Sodium chondroitin sulfate and other viscoelastic substances protect the corneal endothelium during intraocular surgery.

Hyaluronic acid is used topically to promote wound healing. A film containing hyaluronate sodium and carmellose is used to prevent surgical adhesion. Hyaluronic acid is increasingly being used in cosmetic dermatology to treat wrinkles in patients who are sensitive to bovine collagen.

Intra-articular injections of hyaluronic acid formulations of different molecular weights have been used in patients with osteoarthritis and can provide short-term benefit (2).

General adverse effects

The major adverse effect associated with the use of viscoelastic substances, such as hyaluronate sodium, is a transient rise in intraocular pressure in the immediate postoperative period, attributed to its viscoelastic nature, resulting in coating and plugging of the trabecular meshwork. For this reason, it is advisable to dilute hyaluronate sodium at the end of the surgical procedure with a balanced salt solution. Chondroitin sulfate is relatively less likely to precipitate such extreme rises in intraocular pressure because it is cleared rapidly from the trabecular meshwork. However, with any technique or chemical used in surgery there is always the potential for an unexpected adverse effect, and the risks of Viscoat include subepithelial calcium deposition and keratopathy (3).

After intra-articular injection, sodium hyaluronate can cause hemarthrosis, increased joint effusion volume, and possibly phlebitis. Other adverse effects are joint pain,

© 2006 Elsevier B.V. All rights reserved.

septic arthritis, acute pseudogout, and anaphylaxis (4,5). Adverse events of this route of administration reportedly occur in about 2–4% of patients (6).

Organs and Systems

Skin

- An exudative granulomatous reaction started 2 days after the injection of hyaluronic acid (Hylaform) (dose not stated) for perioral wrinkles (7). The eczematous papular skin changes disappeared completely within 6 weeks, and could be provoked by intracutaneous testing with Hylaform (dose not stated). Histological examination showed a foreign body granuloma.

Immunologic

Immediate and delayed hypersensitivity reactions have been reported with hyaluronic acid (8).

Hycanthone

General Information

Hycanthone is a derivative of lucanthone, but has less gastrointestinal and nervous system toxicity. It is effective against both *Schistosoma hematobium* and *Schistosoma mansoni* and is given as a single intramuscular injection in doses of 1.0–2.5 mg/kg (1,2). However, it has largely been superseded in the treatment of schistosomiasis by more recent, less toxic compounds. The most common adverse reactions to hycanthone, which occur in up to half of all patients treated with higher-dose regimens, is nausea and vomiting (3), often associated with abdominal colic and diarrhea. There can be muscle pain, and electrocardiographic changes can occur (4).

Organs and Systems

Liver

Hepatotoxicity occurs with hycanthone; serum transaminases are often raised and less commonly there is overt jaundice (5,6). Hepatitis was the major complication with hycanthone in the treatment of schistosomiasis, sometimes associated with pancreatitis (7,8). Hycanthone has also been evaluated as a potential antitumor agent, being used as a radiosensitizer; here too, hepatitis was a dose-limiting effect, occurring in some patients with doses of 100 mg/m2 per day (3). The lowest dosage that caused hepatitis was 70 mg/m2/day. In several cases the hepatotoxicity proved fatal (SED-11, 597) (7–9).

Long-Term Effects

Mutagenicity

Experimentally, hycanthone has been reported to be mutagenic in *Salmonella typhimurium* and *Escherichia coli*, but no human data are available (10,11).

Tumorigenicity

Experimentally, hycanthone has been reported to be carcinogenic in mice (12,13), but no human data are available.

Second-Generation Effects

Teratogenicity

Experimentally, hycanthone has been reported to be teratogenic (14,15), although no human data are available.

Hydralazine

General Information

Hydralazine is a direct vasodilator that acts on vascular smooth muscle to produce systemic vasodilatation. As a result there is baroreceptor-mediated activation of the sympathetic nervous system and the renin–angiotensin system.

Vasodilators (as monotherapy) are associated acutely with flushing, headache, dizziness, reflex tachycardia, and palpitation. Chronic treatment can be complicated by fluid retention.

Organs and Systems

Cardiovascular

Aggravation of angina, presumably as a result of reflex tachycardia, has been reported with hydralazine.

- Pericarditis has been attributed to hydralazine in a 75-year-old man who developed a full-blown hydralazine-induced autoimmune syndrome (1).

The authors referred to a similar previously published case of late pericarditis after hydralazine treatment.

Nervous system

Peripheral neuropathy has been described in association with deficiency of pyridoxine (vitamin B6) in slow acetylators (2).

Metabolism

Salt and water retention mediated by secondary hyperaldosteronism can complicate hydralazine treatment, leading to weight gain and peripheral edema, loss of blood pressure control, and rarely cardiac failure (SED-8, 474).

Gastrointestinal

Anorexia, nausea, and vomiting can complicate hydralazine treatment, particularly initially (SED-8, 474).

Liver

Acute hepatitis (usually with negative antinuclear antibodies) has been attributed to hydralazine (3–7).

Skin

- A 44-year-old man taking hydralazine (dose not stated) developed a pruritic rash, attributed to a drug-induced lichenoid eruption, based on biopsy findings (8). The hydralazine was withdrawn and the rash resolved in a few weeks.

Immunologic

The lupus-like syndrome (SED-9, 318) with hydralazine occurs particularly in slow acetylators (and only rarely in fast acetylators) and in patients with the HLA-DR4 antigen. Blood dyscrasias and necrotizing vasculitis are additional features.

Current knowledge about the possible mechanisms of drug-induced lupus-like syndrome has been reviewed (9). Three mechanisms seem most plausible. One involves a change, possibly caused by a reactive metabolite, in the way that antigens are processed and presented to T cells, leading to the presentation of cryptic antigens. Another possibility is that a reactive metabolite binds to the class II major histocompatibility antigen and induces an autoimmune reaction analogous to a graft-versus-host reaction. A third possibility is that hydralazine inhibits DNA methylation, leading to an increase in DNA transcription and a generalized activation of the immune system.

A variety of vasculitic diseases, including Wegener's granulomatosis, microscopic polyangiitis, Churg–Strauss syndrome, and crescentic glomerulonephritis, are associated with antineutrophil cytoplasmic antibodies (ANCA) or leukocytoclastic vasculitis. In drug-induced ANCA-positive vasculitis, antimyeloperoxidase antibodies are most often found; they produce a perinuclear pattern of staining by indirect immunofluorescence (pANCA), but antiproteinase 3 (anti-PR3) antibodies can also occur (cANCA).

The possible drug causes of ANCA-positive vasculitis with high titers of antimyeloperoxidase antibodies in 30 new patients have been reviewed (10). The findings illustrate that this type of vasculitis is a predominantly drug-induced disorder. Only 12 of the 30 cases were not related to a drug. The most frequently implicated drug was hydralazine (10 cases); the remainder involved propylthiouracil (3 cases), penicillamine (2 cases), allopurinol (2 cases), and sulfasalazine.

© 2006 Elsevier B.V. All rights reserved.

Second-Generation Effects

Fetotoxicity

Thrombocytopenia has been reported in infants whose mothers were taking hydralazine with no evidence of the lupus-like syndrome (11).

The administration of hydralazine 25 mg bd at 34 weeks to a hypertensive pregnant woman was associated, within 1 week, with atrial extra beats in the fetus. These subsided when hydralazine was withdrawn, and the rest of the pregnancy and delivery was uneventful (12).

- A 29-year-old woman, 26 weeks pregnant, was treated with hydralazine for toxemia of pregnancy. She developed arthralgia and dyspnea and was subsequently found to be antinuclear antibody-positive. Following an induced labor, a low-birth-weight infant was born but died aged 36 hours. At autopsy the neonate was found to have a pericardial effusion and tamponade (13).

Although hydralazine was implicated as the cause of a maternal and neonatal lupus-like syndrome, the toxemia and low birth weight of the child make interpretation of the case difficult.

Hydrazine

General Information

Hydrazine sulfate is sometimes promoted as an alternative cancer cure.

Organs and Systems

Liver

Hydrazine has been reported to cause liver damage (1).

- A 55-year-old man with maxillary sinus cancer declined conventional therapy and opted to treat his condition with hydrazine sulfate obtained via the Internet. He had followed the recommended regimen for 4 months when he developed fulminant hepatorenal failure, hepatic encephalopathy, and profound coagulopathy. He died of severe gastrointestinal hemorrhage.

Hydrocodone

See also Opioid analgesics

General Information

Hydrocodone is a semisynthetic narcotic analgesic and a cough suppressant, similar to codeine. It is metabolized to the *O*- and *N*-demethylated products, hydromorphone and norhydrocodone (1).

Drug Administration

Drug administration route

Five patients who abused prescribed opioids intranasally have been described (2). All took hydrocodone bitartrate plus cocaine ($n = 2$), codeine phosphate ($n = 2$), oxycodone hydrochloride ($n = 2$), or methadone hydrochloride ($n = 1$). The symptoms included nasal obstruction and congestion, foul smelling nasal crusting and discharge, headaches and nasal pain, and in one case dysphagia with odynophagia. Physical findings included a perforated septum, soft palate erosion, and a mucopurulent exudate. All except one patient had positive fungal cultures and two had invasive rhinitis. Not only can intranasal opioids cause septal perforation, commonly associated with intranasal cocaine, but it is also possible that intranasal abuse of opioids, especially hydrocodone, can cause localized immunosuppression, supporting the growth of fungal organisms.

Hydromorphone

See also Opioid analgesics

General Information

Intolerable adverse effects or inadequate analgesia occur in 10–15% of patients with chronic pain given continuous intrathecal morphine. Hydromorphone is a semisynthetic derivative of morphine used extensively in the management of cancer pain. It is more soluble than morphine, has a slightly shorter duration of action, and is about five times more potent when given systemically.

In a retrospective review of 37 patients with chronic non-malignant pain (mostly from failed lumbosacral spine surgery) treated with intrathecal hydromorphone there was an analgesic response in six of the 16 patients who were switched from morphine to hydromorphone because of poor pain relief (1). Opioid-related adverse effects, such as nausea, vomiting, pruritus, and sedation, were also reduced by hydromorphone in the 21 patients who were switched to hydromorphone because of morphine-related adverse effects, especially 1 month after use. These results should be treated cautiously, because of the limitations of a retrospective study that lacks strict inclusion criteria, with obvious population bias and under-reporting, and without standardized procedures for rotation to hydromorphone.

Three randomized, double-blind comparisons of morphine and hydromorphone have been reported. Modified-release hydromorphone hydrochloride 4 mg bd was compared with modified-release morphine sulfate 30 mg bd in 89 patients with cancer pain (2). In all, 88 adverse effects were thought to be directly related to the study medication. Other adverse events were related to the disease process, the re-emergence of pain, or not specified.

In a comparison of hydromorphone and morphine delivered by continuous subcutaneous infusion in 74 patients with severe cancer pain, the number of adverse effects was small and comparable in both groups (3).

When epidural morphine (Duramorph 10 micrograms/kg/hour) was compared with epidural fentanyl (1 microgram/kg/hour) and epidural hydromorphone (1 microgram/kg/hour) in 90 children undergoing orthopedic procedures, hydromorphone was considered to be safe and efficacious (4). The combined incidences of pruritus, nausea, and vomiting were 25, 20, and 10% respectively and for pruritus alone 35, 15, and 8% respectively.

Organs and Systems

Sensory systems

In a retrospective review in a specialized otological center, 12 patients were identified with rapidly progressive hearing loss and a concurrent history of hydrocodone overuse with paracetamol (5). These patients were helped by cochlear implantation.

Drug Administration

Drug administration route

The use of intrathecal hydromorphone in the management of chronic non-malignant pain has been described (1).

Hydroxycarbamide

See also Cytostatic and immunosuppressant drugs

General Information

Hydroxycarbamide (hydroxyurea) is used to treat a variety of cancers, myeloproliferative disorders, and sickle cell disease, and has been studied in patients with HIV infection (1). It inhibits ribonucleotide reductase and increases concentrations of iron nitrosyl hemoglobin, nitrite, and nitrate, suggesting in vivo metabolism of hydroxycarbamide to nitric oxide (2).

Organs and Systems

Hematologic

Concern about the toxicity of hydroxycarbamide, expressed in a report from the AIDS Clinical Trials Group (ACTG 5025 report), has led to a retrospective study of the antiviral activity, immunological effects, and

© 2006 Elsevier B.V. All rights reserved.

tolerability of hydroxycarbamide in combination with didanosine (3). Hematological adverse events were the most frequent and involved 37 of the 65 patients. Neutropenia was the commonest adverse event (26 patients) and it was occasionally accompanied by anemia or thrombocytopenia. However, these effects normalized spontaneously, despite continued therapy.

Of 16 children receiving hydroxycarbamide in combination with nucleoside analogues, 4 developed neutropenia (below 1.5×10^9/l) by weeks 2 or 4 (4). Hydroxycarbamide was temporarily withdrawn and then reintroduced without further ill effects after the neutrophil count had returned to normal.

Mouth and teeth

In a retrospective study of the antiviral activity, immunological effects, and tolerability of hydroxycarbamide in combination with didanosine, mouth ulceration was recorded in eight of the 65 patients and this led to discontinuation in one patient (3).

Pancreas

In a retrospective study of the antiviral activity, immunological effects, and tolerability of hydroxycarbamide in combination with didanosine, there was increased serum amylase activity in 15 of the 65 patients; although asymptomatic, it occasioned withdrawal of therapy in four patients (3).

Skin

The incidence of skin lesions in patients taking hydroxycarbamide is 10–35%. They usually occur after several years of maintenance therapy. However, one patient developed lichen planus-like dermatitis on his hands after just 15 days of treatment (5).

Hydroxycarbamide can cause hyperpigmentation of the nails and palmar creases and leg ulcers (6,7). Leg ulcers occurred in 41 patients taking hydroxycarbamide (8). They had a mean age of 67 years and mean therapy duration of 5 years, and none had any underlying vascular disease. There were megaloblastic erythrocytes trapped in the capillary beds, causing local tissue anoxia, and the authors postulated that the megaloblastic erythrocytes had resulted from hydroxycarbamide and that the ulcers were due to consequent impaired circulation and cutaneous atrophy; they also commented that there was no major vascular disease that could have accounted for the leg ulcers. The degeneration of lichen planus-like skin lesions into full-blown ulcers has been described in 14 patients who developed extremely painful leg ulcers, most commonly on the malleoli. The patients had been taking hydroxycarbamide for an average of 6 years and nine had multiple ulcers (9).

Acral erythema, dermatomyositis-like changes on the backs of the hands, squamous cell neoplasms on sun-exposed sites, and ulcers on the legs, genitalia, and oral mucosae have also been reported (10).

Immunologic

Hydroxycarbamide has been associated with Behçet's syndrome (11).

Body temperature

- A 64-year-old woman with essential thrombocythemia developed a fever after 3 weeks of treatment with hydroxycarbamide 1000 mg/day; the fever subsided on withdrawal and recurred on rechallenge (12).

Drug–Drug Interactions

Busulfan

During long-term follow-up of patients treated with busulfan and hydroxycarbamide for essential thrombocythemia, seven patients (13%) taking hydroxycarbamide developed secondary acute leukemia, myelodysplasia, or solid tumors, compared with only one of the control group; none of the 20 patients who had never been treated with chemotherapy developed secondary malignancies compared with three of the 77 given hydroxycarbamide only and five of the 15 given busulfan plus hydroxycarbamide. This suggests that the combination of busulfan plus hydroxycarbamide causes a significantly increased risk of secondary malignancies (13).

Hydroxyzine

See also Antihistamines

General Information

Hydroxyzine is a first-generation antihistamine, a piperazine derivative, with antimuscarinic and sedative properties.

Organs and Systems

Skin

Two cases of drug allergy have been reported in a 37-year-old woman and a 66-year-old man, who received hydroxyzine for premedication before anesthesia (1,2). In these patients immediate skin tests with the implicated drug were positive.

Second-Generation Effects

Fetotoxicity

Hydroxyzine used in a fairly high dose (600 mg/day) in pregnancy has been reported to produce a neonatal withdrawal syndrome after delivery; this was characterized primarily by hyperactivity and irritability (SEDA-2, 151).

References

Hyoscine

See also Anticholinergic drugs

General Information

Hyoscine is an anticholinergic drug, a stereoisomer of atropine. It is available in different salts, hyoscine hydrobromide and hyoscine butylbromide.

When given parenterally hyoscine butylbromide is effective but very short-acting; when given by mouth it is virtually inactive, even in doses up to 1 g, since it is hardly absorbed.

Hyoscine hydrobromide is used primarily in motion sickness; doses of 0.6 mg appear to be effective, particularly in combination with drugs having a mild central stimulant effect such as ephedrine.

Organs and Systems

Nervous system

Despite being a stereoisomer of atropine, hyoscine tends to have central depressant effects in conditions where atropine might be expected to cause excitation; however, excitation can occur (1). Hyoscine hydrobromide produces somnolence and dryness of the mouth in a high proportion of patients, and when ephedrine is not given the somnolence is likely to be present in the majority; some individuals also have headache, giddiness, and blurred vision.

Transdermal hyoscine is used by some anesthetists to minimize postoperative nausea and vomiting. The safety and efficacy of this form of treatment has been reviewed in an analysis of data from 23 trials involving 979 patients treated with hyoscine and 984 with placebo (2). The authors concluded that of 100 patients who are treated with hyoscine, 17 will escape postoperative nausea and vomiting that would otherwise have occurred; however, 18 will have visual disturbances, 8 will complain of dry mouth, 2 of dizziness, and 1 will become agitated. Although these are not necessarily prohibitive problems, they certainly do need to be considered when choosing a drug for this indication.

Psychological, psychiatric

In one study hyoscine premedication had detrimental effects on memory and on motor tasks compared with placebo, while atropine did not (3), although the difference is unlikely to be absolute. In view of certain of these effects, hyoscine hydrobromide is not a suitable antiemetic for those likely to drive vehicles before the effect has worn off, for example air passengers.

Immunologic

An isolated case of angioedema has been described during the use of hyoscine butylbromide (SEDA-8, 148).

Second-Generation Effects

Pregnancy

Two Japanese primigravidae, aged 25 and 28 years, developed the HELLP syndrome, a severe variant of pre-eclampsia in which there is Hemolysis, Elevated Liver enzymes, and a Low Platelet count (4). They were given parenteral hyoscine butylbromide for abdominal pain and had seizures 60–90 minutes later. One died from intracerebral hemorrhage some days later and the other survived after a cesarean section soon afterward. The authors speculated that anticholinergic drugs may enhance sympathetic nervous system activity, and in particular vasoconstriction, and should be avoided in pre-eclampsia. It is not clear how widespread their use is

© 2006 Elsevier B.V. All rights reserved.

in other countries in managing abdominal pain in these circumstances.

Drug Administration

Drug administration route

A transdermal delivery system has been developed for prevention of motion sickness and vomiting, using an adhesive patch for postauricular application; the drug is released at a uniform rate for 72 hours. The adverse effects of this formulation are qualitatively typical of those reported for the oral and parenteral formulations of hyoscine and its congeners, although comparative studies suggest that the incidence is reduced with transdermal administration. Nevertheless, adverse effects involving the central nervous system, vision, bladder, and skin have been described, as have withdrawal symptoms after the patch is removed.

Dry mouth occurs in about 67% of subjects and drowsiness in about 16%. Transient effects on ocular accommodation, including blurred vision and mydriasis, have also been observed, in some cases possibly due to finger-to-eye contamination. Adverse effects on the central nervous system, including toxic psychosis (5) and hallucinations, have been reported only occasionally, as have other adverse reactions, such as dry, itchy eyes, difficulty in urinating, rashes, and erythema (6).

Attention has been drawn to potentially confusing clinical signs that can occur if a patch is applied for its antiemetic effect before general anesthesia; in one case the patient developed a right fixed pupil and became uncooperative; intravenous physostigmine had to be administered (SEDA-22, 157).

Ibopamine

General Information

Ibopamine is an orally active dopamine derivative that has been studied in patients with congestive heart failure (1). In theory, most, if not all, of the reported adverse effects can be considered to result from the drug's known pharmacological actions. Its gastrointestinal effects can be interpreted as being dopaminergic in nature, the occasional dizziness, flushing, and tremor as beta$_2$-adrenoceptor agonist effects, the tachycardia as an effect of beta$_1$-adrenoceptor stimulation or a reflex response to beta$_2$-adrenoceptor agonism. A reversible leukopenia has been described, but the relation to the drug was uncertain (2).

Ibritumomab

See also Monoclonal antibodies

General Information

Ibritumomab is a murine IgG$_1$ anti-CD20 antibody, the parent of the engineered chimeric antibody rituximab, a monoclonal antibody with mouse variable and human constant regions. It induces apoptosis and has antiproliferative effects. Ibritumomab tiuxetan (Zevalin) is composed of the monoclonal antibody ibritumomab, the linking chelator tiuxetan, and the radioisotope ^{90}yttrium (1).

General adverse effects

A wide range of adverse effects of ibritumomab has been reported. Most were hematological, thrombocytopenia being the most common, followed by a low hemoglobin and leukopenia. The most common non-hematological events were related to infusion and were similar to those reported with rituximab; they included weakness (54%), nausea (35%), chills (15%), and fever (21%) (2,3). Infectious complications during treatment with ibritumomab are rare, pneumonia being the most common. There is no obvious hepatotoxicity.

Organs and Systems

Immunologic

There has been one report of an anti-antibody response to ibritumomab (2).

Long-Term Effects

Tumorigenicity

Acute myelogenous leukemia has been attributed to ibritumomab (4).

- An 80-year-old woman with a small B cell extranodal lymphoma was initially given chlorambucil for 10 months, with complete remission for 2 years. When she developed recurrent lymph node swelling she was given ibritumomab tiuxetan, with near-complete remission. When she developed progressive disease 14 months later, she received cyclophosphamide, vincristine, and prednisone for one cycle. She had persistent pancytopenia, and a bone marrow biopsy showed extensive infiltration by acute myelogenous leukemia.

This seems to be the first case of drug-related acute myelogenous leukemia. Fluorescent in-situ hybridization studies on the bone marrow showed a signal consistent with rearrangement of the mixed myeloid leukemia (MLL) gene on chromosome 11. This abnormality was not present before treatment.

Ibuprofen

See also Non-steroidal anti-inflammatory drugs

General Information

Like other NSAIDs, ibuprofen is a potent inhibitor of prostaglandin synthesis, and many or all of its therapeutic and toxic effects are linked to this characteristic. The general impression is that it is less potent and thus less toxic than indometacin in usual doses, but it has often been used in the past in relatively low doses. In a comparative, double-blind, crossover study of ibuprofen, naproxen, fenoprofen, and

© 2006 Elsevier B.V. All rights reserved.

tolmetin in patients with rheumatoid arthritis, ibuprofen in equieffective doses was the best tolerated; however, patients and physicians preferred naproxen (1).

There are few data on the long-term safety of NSAIDs in the treatment of juvenile rheumatoid arthritis. In a study of the adverse reactions of patients treated with long-term ibuprofen, gastrotoxicity was directly correlated with dosage and 5% withdrew early because they had gastrointestinal bleeding, vomiting, severe rash, hearing loss, and abnormalities of liver function tests (SEDA-16, 110).

High dosages of ibuprofen for 4 years were used in 41 patients with cystic fibrosis to slow progression of lung disease and only two adverse effects (conjunctivitis and epistaxis) were drug-related (SEDA-20, 93).

General adverse reactions

Gastrointestinal adverse effects are the most frequent. They occur in up to 30% of patients and range from abdominal discomfort to serious bleeding or activation of peptic ulcer. Nervous system effects, with headache and dizziness, are very common. Severe renal impairment has not been noted. Blood dyscrasias can occur when high dosage treatment is prolonged. There is no significant general hepatotoxicity, but both the liver and the central nervous system (meningitis) can be affected as part of a hypersensitivity reaction.

Hypersensitivity reactions are uncommon, but they can be severe. Aseptic meningitis, hypotension, fever, conjunctivitis, arthralgias, and leukopenia were reported in a woman with systemic lupus erythematosus (2). Other similar patients have experienced fever with rashes, abdominal pain, headache, nausea and vomiting, signs of liver damage, and meningitis. This type of reaction seems to occur especially (but not exclusively) in patients with connective tissue diseases (SEDA-5, 105) (SEDA-10, 84) and it can be difficult to differentiate between a hypersensitivity reaction and a flare-up of the disease. Ibuprofen can provoke bronchospasm and anaphylaxis in asthmatics (SEDA-22, 116).

Tumor-inducing effects have not been reported.

Organs and Systems

Cardiovascular

Apart from the consequences of salt and water retention, ibuprofen does not affect myocardial or vascular function. Congestive heart failure has rarely been reported (3).

In a small comparison of ibuprofen and indometacin in preterm infants with patent ductus arteriosus there was no apparent difference in the rate of patent ductus arteriosus closure; ibuprofen did not impair cerebral hemodynamics or oxygenation, while indometacin impaired cerebral oxygen delivery (4).

Respiratory

Ibuprofen rarely provokes attacks of asthma in predisposed individuals. There is probably cross-sensitivity with aspirin; a death was reported after an asthmatic patient with no history of aspirin sensitivity took two ibuprofen tablets (SEDA-12, 86).

Pulmonary infiltrates with eosinophilia have been described with ibuprofen (SEDA-18, 104).

Two episodes of acute pulmonary edema and progressive pulmonary infiltrates without eosinophilia have been reported in a man with HIV infection after ibuprofen (SEDA-18, 104).

Nervous system

Headache, vertigo, tinnitus, and insomnia are the most frequent nervous system effects, but are rarely severe. Depression and other psychotic reactions have been reported. Some nervous system reactions (meningism and meningitis, lethargy, and irritability) are thought to result from hypersensitivity (SEDA-9, 91) (SEDA-18, 104) (5). This has been confirmed by a report of aseptic meningitis with increased intrathecal IgG synthesis and evidence of immune complexes in the cerebrospinal fluid (SEDA-16, 110).

Analgesic-induced headache, not uncommon in adults, has also been described in children. One report (6) described 12 children, aged 6–16 years, who gave a history of headaches on at least 4 days a week, for 3 months to 10 years. Eleven of the children had been taking paracetamol, six in combination with codeine, and one was taking ibuprofen alone. They were taking at least one dose of an analgesic for each headache and eight were taking analgesics every day. The headaches presented with increasing frequency and were related to overuse of analgesics, a typical finding in analgesic-induced headache. The analgesics were withdrawn; in six children the headaches resolved completely, another five children experienced a reduced frequency of headaches, and one resumed analgesic abuse.

The second report (7) was a retrospective study of patients seen in a pediatric headache clinic. During 8 months 98 patients were seen for headache; 46 of them suffered from daily or near daily headache and 30 were consuming analgesics daily. Follow-up information was available in 25. The average number of doses of analgesics per week they consumed was 26. The most commonly used medications were paracetamol and ibuprofen. In addition, a minority were taking combinations that contained aspirin, codeine, caffeine, propoxyphene, or butalbital, or other NSAIDs. Abrupt withdrawal of all analgesics concomitant with the use of amitriptyline 10 mg/day (in 22 patients) prompted a significant reduction in the frequency and severity of headache.

Sensory systems

Ocular reactions described to date are reversible and not severe. They include blurred vision, changes in color perception, and toxic amblyopia (8).

Ibuprofen significantly correlated with high-altitude retinal hemorrhages (SEDA-17, 110).

Vortex keratopathy has been described in a woman taking oral ibuprofen (SEDA-21, 105).

Metabolism

An increase in serum concentrations of uric acid has been described with ibuprofen (9).

Hematologic

Ibuprofen prolongs bleeding time, although less than aspirin (10). There are reports that a daily dose of less than 1 g does not affect the bleeding time (11).

© 2006 Elsevier B.V. All rights reserved.

Blood dyscrasias, ranging from thrombocytopenia and granulocytopenia to agranulocytosis and fatal pancytopenia, have been reported. (SED-9, 150). Reversible pure white cell aplasia with bone marrow plasmacytosis and complement-dependent IgG antibody has been observed in one patient (12).

Fatal autoimmune hemolytic anemia has been attributed to ibuprofen in a patient who was taking other drugs (13). Reversible hemolytic anemia has been described during ibuprofen treatment, but tartrazine, the orange dye in the coating of the brand used (Motrin 400), may have been responsible (14).

Gastrointestinal blood loss due to ibuprofen can cause iron deficiency anemia.

Gastrointestinal

When ibuprofen was first introduced, its gastrointestinal tolerance was regarded as better than with other NSAIDs, especially aspirin and indometacin. However, with the use of higher doses, which were probably equipotent with the usual doses of older agents, there seemed to be no significant differences. As with other NSAIDs there is a close correlation between efficacy and adverse effects. Gastrointestinal adverse effects include a variety of symptoms, such as irritation, nausea, anorexia, vomiting, dyspepsia, heartburn, abdominal discomfort, bleeding, hematemesis, and activation of peptic ulcer; 10–30% of patients taking prescription doses (for example for rheumatic conditions) develop these adverse effects (SED-9, 150) (15). It is not possible to give a reliable estimate of the frequency when the drug is used as a self-medication analgesic in lower doses, since exact information on the complications of self-medication is rarely available and there is always likely to be a proportion of misuse (for example ingestion of higher or lower doses than recommended).

Bleeding from a Meckel's diverticulum has been described with oral ibuprofen (SEDA-17, 110).

Irritation of the rectal mucosa after ibuprofen suppositories has also been reported (16). Ulcerative proctitis has been reported in a patient with systemic lupus erythematosus (SEDA-14, 94).

Liver

Ibuprofen is not directly hepatotoxic, but the liver can be damaged as part of a generalized hypersensitivity reaction. Toxic hepatitis with Stevens–Johnson syndrome has been described (17).

Ibuprofen has been rarely thought responsible for liver damage. A recent report has described three patients, 33–44 years old, with chronic hepatitis C infection who developed more than five-fold increases in serum liver transaminases after taking ibuprofen for musculoskeletal pain. In all three there were no associated symptoms of hepatitis, and serum transaminases normalized after ibuprofen was withdrawn (18).

Biliary tract

The vanishing bile duct syndrome has been associated with the use of ibuprofen in an atopic man, but the causal relation was not certain (19).

Urinary tract

Ibuprofen can cause renal impairment, ranging from an insignificant reduction to an acute fall in creatinine clearance associated with a general hypersensitivity reaction, especially in patients with systemic lupus erythematosus or acute tubular necrosis (20). The nephrotic syndrome without renal insufficiency and acute interstitial nephritis without the nephrotic syndrome have been described after self-administration of over-the-counter ibuprofen (SEDA-12, 86).

Irreversible renal insufficiency due to acute cortical necrosis triggered by severe renal hypoperfusion has been reported (SEDA-12, 86). A pharmacokinetic study showed that conversion of inactive *R*-ibuprofen to active *S*-ibuprofen was greater in patients with renal impairment than in healthy controls; this may aggravate renal insufficiency (21).

Acute deterioration in renal function can occur also in other at-risk patients, such as those with renal transplants (22,23).

Skin

Skin rashes usually occur during general hypersensitivity. Urticarial, purpuric, and erythematous changes with pruritus have been reported (15). Bullous pemphigoid has been described after 6 months of treatment and was observed in two other patients on ibuprofen (SEDA-14, 94). Photosensitization has been attributed to ibuprofen (SEDA-17, 110). The association between ibuprofen and dermatological superinfection in children with recent *Varicella* infection has not been demonstrated in a retrospective cohort study (SEDA-22, 116).

Ibuprofen exacerbates psoriasis (SEDA-12, 86) (SEDA-7, 108) (SEDA-8, 102).

Hair

Alopecia has been described in black women; normal hair growth returned after therapy was stopped (SED-11, 183) (24).

Immunologic

Anaphylaxis after ibuprofen was reported in a patient with asthma who was also taking zafirlukast, a leukotriene receptor antagonist (SEDA-22, 116).

Susceptibility Factors

Age

The controversy over the use of ibuprofen as an antipyretic or analgesic is still open and the question of whether it is safer than paracetamol in children has not been answered (SEDA-16, 110) (SEDA-17, 110) (SEDA-19, 96).

Other features of the patient

In patients with a history of peptic ulcer or systemic lupus erythematosus the benefit-to-harm balance must be evaluated before prescribing ibuprofen. The first group is in danger of ulcer exacerbation and the second of a severe generalized hypersensitivity reaction.

© 2006 Elsevier B.V. All rights reserved.

Drug Administration

Drug formulations

Modified-release formulations seem to cause the same adverse effects as conventionally formulated ibuprofen (25), and four-times-daily treatment is better tolerated than twice-daily (SEDA-12, 86).

Ibuprofen lysine is more rapidly absorbed than ibuprofen free acid, but the comparative tolerability of the two formulations is not known (SEDA-20, 93).

Drug overdose

In spite of the large number of prescriptions and over-the-counter sales, acute intoxication is rare. Symptoms are usually limited to nausea and vomiting, but more severe cases of coma, acidosis, mild hypothermia, renal insufficiency, and acute papillary necrosis have been described (SEDA-12, 86) (SEDA-22, 116). Treatment is supportive (SEDA-9, 81).

Drug–Drug Interactions

Aminoglycoside antibiotics

High-dose ibuprofen can slow the progression of lung disease in patients with cystic fibrosis and is usually well tolerated (SEDA-20, 93). However, transient renal insufficiency developed in four children with cystic fibrosis who were taking maintenance ibuprofen when an intravenous aminoglycoside was added to their regimen to treat an exacerbation of lung disease (26). Ibuprofen should probably be stopped during intravenous aminoglycoside therapy.

Antihypertensive agents

Ibuprofen interacts with antihypertensive agents, reducing their efficacy (27).

Aspirin

Patients with arthritis and vascular disease sometimes take both low-dose aspirin and other NSAIDs. However, concomitant treatment with ibuprofen can limit the cardioprotective effects of aspirin, according to the results of a study of the effects of ibuprofen, diclofenac, coxibs, and paracetamol on the antiplatelet activity of aspirin (28). The following combinations of drugs were used: aspirin (81 mg every morning) 2 hours before ibuprofen (400 mg every morning) or in the reverse order; aspirin 2 hours before rofecoxib (25 mg every morning or in the reverse order); enteric-coated aspirin 2 hours before ibuprofen (400 mg tds); and enteric-coated aspirin 2 hours before modified-release diclofenac (75 mg bd). Inhibition of the formation of serum thromboxane B2 (an index of COX-1 activity in platelets) and platelet aggregation by aspirin was blocked when a single daily dose of ibuprofen was given before aspirin, as well as when multiple daily doses of ibuprofen were given. Diclofenac, paracetamol, and rofecoxib did not affect the pharmacodynamics of aspirin. These results suggest that ibuprofen, but not diclofenac, paracetamol, or rofecoxib, antagonizes the irreversible inhibition of platelet COX-1 by aspirin and can therefore limit the cardioprotective effects of aspirin.

This hypothesis has now been supported in a study of over 7000 patients who were discharged after a first admission for cardiovascular disease between 1989 and 1997 and who took low-dose aspirin and survived for at least 1 month (29). The adjusted hazard ratios for all-cause mortality (HR = 1.93; 95% CI = 1.30, 287) and for cardiovascular mortality (HR = 1.73; CI = 1.05, 2.84) were significantly raised in patients who took ibuprofen (mean dose 1210 mg/day) in addition to the aspirin. There was no increase in hazard in patients who combined aspirin with diclofenac, which is consistent with the in vitro data. However, this study had many limitations (30), and further epidemiological studies are needed to address this potentially important interaction. In the meantime, when patients taking low-dose aspirin for cardioprotection also require long-term treatment with an NSAID, diclofenac would be preferable to ibuprofen.

Lithium

Ibuprofen can increase the serum lithium concentration (SEDA-13, 81).

Methotrexate

Ibuprofen can potentiate methotrexate-induced renal toxicity (31).

Pancreatic enzymes

An interaction between ibuprofen and pancreatic enzymes causing serious gastrointestinal damage has been described in animals (SEDA-21, 105).

Phenytoin

Ibuprofen inhibits the metabolism of phenytoin (32).

Sulfonylureas

Ibuprofen (150 mg, 3 doses) for arthralgias was associated with hypoglycemia in a 72-year-old man who was taking glibenclamide 2.5 mg/day for type 2 diabetes mellitus; after the last dose he lost consciousness, and his blood glucose concentration was under 2.2 mmol/l (33).

Tacrolimus

Acute renal insufficiency has been described in concomitant treatment with tacrolimus in two liver transplant recipients (SEDA-18, 104).

Ibuproxam

See also Non-steroidal anti-inflammatory drugs

General Information

Ibuproxam is an NSAID that causes similar adverse effects to other NSAIDs.

Organs and Systems

Gastrointestinal

Gastrointestinal adverse effects have been reported with ibuproxam, including nausea, vomiting, occult gastrointestinal blood loss, and rectal pain (1).

Skin

Skin rashes have been reported with ibuproxam (1).

Reference

1. Scaranelli M, Delli Gatti I, Menegale G, et al. Casi di artrite reumatoide resistent al trattamento con farmaci antiflogistici non-steroidei: uso di dosi piu elevate di ibuproxam. Gaz Med Ital 1981;140:27.

Idoxuridine

General Information

Idoxuridine, which is active against *Herpes simplex* and *Varicella zoster*, has only been used in topical antiherpetic solutions. Idoxuridine has been used to treat superficial keratitis, but with poor results in deep stromal diseases because of poor solubility. However, idoxuridine is unstable and cannot eliminate the virus from the eye. Drug allergy and toxicity occur in 5–8% of patients.

© 2006 Elsevier B.V. All rights reserved.

Drug Administration

Drug administration route

Idoxuridine eye-drops are locally toxic, especially in patients with dry eyes, because of increased concentrations (or reduced tear secretion), and is topically sensitizing. Lacrimal punctum stenosis, lacrimation, follicular conjunctivitis, narrowing of meibomian gland orifices, inhibition of keratocyte mitosis and corneal stromal repair, and reductions in the strength of healing corneal wounds and the rate of epithelial regeneration are observed (1). After prolonged administration many changes in the conjunctival and corneal epithelium can occur, such as conjunctival cicatrization, punctate keratitis, subepithelial and intra-epithelial edema, and corneal opacities. Idoxuridine can also induce the emergence of resistant virus strains (2).

Ifosfamide

See also Cytostatic and immunosuppressant drugs

General Information

Ifosfamide is an alkylating agent belonging to the group of oxazaphosphorines. It is used to treat a variety of solid tumors in children, including rhabdomyosarcoma, soft tissue sarcomas, Wilms' tumor, bone sarcomas, and neuroblastoma, and leukemias and lymphomas in adults. It is also sometimes used in combination with other drugs, such as doxorubicin or cisplatin and etoposide.

Organs and Systems

Cardiovascular

Atrial fibrillation has been attributed to ifosfamide after a dose of only 1800 mg/m^2, with mesna, in a regimen for metastatic breast cancer (1).

Nervous system

Convulsions, severe facial spasms, and trismus occurred 7 hours after an infusion of ifosfamide in a dose of 7 g/m^2, having not occurred at a dose of 5 g/m^2, during a phase II study in patients with solid tumors (2).

Severe encephalopathy has been noted in children treated with ifosfamide (1.8 g/m^2) alone. There were no susceptibility factors, such as impaired renal function or lowered albumin. Electroencephalographic abnormalities and seizures were reversible, despite prolonged coma (3).

In an evaluation of ifosfamide in 57 children with malignant solid tumors, all received 1.6 g/m^2/day for 5 days followed by mesna 400 mg/m^2 at 0.25, 4, and 6 hours after ifosfamide (4). Neurological toxicity occurred in 13 patients. The usual symptoms were somnolence and general weakness followed by confusion, tremors, ataxia, aphasia, urinary incontinence, and cranial nerve paralysis. The symptoms of neurotoxicity disappeared spontaneously within 72 hours of completion of the 5-day course. Some patients had recurrent neurotoxicity on rechallenge. In an analysis of the incidence and features of electroencephalographic changes associated with Ifosfamide/mesna therapy there was no significant association between the electroencephalographic record before and during treatment; electroencephalographic changes developed 12–24 hours before clinical toxicity. Discriminant analysis identified low serum albumin, high serum creatinine concentrations, and pelvic involvement by the underlying malignant disease as susceptibility factors for severe encephalopathy (5).

In 12 of 52 patients treated with ifosfamide there was neurocortical toxicity greater than grade 2 (6). They were successfully treated with intravenous methylthioninium chloride (methylene blue) 50 mg 3-hourly, which was also prophylactic in three patients.

Vitamin B_1 (thiamine) has also been suggested to be beneficial in treating ifosfamide-associated neurotoxicity (7).

Urinary tract

It has been thought that the metabolism of ifosfamide to chloroacetaldehyde is the mechanism whereby ifosfamide causes renal damage. However, this was not confirmed in a study of repeated doses of 6–9 g/m^2 in 15 children, in whom there was no correlation between the pharmacokinetics of ifosfamide or its metabolites and either acute renal toxicity or chronic renal toxicity at either 1 or 6 months after treatment (8). However, there were changes in the metabolism of ifosfamide with time, particularly a reduction in dechloroethylation, which correlated with the risk of chronic nephrotoxicity.

Children and adolescents given cumulative doses of 32–112 g/m^2 had only transient disturbances in renal function (9). In five children with renal tubular Fanconi syndrome caused by ifosfamide, all went on to develop rickets in the face of declining renal function. None had had pre-existing tubular damage and the syndrome developed at cumulative doses of ifosfamide of 39–99 g/m^2. There were low serum bicarbonate and phosphate concentrations, and supplementation of these resulted in bone healing but not renal recovery (10).

The susceptibility factors associated with chronic ifosfamide nephrotoxicity up to 28 months after treatment have been studied in 23 children. The authors concluded that cumulative doses of 100 g/m^2 or higher should be avoided in children with cancers (11).

Like cyclophosphamide, ifosfamide causes a hemorrhagic cystitis in a high proportion of patients, with an occasionally fatal outcome. The damage to urinary bladder epithelium is caused by acrolein, a metabolite that is excreted in the urine. In bone marrow transplant recipients, prior administration of busulfan, which itself causes hemorrhagic cystitis, can increase this risk of oxazaphosphorines (12). Mesna (sodium

© 2006 Elsevier B.V. All rights reserved.

mercaptoethanesulfonate) is used to prevent this adverse effect. It is excreted by the kidney, and it binds and detoxifies acrolein in the urine; mesna also prevents the breakdown of acrolein precursors.

The phosphate disturbance that leads to Fanconi syndrome is well documented with ifosfamide. Of 43 children who received ifosfamide 3.5 g/m^2/day for 5 days for metastatic osteosarcoma, three developed the syndrome (13).

Second-Generation Effects

Fetotoxicity

The effects of second-trimester or third-trimester exposure to ifosfamide are poorly documented, although normal children have been described (14). In a 17-year-old pregnant woman with Ewing's sarcoma doxorubicin and ifosfamide during the 25th to 30th weeks of gestation did not affect the child, which was delivered at 32 weeks (15).

Drug Administration

Drug dosage regimens

There is a higher incidence of ifosfamide encephalopathy associated with the oral form compared with the intravenous form of ifosfamide; this has been attributed to metabolic differences between the two (16).

Drug–Drug Interactions

Cisplatin

Ifosfamide is associated with a peripheral neuropathy when it is given in combination with cisplatin (17). These symptoms improved within a few days after treatment with haloperidol.

Illiciaceae

See also Herbal medicines

General Information

The family of Illiciaceae contains a single genus, *Illicium*, the star anise species.

Illicium species

Illicium anisatum contains sesquiterpenoids, such as anisatin, anisotin, neoanisatin, and pseudoanisatin. *Illicium religiosum* (Japanese star anise) contains shikimic acid, anisatin and neoanisatin. *Illicium verum* (Chinese star anise) contains the monoterpenoid transanethole. Chinese star anise has been used to treat infant colic, but can be confused with Japanese star anise, which contains the neurotoxin anisatin.

© 2006 Elsevier B.V. All rights reserved.

Safrole is a mutagenic and animal carcinogenic monoterpenoid. It is the major component of oil of sassafras, and lesser quantities occur in essential oils from cinnamon, mace, nutmeg, and star anise. Some of its known or possible metabolites have mutagenic activity in bacteria and it has weak hepatocarcinogenic effects in rodents. Experiments in mice have suggested the possibility of transplacental and lactational carcinogenesis.

Adverse effects

When Japanese star anise was mixed into a commercially sold herbal tea, perhaps inadvertently consumption of the tea was associated with adverse events in 63 Dutch consumers (1). Their symptoms occurred 2–4 hours after they drank the tea and included general malaise, nausea, and vomiting. In 22 cases hospitalization was required, and 16 had generalized tonic-clonic seizures. All made a full recovery after withdrawal of the herbal tea. Anisatin is a non-competitive GABA receptor antagonist, which causes nervous system hyperactivity, and the authors believed that this mechanism explained the high rate of seizures in these patients.

- A 1-month-old girl developed status epilepticus after being given a large amount of star anis for colic (2).
- Two infants whose parents gave them star anise herbal tea developed tremors or spasms, hypertonia, hyperexcitability with crying, nystagmus, and vomiting (3). The Chinese star anise tea had been contaminated with Japanese star anise.

From February to September 2001, a matched case-control study was performed in infants aged under 3 months admitted to the pediatric emergency departments of two hospitals in Madrid (4). There were 23 cases, whose symptoms and signs were irritability, abnormal movements, vomiting, and nystagmus. The odds ratio for anise consumption was 18.0 (CI = 2.03, 631). Laboratory analyses showed contamination of *I. verum* by *I. anisatum*.

Iloprost

See also Prostaglandins

General Information

Iloprost is an analogue of prostacyclin (PGI_2), the pharmacodynamic properties of which it mimics, namely inhibition of platelet aggregation, vasodilatation, and cytoprotection (as yet ill-defined). Iloprost has greater chemical stability than prostacyclin, which facilitates its clinical use (1).

Iloprost is mainly used in patients with chronic critical leg ischemia due to atherosclerosis or Buerger's disease. Episodic digital ischemia in patients with systemic sclerosis or related disorders is another use. The most frequently observed adverse effects, facial flushing and headache, are caused by profound vasodilatation.

Most clinical experience with iloprost has been gained in patients with critical leg ischemia. An intermittent intravenous infusion of up to 2 nanograms/kg/minute for 2–4 weeks reduced rest pain and improved ulcer healing in roughly half of the patients with critical leg ischemia, including diabetics. Compared with placebo, the improvement obtained with iloprost was significant in most but not all individual clinical trials. In addition, a meta-analysis showed a 15% reduction in major amputation rate compared with placebo (2).

Observational studies

The use of iloprost has been proposed in patients with systemic sclerosis, a disease that is often characterized by pulmonary hypertension and Raynaud's phenomenon. Three patients with systemic sclerosis who were treated with iloprost developed acute thrombotic events (3). In one case, intestinal infarction occurred 1 day after infusion of iloprost. In another patient the left kidney was not perfused 22 days after the last infusion of iloprost because of thrombosis of the left renal artery. The last patient, 9 months after the start of treatment with iloprost, and 5 days after the last infusion, had an anterolateral myocardial infarction. The authors commented that their observations did not allow them to conclude that there is a direct relation between infusion of iloprost and thrombotic events. However, they said that this possibility should be considered, and they suggested that risk factors for thromboembolism should be carefully evaluated in each patient with systemic sclerosis who is receiving iloprost.

Inhalation of aerosolized iloprost is being tested in patients with severe primary or secondary pulmonary hypertension refractory to conventional therapy. The aim is to produce predominantly pulmonary vasodilatation without significant systemic effects. In an uncontrolled series of 19 patients, the most common adverse effects of inhaled iloprost were coughing, nausea, edema, and thoracic pain (4). In most patients, these effects were transient and rarely required a change in therapy.

Placebo-controlled studies

A multicenter, randomized, parallel-group comparison of two different doses of oral iloprost and placebo has been

conducted, to identify the optimal dose of oral iloprost on the basis of efficacy and tolerability in patients with Raynaud's phenomenon secondary to systemic sclerosis (5). A total of 103 patients were given total daily doses of iloprost of 100 micrograms ($n = 33$) or 200 micrograms ($n = 35$) or placebo ($n = 35$) for 6 weeks. The mean percentage reductions in the frequency, total daily duration, and severity of attacks of Raynaud's phenomenon were greater in the iloprost groups at the end of treatment and at the end of follow-up. Adverse effects were reported by 80% of patients taking placebo, 85% taking oral iloprost 100 micrograms/day, and 97% taking oral iloprost 100 micrograms/day. There were significant differences in the frequency of five types of adverse events. Headache, flushing, nausea, and trismus were all more common with increasing iloprost dose, while flu-like illnesses were most commonly reported in the placebo group. Treatment was prematurely discontinued in 9, 30, and 51% respectively, and discontinuation was precipitated by adverse events in 6, 27, and 51%.

Comparative studies

In a randomized, controlled study of cyclic iloprost or nifedipine in 46 patients with systemic sclerosis, the predictable adverse effects of iloprost (headache, nausea and vomiting, and diarrhea) were common but quickly resolved after the end of the infusion (6). They rarely required a temporary dose reduction. Hypotension occurred less often than with nifedipine.

General adverse effects

The adverse effects of iloprost occur within or above the usual dosage range and are predictable from its pharmacological effects. Minor vascular reactions during infusion (characterized by facial flushing and headache) are so common as to make double-blind trials impossible. Gastrointestinal effects become more prevalent at higher dosages, and include nausea, vomiting, abdominal cramps, and diarrhea. Less common adverse effects include restlessness, sweating, local erythema along the infusion line, wheals, fatigue, and muscle pain. Clinically significant hypotension is rare with the doses tested. The untoward effects resolve rapidly after the infusion is discontinued.

Therapy with iloprost is usually started with a dosage of 0.5 nanogram/kg/minute and increased in increments until either minor vascular reactions occur or a dosage of 2 nanograms/kg/minute has been reached. The optimal total dose remains to be established.

Organs and Systems

Cardiovascular

Myocardial ischemia is unusual during infusion of iloprost. It mainly occurs in patients with pre-existing coronary disease, when it is ascribed to a steal phenomenon detrimental to the subendocardial tissue. As a rule it is transient and exceptionally proceeds to infarction. However, such an event has now been reported in a patient with systemic sclerosis (7).

- A 57-year-old man with a 1-year history of systemic sclerosis and ischemia of several digits received a first infusion of iloprost using the recommended stepwise increasing dosage scheme; he developed sudden chest pain, with inferior ST segment elevation. Emergency coronary angiography showed an occlusion of the circumflex coronary artery, for which a stent was inserted. At angiography 3 years earlier his coronary arteries had been normal. He died 5 months later from cardiogenic pulmonary edema.

Musculoskeletal

Four women with CREST syndrome or systemic sclerosis had pain and eventually contracture of the masseter muscles during infusion of iloprost for severe attacks of Raynaud's phenomenon (8). The adverse effect was quickly reversed by reducing the infusion rate. There were no electrocardiographic or cardiac enzyme changes. The mechanism of this effect is obscure.

Drug Administration

Drug administration route

An oral formulation has been investigated in patients with Raynaud's phenomenon secondary to systemic sclerosis and in patients with severe ischemia due to Buerger's disease or to atherosclerosis. The first reports were not particularly encouraging in terms of efficacy. Tolerance is acceptable: 6% of patients discontinued iloprost compared with 2% with placebo (9,10).

Imidapril

See also Angiotensin converting enzyme inhibitors

General Information

Imidapril is a long-acting, non-sulfhydryl ACE inhibitor that has been used in patients with hypertension, congestive heart failure, acute myocardial infarction, and diabetic nephropathy. It is a prodrug, rapidly converted in the liver to its active metabolite imidaprilat, which has a half-life of about 15 hours. Imidapril and its metabolites are mainly excreted in the urine.

Organs and Systems

Respiratory

The incidences of cough with imidapril and enalapril have been compared in a poorly designed open study in 489 hypertensive patients (1). The authors claimed a significantly smaller incidence of cough with imidapril. However, because of important methodological flaws, this result cannot be trusted.

Mineral balance

Hyperkalemia is a well-known adverse effect of ACE inhibitors and can sometimes be severe (2).

- An 85-year-old woman with diabetes mellitus and a prior myocardial infarction, who was taking ioxoprofen and imidapril, lost consciousness owing to marked bradycardia caused by hyperkalemia (7.4 mmol/l). An electrocardiogram showed T wave changes compatible with hyperkalemia. After right ventricular pacing she promptly recovered consciousness. She was given glucose and insulin and her plasma potassium fell to 4.1 mmol/l within 3 hours. Simultaneously her heart rate became normal.

Imipraminoxide

See also Tricyclic antidepressants

General Information

Imipraminoxide is an imipramine metabolite. In a comparison with the parent drug, efficacy was identical; adverse effects were of the same type but possibly less frequent (1).

Reference

Imiquimod

General Information

Imiquimod is an immune response enhancer that induces production of interferon and several other cytokines. It is used, in formulations containing 5%, to treat external genital and perianal warts/condylomata acuminata in adults (1). As imiquimod-treated warts regress, serum concentrations of interferon-alfa, interferon-beta, interferon-gamma, and tumor necrosis factor rise (2). Trials of imiquimod have failed to identify any particular systemic or laboratory abnormalities.

In one study, there was no deleterious effect on disease progression in HIV-infected patients, and the incidence of local adverse events with imiquimod (5% three times a week) for the treatment of anogenital warts was lower than has previously been reported in healthy individuals (3). In an uncontrolled trial of topical imiquimod 5% for the treatment of common warts and molluscum contagiosum in otherwise healthy patients, fever, healing with scarring, and healing with hyperpigmentation were each reported by one participant (4).

Organs and Systems

Skin

In randomized, double-blind studies, the most common adverse effects were inflammatory reactions at the injection site (mostly erythema and itching), which usually occurred after 2–5 weeks of treatment (5–7). These local reactions included erythema, erosions, excoriation, flaking, edema, scabbing, and induration, and were rarely severe enough to warrant withdrawal. Mild to moderate irritation has to be expected in up to 70% of patients if a 5% imiquimod cream is applied three times per week (6).

Immunoglobulins

General Information

Immunoglobulin preparations are concentrated protein solutions derived from the pooled plasma of adults or animals. They contain specific antibodies in proportion to the infectious and immunization experience of the population from whose plasma they are prepared (1). Large numbers of donors (at least 1000 donors per lot of final product) are used, in order to ensure inclusion of a broad spectrum of antibodies. Intravenous immunoglobulin is also derived from the pooled plasma of adults, but the alcohol-fractionation procedure is modified to a product suitable for intravenous use. The use of intravenous immunoglobulins in selected immunodeficiency and autoimmune diseases has been reviewed (2).

Specific immunoglobulins, termed "hyperimmune globulins," are derived from human donors known to have high titers of the desired antibody. Specific immunoglobulin preparations for use in infectious disease prevention include hepatitis B, rabies, tetanus, *Varicella zoster*, vaccinia, and cytomegalovirus immunoglobulin.

Specific immunoglobulins of animal origin still currently in use in some countries include antirabies immunoglobulin, diphtheria antitoxin, botulinum antitoxin, antivenins, antilymphocyte globulin, and antithymocyte globulin. Horse antisera against diphtheria (and subsequently against tetanus as well) were produced and used in therapy from about the beginning of the 20th century. Antidiphtheria and antitetanus immunoglobulins are now produced almost exclusively as fractions of plasma of human origin. There are, however, a few cases in which xenogeneic antisera are still used, despite their many and often serious adverse effects.

Uses

Preparations of human immunoglobulins given by intramuscular/subcutaneous administration are mainly given to prevent or treat specific diseases, such as rhesus disease (anti-D) or certain viral infections, for example measles, hepatitis A, hepatitis B, rabies, and cytomegalovirus. Polyclonal antilymphocyte preparations (for example antilymphocyte globulin and antithymocyte globulin) have been developed because of evidence that T cells are primarily responsible for rejection of transplants. Indications for treatment with, for example, horse antilymphocyte globulin and/or antithymocyte globulin are very much the same as the indications for the mouse monoclonal anti-CD3 (muromonab), namely acute rejection of transplants, and aplastic anemia (3,4).

Preparations for intravenous administration are mainly used in patients with general immune deficiency states (primary or secondary) or diseases like idiopathic thrombocytopenic purpura (ITP) and autoimmune diseases (5,6). Neurological disorders (for example Guillain–Barré syndrome and chronic demyelinating polyneuropathy) have been treated with intravenous immunoglobulin (7–9).

The efficacy and safety of intravenous immunoglobulin have been reported in primary and secondary immunodeficiency, as well as in some immune disorders such as idiopathic thrombocytopenic purpura, Kawasaki disease, and Guillain–Barré syndrome (10–15). Intravenous immunoglobulin is also used empirically in a variety of several autoimmune diseases (16). Higher dosages of intravenous immunoglobulin are used for autoimmune indications (400–2000 mg/kg) than in immunodeficiency diseases (100–400 mg/kg). Minor adverse effects, such as headache, myalgia, chest discomfort, and fever, occur in 10% of patients (17). The efficacy of intravenous immunoglobulin has been reported in patients with membranous and membranoproliferative lupus nephritis (16). High-dose intravenous immunoglobulin has also been beneficial in myasthenia gravis, multiple sclerosis, and multifocal motor neuropathy (18,19) and in patients with pemphigus vulgaris and bullous pemphigoid unresponsive to conventional immunosuppressive drugs (20,21).

Intravenous immunoglobulin administered to allogeneic bone marrow transplant recipients modifies graft-versus-host disease and prevents interstitial pneumonia and infections (14).

The use of intravenous immunoglobulins in selected immunodeficiency and autoimmune diseases has been reviewed (2).

Mechanisms of action

The effect of immunoglobulin therapy is either protection against microorganisms (antibody substitution, passive immunization), or immunomodulation, or both. The mechanism of the response in non-infectious diseases is

© 2006 Elsevier B.V. All rights reserved.

still not clear, but in idiopathic thrombocytopenic purpura an early fall in platelet-associated IgG and IgM may be a primary event, due to interference with antibody binding by platelets (22). Several other mechanisms of action of intravenous immunoglobulin in autoimmune diseases have been suggested, such as enhanced suppressor activity, Fc receptor blockade on neutrophils and macrophages (23), inhibition of complement activation and modulation of anti-idiotype responses (24), cytokine modification, neutralization of superantigens, and regulation of T cells and the idiotypic network (16,25). The suppression of polyclonal immunoglobulin biosynthesis induced by high-dose immunoglobulin infusions has also been suggested as a possible mechanism (26).

General adverse effects

Specific immunoglobulins

When administering different lots of the same product of equine rabies immunoglobulin, significant differences in adverse reactions, reflecting differences in production or purification processes and protein content, have been observed (27). It has been concluded in the past that the incidence of reactions to antirabies immunoglobulin is particularly high, but any of these immunoglobulins can cause severe reactions. The WHO has recommended that animal immunoglobulins should be used only after tests to rule out hypersensitivity.

A review of the discovery of antitoxins, the development of antibody formulations, and possible adverse effects has appeared (28).

Intramuscular immunoglobulin

Allerglobuline is a human gammaglobulin formulation, given intramuscularly, that has been reported to have a protective effect against type I allergic diseases and chronic infections of the upper respiratory tract in both adults and children. In 64 patients given allerglobuline, pain and inflammation at the injection site were the most common adverse effects (29). Fever, drowsiness, headache, nausea, back pain, and conjunctivitis occurred in only few patients. One patient had a rash and myalgia after the third injection; when the rash occurred again after the fourth injection, the patient was withdrawn.

Intravenous immunoglobulin

Adverse effects of intravenous immunoglobulin are generally mild and self-limiting (25). Although more common during the first two infusions, reactions appear to be primarily related to the speed of infusion. When infusions are given over a 1–3-hour period, the incidence of reactions is less than 5% and they occur during the transfusion; when infusions are given rapidly, the reactions may appear soon after completing the infusion. In about 10% of cases they occur 30–60 minutes after the start of the infusion.

Reactions include flushing, myalgia, headache, fever, chills and shaking, low backache, nausea and vomiting, diarrhea, chest tightness and shortness of breath, wheezing, changes in blood pressure, tachycardia, and rashes (30,31). Most of the adverse effects are related to the rate of administration and can be attenuated by slowing the rate of the infusion (32) or by prior administration of hydrocortisone and/or an antihistamine. When infusions are given over a 1–3-hour period, the incidence of reactions is less than 5% and they occur during the transfusion; when infusions are given rapidly the reactions may appear soon after completing the infusion. The current high dosage of 0.8–1.0 g/kg intravenous immunoglobulin for 1–2 days (instead of the original dosage regimen of 0.4 g/kg for 5 days) for patients with idiopathic thrombocytopenic purpura is probably associated with an increased risk of adverse effects (33).

The rate of adverse effects associated with intravenous immunoglobulin varies among different studies, which has been attributed to factors such as the indication, the dosage, the infusion rate, and the patient's age (12). In one study, headache and chills were related to a higher dosage.

Of 37 patients with primary hypogammaglobulinemia who received 1235 immunoglobulin infusions, 10 had adverse reactions during 34 infusions (2.8% of all infusions), but only five reactions were moderately severe. The reactions are related to the rate of administration (34); a rate of 5 mg/kg/minute was well tolerated.

Of 56 patients with autoimmune diseases who received high dosages of intravenous immunoglobulin, 20 had at least one adverse effect after one or more courses of treatment (12). The most frequently reported adverse effects were low-grade fever, headache, and chills. The authors concluded that the occurrence of adverse effects with intravenous immunoglobulin was not related to the clinical response to treatment. However, patients who developed adverse effects during the first course of treatment were more at risk of adverse effects during subsequent courses.

Patients with thrombocytopenia generally tolerate intravenous immunoglobulin well (35). In 16 young patients aged 9 months to 22 years with immune-mediated hemocytopenias (13 with childhood immune thrombocytopenic purpura), who received a total of 210 infusions, minimal adverse effects (transient headaches) were experienced during only four infusions, and later infusions were problem-free in three of the four patients (36).

The most frequent adverse effects of intravenous immunoglobulin (Sandoz) for the treatment of various disorders (affecting 1–3% of patients in all) were headache, nausea, vomiting, and fever. Some other mild symptoms have an incidence below 1%, including abdominal pain, diarrhea, fatigue, malaise, dizziness, myalgia, and chest tightness.

Allerglobuline is an intravenous human gammaglobulin formulation that has been reported to have a protective effect against type I allergic diseases and chronic infections of the upper respiratory tract in both adults and children. In 64 patients given allerglobuline, pain and inflammation at the injection site were the most common adverse effects (29). Fever, drowsiness, headache, nausea, back pain, and conjunctivitis occurred in only few patients. One patient had a rash and myalgia after the third injection; when the rash occurred again after the fourth injection, the patient was withdrawn.

Polyclonal antilymphocyte immunoglobulins

Short-term toxicity from polyclonal antilymphocyte immunoglobulins has been particularly marked in

© 2006 Elsevier B.V. All rights reserved.

patients treated with combined antilymphocyte/antithymocyte globulin preparations from immunized horses (37). Immediate adverse effects include leukopenia and thrombocytopenia, fever, arthralgia, rash, urticaria, hepatotoxicity, hyperglycemia, hypertension, and diarrhea (38). A later adverse effect is serum sickness. Many of the effects may be due to an increase in tumor necrosis factor (39).

The longer-term effects of immunosuppression, and in particular the residual hematological and immunological abnormalities in patients with aplastic anemia treated with antilymphocyte globulin, have been documented: there is toxicity to hemopoietic cells, eventually leading to clonal marrow diseases years after treatment (37). Paroxysmal nocturnal hemoglobinuria, refractory sideroblastic anemia, chronic myelomonocytic leukemia, or acute leukemia can develop 4–10 years after treatment (40).

Organs and Systems

Cardiovascular

Intravenous immunoglobulin expands the plasma volume and increases blood viscosity, which can lead to volume overload in patients with cardiac insufficiency (41). Stroke, thromboembolic events, and myocardial infarction have been reported after high-dose treatment with intravenous immunoglobulin, which increases plasma viscosity (41–43).

Thrombosis in elderly patients with an increased risk of thrombosis, such as those with hypertension or previous episodes of infarction, has been described (44). A few cases of thrombosis subsequent to intravenous immunoglobulin have been reported, including myocardial infarction in five patients, stroke in four cases, and spinal cord ischemia in one (45). It has been postulated that these events are induced by platelet activation and increased plasma viscosity (12).

Several cases of thrombosis have been reported after administration of intravenous immunoglobulin (31).

- A 75-year-old man with idiopathic thrombocytopenia purpura who was treated with intravenous immunoglobulin developed recurrent myocardial ischemia (46).
- A 54-year-old woman with idiopathic thrombocytopenic purpura received intravenous immunoglobulin 1 g/kg/day for 2 days and had an ischemic stroke with hemiparesis; 3 days later she had a deep vein thrombosis (47).
- A 33-year-old woman with Evans' syndrome received intravenous immunoglobulin 400 mg/kg/day and developed a deep vein thrombosis after 1 week (47). She was treated with warfarin, and 6 months later received an additional course of intravenous immunoglobulin for recurrent hemolytic anemia; 1 day later she died of pulmonary thromboembolism.
- A 70-year-old woman with polycythemia rubra vera and Guillain–Barré syndrome, but no known risk factors for thrombosis, had a cerebral infarction 10 days after receiving intravenous immunoglobulin; the authors wondered whether there was a relation to the polycythemia vera (48).

In a randomized, controlled study in 56 patients with untreated autoimmune thrombocytopenic purpura, who were treated with intravenous immunoglobulin 0.7 g/kg/day for 3 days, one had a deep vein thrombosis complicated by pulmonary embolism (49). One of 10 children with toxic epidermal necrolysis, for which they were given intravenous immunoglobulin 0.5 g/kg/day, developed a deep vein thrombosis requiring heparin (50). Of the 10 children, this child was the only one who received intravenous immunoglobulin for 7 days instead of the standard 4-day course.

- Transient hypertension occurred in a patient with dermatomyositis during therapy with intravenous immunoglobulin (51). In the past, his diastolic blood pressure had been 104–106 mm Hg, but he was normotensive with antihypertensive drug medication.

Several mechanisms for this transient hypertension were postulated, for example stimulation of the vascular endothelium to secrete endothelin to inhibit nitric oxide synthesis.

It has been recommended that patients with cardiac diseases should be monitored during intravenous immunoglobulin therapy, because hypertension and cardiac failure have occurred, presumably as a result of fluid overload or electrolyte shifts (52).

Respiratory

- A 35-year-old woman with idiopathic thrombocytopenic purpura treated with high dosages of intravenous immunoglobulin developed a recurrent lymphocytic pleural effusion (53).
- In a patient with Guillain–Barré syndrome, and a history of ischemic heart disease, intravenous immunoglobulin 400 mg/kg for 5 consecutive days caused severe bronchospasm and hypercapnia after a dose of 12.5 g had been given (15). The complaints disappeared after withdrawal of the intravenous immunoglobulin.

Nervous system

Headache occurred in 25% of all patients who received an infusion of intravenous immunoglobulin, probably related to larger volumes and fluid shifts, protein loads, and infusion rates (54). Intravenous immunoglobulin caused severe headache in 56% of patients without a history of migraine (55). The pathogenesis of this headache is unknown.

Severe headache has also been reported in children with idiopathic thrombocytopenic purpura using intravenous immunoglobulins (33). In a randomized, controlled study of patients with myasthenia gravis, two of six patients who received intravenous immunoglobulin developed severe headache after the initial dose of 2 g/kg (56).

In 14 patients with primary immunodeficiency disease, progressive neurodegeneration occurred and a possible relation to immunoglobulin therapy could not be ruled out (57).

Aseptic meningitis

Aseptic meningitis is characterized by headache, photophobia, nausea, vomiting, and meningism, and is confirmed by cerebrospinal fluid pleocytosis with 10–90%

© 2006 Elsevier B.V. All rights reserved.

polymorphonuclear cells, increased concentrations of several proteins, and negative cultures (SEDA-22, 344) (54,58,59). It has been described in 1–15% of patients receiving high dosages of intravenous immunoglobulin (60,61) and especially in subjects with a history of migraine (25,43,60). However, aseptic meningitis has also been reported after a low dose of intravenous immunoglobulin.

- A 50-year-old man developed aseptic meningitis after a low dose of intravenous immunoglobulin (3.5 g) (60). A few weeks after the first infusion, he received a second infusion and again developed symptoms of aseptic meningitis.

The authors thought it unlikely that aseptic meningitis had been caused by an allergic reaction. They proposed that the mechanism of aseptic meningitis involved the entry of immunoglobulin molecules into the cerebrospinal fluid, causing an inflammatory reaction.

It has also been suggested that release of histamine, serotonin, and prostaglandins affects the meningeal microvasculature (31).

- Two children with idiopathic thrombocytopenic purpura developed aseptic meningitis after receiving intravenous immunoglobulin 1 g/kg/day, with unusual large numbers of leukocytes in the cerebrospinal fluid (62).

To prevent aseptic meningitis, it has been advised that intravenous immunoglobulin should be infused at a slow rate and that diluted immunoglobulin solutions should be used (58). Aseptic meningitis can be prevented by the administration of propranolol (41,58). In addition, prehydration and an antihistamine have been helpful in some patients (41,58).

Possible mechanisms of aseptic meningitis include hypersensitivity reactions, stabilizing products, cytokines, cerebrovascular sensitivity, and direct meningeal irritation. It has been suggested that it is caused by aggregated immunoglobulin, antibody–antigen complex formation with subsequent complement activation, or stabilizing carbohydrates used during manufacture (30,59).

Cerebrovascular disease

Stroke and ischemic encephalopathy, probably caused by cerebral vasospasm after intravenous immunoglobulin, have been reported as possible complications of intravenous immunoglobulin (63).

- Hemiplegia occurred on the third day of intravenous immunoglobulin therapy in a 58-year-old man with graft-versus-host disease after transfusion of non-leukocyte-depleted erythrocytes (64). The hemiplegia resolved one day after withdrawal of intravenous immunoglobulin.
- Hemiplegia occurred in a child given intravenous immunoglobulin for idiopathic thrombocytopenic purpura (65).

The authors of both reports suggested that the hemiplegia had been caused either by transient hyperviscosity or by vasospasm.

Cerebral vasospasm, cerebral vasculitis, and serum hyperviscosity have been implicated in the pathogenesis of cerebral infarction after intravenous immunoglobulin (66).

Metabolism

Blood glucose should be monitored in patients with diabetes mellitus who receive glucose-containing intravenous immunoglobulin (41).

Hematologic

It has been recommended that the blood count be monitored during intravenous immunoglobulin therapy if there is evidence of mild leukopenia, neutropenia, or thrombocytopenia before the first infusion (18).

Erythrocytes

Severe acute hemolysis due to acquisition of red cell alloantibodies from donor serum has been reported (67–69). In other cases, the suggested mechanism of hemolytic anemia after high dosages of intravenous immunoglobulin was the presence of anti-A and/or anti-B antibodies in the plasma product (70).

Various immunoglobulin products contain IgG of molecular weight of a dimer or greater (over 300 kDa), which in the presence of serum can mimic immune complexes and bind to erythrocytes via CR1 (71). Especially in young adults, the immune complex-like moieties in intravenous immunoglobulin bind to erythrocytes and serve as opsonins in the mediation of erythrocyte sequestration, resulting in significant drops in hematocrit and hemoglobin concentrations (71). It has been suggested that the presence of immune complex-like moieties bound to erythrocyte CR1 after intravenous immunoglobulin treatment is correlated with in vivo hemolysis.

- Severe hemolytic anemia after high doses of intravenous immunoglobulin occurred in a 23-year-old woman with polymyositis (72).

This adverse reaction was probably due to the presence of allohemagglutinins A and B and high molecular weight IgG complexes in the formulation. Specifications in pharmacopeial monographs and product licenses require that intravenous immunoglobulin be free of significant titers of anti-A anti-B antibodies (SEDA-24, 385).

Leukocytes

High-dose immunoglobulin has been reported to cause neutropenia (31,73,74), disseminated intravascular coagulation and serum sickness (75). Neutropenia after intravenous immunoglobulin is frequent and seems to be transient and self-limiting (76). Neutropenia is not dose-related in the therapeutic range of doses.

It has been suggested that transient neutropenia can be induced by the presence of antineutrophil antibodies present in intravenous immunoglobulin. However, the possibility that immunoglobulin-mediated neutrophil agglutination causes pseudoleukopenia has also been raised (74). Increased leukocyte aggregation in the circulating pool of peripheral blood, induced by intravenous immunoglobulin, is particularly observed in people with hyperfibrinogenemia (74). It has been suggested that leukopenia detected by electronic counting is not necessarily associated with a real reduction in the absolute number of white blood cells in the peripheral blood, but is artefactual (74).

© 2006 Elsevier B.V. All rights reserved.

Platelets

In elderly patients, thrombotic events have been described in up to 10% in patients aged over 60, some of them fatal. Thrombotic events may be related to a rapid rise in numbers of circulating platelets (44,77).

Several cases of intravenous immunoglobulin-related thrombosis have been reported (78,79). It can be either venous or arterial (80). It has been suggested that thrombosis can be caused by platelet activation and increased plasma viscosity (79). In patients with vascular risk factors, such as old age, hypertension, and a history of stroke or coronary artery disease, complications, such as myocardial infarction, pulmonary embolism, stroke, and acute spinal cord events, have been described (80). Intravenous immunoglobulin enhances platelet aggregation and the release of adenosine triphosphate in human platelets in vitro. In addition, there is a dose-related increase in plasma viscosity with increasing plasma immunoglobulin concentration (79,80).

Liver

Although transient rises in liver enzymes have been documented, they are not considered to be serious (68).

Fatal hepatic veno-occlusive disease, characterized by hyperbilirubinemia, hepatomegaly, ascites, and weight gain, has been associated with intravenous immunoglobulin administered prophylactically to prevent transplant-related infections (79). To avoid such thrombotic complications, intravenous immunoglobulin should be infused at a slower rate in patients at risk, and high dosages (400–1000 mg/kg) should not be infused.

Urinary tract

Renal insufficiency after high dosages of intravenous immunoglobulin has been observed, mostly in patients with pre-existing renal disease (81). Acute renal insufficiency occurred within 7 days after the administration of intravenous immunoglobulin, with a peak at 5 days. About 40% of patients needed dialysis and 15% died despite treatment (all with severe underlying diseases); the mean time to recovery in survivors was about 10 days (82).

The US FDA has issued recommendations on safety precautions that physicians should take to reduce the potential risk of acute renal insufficiency, which appears to be uncommonly associated with infusion of intravenous immunoglobulin products (83,84). Since 1981, the FDA has received over 114 reports of renal dysfunction and/or acute renal insufficiency in patients given immunoglobulin, and a total of 17 deaths have been reported (32). As the problems have been associated with the use of specific immunoglobulin products, the FDA advises, that "physicians should carefully weigh the potential benefits of administering sucrose-containing intravenous immunoglobulin products against the risks of causing renal damage." Other cases of acute renal insufficiency have been described after the intravenous infusion of immunoglobulin (SEDA-22, 345) (73).

The pathophysiology of acute renal insufficiency due to immunoglobulins is probably related to hyperosmolar renal damage, due to sucrose present in 50 ml intravenous formulations (13,43,85–87). Acute renal insufficiency has also been attributed to sucrose in a kidney allograft recipient treated with intravenous immunoglobulin (88). The high solute load in the kidney can cause osmotic damage (32,82). The histopathology of renal tissue shows osmotic tubular injury, tubular vacuolization, and tubulointerstitial infiltrates (89,82). Cytological findings in the urine included the presence of macrophage-like tubular epithelial cells with multivacuolated cytoplasm (90). Formulations of intravenous immunoglobulin with sucrose as a stabilizer should not be used in patients with renal disease (31,81,91).

In a retrospective study of a heterogeneous group of 119 patients receiving intravenous immunoglobulin, two developed irreversible renal insufficiency and six had a rise in serum creatinine. These patients had received high dosages of two different formulations of intravenous immunoglobulin, one containing sucrose 1.76 g per gram of intravenous immunoglobulin; the other 0.5 g per gram. There was no relation between the amount of sucrose in the intravenous immunoglobulin and the development of renal insufficiency (82).

Studies in rats have suggested that after pinocytosis by renal tubular cells, sucrose is incorporated into phagolysosomes (32). The intracellular accumulation of sucrose leads to vacuole formation and cellular swelling. On withdrawal, renal insufficiency resolves in most cases. However, sometimes hemodialysis is necessary (69,89).

Risk factors for this adverse effect are pre-existing renal disease, age over 65 years, dehydration, diabetes mellitus, hypertension, and a high infusion rate (SEDA-22, 345) (10,13,32,43,86,92). To minimize the risk of renal insufficiency, it has been suggested that immunoglobulin should be diluted with hypotonic fluid, that the infusion rate should be reduced, and that dosing intervals should be increased (89). Patients should be adequately hydrated and potent diuretics should be avoided (10).

In most cases the acute renal insufficiency is reversible and recovery occurs after 7–15 days (10).

It has been suggested that kidney function should be monitored during intravenous immunoglobulin therapy if it is abnormal before the first infusion (18). In addition, these patients should be adequately hydrated during treatment with intravenous immunoglobulin (52).

Skin

Skin reactions to intravenous immunoglobulin are rare (52,93–95). Other reported reactions include urticaria, maculopapular rashes, petechiae, eczema, and erythema multiforme (31,96).

Pompholyx has been observed 5–7 days from the last day of therapy in three of 23 neurological patients treated with intravenous immunoglobulin (17,97). Pompholyx occurs on the palms of the hands and is characterized by small papules, subdermal vesicles, desquamation, and crusting.

Cutaneous vasculitis has been attributed to intravenous immunoglobulin (96)

- In a patient with type II mixed cryoglobulinemia, intravenous immunoglobulin caused severe cutaneous vasculitis accompanied by an increased cryocrit (98).

A simple method of mixing the patient's serum in vitro with intravenous immunoglobulin could probably predict this.

© 2006 Elsevier B.V. All rights reserved.

Hair

There have been a few cases of alopecia after the concomitant administration of intravenous immunoglobulin and steroid (49,99–102).

Immunologic

The administration of equine or other immunoglobulins is associated with a considerable risk of adverse effects and can produce virtually any type of early or late hypersensitivity reaction, ranging from asthma and urticaria to serum sickness and fatal anaphylaxis (103–106). Encephalitis (107), myocarditis (108), nephritis (109), and uveitis (110) can all be manifestations of such reactions. In one case, leukocytoclastic vasculitis was attributed to human immunoglobulin (96).

Of systemic reactions to immunoglobulins, those of an inflammatory nature are thought to be due to the presence of small complexes or microaggregates, probably leading to activation of the complement system. The symptoms are usually mild and influenza-like, and generally respond to slowing down or temporary interruption of the infusion. They include headache, hypotension, sweating, chills, fever, nausea, and vasomotor reactions. The frequency of such adverse reactions has fallen, probably because of the improved quality of the preparations. In 1978, the frequency of adverse reactions was as high as 55% in those receiving intravenous preparations containing 10–13% polymeric immunoglobulin, whereas by 2000, intravenous immunoglobulin preparations caused adverse reactions in only 3–4% (5). The more severe reactions may also be complement-mediated and may be due to a spontaneous activation of the complement system by the immunoglobulin preparation concerned; immunoglobulin aggregates may again be involved. The symptoms may be similar to those of inflammatory reactions, though they can be more severe. Such serious effects, including rare reactions of an anaphylactic type, may occur in as few as one in 6000 cases (111).

IgA deficiency is one of the more commonly encountered genetic disorders, and homozygotic deficiency is present in 0.3–0.03% of Caucasian populations. Such individuals may develop anti-IgA antibodies and have serum-sickness-like symptoms after the first administration of immunoglobulins, sometimes experiencing more severe reactions after repeated injections (112–114). A mild reaction due to sensitization to genetic IgA variants can also occur. Selective IgA deficiency is a contraindication to intravenous immunoglobulin, because of the risk of anaphylactic shock in patients with IgA deficiency and IgE or IgG antibodies against IgA, which react with IgA in intravenous immunoglobulin (13,17,30,31,41,52,61,94).

Some reports suggest that anaphylaxis due to intravenous immunoglobulin infusion occurs most often in patients with primary hypogammaglobulinemia (115,116). However, anaphylactic reactions have been seen in two atopic patients with idiopathic thrombocytopenic purpura, and the authors warned that children with atopic disease should not receive intravenous immunoglobulin (117).

In recipients of left ventricular assist devices awaiting cardiac transplantation treated with intravenous immunoglobulin, clinical manifestations of immune complex disease occurred during four of 27 (15%) monthly courses (118). The immune complex disease was characterized by fever, arthralgia, and maculopapular rashes.

Intravascular hemolysis is a rare adverse effect of immunoglobulins, due to the presence of anti-blood group antibodies (119–123).

Body temperature

Intravenous immunoglobulin can cause malaise and fever in patients with infections, probably through a temporarily increased titer of antibodies against different pathogenic microorganisms (124).

Multiorgan failure

Multiorgan failure has been described after intravenous infusion of immunoglobulin (125).

- A 3-year-old mentally retarded girl was given intravenous sulfonated immunoglobulin for prophylaxis of measles. After infusion of about 100 mg, she became cyanotic, confused, and tachycardic. Despite hydrocortisone she developed hypotensive shock. Multiorgan failure developed, with symptoms of disseminated intravascular coagulation, acute renal insufficiency, hepatic dysfunction, respiratory distress syndrome, and rhabdomyolysis. After plasma exchange and continuous hemofiltration she recovered without sequelae. The drug-induced lymphocyte stimulation test using gammaglobulin was negative. In addition, serum concentrations of IgA and IgG were normal. However, concentrations of cytokines, such as interleukin-6, TNF-α, and soluble interleukin-2 receptor, were very high. Complement C3, C4, and CH50 were reduced, but C3a was raised.

The authors suggested that an unknown mechanism associated with intravenous immunoglobulin infusion had caused non-specific activation of complement systems accompanied by fulminant hypercytokinemia.

Second-Generation Effects

Teratogenicity

Intravenous immunoglobulin is indicated for idiopathic thrombocytopenic purpura in pregnancy. No fetal abnormalities have been reported (101).

Susceptibility Factors

Because of reports of severe adverse effects, the presence of rheumatoid factor in patients with B cell neoplasia may constitute a contraindication to intravenous immunoglobulin (83).

Autoimmune disease

The risk of reactions to antilymphocyte globulin is increased in patients with autoimmune disease (126). Fever and chills, sometimes with extreme hyperpyrexia, nausea and vomiting, urticaria, and reduced platelet and granulocyte counts were reported after the administration of horse antithymocyte globulin.

© 2006 Elsevier B.V. All rights reserved.

Infusion of intravenous immunoglobulin 0.14 g/kg in 17 patients with autoimmune diseases, in whom circulating immunoglobulins had been depleted, was associated with a high incidence of serious adverse effects (94). Treatment was terminated in four patients because of adverse effects, including urticaria, severe hypotension, arthralgia, and chest discomfort.

In two reviews of intravenous immunoglobulin in systemic lupus erythematosus, there was worsening proteinuria and/or a rise in serum creatinine (127,128), whereas others treating similar patients did not detect deterioration (117,129).

Transplant recipients

The adverse effects of rabbit antithymocyte globulin in transplant recipients were pain and erythema at the injection site and in one instance polyarthritis with urticaria (130). Four cases in which malignant lymphoma developed in renal transplant recipients treated with antithymocyte globulin of animal origin have been reported (131).

Drug Administration

Drug contamination

Specifications in pharmacopeial monographs and product licences require intravenous immunoglobulin products to be free from significant amounts of anti-A and anti-B antibodies (132). It has been advised that a specification be adopted that will prevent the use of batches of intravenous immunoglobulin with abnormally high anti-D titers (over 1:64) (132).

Coagulation factors

Activated factor XIa has been demonstrated in samples of reconstituted intravenous immunoglobulin from eight different manufacturers (11). The degree of factor XIa contamination in intravenous immunoglobulin correlated with the manufacturer, suggesting that the purification process can affect residual factor XI concentration. Factor XIa can activate factor IX to factor IXa, and it can be hypothesized that there is a direct correlation between the presence of factor XI in intravenous immunoglobulin products and an increased risk of thrombotic complications.

Transmission of infection

The transmission of viral infections by immunoglobulins has occasionally been suspected. However, intravenous immunoglobulin preparations are considered relatively safe, and there are no reports of transmission of HIV or hepatitis B (44,101). This is probably because of the high degree of viral inactivation of the cold ethanol fractionation and the screening of every donation for several viruses, such as HIV and hepatitis B and C (85). Of 56 patients with autoimmune diseases who received 167 infusions of intravenous immunoglobulin, none developed antibodies to human immunodeficiency virus and hepatitis C virus or hepatitis B surface antigen (12).

In 1994, several cases of hepatitis C were reported, all traceable to a specific product (Gammagard®) (133). However, since the introduction of additional viral inactivation steps, such as solvent detergent, intravenous immunoglobulin is not considered to pose an infectious risk (69,101,134).

There has been some concern about possible transmission of hepatitis G. However, hepatitis G is an enveloped flavivirus with homology to hepatitis C and is probably also inactivated by the current procedures (58).

Although transmission of Creutzfeldt–Jakob disease through blood components and plasma products has never been documented, the FDA has suggested that there is a theoretical possibility that blood products may carry the responsible agent (135).

Transmission of hepatitis B and HIV after infusion of intravenous immunoglobulin has never been reported.

Life-threatening fulminant hepatitis due to transmission of human parvovirus B19 by intravenous immunoglobulin has been reported (136). The manufacturing process of this intravenous immunoglobulin product includes pasteurization (60°C for 10 hours), treatment with polyethylene glycol, ethanol fractionation, and nanofiltration. Removal of the small, non-lipid-enveloped parvovirus B19, which is highly resistant to different virus-reducing and inactivating steps, requires 15 nm nanofiltration.

A novel DNA virus, TT virus, has been implicated as a cause of post-transfusion hepatitis. A high prevalence of TT virus infection has been found in patients who received blood or blood components, such as factor VIII and IX concentrates. However, the PCR for TT virus DNA was negative in all 17 patients with immunodeficiency, who were treated prophylactically with intravenous immunoglobulin, as well as in 15 tested immunoglobulin formulations (137).

Drug administration route

Intramuscular, subcutaneous

Adverse effects associated with intramuscular or subcutaneous administration of immunoglobulin are extremely rare, and are usually related to IgA deficiency in the patient or to additives in the preparation (for example preservatives). Adverse effects associated with intravenous immunoglobulin are more frequently seen and may be either local or systemic (138,139). Local reactions are essentially attributable to the technique used and are not specific to the intravenous immunoglobulin.

Intravenous

Intravenous immunoglobulin is approved for the following indications: primary immune deficiencies, immune-mediated thrombocytopenia, Kawasaki disease, bone marrow transplantation, chronic B cell lymphocytic leukemia, and pediatric HIV infection (135). In addition, intravenous immunoglobulin is a promising immunomodulatory therapy for several neurological diseases, such as Guillain–Barré syndrome, chronic inflammatory demyelinating polyneuropathy, and multifocal motor neuropathy (41). Intravenous immunoglobulin has also been used in the treatment of several other antibody-mediated diseases, such as dermatomyositis, autoimmune neutropenia, pemphigus vulgaris, and pemphigus foliaceus (140–142).

Mild adverse effects of intravenous immunoglobulin, such as headache, chills, nausea, backache, and flushing, occur at a rate of 5–10% (101,135). Most of these

© 2006 Elsevier B.V. All rights reserved.

reactions are self-limiting and associated with over-rapid infusion (41). In patients with adverse reactions to intravenous immunoglobulin there was a significant rise in plasma IL-6 and thromboxane B_2 (143).

Drug–Drug Interactions

Contrast media

Acute renal insufficiency after intravenous immunoglobulin therapy has been reported in association with the injection of iodinated radiocontrast agents (144). Contrast media and intravenous immunoglobulin formulations containing maltose or sucrose both have toxic effects on renal cells.

Interference with Diagnostic Tests

Serum sodium measurement

Pseudohyponatremia, a laboratory artefact due to hyperproteinemia, has been observed during intravenous immunoglobulin treatment (145).

- In a 38-year-old man with end-stage renal insufficiency and thrombocytopenia secondary to systemic lupus erythematosus, pseudohyponatremia occurred after treatment with intravenous immunoglobulin 1 g/kg for 2 days (146).

This phenomenon is explained by the fact that intravenous immunoglobulin increases the non-aqueous phase of the plasma, resulting in a relative loss of plasma water volume. Sodium is virtually restricted to serum water, so each volume of plasma measured will contain less sodium and be interpreted as hyponatremia. Using a direct ion-selective electrode avoids this problem.

Immunotherapy

General Information

Desensitization is used in the treatment of IgE-mediated disease. Increasing doses of an allergen are injected subcutaneously over a varying time span. The aim of the treatment is to decrease sensitivity to the allergen and prevent the clinical symptoms caused by exposure to the allergen. Following immunotherapy, there can be an initial rise in specific serum IgE to the allergen, followed by a fall in specific IgE and a rise in specific IgG (blocking antibody). Immunotherapy also leads to reduced mediator release from mast cells in vitro, altered lymphocyte subsets, and down-regulation of cytokine secretion (interleukins 2, 4, and 5) by T cells (1).

It has been estimated that 60 million patients receive this treatment annually (2). Bearing in mind that about 40% of the population have atopy and that about half of these develop clinical disease ranging from rhinitis to life-threatening asthma, the scope for an effective and safe programme of desensitization is very large. However, there is no consensus on which extracts should be used, how often therapy should be given, and how long it should be continued if there is clinical improvement.

Efficacy

As far as the efficacy of immunotherapeutic desensitization is concerned, the merits of the treatment must be judged on the basis of:

1. Relief of symptoms and signs—a reduction in the response of a target organ to the specific allergen. In pollen rhinoconjunctivitis, a reduced response to the instillation of pollen into the conjunctival sac would be relevant. A reduction in the skin reaction to the specific allergen, especially a reduction in the late phase skin response (IgE-mediated), may be demonstrated. In asthma, a reduction in the specific bronchial response to inhaled allergen with an associated reduction in non-specific reactivity (measured by histamine or methacholine provocation) would indicate a response to treatment.
2. A reduction in or elimination of drug treatment.

Risks of desensitization

The risks of desensitization have to be set against the chance of benefits. The dominant risk is that of an allergic reaction. Subcutaneous injection of allergenic extracts can lead variously to:

- a transient wheal and flare at the injection site
- a localized delayed subcutaneous swelling with itching
- a systemic reaction in which urticaria, asthma, and hypotension may occur, the reaction not being severe enough to be classified as anaphylaxis
- anaphylaxis.

Large local reactions should be managed by a temporary reduction in the dose of the allergen, the use of antihistamines if needed, and ice applied to the injection site. Systemic reactions may resolve spontaneously or after one injection of adrenaline.

Anaphylaxis can be fatal and requires immediate treatment and measures to prevent recurrence. The Committee on Safety of Medicines, in a report cited below, recommended that allergenic products should only be given when facilities for full cardiopulmonary resuscitation are immediately available and that patients should be kept under medical observation for at least 2 hours after receiving an injection (3).

There is at present no evidence of any undesirable long-term adverse effect of repeated courses of allergenic

extracts, although non-allergic individuals may develop hypersensitivity, particularly when they receive extracts that contain aluminium. An isolated case of extensive subcutaneous inflammation and fibrosis with overlying skin changes was seen in a patient after 5 months of maintenance therapy (SEDA-17, 207).

The extent and timing of the risk has been delineated in some individual studies. In 419 patients treated with extracts of grass pollen or house dust mite adsorbed on to aluminium hydroxide, local reactions occurred in 10.5% and systemic reactions in 4.8% (4). In a survey of 27 806 injections there were 143 (0.51%) systemic reactions, of which 83% were mild and 17% (that is five reactions) needed treatment with adrenaline (5).

In a 10-year review (1981–91) of the reactions caused by subcutaneous immunotherapy, when 192 505 injections were given to 2206 outpatients, there were 115 systemic reactions, with no deaths. The most frequent reaction (67% of the total) was asthma with urticaria, while asthma alone occurred in 22%. Systemic reactions were much more frequent in asthmatic patients, although one-third of patients with reactions had never previously suffered from asthma. Most systemic reactions occurred during maintenance therapy. Almost always a reaction occurred within 30 minutes of the injection and was promptly controlled by routine therapy (SEDA-21, 189).

Improved formulations

It has been suggested that tyrosine-absorbed formulations with relatively short half-lives may be more dangerous in terms of immediate anaphylaxis. The alumpyridine formulation Allpyral has a long half-life, and in the UK over 4 million injections have been given with no deaths reported. Most allergen extracts are today in fact alum-precipitated, thus slowing absorption of the allergen, providing sustained immune stimulation and reducing the risk of serious anaphylaxis. Further modifications of standard allergens have been tried. Interaction between formaldehyde and allergen extract causes changes in the net charge of the allergen proteins and their tertiary structure. This reduces allergenicity/IgE-binding activity but retains immunogenicity, allowing more "allergoid" than untreated allergen to be injected before anaphylactic symptoms occur. At the higher doses tolerated a higher specific IgG concentration results. The adsorption of the allergoid on to aluminium hydroxide results in a depot formulation.

Enzyme-potentiated allergen is formed when low doses of allergen are mixed with beta-glucuronidase. It has been claimed that this formulation of allergen results in minimal or no adverse effects (6).

An alternative to injection treatment is oral immunotherapy. Gastric protein degradation prevents the use of orally administered peptide immunotherapy, but an oral delivery system using enteric-protected antigen protopolysaccharide microspheres has been developed. These formulations have been assessed in clinical trials, but to date the patient numbers have been too small to allow any useful conclusions about efficacy or the risk of adverse effects (SEDA-21, 189) (SEDA-21, 190) (SEDA-22, 196).

Benefit to harm balance

The benefit to harm balance in desensitization treatment was examined in a meta-analysis published in 1995, covering 20 randomized, placebo-controlled, double-blind trials of allergen immunotherapy for asthma. Systemic reactions occurred in a mean of 32% (20–44%) of patients, but anaphylaxis was reported on only four occasions. It was concluded that immunotherapy was a treatment option in highly selected patients with extrinsic allergic asthma where a clinically relevant and unavoidable allergen is identified (7).

The US Food and Drug Administration appointed a panel of experts to review desensitization therapy in 1974. The panel concluded that extracts used in accordance with generally accepted principles are associated with a minimal and acceptable risk of immediate reaction.

The Committee on Safety of Medicines reviewed the UK experience with desensitization in 1986, weighing efficacy against risk. They considered the evidence for efficacy and found it convincing for ragweed pollen, bee and wasp venom, and some antibiotics, but thought the evidence for grass pollen and house-dust mite less convincing. The Committee warned of the dangers of anaphylaxis and bronchospasm and noted that 26 patients had died since 1957, 5 in the preceding 18 months. With different products the risk of death varied from one in 8000 to one in 321 750 with no deaths recorded with some formulations. Anaphylaxis and bronchospasm had been reported with all formulations, the incidence varying from one in 300 to one in 14 998 (3).

The Committee on Allergen Standardization of the American Academy of Allergy and Immunology investigated 46 fatalities that occurred during immunotherapy or skin testing. They noted that the nature and severity of the initial symptoms did not appear to predict the fatal outcome or indicate the cause of death (SEDA-13, 136). In the 5 years from 1985 to 1989, 17 deaths due to allergen immunotherapy were reported, of which 16 were in patients with asthma. None occurred with skin testing. Unstable asthma or accidental overdoses were major contributory factors. The annual fatality rate in the USA from administration of allergenic extracts is low, at one fatality per 2 million doses (8).

Risk management

Some circumstances of special risk can be identified and avoided (9). The frequency of systemic reaction varies from less than 1% in patients receiving conventional immunotherapy to more than 36% in patients receiving rush immunotherapy. Common risk factors for a fatal or systemic reaction include a history of asthma, increasing allergen dose, high allergen sensitivity, a previous systemic reaction and injection during the active allergen season.

The Canadian Society of Allergy and Clinical Immunology have published guidelines for the use of allergen immunotherapy and these are similar to those developed by the American Academy of Allergy, Asthma, and Immunology. They recommend therapy with specific, standardized allergenic materials, administered in high-dose schedules, to patients with allergy to

insect stings or allergic rhinoconjunctivitis, and in some patients with asthma. The latter should be correctly diagnosed by a meticulous history, confirmed by positive skin tests and be insufficiently controlled by allergen avoidance and appropriate drug treatment (10).

The Thoracic Society of Australia and New Zealand and the Australasian Society of Immunology and Allergy have published guidelines for the use of specific allergen immunotherapy in the treatment of asthma patients (2). These should be read by practitioners who are considering immunotherapy for patients, especially those with asthma, who have a higher risk of a serious systemic reaction.

Specific allergens

Dermatophagoides farinae

The incidence of adverse systemic reactions during immunotherapy for perennial allergic rhinitis using standardized extracts of *Dermatophagoides farinae* has been estimated in 386 patients who received 22 722 injections. The incidence of systemic reactions was 6.22% per patient and 0.12% per injection. Systemic reactions began 3–30 minutes after an injection (average 11 minutes). Asthma, atopic dermatitis, and a high concentration of IgE (but not specific IgE) in serum were identified as important risk factors for severe systemic reactions. Systemic reactions occurred in 12 of 18 patients who had an IgE concentration over 100 U/ml and asthma and/or atopic dermatitis. In patients who had none of these risk factors the incidence of systemic reaction was 1.64% per patient. The authors estimated that the rate of systemic reactions could be reduced by 75% if patients with identified risk factors were strictly excluded from immunotherapy for allergic rhinitis (11).

Insect venoms

The efficacy of desensitization using subcutaneous maintenance venom immunotherapy is well established and is usually considered in patients with severe systemic allergic reactions to both yellow jacket and bee venom (grade III or IV according to Mueller).

Among 160 patients who were mostly allergic to bee venom and who were assessed for systemic allergic reactions to sting challenges while increasing the intervals of maintenance venom immunotherapy from 4–6 weeks to 3 months there were no serious adverse events (12). Two of 44 patients, who were deliberately stung during the 3-monthly maintenance therapy, had a mild systemic reaction. After withdrawal of venom immunotherapy, 22 patients allergic to bee venom were sting-challenged; one had a mild systemic reaction. In conclusion, the conventional 4–6 week maintenance interval can be safely extended to 3 months in most patients without any adverse events.

In 36 patients with a history of systemic reactions (grade III or IV according to Mueller) after exposure to a wasp sting, who were given immunotherapy with aluminium hydroxide-adsorbed wasp venom extract in an open retrospective study, a maintenance monthly depot of 50 000 SQU (50 micrograms) of venom was used (13). After the first year, the dose was injected every other month. Desensitization therapy was well tolerated. There were few mild local adverse events. Thirteen patients were exposed to stings during maintenance immunotherapy and four after withdrawal at the end of the 5-year treatment period. Field stings only provoked local skin reactions.

Near-fatal anaphylaxis, a rare complication of immunotherapy, has been reported (14).

- A 55-year-old man was stung by a *Polistes* wasp and had an anaphylactic reaction. Intradermal skin tests with wasp venoms were negative. Intradermal honeybee venom 1.0 microgram/ml and *Polistes* wasp venom 0.1 microgram/ml produced induration and erythema. Venom immunotherapy was given using the protocol of the Bayer Corporation: monthly maintenance injections of Bayer honeybee venom and *Polistes* wasp venom, 100 micrograms of each for 13 months without incident. Because of a national shortage of *Polistes* wasp venom manufactured by Bayer, *Polistes* wasp venom manufactured by ALK was substituted. Within minutes of receiving injections of 100 micrograms of Bayer honeybee venom and ALK *Polistes* wasp venom (both from new vials) he became light-headed and developed syncope. He recovered consciousness but remained hypotensive (74/0 mmHg). In a serum sample 2 hours after the start of the reaction serum tryptase was raised at 38 micrograms/ml (reference range 5.6–14 micrograms/ml) and IgE anti-honeybee venom and IgE anti-*Polistes* wasp venom concentrations were 3 and 10 ng/ml respectively.

The authors performed RAST inhibition to measure the relative potencies of the different venom extracts using the patient's serum as a source of IgE anti-venom. Although they initially suspected the new source of *Polistes* wasp venom, the relative potency tests showed greater variation in the honeybee venom. The IgG concentrations were consistent with this finding. This report emphasizes the care that must be taken with the preparation of each injection, especially when using a new batch of antigen.

Serum sickness has been described as a result of immunotherapy for wasp venom hypersensitivity. The illness was severe and treatment with glucocorticoids and seven plasma exchanges was required to induce a remission. There were two further relapses requiring the same treatment before recovery (SEDA-22, 197).

A follow-up of patients for 5 years after stopping venom immunotherapy has been reported. The authors concluded that the residual risk of a systemic reaction to a sting was 5–10% in adults. No severe or life-threatening reactions occurred with 270 challenge stings in 74 patients after 1–5 years without venom immunotherapy. The authors have extended these observations to 5–10 years and attempted to identify patients at greater risk of a reaction. Patients were surveyed for 3 consecutive years to determine the frequency of systemic reactions to field stings and the course of venom sensitivity. The patients included the original 74 (group 1) and 51 other patients followed after stopping venom immunotherapy (group 2). Eleven of the 74 patients in group 1 had field stings again after 3–7 years without venom immunotherapy. One systemic reaction (dyspnea) was reported. Of the 51 patients in group 2, 15 were stung, of whom 4 (26%) had systemic reactions, including respiratory symptoms necessitating the use of adrenaline. Six of the 13 patients (groups 1 and 2) with a systemic reaction to a sting after stopping

venom immunotherapy had had a systemic reaction during venom immunotherapy (to an injection or a sting). Only six of 76 patients who had no reaction during venom immunotherapy had a systemic reaction when stung after cessation of venom immunotherapy. Other risk factors were persistent strongly positive skin test sensitivity and the severity of the pretreatment reaction (15).

Indanediones

General Information

Indanediones have the same anti-vitamin K action as the coumarins. However they are generally more toxic than the coumarins, and can cause allergic reactions capable of involving many organs and sometimes resulting in death (1). These reactions are mainly observed with phenindione and are very rare with other indanediones, such as fluindione.

In an MRC trial (2), a 2.25% incidence of reactions necessitated withdrawal of phenindione.

Organs and Systems

Cardiovascular

As with the coumarins, the main complication of the indanediones is bleeding. The incidence of hemorrhage varies, depending on the age of the patient, the intensity of treatment, and the indication for using an anticoagulant. Hematuria, bruising, and gastrointestinal bleeding are the commonest signs. The most common site of fatal hemorrhage is intracranial (3).

Hematologic

Agranulocytosis can occur during the first month of treatment with phenindione (4). Anemia, thrombocytopenia (5), and leukemoid reactions (6) have also been described.

Liver

Hepatitis can rarely occur during indanedione treatment, most often with phenindione, although occasionally with fluindione (7,8). The mechanism is probably allergic. Resistance to treatment may be associated with the appearance of this reaction (8).

Urinary tract

Phenindione can cause renal insufficiency and the nephrotic syndrome, usually preceded by fever and skin reactions. In such cases, renal biopsy shows interstitial edema with infiltration by eosinophils and plasma cells. Tubular necrosis has also been observed(9).

Skin

Skin reactions are the commonest manifestations of allergic reactions. They generally occur during the first month of treatment and include erythematous, scarlatiniform, papular, and urticarial rashes, sometimes accompanied by fever. Severe exfoliative dermatitis has been reported (10,11).

Skin necrosis can occur during therapy with phenindione (12), as it does with the coumarin congeners.

Second-Generation Effects

Lactation

Massive neonatal scrotal hematoma occurred while the breast-feeding mother was taking phenindione (13).
