Pentetrazol (pentylenetetrazol) is a central and respiratory stimulant, similar to doxapram hydrochloride. It is a $GABA_A$ receptor antagonist and is anxiogenic (1). It has been used in respiratory depression and has also been included in multi-ingredient formulations for respiratory tract disorders, including cough, and for the treatment of hypotension and pruritus. However, the general consensus is that pentetrazol does not have a place in the treatment of respiratory depression (2).

Adverse reactions were mild in a controlled study of the efficacy of pentetrazol, alone and in combination with nicotinic acid, in 30 chronic hospitalized elderly patients. Improvement was better with the combined treatment, and only one subject, a 71-year-old woman, developed restlessness, anorexia, and weight loss (3).

Irritability, altered consciousness, and autonomic reactions, together with improvement in thought content and memory testing were noted in a double-blind, placebo-controlled study of pentetrazol 200 mg/day in 20 elderly patients. Nine of the ten patients lost weight (4).

Pentoxifylline

General Information

Pentoxifylline (oxipentifylline) is a methylxanthine that antagonizes the vasoconstrictor effects of catecholamines and increases cyclic AMP concentrations, causing smooth muscle to relax. It has also been claimed to correct impaired microcirculation, by improving various factors that disturb blood rheology, and to reduce the generation of toxic free radicals from leukocytes during ischemic leg exercise in patients with intermittent claudication. Pentoxifylline has been used to suppress overproduction of tumor necrosis factor alfa in conditions such as falciparum malaria and rheumatoid arthritis and in transplant recipients, with varied success.

Comparative studies

In 52 adults with cerebral malaria who were randomized to either quinine dihydrochloride alone ($n = 32$) or a combination of quinine and pentoxifylline ($n = 20$), the addition of pentoxifylline significantly improved coma resolution time from 64 to 22 hours and reduced mortality from 25% to 10% (1). Three days after therapy, serum tumor necrosis factor alfa concentrations fell significantly in those who received pentoxifylline. Pentoxifylline caused no serious adverse effects that necessitated withdrawal.

Placebo-controlled studies

The efficacy of pentoxifylline in treating claudication has been evaluated in double-blind, controlled trials in Europe and the USA. Several of these trials have shown that pentoxifylline 400 mg tds increases the walking distance significantly more than placebo in patients with claudication. However, critics remain skeptical about the real value of pentoxifylline, because of a negative correlation between the trial sample sizes and its effects, reflecting an overestimate of drug effect in highly selected trial populations (2). In a trial in almost 300 patients with acute ischemic stroke, the neurological deficit improved more rapidly with pentoxifylline in the initial phase, but the difference was not significant at the end of 1 week (3).

In a placebo-controlled trial in 114 patients with critical limb ischemia, twice-daily intravenous pentoxifylline 600 mg produced unimpressive results (4).

Unwanted effects of pentoxifylline recognized in the double-blind studies were gastrointestinal symptoms (chiefly nausea, vomiting, and bloating) and dizziness. Although common, they required drug withdrawal in only about 3% of patients.

Organs and Systems

Nervous system

Aseptic meningitis has been reported in a patient taking pentoxifylline (5).

- A 37-year-old woman with mixed connective tissue disease took pentoxifylline 400 mg/day for Raynaud's

phenomenon. After 12 days she complained of headache, myalgia, and neck pain and developed a fever. She recovered promptly after withdrawal of the drug. A few weeks later, she took a single tablet of pentoxifylline and within 1 hour developed the same symptoms together with chills, vomiting, and diarrhea. Neurological examination was normal, but the cerebrospinal fluid contained a large number of leukocytes. Bacteriological and virological tests were negative.

A diagnosis of aseptic meningitis was made and pentoxifylline was thought to have played a causative role because of the suggestive symptoms after first exposure, the close temporal relation on rechallenge, and the quick recovery after withdrawal. The authors argued that the underlying disease may have had a predisposing role, since aseptic meningitis secondary to pentoxifylline has never been reported in the thousands of patients who have used it for peripheral arterial disease. On the other hand, aseptic meningitis occurs with NSAIDs in patients with connective tissue diseases.

Psychological, psychiatric

Rare cases of hallucinations in elderly people have been ascribed to a stimulant effect of pentoxifylline on the central nervous system (SEDA-18, 219).

Hematologic

A single case of bleeding duodenal ulcer after a single dose of pentoxifylline was reported as being possibly secondary to disturbed platelet function induced by the drug (6). However, the effects of pentoxifylline on platelet function have not been very consistent, and the use of pentoxifylline may have been purely coincidental.

Immunologic

In an open, randomized, controlled trial in 56 children with cerebral malaria, the 26 children who received pentoxifylline 10 mg/kg/day by continuous infusion had significantly shorter periods of coma than the controls. The pentoxifylline recipients showed a trend toward a lower mortality. Pentoxifylline has an inhibitory effect on the synthesis of tumor necrosis factor alfa. The better outcome in the treated group was associated with a fall in tumor necrosis factor alfa serum concentrations on the third day of treatment in a few subjects; this was not seen in the controls (7).

However, in a later, randomized, placebo-controlled trial pentoxifylline neither reduced tumor necrosis factor alfa serum concentrations nor affected the clinical course in 51 patients who received it as adjunctive treatment to standard antimalarial therapy in a dosage of 20 mg/kg/day over 5 days (8).

Pergolide

General Information

The adverse effects of pergolide, a dopamine receptor agonist, resemble those of bromocriptine (SEDA-10, 118) (SEDA-13, 113).

It is almost universally accepted that directly acting dopamine receptor agonists have less efficacy than levodopa, although the reasons are not clear. Neurologists from London have sought to question this assumption by using cabergoline ($n = 11$) and pergolide ($n = 7$) at considerably higher doses than recommended (1). The actual mean doses were 8.8 and 9.4 mg/day, compared with recommended maxima of 6 and 5 mg/day respectively. The high doses were tolerated by the patients for 2.3–2.5 years; mild dyskinesias ($n = 7$), ankle edema ($n = 3$), and hallucinations ($n = 1$) were the only reported adverse effects. The authors concluded that the therapeutic window for these drugs is apparently much greater than is generally accepted, and that higher doses can be given safely with potentially enhanced efficacy.

In 41 patients with Parkinson's disease who took pergolide, confusion and hallucinations were the adverse effects that were most likely to result in withdrawal of pergolide (2). Symptoms suggestive of dose-related angina pectoris occurred in four patients in the open phase and two patients in the earlier double-blind phase; these symptoms were easily controlled by dosage reduction or withdrawal of pergolide without sequelae. There was leukopenia in one patient.

© 2006 Elsevier B.V. All rights reserved.

Organs and Systems

Cardiovascular

Symptoms suggestive of dose-related angina pectoris were observed in a number of patients, either early or late in treatment, but they were easily controlled by dose reduction without sequelae (2).

Pergolide can cause severe hypotension in patients already receiving antihypertensive agents (3).

Respiratory

Pleuropulmonary disease, especially with a fibrotic component, has been reported with all the ergot alkaloids after long-term use.

- A 65-year-old man, who had been taking pergolide 3.5 mg/day for 3 years to treat restless legs syndrome, presented with progressive weight loss, fatigue, and dyspnea (4). The history was of at least 2 years duration. A chest X-ray showed a loculated right hydropneumothorax, and a bloody pleural exudate was aspirated with no cytological evidence of malignancy. An open biopsy showed inflammatory changes and fibrosis. After withdrawal of pergolide and a short course of corticosteroids he made a full clinical and radiological recovery.
- A 73-year-old man who had taken pergolide 1.5 mg/day for 4 months developed dyspnea, bilateral pleural effusions, and severe edema of the legs up to the scrotum (5). There was no pleural thickening or any evidence of cardiac failure or nephrotic syndrome. These clinical features were resistant to diuretic therapy but resolved completely within a month of withdrawal of pergolide. The mechanism of this type of very rare reaction is totally unknown.

Nervous system

Long-term assessment pointed to confusion and hallucinations as the adverse effects most likely to occur requiring withdrawal of the drug (SEDA-15, 3) (2). Owing to its potency as a dopaminergic drug in patients with Parkinson's disease, dyskinesias can occur.

Sleep disorders can occur with pergolide, as with other dopamine receptor agonists.

- A 57-year-old woman and a 61-year-old man taking pergolide 4.5 mg/day and 5 mg/day respectively both suffered sleep disorders; the woman did not suffer from sleepiness but had abrupt sleep episodes, while the man was sleepy for much of the day (6). These were high doses and a reduction to 3 mg/day led to cessation of sleepiness in both patients.

Hematologic

Dose-related leukopenia developed in one patient (2).

Serosae

Most of the dopamine receptor agonists in current use are ergot derivatives, and these are known to cause serosal fibroinflammatory syndromes.

- Three men aged 61–70 years, who had taken pergolide 1–3.75 mg/day for 18–24 months for Parkinson's disease developed pericardial, pleural, or retroperitoneal fibrosis (one case of each) (7). Despite drug withdrawal, one patient needed pericardial exploration, one was left with residual evidence of severe ureteric obstruction, and one was left with persistent pleural disease.
- Pergolide 3 mg/day has been associated with retroperitoneal fibrosis in an 83-year-old woman after 18 months (8). She required ureteric stents, which were removed 2 years later, after her renal function had remained stable. Because of deterioration in her Parkinson's disease the non-ergot dopamine receptor agonist ropinirole was started and treatment was uneventful after 12 months.
- A 63-year-old British woman with Parkinson's disease was given pergolide in an attempt to minimize motor fluctuations in response to levodopa (9). After taking 4.5 mg/day for 8 months she developed shortness of breath and ankle swelling. This gradually deteriorated over the next year, despite diuretic therapy, and by that time her serum creatinine was 807 μmol/l and her hemoglobin was 8 g/dl. She had bilateral hydronephrosis on ultrasound scanning and a CT scan confirmed retroperitoneal fibrosis, which was successfully treated with nephrostomy and stenting, with resolution of the hydronephrosis. Pergolide was discontinued.

Dutch authors have described four patients, men aged 63–65 years, who had been treated for Parkinson's disease for 3–5 years with various doses (not all specified) of pergolide (10). In three cases pleural fibrosis was demonstrated on biopsy, while in the fourth there was pleural effusion with no histological evidence. On drug withdrawal there was clinical and radiological improvement in three cases but not in the fourth. On reviewing reports of similar adverse drug reactions the authors noted that the age and male preponderance of their patients was in keeping with previous reports. They observed that the dosage was generally higher in patients with retroperitoneal fibrosis compared with those with pleuropulmonary fibrosis. The duration of drug exposure was also a significant risk factor. Clearly, the fact that changes are often irreversible emphasizes the need for early detection and high levels of awareness of these problems.

- A 67-year-old man developed pericardial fibrosis and thickening while taking pergolide for Parkinson's disease (11). The symptoms and signs of heart failure emerged after 11 months, but the possible causative role of the drugs was not suspected for some months while the pericardial changes progressed, as did cardiac failure.

In this case the changes appeared to be wholly reversible on drug withdrawal.

Hair

Treatment with pergolide has very rarely been associated with reversible alopecia (12).

Sexual function

Czech neurologists have described seven men, aged 35–70 years, in whom sexual behavior was greatly increased and who had frequent spontaneous penile erections (13). All had been taking levodopa, to which pergolide 3 mg/day had been added, and all had advanced fluctuating

© 2006 Elsevier B.V. All rights reserved.

Parkinson's disease. In one case the dosage of pergolide was halved and in two others ropinirole or entacapone were used as alternatives, in all cases with reduction of the hypersexual symptoms. The other four patients continued to take pergolide, with persistence of the symptoms, to which they and their partners adjusted.

Second-Generation Effects

Teratogenicity

Parkinson's disease is very rare in pregnancy, but has been described (14).

- A 36-year-old woman with a 4-year history of Parkinson's disease, who had been taking pergolide 3 mg/day and levodopa 200 mg/day continued to take it during pregnancy. The end-of-dose wearing-off effect completely disappeared, and reappeared at their previous intensity after delivery. There were no adverse effects in the mother. The baby was healthy at birth and remained so at the time of the report, at the age of 13 months.

Perindopril

See also Angiotensin converting enzyme inhibitors

General Information

Perindopril is a prodrug ester of perindoprilat, an ACE inhibitor that has been used in patients with hypertension and heart failure. An updated review of its use in hypertension has appeared (1).

A large French open postmarketing study in 47351 hypertensive patients treated with perindopril for 12 months did not show unexpected adverse effects. The safety profile was similar to that of ACE inhibitors as a class (2).

Organs and Systems

Respiratory

Two cases of pneumonitis have been reported with perindopril (3). The second case was more convincing, because of the result of involuntary rechallenge, but the two cases had typical features of drug-induced pneumonitis. The authors referred to two previous reports of less typical but very likely cases of pneumonitis with captopril.

Skin

UVA photosensitivity induced by perindopril has been reported (4).

Peroxides

See also Disinfectants and antiseptics

General Information

Solutions of hydrogen peroxide containing 5–7% H_2O_2 are used for cleaning wounds and ulcers. The disinfectant and deodorant actions of hydrogen peroxide occur by oxidation of cell materials during the rapid release of oxygen while hydrogen peroxide is in contact with the tissues. The solution does not penetrate well, but the effervescence provides a mechanical means for detaching

© 2006 Elsevier B.V. All rights reserved.

necrotic tissue from inaccessible parts of wounds. It should not be used in closed body cavities. The germicidal action of hydrogen peroxide is relatively weak and of short duration.

Residues on insufficiently rinsed equipment disinfected by hydrogen peroxide can provoke local irritation, burns, and general reactions. Non-specific inflammation has been reported, with instantaneous blanching and effervescence on the surfaces of the intestinal mucosa during endoscopy (1).

Organs and Systems

Respiratory

Pneumomediastinum caused by subcutaneous emphysema has been reported in a 30-year-old man after the application of hydrogen peroxide solution to a root canal. The patient had acute pulpitis of the lower right third molar, treated by extirpation followed by irrigation with 3% hydrogen peroxide solution. Soon after irrigation, subcutaneous emphysema developed (2).

Hematologic

Hemolysis was reported after hemodialysis therapy with a dialysis fluid inadvertently contaminated with hydrogen peroxide (3).

Perphenazine

See also Neuroleptic drugs

General Information

Perphenazine is a phenothiazine neuroleptic drug.

Organs and Systems

Hematologic

Aplastic anemia, defined by the presence of pancytopenia and a hypocellular bone marrow in the absence of any abnormal blood cells, is a serious reaction that has been attributed to perphenazine in a single case (1).

- A 23-year-old man with schizophrenia taking perphenazine 4 mg bd, benzatropine mesylate 2 mg/day, lithium carbonate 600 mg each morning and 900 mg at bedtime, and famotidine 40 mg/day developed fatigue, shortness of breath, dizziness, light-headedness, and general debility. He had a pancytopenia, which persisted in spite of blood transfusions. Bone-marrow aspiration showed hypocellularity, absent megakaryocytes, reduced erythropoiesis and myelopoiesis, increased iron storage, and a relative excess of lymphoid cells. All medications were withdrawn and he was given lorazepam 2 mg bd. He recovered after 8 months.

Pertussis vaccines

See also Vaccines

Note on abbreviations

DTP = Diphtheria + tetanus toxoids + pertussis
DTaP = Diphtheria + tetanus toxoids + acellular pertussis
DTwP = Diphtheria + tetanus toxoids + whole cell pertussis

General Information

Whole-cell and acellular pertussis vaccines have been reviewed, with emphasis on the protectivity of the various virulence factors and antigens (1). The authors summarized their review as follows: although *Bordetella pertussis* has at least five proteins required for virulence and an additional two "toxic" components, only serum neutralizing antibodies to pertussis toxin have been shown to confer immunity to pertussis.

Acellular pertussis vaccine

Quality control of acellular pertussis vaccines presents particular problems related to the various methods used for preparation of the active components, the different compositions of the final formulations, and different amounts of antigen. Researchers in the National Institute for Biological Standards and Control in the UK have presented a strategy capable of addressing the key problem areas likely to be encountered with all existing types of acellular pertussis vaccines and combinations (2). Their proposal could be considered as a starting point for improvement of quality control programs for these vaccines.

An overview of clinical trials with a special diphtheria and tetanus toxoids and acellular pertussis (DTaP) vaccine has been published (3). The vaccine contains as pertussis components purified filamentous hemagglutinin, pertactin, and genetically engineered pertussis toxin. The vaccine induces high and long-lasting immunity and is at least as efficacious as most whole-cell pertussis vaccines and similar in efficacy to the most efficacious acellular

© 2006 Elsevier B.V. All rights reserved.

pertussis vaccines that contain three pertussis antigens. The vaccine is better tolerated than whole cell vaccines and has a similar reactogenicity profile to other acellular vaccines.

A vaccine containing diphtheria and tetanus toxoids and acellular pertussis with reduced antigen content for diphtheria and pertussis (TdaP) has been compared with a licensed reduced adult-type diphtheria–tetanus (Td) vaccine and with an experimental candidate monovalent acellular pertussis vaccine with reduced antigen content (ap) (4). A total of 299 healthy adults (mean age 30 years) were randomized into three groups to receive one dose of the study vaccines. The antibody responses (anti-diphtheria, anti-tetanus, anti-pertussis toxin, anti-pertactin, anti-filamentous hemagglutinin) were similar in all groups. The most frequently reported local symptom was pain at the injection site (62–94%), but there were no reports of severe pain; redness and swelling with a diameter of 5 cm or more occurred in up to 13%. The incidence of local symptoms was similar after TdaP and Td immunization. The most frequently reported general symptoms were headache and fatigue (20–50%). The incidence of general symptoms was similar in the TdaP and Td groups. There were no reports of fever over 39°C. No serious adverse events were reported.

Japanese studies of acellular vaccines

The first generation of the new acellular vaccines was developed in Japan in the late 1970s (Sato). Since late 1981, acellular vaccines have replaced the whole-cell pertussis vaccines for use in the Japanese immunization program. Two types of acellular pertussis vaccine have been produced by six Japanese manufacturers (5,6) (SEDA-12, 276) (SEDA-13, 283) (SEDA-14, 279). No doubt as a result of these measures the rate of reported serious reactions has decreased in Japan. During the period 1975–81, when whole-cell vaccines were given, the rate was 0.4 per million doses, compared with a rate of 0.25 per million doses during the period 1982–84 (7). In 1988, Kumura and Kuno-Sakai (8) summarized the experience gained in Japan since the introduction in 1981 of the new DTP vaccines containing acellular pertussis components. Acellular vaccines seem to be effective in Japan, since in parallel with their wider use the numbers of reported cases of pertussis and pertussis deaths have declined. Reactogenicity (as expressed by fever or local reactions) was very low. Kimura and Kuno-Sakei cited reports of Quincke's edema-like swelling of the whole arm following the third injection (0.17% of vaccinees) and the booster injection (2.61%), respectively. Data on more severe adverse events have been collected from 1970 to 1986 in the framework of the National Adverse Reaction Compensation System (SED-12, 818). Kimura and Kuno-Sakei considered the vaccines to be safe and effective enough to eliminate pertussis in Japan in the future (8).

European studies of acellular vaccines

The epidemiological circumstances in Sweden and in parts of Germany and Italy, where the immunization programs against pertussis using whole-cell vaccine had been discontinued or reduced because of public concern about rare severe adverse events, offered good opportunities to assess the clinical efficacy and safety of acellular pertussis vaccines. In Germany, both controlled field trials and a household contact study were carried out. Different mono-component and multi-component acellular vaccines from European and US manufacturers were used in European trials. They comprised a mono-component vaccine composed only of detoxified pertussis toxin (toxoid); a two-component vaccine composed of pertussis toxin and filamentous hemagglutinin; a three-component vaccine composed of pertussis toxin, filamentous hemagglutinin, Pertactin; and another five-component vaccine composed of pertussis toxin, filamentous hemagglutinin, Pertactin, and fimbriae antigens 2 and 3. In some instances they were compared directly with whole-cell pertussis vaccines. In general, the acellular vaccines were found to be immunogenic, epidemiologically effective, and less reactogenic than the whole-cell pertussis-component vaccines as assessed in terms of fever, pain, fretfulness, and local reactions at the injection site. Based on the results, acellular pertussis vaccines have since been licensed in many countries of the world both for primary and booster immunization. Details regarding the results and conclusions of the large-scale field trials completed in 1994 and 1995 in Germany, Italy, and Sweden have been reviewed (SEDA-19, 298), as have reports on other clinical trials using acellular pertussis vaccines (SED-12, 818) (SEDA-12, 277) (SEDA-13, 283) (SEDA-14, 279) (SEDA-15, 350) (SEDA-16, 382) (SEDA-17, 370) (SEDA-18, 332) (SEDA-20, 289) (SEDA-21, 230). The optimal composition of acellular vaccines has not yet been determined: the number of antigens still varies from one to five, and antigen amounts are also different. Post-licensing studies will therefore be of the utmost importance in studying the induction of herd immunity and possible rare events.

Local effects of acellular vaccines: effect of number of injections

Data on the use of a single DTaP vaccine for four-dose or five-dose series are limited, but the available data show a substantial increase in the frequency and magnitude of local reactions with successive doses. The accompanying tables show reactions after the fourth dose (Table 1) and fifth dose (Table 2). The original data and references are included in the supplementary recommendations of the Advisory Committee on Immunization Practices (ACIP) on the use of DTaP vaccines in a five-dose series (9). Reports from Alberta and British Columbia provinces, Canada, have suggested that the incidence rates of severe local adverse reactions may increase with each dose (third, fourth, fifth) in preschool children (10).

Limb swelling after booster doses of acellular vaccines

Swelling involving the entire thigh or upper arm has been reported after booster doses of different acellular pertussis vaccines, for example in a German study during April 1993 to November 1994 using a fourth dose of Infanrix. There was an increase in thigh circumference in 1.2–3.2% of children; swelling began within 48 hours of a booster dose and the mean duration was 3.9 (range 1–7) days; the

Induration	14%		21% >5 cm
Tenderness	38%		

mean increase in circumference was 2.2–5.0 cm; in a few children, the swelling interfered with walking.

Similar swelling and substantial local reactions have been observed in fourth-dose and fifth-dose follow-up studies from the Multicenter Acellular Pertussis Trial, which examined 12 different DTaP vaccines, and in recent studies of the fifth dose of Tripedia and Infanrix in Germany. The pathogenesis of both substantial local reactions and limb swelling is unknown. Associations with pertussis toxoid, diphtheria toxoid, or aluminium in the vaccine have been discussed. Because reports to date have suggested that the reactions are self-limited and resolve without sequelae, and in recognition of the benefits of a fifth dose of DTaP, the ACIP has recommended that a history of extensive swelling after the fourth dose should not be considered to be a contraindication to a fifth dose of DTaP. Parents or caregivers of children who receive fourth and fifth doses of a DTaP series should be informed of the increases in reactogenicity that have been observed (9).

Whole-cell pertussis vaccine

Pertussis whole cell vaccine is an adsorbed suspension of inactivated pertussis bacteria. The vaccine is available in monovalent form or in combination with diphtheria and tetanus toxoids (DTP). DTP vaccine is the preparation of choice in routine immunization practice.

Local reactions are common after DTP immunization (40–70% of the vaccinees) but are usually self-limiting (10). A nodule may be palpable at the injection site of adsorbed products for several weeks. Abscess at the injection site has been reported (6–10 per million vaccinees). Mild to moderate fever (38.0–40.4°C) occurs frequently (about 50% of vaccinated infants), generally within several hours of administration, persisting for 1–2 days. Fever and other systemic symptoms are much less common following immunization with preparations not containing the pertussis component. Arthus-type hypersensitivity reactions occur, particularly after booster doses. Rarely, severe systemic reactions (urticaria, anaphylaxis) have been reported.

The non-neurological adverse effects of whole-cell immunization have been reviewed (SED-12, 815) (SEDA-16, 379) (SEDA-17, 370) (SEDA-18, 330). The most frequent are mild fever, drowsiness, and reduction in appetite; a very small percentage of vaccinees experience more severe fever, redness, swelling, pain, "fussiness", or vomiting.

A follow-up study has been carried out in 105 children with collapse (a hypotonic-hyporesponsive episode or a shock-like syndrome) after their first immunization with DTwP + IPV vaccine (11). Information about subsequent immunizations, health, and development in 101 of the children was supplied by child health-care units. The parents of one child refused further immunization, 16 children completed their schedule with the combination diphtheria + tetanus + poliomyelitis vaccine (DT-IPV), and the other 84 children received further pertussis vaccine (DTP-IPV), totalling 236 doses; 74 children received the complete series of three additional doses. None of the children had recurrent collapse, and other adverse events were only minor. About half were given paracetamol prophylactically for the first subsequent dose; most of them did not take it for further doses. The authors suggested that it is unnecessary to withhold further doses of pertussis vaccine in a child with collapse after a previous dose. It has been suggested that the threat of natural pertussis in non-immunized children should be taken much more into account than the fear of developing a collapse reaction (12). In another study (13) in the USA, one of the 14 children not completely immunized because of a hypotonic-hyporesponsive episode after a previous dose later developed natural pertussis, which lasted for 3 months and was transmitted to both her parents.

Acellular pertussis vaccine versus whole-cell pertussis vaccine

In a randomized, double-blind trial to determine the efficacy of vaccination against *Bordetella* infection, a

multi-component acellular pertussis has been compared with a whole-cell product and diphtheria + tetamus toxoids (DT) in 8532 infants aged 2–4 months, who received four doses of either DTwP or DTaP vaccine at 3, 4.5, 6, and 15–18 months of age, and 1739 controls, who received three doses of DT vaccine at 3, 4.5, 15–18 months of age (14). All the vaccines were generally well tolerated. However, adverse reactions were significantly less common after DTaP compared with DTwP vaccine. Persistent inconsolable crying was four times more common in DTwP recipients than in DTaP recipients. High fever, 40.5°C or over, was three times more common in DTwP vaccinees than in DTaP vaccinees. Only one DTaP recipient had a convulsion in temporal relation to immunization.

The 2000 Childhood Immunization Schedule, proposed by the Advisory Committee of Immunization Practices (ACIP), the American Academy of Pediatrics, and the American Academy of Family Physicians, recommended that acellular pertussis vaccines be exclusively chosen for routine use in the USA (15).

One evaluation of the results of two studies in a total of 182 children primed either with acellular or with whole-cell pertussis vaccines at 2, 4, and 6 months of age and boosted with an acellular vaccine has shown that booster doses of acellular vaccine are safe and immunogenic (16). Local adverse reactions after booster immunization with acellular vaccine were more common in children primed with acellular vaccine than in those primed with whole-cell pertussis vaccine (68 versus 33%). In another and similar study, children primed with acellular or whole cell pertussis combined with DT vaccine have been boosted with a recombinant acellular pertussis vaccine combined with DT vaccine. The vaccine was highly immunogenic and safe (17).

From 1991 to 1993 about 27 million doses of DTP vaccine and 5 million doses of DTaP (that is acellular) vaccine were distributed in the USA. The results of a postmarketing comparison of the safety of acellular pertussis vaccines with whole-cell pertussis vaccines have been published. The rates of reported adverse events per 100 000 immunizations were significantly lower after the administration of DTaP vaccine than after DTP vaccine for the following outcomes: all reports (2.9 versus 9.8); fever (1.9 versus 7.5); seizures (0.5 versus 1.7); and hospitalizations (0.2 versus 0.9) (18).

The safety and immunogenicity of 12 acellular pertussis vaccines and one whole-cell pertussis vaccine given as a fourth dose have been compared in 1293 children aged 15–20 months. In general, DTaP vaccines were associated with fewer adverse events than a US-licensed DTwP vaccine (SEDA-22, 342).

A randomized, controlled comparison of two-component, three-component, and five-component acellular pertussis vaccines and a whole-cell pertussis vaccine has been carried out in 82 892 infants who were immunized either at age 3, 5, and 12 months, or at 2, 4, and 6 months. High fever and seizures occurred more often after whole-cell vaccine than after any of the acellular vaccines. Hypotonic-hyporesponsive episodes also occurred significantly more often in the whole-cell group and were more frequent in the acellular groups than previously reported (SEDA-22, 342).

An informal consultation of invited epidemiologists, infectious disease clinicians, immunologists, representatives of regulatory agencies for biological products, and other scientists and public health officials was held in Geneva on 18–19 May 1998 on the control of pertussis using whole-cell and acellular pertussis vaccines. The consultation was called jointly by the Children's Vaccine Initiative and the World Health Organization Global Program on Vaccines. The report of the meeting including the conclusions at full length has been summarized (SEDA-22, 341). The main conclusions read as follows. Whole-cell vaccines of documented quality have proved to be highly effective tools for preventing pertussis. Acellular pertussis vaccines are valuable alternatives to whole-cell vaccines for immunization in infancy. Because of their safety profiles, acellular vaccines may be preferred alternatives in industrialized countries, in which pertussis vaccination with whole-cell vaccines is not widely accepted. In each country, recommendations for the use of pertussis vaccines will be based on local risk–benefit and cost–benefit analyses. The use of acellular vaccines in many circumstances can be further considered for booster doses (fourth and fifth doses) in improving pertussis control after evaluation by local authorities of the epidemiological, cost, and programmatic issues. Additional data on the potential benefit of booster doses using acellular pertussis vaccines in adolescence or older ages are needed. The current control regulations and recommendations for pertussis vaccines (whole-cell and acellular) needs thorough review in the light of recently available scientific data, and appropriate revisions should be made (19).

Comparisons of DTP and DT

An older study in the USA compared the rates of both minor and more serious reactions in 15 752 children 0–6 years of age to DTP vaccine and in 784 children to DT vaccine. The frequencies of minor reactions associated with DTP and DT are shown in Table 3. The reactions after DT were not only less frequent, but also less severe. Convulsions and hypotonic-hyporesponsive episodes each occurred in one per 1750 immunizations (20).

Data from the Monitoring System for Adverse Events Following Immunization (MSAEFI) (SEDA-13, 274) show that the adverse effects rate for DTP vaccine was twice as high as that for DT vaccine. The most reported adverse effect was fever (59% of all reports) followed by

Table 3 Frequencies of minor reactions associated with DTP and DT

Adverse effect	DTP (%)	DT (%)
Fitfulness	53	23
Pain	51	9.9
Fever	47	9.3

local reactions (36%) (21). Similar results have been published by Dittmann (13.5 severe adverse effects per million vaccinees after DTP immunization and 4.8 reactions per million vaccinees after DT immunization) (22) and by Miller and colleagues (23).

Tetravalent, pentavalent, and hexavalent immunization

DTaP or DTwP vaccine can be combined with other antigens, such as *Haemophilus influenzae* type b (Hib), inactivated poliovirus (IPV), and hepatitis B vaccine. In children DTaP or DTwP vaccines form the basis for such combinations, while in adults it is mostly Td vaccine. Current safety concerns regarding combination vaccines have been defined and reviewed (24). The author concluded that there is no evidence that adding vaccines to combination products increases the burden on the immune system, which can respond to many millions of antigens. Combining antigens usually does not increase adverse effects, but it can lead to an overall reduction in adverse events. Before licensure, combination vaccines undergo extensive testing to assure that the new products are safe and effective.

The frequency, severity, and types of adverse reactions after DTP-Hib immunization in very pre-term babies have been studied (25). Adverse reactions were noted in 17 of 45 babies: nine had major events (apnea, bradycardia, or desaturation) and eight had minor reactions (increased oxygen requirements, temperature instability, poor handling, and feeding intolerance). Babies who had major adverse reactions were significantly younger at the time of immunization than the babies who did not have major reactions. Of 27 babies immunized at 70 days or less, nine developed major reactions compared with none of those who were immunized at over 70 days.

The Hexavalent Study Group has compared the immunogenicity and safety of a new liquid hexavalent vaccine against diphtheria, tetanus, pertussis, poliomyelitis, hepatitis B, and *Haemophilus influenzae* type b (DTP + IPV + HB + Hib vaccine, manufactured by Aventis Pasteur MSD, Lyon, France) with two reference vaccines, the pentavalent DTP + IPV + Hib vaccine and the monovalent hepatitis B vaccine, administrated separately at the same visit (26). Infants were randomized to receive either the hexavalent vaccine ($n = 423$) or (administered at different local sites) the pentavalent and the HB vaccine ($n = 425$) at 2, 4, and 6 months of age. The hexavalent vaccine was well tolerated (for details, see Table 4 and Table 5). At least one local reaction was reported in 20% of injections with hexavalent vaccine compared with 16% after the receipt of pentavalent vaccine or 3.8% after the receipt of hepatitis B vaccine. These reactions were generally mild and transient. At least one systemic reaction was reported in 46% of injections with hexavalent vaccine, whereas the respective rate for the recipients of pentavalent and HB vaccine was 42%. No vaccine-related serious adverse event occurred during the study. The hexavalent vaccine provided immune responses adequate for protection against the six diseases.

Organs and Systems

Nervous system

The question of nervous system complications and persistent brain damage after whole-cell pertussis vaccination has been argued for a long time. During the 1980s it was debated by physicians as well as by the general public in several countries. Reports, publications, and national evaluations of the matter led some countries to change their national pertussis immunization policy. In the autumn of 1981, Japan replaced the whole-cell vaccine with acellular pertussis vaccine developed by Sato in Japan. Sweden ended its pertussis (whole-cell vaccine) immunization program in 1979. As a result of the prominence accorded

to the risks involved, the pertussis vaccine coverage rates in the UK fell sharply at the beginning of the 1980s, but were increasing again when some large pertussis epidemics occurred as a result of diminished population immunity. In the 1980s, in the erstwhile Federal Republic of Germany, pertussis immunization was only recommended for children at special risk but from 1991 onwards the approach changed again and use of DTP was advised throughout what was now a united Germany. Severe neurological adverse effects of whole-cell pertussis immunization has been reviewed in detail, including reports on the legal cases brought in the English High Court pertussis vaccine trials (SED-12, 817).

It would now seem that the long debate has been resolved. The first step toward its resolution was taken in a review of all information available worldwide which was presented in a report produced in 1991 by the Institute of Medicine of the National Academy of Sciences, Washington (27) (SED-12, 817). It was concluded that:

- there is evidence indicating a causal relation between DTP vaccine and anaphylaxis, febrile seizures and inconsolable crying;
- there is weaker evidence pointing to a relationship between DTP vaccine and acute encephalopathy and hypotonic-hyporesponsive episodes;
- there is no reason to believe in an association between vaccination and the occurrence of infantile spasms, afebrile seizures, hypsarrhythmia, Reye's syndrome, or sudden infant death syndrome;
- there is insufficient evidence to indicate either the presence or absence of a causal relation between DTP vaccine and chronic neurological damage, epilepsy, aseptic meningitis, erythema multiforme or other rash, Guillain–Barré syndrome, hemolytic anemia, juvenile diabetes, learning disabilities and attention-deficit disorder, peripheral mononeuropathy, or thrombocytopenia.

In 1993, Miller and colleagues (28) and Madge and colleagues (29) presented the results of a 10-year follow-up study of the National Childhood Encephalopathy Study (NCES) carried out in 1976–79. The findings suggested a small excess risk of severe acute neurological events within 7 days of pertussis immunization, but the risk of permanent damage due to the vaccine, if any, was slight. Follow-up of cases and controls from this study for some years has shown that significantly more children with such illnesses die or suffer subsequent educational, behavioural, or neurological deficits than expected by comparison with controls, but the number of cases associated with pertussis vaccine was small and statistically vulnerable.

The committee responsible for the report of the Institute of Medicine concluded in 1994 that the recent findings from the NCES necessitated a review of the conclusion that the evidence is insufficient to indicate a causal relation between DTP and permanent neurological damage. After having reviewed the new NCES data, the committee declared that the balance of evidence was consistent with a causal relation between DTP vaccine and the forms of chronic nervous system dysfunction described in the NCES in children who have a serious acute neurological illness within 7 days after receiving DTP vaccine. This type of serious acute neurological response to DTP is rare. The estimated excess risk ranged from 0 to 10.5 per million immunizations. The evidence remains insufficient to indicate the presence or absence of a causal relation between DTP vaccine and chronic nervous system dysfunction under any other circumstances (30).

Finally, Gangarosa and colleagues have reviewed in detail the so-called pertussis vaccine encephalopathy. Seven epidemiological studies have been conducted; they show that neurological reactions are exceedingly rare with whole-cell pertussis vaccines (SEDA-21, 329).

Susceptibility factors

The (US) Immunization Practices Advisory Committee (ACIP) has recommended that a personal history of a prior convulsion should be evaluated before initiating or continuing immunization with vaccines containing a

© 2006 Elsevier B.V. All rights reserved.

pertussis component. The presence of an evolving neurological disorder contraindicates pertussis immunization. Other contraindications to the receipt of pertussis vaccine are hypersensitivity to vaccine components or a history of a severe reaction following an earlier dose (31). Reviewing the data on the relation between a family history of convulsions and immunization with pertussis-containing vaccines, both the ACIP as well as the US Committee on Infectious Diseases considered that a family history of convulsions in parents and siblings was not a contraindication to pertussis immunization. The ACIP and other authors, believe that the use of an antipyretic (for example paracetamol given at a dose of 15 mg/kg at the time of DTP immunization and again 4 hours later) in conjunction with DTP vaccine may be reasonable in children with personal or family histories of convulsions since it will reduce the incidence of post-immunization fever (32,33).

Skin

Bullous pemphigoid has been attributed to DTP-IPV vaccine (34).

- A previous healthy 3.5-month-old infant developed bullous pemphigoid 3 days after receiving a first dose of DTP-IPV vaccine. *Staphylococcus aureus* was isolated from purulent bullae. The lesions resolved rapidly after treatment with antibiotics and methylprednisolone.

The authors mentioned 12 other cases of bullous pemphigoid, reported during the last 5 years, that had possibly been triggered by vaccines (influenza, tetanus toxoid booster, and DTP-IPV vaccine).

Immunologic

Data from the Third National Health and Nutrition Survey (1988–94) have been used to analyse the possible effects of DTP or tetanus immunization on allergies and allergy-related symptoms among 13 944 infants, children, and adolescents aged 2 months to 16 years in the USA (35). The authors concluded that DTP or tetanus immunization increases the risk of allergies and related respiratory symptoms in children and adolescents. However, the small number of non-immunized individuals and the study design limited their ability to make firm causal inferences about the true magnitude of effect.

It has been suggested that the development of a sterile abscess represents an idiosyncratic reaction of some individuals, perhaps genetically determined, which causes a granulomatous response to antigens, irrespective of the location of the vaccine (36). Others maintain that it is caused by a contaminated needle track or to vaccine material coating the outside of the needle, resulting from the lack of a proper injection technique.

Susceptibility Factors

Age

Details regarding the age-related efficacy of the use of paracetamol and the inefficacy of prophylactic paracetamol given in a single dose have been published (SEDA-14, 277).

Drug Administration

Drug formulations

In a study of local and systemic reactions following 9920 DTP immunizations there were significant differences relating to different manufacturers and different vaccine lots (37).

Drug additives

Eight children developed urticaria within 30 minutes after administration of a diphtheria + tetanus + acellular pertussis (DTaP) vaccine that contained gelatin as a stabilizer (38). None of the children had anti-gelatin IgE, and only two had detectable concentrations of anti-toxoid IgE to diphtheria and pertussis toxoids. No methods to measure anti-thiomersal and anti-alum IgE were available. The authors recommended the development of such methods, which could improve research into the causality of adverse effects of this sort.

Drug administration route

The "two-needle strategy," based on the hypothesis that changing the needle on the syringe after drawing up the DTP vaccine and before injecting reduces local reactions by eliminating deposition of aluminium adjuvant in the subcutaneous track of the needle, has been evaluated (39). When immunizing 223 children using this strategy and 200 others using the "one-needle strategy," there was no significant difference in the occurrence of local or systemic reaction.

Pethidine

General Information

Pethidine (meperidine) is about one-tenth as potent as morphine in terms of analgesia. It is metabolized in the liver by hydrolysis and conjugation, either directly or via *N*-demethylation to norpethidine. Norpethidine (normeperidine) is significantly less analgesic, with a longer half-life (15–20 hours).

There has been a systematic review of the postoperative analgesic efficacy and adverse effects of pethidine and ketorolac compared with placebo in published randomized, controlled, double-blind studies (1). The authors reviewed studies of moderate to severe postoperative pain relief and the use of single doses by injection (intravenously or intramuscularly) or orally. Studies of epidural, intrathecal, or intravenous administration using patient-controlled analgesia were excluded. Of the 24 placebo-controlled pethidine studies, only 8 met the inclusion criteria and these generated 10 pethidine versus placebo comparisons and 254 patients given pethidine 50 mg or 100 mg intramuscularly. No studies of oral or intravenous pethidine at any dose met the inclusion criteria. Only the eight comparisons of pethidine 100 mg versus placebo ($n = 203$) had sufficient information available for analysis of adverse effects. The overall conclusion was that opioids carry a small but finite risk of serious adverse effects, such as respiratory depression, and a greater risk of minor adverse effects than single-dose injected or oral NSAIDs like ketorolac. Analgesia from the injected opioid or NSAID was equivalent to that achieved with oral NSAIDs. For those who cannot swallow, the choice is injected opioids like pethidine.

In a double-blind, randomized, placebo-controlled study, 40 patients who were scheduled for elective cesarean section under spinal anesthesia were given intrathecal 0.5% hyperbaric bupivacaine 2 ml together with either 5% pethidine 0.2 ml or isotonic saline (2). The pethidine group had a significantly greater incidence of intraoperative nausea or vomiting, with significantly better immediate postoperative analgesia, which was not sustained 4 hours after surgery.

In a randomized, controlled study in 611 mothers, 310 were randomized to intramuscular pethidine up to 300 mg and 301 to epidural 0.25% bupivacaine 10 ml with an infusion of 0.125–0.25% bupivacaine (3). There were no significant differences in analgesic efficacy, adverse effects, or the incidence of backaches.

Organs and Systems

Cardiovascular

- A 70-year-old patient with a metastatic carcinoid tumor of the liver presented with a hypertensive crisis after being given pethidine 10 mg/hour by continuous intravenous infusion (4). The patient remained hypertensive with a systolic blood pressure of 210 mmHg, even after chemoembolization of the tumor. The blood pressure fell when pethidine was withdrawn and nitroprusside was given. The serum 5-HT concentration was 15 μmol/l (reference range 0.17–0.26) and the urine 5-hydroxyindoleacetic acid concentration was 1311 mg/g of creatinine (reference range less than 10).

The authors postulated that the hypertensive crisis had occurred from the release of 5-HT from the tumor and blockade by pethidine of 5-HT re-uptake.

When used for sedation in children undergoing esophagogastroduodenoscopy, hypoxia with dysrhythmias was more likely to occur with a combination of pethidine and diazepam than with pethidine and midazolam (SEDA-18, 81).

Nervous system

Cases of severe reversible neurotoxicity and parkinsonism are on record (SED-11, 143) (SEDA-18, 82) (5,6). Severe nervous system syndromes may also result from interactions (see the monograph on Opioid analgesics).

Although seizures are uncommon, several cases have been reported, including when pethidine was used in PCA. The metabolite norpethidine is considered to be of significant importance in provoking seizures. Risk factors are renal insufficiency, sickle-cell anemia, high doses of pethidine, and concurrent administration of phenothiazines or drugs that induce hepatic enzymes (SEDA-16, 85) (SEDA-18, 82) (SEDA-19, 85). Myoclonus can occur (7). Norpethidine is twice as likely as pethidine to cause convulsions. The seizures occur at a norpethidine concentration range of 0.38–9.9 μg/ml, and only few reports have described convulsions within the first 24 hours of pethidine treatment.

- A 35-year-old woman, who was admitted for elective laparotomy and ileostomy formation was given patient-controlled analgesic with pethidine for postoperative analgesia (8). The device was set to deliver 20 mg of pethidine with a 5-minute lock-out period and no hourly limit. At 4 hours postoperatively she did not have pethidine-related neurotoxicity, but at 23 hours she had myoclonic jerks and facial twitching followed by a brief generalized tonic-clonic seizure and postictal sequelae. The pethidine was withdrawn and there was no further seizure activity. She had self administered a total of 2700 mg. The norpethidine concentration was 1.8 μg/ml.

Two of three patients with seizures due to norpethidine toxicity (9–11) had renal disease.

- A 46-year-old woman with previous extensive urological problems, including ureteric stricture and recurrent urinary tract infections, was given pethidine in a total cumulative dose of 1500 mg postoperatively over 12 hours when she presented with a single tonic-clonic seizure that lasted 30 seconds. The pethidine concentration was 1200 ng/ml and the norpethidine concentration 2100 ng/ml.
- A 72-year-old patient with end-stage renal insufficiency undergoing peritoneal dialysis developed myoclonic contractions and a generalized tonic-clonic seizure 48 hours after having been given pethidine in a total cumulative dose of 250 mg intravenously and 600 mg

© 2006 Elsevier B.V. All rights reserved.

orally. The neurotoxicity resolved after withdrawal of pethidine and 4 hours of hemodialysis.
- A 2-month-old boy presented with muscle rigidity of the arms and legs, catatonia, and an exaggerated startle reflex after being erroneously given a single dose of pethidine 1 mg/kg. The symptoms subsided without any active intervention.

Two case reports have highlighted the potential danger of injecting pethidine into the lateral thigh region, which can cause injury to the femoral nerve branch to the vastus lateralis, causing muscle atrophy (12).

In a retrospective survey of 355 medical records of patients who received intravenous PCA pethidine between 1988 and 1994 the mean consumption by patients who had used over 600 mg/day of pethidine was 13.3 mg/kg/day in asymptomatic patients and 16.9 mg/kg/day in the 2% of patients who presented with central nervous system excitatory signs and symptoms (muscle twitches, jitteriness, agitation, and hallucinations) (13). The authors recommended a maximum safe dose of pethidine by PCA of 10 mg/kg/day for no more than 3 days.

Gastrointestinal

A study in which it was intended to recruit 90 women in labor for a comparison of intrathecal bupivacaine 2.5 mg, fentanyl 25 μg, pethidine 15 mg, and pethidine 25 mg was stopped prematurely after only 34 had been recruited, because of a significant increase in the incidence of nausea and vomiting in the patients who received the two doses of pethidine (14).

Immunologic

Pethidine causes histamine release (7). Of 16 patients given pethidine (mean dose 4.3 mg/kg), 5 had signs of the effects of histamine (hypotension, tachycardia, erythema) and raised histamine concentrations (7).

- A 42-year-old patient presented with generalized pruritus, erythema, urticaria, facial angioedema, dysphagia, dysphonia, and dizziness 15 minutes after a single intramuscular dose of pethidine 100 mg for severe renal colic (15). Prick tests and intradermal tests with pethidine and other compounds confirmed an allergic reaction to pethidine.

Long-Term Effects

Drug dependence

The interaction between the drug-dependent patient and health professional has been investigated in a retrospective study of the medical records of 20 patients with chronic organic pain and perceived as being dependent on pethidine (16). The fact that the patients were perceived as being addicted may have influenced the adequate management of their chronic intractable pain, precipitated poor staff–patient relationships, created a lower pain threshold or tolerance due to anxiety and depression, and led to overuse of placebo, leading to inadequate analgesia. All of these factors may then have led to craving-like behavior and demands for more analgesics, further fuelling the negative stereotyped perception of the addicted personality. The authors suggested that people with dependence-related problems should be evaluated for suicidal intent; concurrent psychiatric illnesses should be treated; and precipitating factors that make pain worse should be identified. Medical and other staff should be educated about the use of opiate analgesics and concepts of dependence, in order to reduce negative judgmental attitudes and misconceptions.

Second-Generation Effects

Fetotoxicity

Pethidine is commonly used in some countries as an analgesic in maternal labor. The analgesic and adverse effects of intramuscular pethidine 5 mg plus diamorphine 100 mg in labor have been studied in a randomized, double-blind, controlled study in 64 multiparous and 69 nulliparous women (17). There was a significantly higher incidence of low Apgar scores at 1 minute after pethidine compared with diamorphine. The study also confirmed that for women who requested intramuscular narcotic analgesia, neither diamorphine nor pethidine provided good pain relief, suggesting that there is a need to consider alternatives.

Pethidine 50 mg plus promethazine 25 mg given intravenously to 14 mothers in labor caused a significant change in fetal heart rate indices 40 minutes after administration (18). There were significant changes in fetal heart rate acceleration of at least 10 beats/minute, acceleration of at least 15 beats/minute, time spent in episodes of high variation, and short-term variation.

Susceptibility Factors

Renal disease

Norpethidine (normeperidine) accumulates in cases of renal insufficiency (19), leading to symptoms of overdosage.

Hepatic disease

Patients with cirrhosis and acute viral hepatitis can have a 50% reduction in pethidine clearance (SEDA-19, 85).

Drug Administration

Drug dosage regimens

In a double-blind study of 60 patients undergoing elective carpal tunnel release given pethidine 0, 10, 20, 30, 40, or 50 mg in addition to intravenous regional anesthesia with lidocaine 0.5%, the duration of analgesia increased dose-dependently with 0, 10, 20, and 30 μg (20). In those given pethidine 30, 40, and 50 μg there was a significantly higher incidence of sedation, pruritus, nausea, vomiting, and respiratory depression with no increase in analgesic effect. These results support an optimal dose of pethidine 30 mg when used with 0.5% lidocaine for postoperative analgesia.

© 2006 Elsevier B.V. All rights reserved.

In a prospective, randomized, single-blind study in 45 men undergoing lower abdominal surgery using one of three doses of intrathecal pethidine (1.2, 1.5, or 1.8 mg/kg) there was no difference in the incidence of adverse effects among the three groups (21). The authors postulated that increasing the dose of pethidine from 1.2 to 1.5 mg/kg increased the duration of analgesia but not the level of sensory block, without an increase in adverse effects.

In 40 patients undergoing prostatectomy with spinal anesthesia with lidocaine 5% (75 mg) intrathecally, either alone or co-administered with pethidine 0.15 or 0.30 mg/kg, the higher dose of pethidine reduced the requirement for parenteral analgesics with a non-significant incidence of pethidine-related adverse effects (22).

Drug administration route

Epidural versus intravenous

In a double-blind, randomized, controlled study, 17 patients undergoing gastrectomy were given epidural PCA pethidine (10 mg bolus and a 4-hourly maximum dose of 3 mg/kg) and were compared with 20 patients after gastrectomy who were given the same regimen intravenously (23). The mean pethidine consumption in the first 24 hours was 33% less in the epidural group than in the intravenous group. Pain scores, adverse effects profiles, patient satisfaction, and patient outcome were similar. However, the sample size was small, and even though the study was intended to be double-blind, the route of pethidine administration and the patient's perception of an intravenous and epidural injection might have caused bias.

Rectal

Rectal pethidine is not advised in children, owing to enormous variability in systemic availability (SEDA-18, 82).

Drug overdose

Cardiac arrest occurred after pethidine overdose (24).

- A 2-month-old boy had a cardiac arrest when he was given a combination of pethidine, promethazine, and chlorpromazine in 10 times the recommended dose by the wrong route (intravenously rather than intramuscularly). Within seconds he became apneic and stiff. Cardiopulmonary resuscitation was instituted, including two intravenous doses of adrenaline 0.06 mg and naloxone 0.6 mg, with recovery 7 minutes after the incident and complete resolution 24 hours later.

Drug–Drug Interactions

Cimetidine

The hepatic metabolism of pethidine can be inhibited by cimetidine, leading to respiratory depression and sedation (25,26).

Phenytoin

Phenytoin enhances the metabolism of pethidine (27).

Selegiline

A syndrome resembling the serotonin syndrome has been reported in a patient taking pethidine plus selegiline (28).

- A woman with Parkinson's disease, taking selegiline 5 mg bd, pergolide 0.75 mg bd, co-careldopa 440 mg qds, imipramine 175 mg qds, and desipramine 25 mg qds, was given pethidine, 325 mg over 3 days, and hydroxyzine for pain. After 2 days she became restless and irritable, and after 4 days she developed delirium, muscle rigidity, sweating, and fever. The symptoms resolved when selegiline was withdrawn.

The authors did not discuss the role of the tricyclic antidepressants in this presentation.

Phenazone

General Information

Phenazone, commonly known as antipyrine, is still used therapeutically in some countries, although it is now used mainly as a marker of hepatic enzyme drug metabolizing activity. It is an old compound with little recent investigation, usually taken in combination with other analgesics, and an exact analysis of its adverse effects is impossible. Phenazone seems to have a low toxicity index, in correspondence with its weak anti-inflammatory effect. Allergic reactions are very rare (SEDA-6, 92) (SEDA-14, 92) (SEDA-16, 108), but subjects undergoing the phenazone test should be informed of the potential risk.

Organs and Systems

Hematologic

Hemolysis can occur in patients with glucose-6-phosphate dehydrogenase deficiency. An immediate reaction after a single test dose, in the form of latent leukopenia, has also been reported (1), with previous sensitization to pyrazolone derivatives as the most probable explanation. Agranulocytosis has been observed in six women after the use of a phenazone-containing cream (SEDA-18, 101).

Gastrointestinal

Only chronic abuse of phenazone, probably together with other more aggressive antipyretics, can cause gastric symptoms (2).

Urinary tract

Phenazone nephrotoxicity is well-established, but information is limited. Experimental papillary necrosis can easily be provoked; analgesic nephropathy is probably a real danger with antipyrine, especially when it is combined with a stronger inhibitor of prostaglandin synthesis. The effect is probably toxic, since inhibition of prostaglandins is not a marked characteristic of phenazone. Two reports have suggested a causal link between phenazone and renal carcinoma, as is well-known for phenacetin (3,4), but this has not been confirmed.

Skin

Urticarial rashes and erythema are the most common adverse effects of phenazone, followed by maculopapular eruptions, erythema multiforme, erythema nodosum, or even angioedema (5).

Phenazopyridine

General Information

Phenazopyridine, an azo dye, is used as a urinary tract analgesic. However, because of toxicity, the standard use of phenazopyridine as part of a fixed-dose combination no longer seems justified.

Organs and Systems

Nervous system

Aseptic meningitis was diagnosed in a patient who had three distinct episodes of fever and confusion after taking phenazopyridine (SEDA-13, 84).

Hematologic

Hematological adverse effects of phenazopyridine include methemoglobinemia and hemolytic anemia, particularly after overdosage (1,2).

Liver

Liver toxicity has been reported with phenazopyridine (3).

Urinary tract

Because of nephrotoxicity (oliguria, cylindruria, and reduced creatinine clearance, with crystal deposits in renal tubules and interstitial tissue) (4) phenazopyridine should not be used in patients with suspected renal disease and insufficiency, or in patients with glucose-6-phosphate dehydrogenase deficiency. Bladder stones have also been described (5).

Skin

Yellow discoloration of the nails has been attributed to long-term therapy with phenazopyridine (6).

Phencyclidine

General Information

Phencyclidine or 1-(1-phenylcyclohexy-1) piperidine (known as PCP or "angel dust") was originally developed as an anesthetic, but was abused as an illicit drug from the late 1960s onwards. It is an antagonist at the *N*-methyl-d-aspartate (NMDA) subtype of glutamate receptors and a dopamine receptor agonist. It has anticholinergic properties through blockade of ion channels in acetylcholine receptors. It is still used in some countries as an antiparkinsonian agent (SED-11, 86) (1–3).

The psychoactive effects of phencyclidine are stimulant and similar to the effects of hallucinogens. Hallucinations are often bizarre, frightening, and challenging. Aggressive behavior, usually with amnesia, is common. Self-destructive actions are also seen. Overdosage is associated with paresthesia, slurred speech, ataxia, and later catatonia, dilated pupils, and coma, with tachycardia, hypertension, and dysrhythmias. Seizures and deaths have occurred (SED-11, 86) (4).

General Information

Phenelzine is a non-selective monoamine oxidase (MAO) inhibitor.

Organs and Systems

Nervous system

A potential risk of using a non-selective inhibitor in patients with Parkinson's disease is illustrated by separate reports of the appearance of parkinsonism in patients taking phenelzine (1,2).

- Speech blockage, so called, has been reported in a 34-year-old woman who had taken phenelzine 45 mg/day for 2 months (3). The adverse effect disappeared on

withdrawal and did not recur when her depression was successfully treated with maprotiline 175 mg/day.

Psychological, psychiatric

In a carefully controlled 3-week comparison of phenelzine (up to 90 mg/day, mean 77 mg) and imipramine (up to 150 mg/day, mean 139 mg), four patients developed antisocial behavior, three overt paranoid psychosis, and one a hypertensive crisis, despite all precautions to avoid interacting foods and drugs (4).

There has also been a report of delusional parasitosis with phenelzine (SEDA-17, 14).

Dose-related visual hallucinations have been reported in a patient with macular degeneration taking phenelzine (the Charles Bonnet syndrome); the authors discussed the possibility that deprivation-induced visual phenomena had been intensified by increased central monoamine concentrations (5).

Nutrition

Authors who reported a case of carpal tunnel syndrome due to pyridoxine deficiency in a patient taking tranylcypromine (SEDA-9, 21) later collected data (6) on six patients taking phenelzine (up to 75 mg/day for up to 4 months). All developed low concentrations of pyridoxine and a variety of symptoms, including numbness, paresthesia, and edema of the hands, as well as an "electric shock" sensation in the head, neck, and arms. The symptoms resolved completely after the addition of pyridoxine 150–300 mg/day to the treatment regimen.

Hematologic

Leukopenia and agranulocytosis are well-recognized complications of treatment with tricyclic antidepressants and have been reported with some second-generation compounds. In a report of leukopenia in a patient taking phenelzine, attention was drawn to five other unpublished cases and to previous published reports involving isocarboxazid, tranylcypromine, and tryptamine (7).

Long-Term Effects

Drug withdrawal

In a study of the use of phenelzine in continuation therapy after recovery from an acute episode of depression, relapse rates were higher in patients subjected to tapered withdrawal than in those who continued taking the therapeutic dose (8).

In a study of the effects of sudden drug withdrawal in 34 patients taking phenelzine and 17 taking tricyclic antidepressants who had been treated for a mean duration of over 9 months, depressed patients taking phenelzine had significantly more symptoms than depressed patients taking tricyclic antidepressants, and a third of them relapsed, compared with a quarter taking the tricyclic (9). At 3 months follow-up 47% of the patients taking phenelzine had resumed treatment compared with 23% taking the tricyclic. An attempt to distinguish between withdrawal symptoms and relapse on the basis of the rapidity and severity of symptoms was unsuccessful, but about a third of the patients in both groups developed new symptoms of adrenergic hyperactivity, including anxiety and perceptual disturbances.

Acute psychotic symptoms have been reported in two young women shortly after withdrawal of long-term phenelzine 90 mg/day (10).

Tumorigenicity

A single case of angiosarcoma in the liver has been reported in a patient taking phenelzine (11); similar tumors have occurred in mice treated with phenelzine.

Drug–Drug Interactions

Amantadine

A possible hypertensive interaction of phenelzine with amantadine in Parkinson's disease has been reported (SEDA-10, 17).

Clonazepam

A flushing reaction has been associated with an interaction of phenelzine with clonazepam (SEDA-17, 17).

Venlafaxine

There have been reports of serotonin toxicity when venlafaxine was combined with therapeutic doses of conventional MAO inhibitors (SEDA-20, 21). The serotonin syndrome has been reported in four patients who were switched from the MAO inhibitor phenelzine to venlafaxine (12). In two of them, the 14-day washout period recommended when switching from phenelzine to other antidepressant drugs had elapsed.

- A 25-year-old woman, who had taken phenelzine (45 mg/day) for refractory migraine and tension headache, suffered intolerable adverse effects (weight gain, edema, and insomnia). Phenelzine was withdrawn and 15 days elapsed before she took a single dose of 37.5 mg of venlafaxine. Within 1 hour she developed agitation, twitching, shakiness, sweating, and generalized erythema with hyperthermia (38°C). Her symptoms resolved within 3 hours with no sequelae.

This suggests that even after the recommended 2-week washout from MAO inhibitors, venlafaxine can provoke serotonin toxicity in some patients.

Phenindamine

See also Antihistamines

General Information

Phenindamine is an antihistamine that is reputed to cause stimulation rather than sedation in some patients. However, in one small study the central nervous system effects of phenindamine were intermediate between those of terfenadine and diphenhydramine (1).

Reference

Pheniramine

See also Antihistamines

General Information

Pheniramine is a first-generation antihistamine.

Organs and Systems

Skin

Skin reactions with parenteral pheniramine maleate are uncommon. Relapsing generalized multiple evanescent pruritic erythematous weals after antihistamine and steroid injections have been reported in a 29-year-old woman (1).

Cutaneous reactions have also been reported with pheniramine in eye-drops (2).

- A 30-year old woman who used pheniramine eye-drops for allergic oculorhinitis developed eyelid dermatitis (2). Patch testing showed positive reactions on days 2 and 3.

Phenmetrazine and phendimetrazine

See also Anorectic drugs

General Information

Phenmetrazine and phendimetrazine are central stimulants and indirect sympathomimetics related to dexamfetamine. Phendimetrazine is about 30% rapidly metabolized to phenmetrazine (1). Their reported adverse effects include glossitis, stomatitis, dry mouth, nausea, abdominal pain, cramps, constipation, difficulty in micturition, and headache.

Organs and Systems

Cardiovascular

A dilated cardiomyopathy has been associated with chronic consumption of phendimetrazine (2).

Nervous system

The main adverse effects of phenmetrazine reflect central nervous system stimulation and resemble those of other stimulants. There have been reports of encephalopathy as a result of phenmetrazine toxicity. There were also two cases of damage to the central nervous system after long-term treatment with phenmetrazine; in one, there were disseminated lesions, and in the other, hemiparesis and sensory motor aphasia (3).

Urinary tract

Phendimetrazine has reportedly caused acute interstitial nephritis (4).

Long-Term Effects

Drug abuse

There are many reports of abuse of phenmetrazine. Nervousness, hyperexcitability, euphoria, and insomnia,

© 2006 Elsevier B.V. All rights reserved.

although less frequent than with amphetamines, have been observed with average doses. Dizziness, headache, nausea, dryness of the mouth, and urticaria have also been recorded. With large doses these adverse reactions were more pronounced. Paranoid psychosis was produced in addicts, and with chronic ingestion psychotic manifestations were evident as with amphetamine.

In Sweden, phenmetrazine has been extensively abused and misused, sometimes with intravenous use. Addicts who had previously been taking morphine stated that phenmetrazine gave them a sense of well-being and overconfidence. There was a high incidence of criminal activity in phenmetrazine users whose primary objective was obtaining money for the drug. Their average doses were 3060 tablets at a time, repeated 4–5 times a day (SED-9, 15).

Second-Generation Effects

Teratogenicity

Very rarely, congenital defects in the newborn have been associated with phenmetrazine consumption by the expectant mother.

Phenobarbital

See also Antiepileptic drugs

General Information

Because it is cheap and of unquestioned efficacy, phenobarbital is still widely prescribed around the world, although in developed countries its use has fallen since the introduction of drugs that are better tolerated. Its most common adverse effects are sedation (to which partial tolerance develops), cognitive dysfunction, and in children hyperkinesia and other behavioral disturbances.

In a randomized trial in newly diagnosed patients, adverse effects leading to withdrawal were more common with phenobarbital (22%, mostly drowsiness and lethargy) than with all other drugs combined (carbamazepine 11%, phenytoin 3%, valproate 5%) (1).

Pretreating patients with phenobarbital can reduce the impact of adverse events when primidone is introduced. Of 30 patients with intractable partial epilepsy pretreated with phenobarbital before starting primidone (500 mg/day increasing by 125–250 mg/day every 3 weeks until adverse events or a seizure-free state was reached), 26 tolerated the introduction of primidone with minimal or no adverse events (2). Only one patient had to discontinue primidone during the initial 4 weeks because of severe dizziness. Three other patients had dizziness severe enough to interfere with their activities and this disappeared in two patients after the dose was lowered.

Organs and Systems

Nervous system

Unusual manifestations of neurological toxicity of phenobarbital include regression of developmental milestones mimicking a neurodegenerative disorder in young children (SEDA-19, 72) and unilateral choreiform hyperkinesia as a possible withdrawal symptom (SEDA-22, 82).

In a 12-month trial in 109 epileptic children randomized to monotherapy with phenobarbital (maintenance dosage 3.0 mg/kg/day) or phenytoin (5.0 mg/kg/day) in rural India there were no significant differences in either efficacy or toxicity (3). In particular, behavioral adverse effects were not more common with phenobarbital. The findings suggest that phenobarbital is an acceptable first-line agent for childhood epilepsy in rural settings in developing countries.

In 114 patients, of whom 72% took phenobarbital, one had ataxia due to phenobarbital toxicity (4).

Psychological, psychiatric

Phenobarbital-induced behavioral disturbances, especially hyperkinesia, are especially common in children, with an incidence of 20–50%; drug withdrawal is required in 20–30% of cases. It is unclear whether and to what extent adults are affected in this way.

Skin

Rare effects of phenobarbital include erythroderma and an atypical lymphocytosis that mimics cutaneous T cell lymphoma (SEDA-18, 67).

Toxic epidermal necrolysis has been reported in a 62-year-old woman and a 72-year-old man who had taken phenobarbital 100 and 150 mg/day respectively (5).

Musculoskeletal

The incidence of barbiturate-induced Dupuytren's contracture, frozen shoulder, Ledderhose syndrome, Peyronie's disease, fibromas, and joint pains may be up to 10% (6). Most affected patients develop connective tissue changes in the first year, although these become disabling at a later stage. These complications should be recognized early, since they are often reversible (SED-12, 137) (7).

Immunologic

Giant cell myocarditis has been reported in a patient taking phenytoin, phenobarbital, and mephobarbital and in one taking primidone (8).

© 2006 Elsevier B.V. All rights reserved.

Death

The efficacy of a single intramuscular dose of phenobarbital (20 mg/kg) in preventing seizures in childhood cerebral malaria has been the subject of a randomized, placebo-controlled study in 340 children in Kenya (9). Seizure frequency was significantly lower with phenobarbital than placebo: 18 versus 46 children had three or more seizures of any duration (OR = 0.32; 95% CI = 0.18, 0.58). However, mortality was doubled (30 versus 14 deaths; OR = 2.39; CI = 1.28, 4.64). The frequency of respiratory arrest was higher with phenobarbital than with placebo, and mortality was greatly increased in children who received phenobarbital plus three or more doses of diazepam (OR = 32; CI = 1.2, 814). The authors felt that although phenobarbital was effective, the risks were too high to recommend using it.

Second-Generation Effects

Teratogenicity

There is an association of phenobarbital with oral clefts and cardiac malformations (10). This is also the case for methylphenobarbital (10).

Fetotoxicity

After prenatal exposure to anticonvulsants, small head size has been observed in neonates and cognitive impairment in infancy. However, it is currently unknown whether these effects are permanent or disappear later in life. Head size and cognition have been studied in adults who had been exposed in utero to phenobarbital plus phenytoin and who as neonates had a significantly smaller occipitofrontal circumference than neonates who had been exposed to phenobarbital alone or controls (mean difference 0.7 cm) (11). There was no difference in cognitive functioning between the exposed and the control groups, and most of the exposed subjects had normal intellectual capacity. However, 12% of the exposed subjects versus 1% of the controls had persistent learning problems. In addition, more of the exposed subjects were mentally retarded. The authors concluded that the combination of phenobarbital plus phenytoin reduced neonatal head size, which was not associated with reduced cognitive functioning in adulthood, but was associated with learning problems and mental retardation.

Susceptibility Factors

Patients with brain metastases treated with radiotherapy seem to have increased susceptibility to phenobarbital-induced toxic epidermal necrolysis (SEDA-19, 72). In a 53-year-old man taking phenobarbital, eruptions were limited to the sites of radiation, which were multiple (12).

Drug–Drug Interactions

Clozapine

Compared with 15 patients taking clozapine alone, seven patients taking similar dosages in combination with phenobarbital had significantly lower plasma clozapine concentrations (232 versus 356 ng/ml) (13). Plasma norclozapine concentrations did not differ between the two groups, whereas clozapine *N*-oxide concentrations were significantly higher in the phenobarbital group. These findings suggest that phenobarbital stimulates the metabolism of clozapine, probably by inducing its *N*-oxidation and demethylation. Although the clinical implications remain to be defined, an increase in clozapine dosage requirements may be considered in patients co-medicated with phenobarbital.

Phenols

See also Disinfectants and antiseptics

General Information

Phenol is a benzyl alcohol and a major oxidized metabolite of benzene that was introduced into medicine as an antiseptic (1). Although it can be prepared in an aqueous solution or in glycerine, it appears to be more effective when mixed in aqueous compounds. At a concentration of 0.2% it is bacteriostatic and at over 1% bactericidal (2). In addition to its uses as an antiseptic and disinfectant, phenol is also used as a sclerosant, as a local anesthetic on the skin, and as an analgesic, by injection into nerves or spinally, but its use was limited by severe adverse effects. Current medical uses include cosmetic face peeling, nerve injections, and topical anesthesia. It is also an ingredient of various topical formulations, and is used as an environmental disinfectant.

Systemic adverse effects can occur through absorption from intact skin or wounds, by ingestion, or by absorption of vapor through the skin or via the lungs. They include central nervous stimulation followed by depression, seizures, coma, tachycardia, hypotension, dysrhythmias, pulmonary edema, metabolic acidosis, and hepatic and renal injury. Serious adverse reactions due to percutaneous absorption can occur and death has been described several times. The signs and symptoms of phenol toxicity have been reviewed (3–7) and are listed in Table 1.

Nonoxynols are ethoxylated alkyl phenols that are synthesized from alkylbenzene nonoxynol by reacting it with ethylene oxide to produce ethylene oxide polymers of various lengths. Each nonoxynol is followed by a number that indicates the approximate number of ethylene oxide groups it contains. In cosmetic products, nonoxynols are used as emulsifying, wetting, foaming, and solubilizing agents. They are used in hair and skin products, and in bath, shaving, and fragrance formulations (8). The non-ionic surfactant properties of nonoxynols allow them to be used in a wide variety of industrial, household, agricultural, and pharmaceutical products. Nonoxynol-9 and nonoxynol-10 are surface-active agents used in antiseptic formulations, such as Hibitane solution, Betadine solution, Hexomedine transcutanée, and Hexomedine ointment. They are the most commonly used spermicidal contraceptives and have been recommended in the prevention of sexually transmitted diseases and in human immunodeficiency virus prophylaxis (9).

Table 1 The signs and symptoms of phenol toxicity

System	Symptoms
Cardiovascular	Cyanosis, cardiac dysrhythmias, electrocardiographic abnormalities, circulatory failure, collapse
Respiratory	Respiratory failure
Nervous system	Dizziness, coma
Sensory systems	Darkening of the cornea
Hematologic	Methemoglobinemia
Gastrointestinal	Abdominal pain
Urinary tract	Hemoglobinuria
Skin	Darkening of the face and hands

Pentachlorphenol is a disinfectant that is used in commercial laundries. In 1967 a hospital laundry accidentally used a product containing sodium pentachlorphenolate for a final rinse in the laundering of diapers and infants' bed linen. Twenty newborn infants developed sweating, tachycardia, tachypnea, hepatomegaly, and metabolic acidosis. Six children with severe reactions were subjected to exchange blood transfusion and in each instance there was a dramatic improvement. Two babies died before exchange transfusion could be carried out; postmortem examination showed fatty change in the liver and hydropic and fatty degeneration in the renal tubules and myocardium. There were toxic concentrations of pentachlorphenol in the serum of one patient and autopsy tissue of another.

The phenol derivatives paratertiary butylphenol and amylphenol are used in proprietary germicides.

The permeability of the human epidermis to many phenolic compounds correlates with their lipophilic pattern. However, phenolic compounds appear to produce denaturation in the skin, and an additional increase in permeability is attributed to the resulting damage to the epidermis. Complications of topical phenol, notably cardiac dysrhythmias, including death, can be caused by phenol face peels (10).

Phenol is so rapidly absorbed through the skin that severe systemic effects and even death can result within minutes to hours.

- A 90% solution of phenol spilled over the left sole and shoe of a 47-year-old tanker driver (11). He neither removed his soaked shoe nor attempted to decontaminate himself. He continued driving for 4.5 hours, after which he had vertigo and faintness. Fire fighters removed him from the vehicle, took off his shoes and clothes, and thoroughly washed his leg with copious amount of water. On admission to hospital he was alert but confused, his heart rate was 146/minute, his blood pressure 160/100 mmHg, and there was tense swelling and blue-black discoloration of his left foot, ankle, and distal part of the leg (3% total body surface area), with hypalgesia and hypesthesia over the affected area. His leg was irrigated with large amounts of water, longitudinal incisions of his left foot were performed, and he was transferred to the intensive care unit. Shortly afterwards, he developed rapid atrial fibrillation, ventricular extra beats, reduced blood pressure (90/60 mmHg), and fever of 38.3°C. He was treated with intravenous crystalloids, verapamil, dopamine, and phenylephrine. All the systemic symptoms resolved in 24 hours. Blood and urine cultures were negative. Over the next 3 weeks he was treated with 0.25% troclosene dressings and 1% micronized silver sulfadiazine, until the swelling resolved and the wound had healed. On discharge from hospital and at a 4-month follow up, only blue-black discoloration was noted.

Phenol can be applied percutaneously by the use of a monopolar needle electrode or by open injection when the nerve is exposed surgically. In addition, main nerve trunks or motor branches can be injected, depending on the clinical indication.

© 2006 Elsevier B.V. All rights reserved.

Organs and Systems

Cardiovascular

Phenol is cardiotoxic, and various cardiac dysrhythmias have been noted after application to the skin, or less commonly when it has been used for neurolysis. Ventricular extra beats occurred during topical application of phenol and croton oil in hexachlorophene soap and water for chemical peeling of a giant hairy nevus (12). Three of sixteen children treated with motor point blocks for cerebral palsy with a phenolic solution under halothane anesthesia developed cardiac dysrhythmias (13). Severe cardiac dysrhythmias followed by circulatory arrest occurred in an elderly patient with pancreatic cancer, injected with a phenolic solution to produce splanchnic neurolysis (14). The authors recommended that ethanol should replace phenol for this purpose.

In New Zealand, a patient died with brain damage after a cardiac arrest after being exposed to a chemical face peeling solution containing 64% phenol, Exoderm (15). The New Zealand Ministry of Health issued a public statement concerning the safety of phenol solutions.

Respiratory

Acute life-threatening epiglottitis developed in one patient after the use of a throat spray containing the equivalent of 1.4% phenol. The reaction may have been anaphylactic or a direct toxic effect (16).

Nervous system

Early reports suggested that phenol caused selective damage only to small sensory nerve fibers (17). However, later studies showed that in concentrations of 1–7% it caused indiscriminate damage to efferent and afferent nerve fibers (18). At concentrations under 1%, phenol appears to have a local anesthetic affect, which is fully reversible (19). However, at higher concentrations it causes both Wallerian degeneration and axonal demyelination, leading to muscle denervation. After injection of 2% aqueous phenol there can be damage to the microcirculation around nerves, leading to occlusion of small blood vessels and fibrosis in the injected area (20).

The most common adverse effect of phenol injection is pain during injection, often described as a burning or stinging sensation. It can be associated with edema several hours after injection. The application of ice and the use of non-steroidal anti-inflammatory drugs often help to minimize the discomfort. In some studies, lidocaine mixed with phenol has been used to help diminish the local pain response associated with injection (21).

The most worrying adverse effect related to phenol injection is dysesthesia, caused by involvement of sensory nerve axons when perineural injection is attempted. Dysesthesia has been reported from a few days to about 2 weeks after injection; most patients describe a neuropathic component, including a burning pain with light tactile stimulation and involvement of only a small portion of the sensory distribution of the nerve that was blocked (22).

Sensory loss or loss of voluntary motor strength are not uncommon in the first few days after chemical neurolysis with phenol (23), but permanent loss, other than motor changes associated with the reduction in hypertonia, is less frequent (24,25). A muscle that is already weak is more susceptible to further weakening with chemical neurolysis (26).

- Loss of all sensation and strength after chemical neurolysis occurred in the distribution of the posterior tibial nerve after mixed sensorimotor block of this nerve, in this case after five blocks of the nerve or its motor branches over several years. Some strength and partial sensation returned after surgical lysis of excessive fibrous tissue at the site where the injection had been performed (27).

Chemoneurectomy with aqueous phenol injection in 116 selected patients with spastic cerebral palsy, in whom 246 peripheral nerves were blocked, caused complications in 11 patients (28). Five patients, in whom the posterior tibial nerve was blocked, developed paresthesia: one had complete loss of sensation, which recovered spontaneously after a couple of days; and three had pain at the site of injection or in the distribution of the injected nerve, lasting for a few days to a month. In another study there was a 3% complication rate in 98 blocks (29), while adverse effects occurred in nine of 150 blocks, with muscle weakness in eight cases and painful paresthesia in one (30).

Liver

Neonatal jaundice has been associated with the use of phenolic disinfectants in nurseries, not only when used in excessive concentrations, but also when applied in the recommended dilution (SEDA-5, 258) (SEDA-8, 246) (SEDA-11, 484).

Chronic liver disease has been attributed to long-term household poisoning with pentachlorphenol (31).

Skin

Phenol-related contact pemphigus has been described (22).

- A 32-year-old otherwise healthy woman developed oral erosive lesions of 6 weeks duration and a bullous eruption on her legs, back, and chest of 2 weeks duration. She had bullae and erosions on the left thigh and bullae on the legs, back, abdomen, and chest. There was no family history of pemphigus. Pemphigus vulgaris was diagnosed, and she was given prednisone 100 mg/day. She went home for weekends during hospitalization, and returned to hospital each time with worse lesions. She reported working with a cleaning agent that she had begun using before the onset of the disease. The cleaning agent contained nonyl phenol, and she challenged herself at her next visit home by putting the same agent on her hands for a full day. As a result, new bullae appeared in the mouth. She was advised to stop using the product and was discharged a few days later taking prednisone 80 mg/day, which was tapered as the disease subsided. No new lesions appeared after 1 year of follow-up.

Depigmentation has been attributed to germicides (O-Syl® and Ves-Phene®), containing a mixture of the

© 2006 Elsevier B.V. All rights reserved.

phenol derivatives paratertiary butylphenol and amylphenol, in five hospital workers and seven other patients who had used them as household disinfectants. Patch tests with the phenolic components of the disinfectants on the patients and controls showed that virtually any moderately irritating phenolic compound can depigment the skin, but of those tested, paratertiary butylphenol and amylphenol most often depigmented the skin without producing toxic inflammation. Initial signs of depigmentation appeared 6 months after using the phenolic mixtures. Within 1 year, two of five patients noted a spontaneous return of pigment; another continued to use the product and there was no evidence of repigmentation (SEDA-11, 485) (32).

Musculoskeletal

Intramuscular injection of phenol can cause pain and swelling in the muscle (33,34). Sometimes, a firm nodular swelling develops in the calf 1–3 weeks after intramuscular neurolysis (35), particularly when larger quantities of phenol are injected into the intramuscular branches of the tibial nerve. This can usually be avoided by limiting the quantity of phenol injected to the minimum necessary and by applying cold packs to the injected area after the procedure.

Muscle necrosis and round cell infiltrates have been seen in histological studies of animal muscle recently injected with phenol, but not after a few months have passed (36).

Immunologic

Contact dermatitis in patients exposed to nonoxynols was initially considered to result from irritation, but allergic reactions have also been reported (37). Nonoxynol contact allergy has been described in two patients who developed contact photosensitivity to nonoxynol-l0 in the antiseptic product Hexomedine transcutanée (38). Among 32 control subjects, 13 had positive photopatch tests to Hexomedine transcutanée and four had positive photopatch tests to nonoxynol-10. Surprisingly, the authors observed that only undiluted nonoxynol was phototoxic. In another study, nonoxynol-9 was found to be rarely sensitizing and compatible with latex and silicone lubricants used in condoms (39).

There is evidence of immunosuppressive effects due to interference by dibenzo-p-dioxin and/or dibenzofuran with the chemical properties of pentachlorphenol (SEDA-11, 485) (40).

Death

Phenol can be fatal in the newborn.

- A 1-day-old child died 11 hours after 2% phenol had been applied to the umbilicus. The postmortem blood concentration of phenol was 125 µg/ml (SEDA-11, 485)(7).
- A 6-day-old child developed cerebral symptoms, circulatory failure, and methemoglobinemia after application of a phenol camphor solution (30% phenol, 60% camphor) to a skin ulcer. The child recovered after exchange transfusion (SEDA-11, 485)(7).

Drug Administration

Drug administration route

A phenol solution of 89% was mistakenly sprayed into the nostrils of a 79-year-old man (41). Immediately, blanching and local erythema developed. It was expected that the patient would develop a significant local burn and possibly systemic toxicity, but neither developed. This may have been due to the amount sprayed or the relatively small body surface area covered by the phenol.

Phenoperidine

General Information

Phenoperidine is a potent opioid analgesic often used in neuroleptanalgesia and as a respiratory depressant in ventilated patients.

Organs and Systems

Cardiovascular

Intracranial hypertension occurred within 1 minute in a patient with a severe head injury who received phenoperidine 1 mg intravenously. It was associated with a reduction in arterial blood pressure. A similar reaction occurred when a second 1 mg bolus was given 8 hours later (SED-11, 146) (1).

Phenoxybenzamine

General Information

Phenoxybenzamine is a non-selective irreversible alpha-adrenoceptor antagonist. It is given orally in total daily doses up to 60 mg in pheochromocytoma, and lower doses have been used to relieve bladder obstruction before surgery. The maximum effect may be delayed because of irregular absorption, and even after intravenous use it may not be attained for 1 hour. Some of the most severe effects, that is hypotension and syncope with tachycardia, can therefore occur unexpectedly. In a review of published reports from 1966 to 2002 phenoxybenzamine improved bladder function in adult men with retention due to inguinal hernioplasty, in women with retention caused by vaginal repair, and in children with myelomeningocele, in whom there was also a reduced incidence of urinary tract infections (1). The most common adverse events were dizziness, impotence and ejaculatory dysfunction, and nasal stuffiness. No drug-related tumors were reported. Phenoxybenzamine can also cause miosis, lassitude, and gastrointestinal upsets.

Organs and Systems

Cardiovascular

In patients with myocardial infarction, in whom phenoxybenzamine has been used to improve circulation, it can cause or aggravate pulmonary edema; this could be explained by severe hyponatremia during treatment with phenoxybenzamine (SEDA-13, 113).

Psychological, psychiatric

Panic attacks have been described in one case, a week after withdrawal of the drug; the causal association was not certain (SEDA-17, 163).

Susceptibility Factors

Renal disease

Because a large proportion is renally excreted, dosages should be reduced in renal disease.

Other features of the patient

In view of the nature of its effects, phenoxybenzamine should be used sparingly in cardiovascular disease.

Drug Administration

Drug administration route

When phenoxybenzamine is injected intradermally or when it is extravasated during intravenous administration, it can cause both extremely severe necrotic reactions and an allergic response.

Phentermine

See also Anorectic drugs

General Information

Despite the withdrawal of the fenfluramines, the appetite suppressants phendimetrazine and phentermine have remained in widespread use for the treatment of obesity.

With phentermine, adverse effects due to stimulation of the central nervous system are less than with dexamfetamine, although in one study withdrawal because of adverse effects was as high as 16 of 177 patients (9%); 2 of 13 healthy young volunteers withdrew because of unacceptable stimulation (1).

Organs and Systems

Cardiovascular

In a systematic review of 1279 patients taking fenfluramine, dexfenfluramine, or phentermine, evaluated in seven uncontrolled cohort studies, 236 (18%) and 60 (5%) had aortic and mitral regurgitation respectively (2). Pooled data from six controlled cohort studies yielded, for aortic regurgitation, a relative risk ratio of 2.32 (95% CI = 1.79, 3.01) and an attributable rate of 4.9% and, for mitral regurgitation, a relative risk ratio of 1.55 (95% CI = 1.06, 2.25) with an attributable rate of 1.0%. Only one case of valvular heart disease was detected in 57 randomized controlled trials, but this was judged unrelated to drug therapy. The authors concluded that the risk of valvular heart disease is significantly increased by the appetite suppressants. Nevertheless, valvulopathy is much less common than suggested by previous less methodologically rigorous studies.

Spontaneous rupture of a retroperitoneal aneurysm occurred in a 70-year-old woman who had been taking phentermine hydrochloride, 30 mg/day, for about 1 month (3). Other long-term medications included fluoxetine and amitriptyline, and she had no history of coronary artery disease, hypertension, diabetes, or complications of pregnancy. Although it is plausible that phentermine could have contributed to the ruptured aneurysm, other possibilities should be considered, particularly rupture of an anomalous retroperitoneal blood vessel.

Fatal pulmonary hypertension occurred in a 32-year-old man who had been taking phentermine in unknown doses for 4 months (SED-9, 16).

Nervous system

Insomnia is one of the most common adverse effects of phentermine. In a survey in Edinburgh, 20% of the subjects taking phentermine reported insomnia compared with 6% of those taking placebo (SED-9, 13).

Urinary tract

Phentermine can cause allergic interstitial nephritis (4).

- A 47-year-old mildly obese woman began a weight reduction program that included anorectic therapy with phentermine and phendimetrazine. She had normal renal function at the start of therapy. After 3 weeks of treatment she fell ill and discontinued treatment. She was subsequently found to have leukocyturia, a rash on her face and chest, and a rise in serum creatinine from 67 to 175 μmol/l (0.8–2.1 mg/dl). Renal biopsy confirmed the diagnosis of acute interstitial nephritis. She was treated with corticosteroids, and her renal function returned to normal.

Long-Term Effects

Drug abuse

Some cases of toxic psychosis have been reported with abuse doses of phentermine (5).

Drug–Drug Interactions

Fluoxetine

Following the withdrawal of the fenfluramines, alternative combinations have been explored as appetite suppressants. In an open study of a combination of phentermine + fluoxetine in 16 obese patients with

© 2006 Elsevier B.V. All rights reserved.

binge-eating disorder, in the setting of cognitive behavioral therapy, there were significant reductions in weight, binge frequency, and psychological distress by the end of treatment; however, the patients regained most of the weight within 1 year (6). At follow-up at 18 months there was still a reduction in binge eating in patients who continued maintenance treatment. The results did not support the long-term value of adding phentermine + fluoxetine to cognitive behavioral therapy for binge-eating disorder. It is worth emphasizing that it is not known whether phentermine + fluoxetine is also associated with cardiac valvulopathy. Moreover, the recognition that phentermine is a monoamine oxidase inhibitor (7) raises further concerns about its safety.

Phentolamine

General Information

Phentolamine is a non-selective alpha-adrenoceptor antagonist. It is used to treat hypertensive crises attributable to the effects of noradrenaline, as in pheochromocytoma and during the interaction of monoamine oxidase inhibitors with amine-containing medicaments and foods (1). Its adverse effects are similar to those of phenoxybenzamine.

Phenylbutazone

See also Non-steroidal anti-inflammatory drugs

General Information

Phenylbutazone was originally a solubilizing agent for aminopyrine and was first used to treat rheumatoid arthritis and allied disorders in 1949. Phenylbutazone and its related compounds were used worldwide until the early 1980s when, following growing concern about their safety, Ciba-Geigy published its own international assessment on phenylbutazone (Butazolidine) and oxyphenbutazone (Tanderil), which summarized reports on 1182 deaths associated with them from their initial use until 1982 (SEDA-9, 85). The report showed that the percentage of serious unwanted effects was high for both drugs, and in both cases the most frequent problems were dermatological and hematological, closely followed by gastrointestinal disorders.

Since 1983 phenylbutazone and oxyphenbutazone have been removed from the market in many countries or have been limited to specific indications. In 1985, Ciba-Geigy decided to stop sales of systemic dosage forms of oxyphenbutazone worldwide and to reduce the indications for phenylbutazone (SEDA-9, 85) (SEDA-10, 78). Nevertheless, phenylbutazone is still to be found in many places. Phenylbutazone and its congeners are now used only for ankylosing spondylitis and sometimes for acute gout, psoriatic arthritis, and active rheumatoid arthritis in patients who have not responded to other therapy, including other NSAIDs. For other indications, less toxic alternatives suffice (1,2).

All combinations of butazone derivatives and a corticosteroid have been removed from the market, even in Germany, one of the most lenient countries in the regulation of phenylbutazone use.

Significant adverse effects can affect up to 40% of patients (3).

Pyrazinobutazone is pyrazine phenylbutazone, which is metabolized to phenylbutazone (4).

General adverse effects

Most of the adverse effects of phenylbutazone are on the gastrointestinal system; they include symptoms ranging from gastric irritation to ulcer perforation and bleeding. Salt and water retention leads to edema, which is undesirable in older patients, and even to congestive heart failure. Hematological adverse effects include blood dyscrasias, lymphadenopathy, and agranulocytosis. Hepatotoxicity and nephrotoxicity occur (5). Headache is common, but other nervous system effects are mild. Acute poisoning can be successfully treated by hemoperfusion (6). Hypersensitivity reactions can be very severe (7); asthma and systemic lupus erythematosus have been reported. Tumor-inducing effects have not been reported.

Organs and Systems

Cardiovascular

Salt and water retention (see the section on Fluid balance in this monograph) are particularly dangerous for patients

with impaired cardiac function. Hypertension due to increased plasma volume readily occurs.

Respiratory

Left ventricular failure can result in pleural effusions. Asthma can be provoked. Cross-reactivity with aspirin has been noted (8). A picture resembling allergic alveolitis has been described (9).

Nervous system

Therapeutic doses of phenylbutazone can be followed by headache, dizziness, and vertigo (10). Overdose can cause coma and convulsions (11).

Sensory systems

Phenylbutazone can damage the eyes. Conjunctivitis, damage to the cornea with vascularization and scarring, adhesion of the lids to the eyeballs, amblyopia, retinal hemorrhage, and even blindness have been reported (12).

Psychological, psychiatric

Psychomotor reactions to phenylbutazone when driving have been reported (13).

Endocrine

Because of interference with iodine uptake, hypothyroidism and goiter can result (14). The condition is reversible, but an obstructive syndrome due to thyroid enlargement has been observed (14).

Fluid balance

As many as 10% of patients show signs of salt and fluid retention and edema (7). Increased intravascular fluid volume is responsible for dilution anemia and increasing cardiac load (SED-8, 216). There is still no explanation for the water-retaining effect, but it might reflect increased production of antidiuretic hormone.

Hematologic

Phenylbutazone causes blood dyscrasias (SED-8, 213) (SEDA-2, 92) (7,15). The most serious adverse effect is aplastic anemia which, according to Swedish and British sources, ends fatally in almost 50% of cases (15,16,17). More than 1100 deaths are on record with the principal manufacturer (SEDA-8, Essay).

Specific anti-platelet antibodies can cause thrombocytopenic purpura (18), which can be fatal. The increased risk of leukemia after phenylbutazone could be secondary to bone marrow depression (SED-9, 143) (19).

Agranulocytosis and liver injury have been described in a patient with Reiter's syndrome who took pyrazinobutazone for 6 weeks (20). Other causes of agranulocytosis and hepatic damage were excluded and a lymphocyte transformation test showed significant lymphocyte proliferation in response to pyrazinobutazone.

Gastrointestinal

A potent gastric and intestinal irritant, phenylbutazone can cause ulcers and bleeding. In one study in 1975, when the drug was widely used, 19% of 241 cases had acute gastrointestinal bleeding due to phenylbutazone (21). According to the UK's Committee on Safety of Medicines, 120 of 1967 adverse reactions attributed to phenylbutazone and its metabolite oxyphenbutazone involved gastrointestinal bleeding, and 32 ended fatally (22). The risk of developing a peptic ulcer during phenylbutazone therapy is estimated at 1–3% (SED-8, 214). Perforation has also been repeatedly observed (21,23). Other adverse effects are nausea, vomiting, abdominal pain, heartburn, diarrhea, and abdominal discomfort.

Even rectal and enteric-coated formulations can cause adverse reactions in the upper gastrointestinal tract. In one double-blind, crossover trial, plain naproxen caused fewer gastrointestinal adverse effects than enteric-coated phenylbutazone (Butacote) (24).

Phenylbutazone suppositories can cause rectal irritation, with mucosal defects, severe hemorrhagic proctitis (25), perforation of the large bowel, and necrotizing colitis (26).

Gastrointestinal toxicity has been reported in a patient treated short-term with pyrazinobutazone (27).

Liver

Hepatotoxicity has been clearly documented (28). Phenylbutazone causes three types of liver damage through three separate pathogenic mechanisms:

1. acute hepatic necrosis after overdosage, related to the hepatotoxicity of phenylbutazone and/or its metabolites;
2. mild hepatocellular damage (with or without cholestasis) and granulomas (sometimes also found at extrahepatic sites, with varying degrees of steatosis); these changes are the result of hypersusceptibility and possibly a certain degree of toxicity;
3. more pronounced hepatocellular damage with cholestasis but without granulomas; toxicity plays a more important role than hypersusceptibility.

Concomitant treatment with other hepatotoxic agents can predispose to phenylbutazone-induced liver toxicity.

Urinary tract

Although adverse renal effects can occur with any NSAID, phenylbutazone-induced nephrotoxicity has mainly been reported when the drug was taken in association with other anti-inflammatory agents (SED-8, 215) or when taken alone in a high dose (29).

Skin

Skin eruptions, Quincke's edema, and even epidermal necrolysis (SEDA-5, 100) (30,31) can develop during or after phenylbutazone therapy.

Considerable local irritation and pain at the site of injection are sometimes followed by necrosis. Sterile abscess formation has also been reported (32).

Long-Term Effects

Mutagenicity

Phenylbutazone infusion for 10 days induced chromosomal abnormalities in patients with rheumatoid arthritis (33), although the significance of this finding is not clear.

© 2006 Elsevier B.V. All rights reserved.

Second-Generation Effects

Lactation

If phenylbutazone is taken during lactation, only small amounts are found in the milk (34).

Susceptibility Factors

Age

The risk of adverse reactions to phenylbutazone increases with age (SED-8, 213) (17).

Other features of the patient

The specific risks of salt and water retention in cardiac and renal disease have already been mentioned. The potential for ulcerogenic activity should be kept in mind if phenylbutazone is given to a patient with a history of peptic ulceration. Patients who are hypersensitive to other drugs (especially aspirin) should be carefully monitored when taking phenylbutazone.

Drug Administration

Drug overdose

Acute intoxication with phenylbutazone is dominated by metabolic acidosis, which can progress to coma, seizures, hypotension, shock, and oliguria. Kidney and liver reactions, acute bone marrow depression, and acute perforation of peptic ulcer have all been described (5,11,35).

Drug–Drug Interactions

Antihypertensive agents

Inhibition of the effect of antihypertensive agents by phenylbutazone can probably be explained by salt and water retention (36).

Aspirin

Phenylbutazone interferes with the tubular excretion of aspirin (3).

Coumarin anticoagulants

Phenylbutazone displaces warfarin from binding sites on serum albumin, temporarily increasing its effects before the clearance of warfarin increases because of an increase in the unbound fraction (37). If that were the only mechanism, this interaction would not be important. However, phenylbutazone also inhibits the metabolism of *S*-warfarin and induces the metabolism of *R*-warfarin (38); the half-life of racemic warfarin is unchanged, but because the *S* isomer is more potent than the *R* isomer, the action of warfarin is potentiated (SED-9, 144) (36,39).

Oral hypoglycemic drugs

Phenylbutazone can potentiate the hypoglycemic effects of the sulfonylureas acetohexamide (40), chlorpropamide (41), tolbutamide (42), and glibenclamide (43). One mechanism of this interaction is interference with tubular excretion (3).

Penicillins

Phenylbutazone interferes with the tubular excretion of penicillins (3).

Phenytoin

Phenylbutazone can reduce the clearance of phenytoin by inhibiting CYP2C9 (44).

Sulfonamides

Phenylbutazone can displace sulfonamides from protein-binding sites (SED-9, 144) (45).

Interference with Diagnostic Tests

Thyroid function tests

Phenylbutazone inhibits thyroid uptake of iodine and/or competes for protein-binding sites with thyroxine (SED-9, 145) (46,47), and can thus interfere with the use of thyroid function tests.

Phenylephrine

General Information

Phenylephrine is seldom given systemically but is still commonly used as a mydriatic for both diagnostic and therapeutic purposes. Ocular application of phenylephrine 10% in pledget form is used to produce hemostasis in laser-assisted in-situ keratomileusis (LASIK) surgery and other ophthalmic surgical procedures. Phenylephrine is in some countries available in a non-prescription concentration of 0.12% for use as an ocular decongestant. Phenylephrine (up to 10 mg intramuscularly) has similar properties and uses to other alpha-adrenoceptor agonists.

The incidence of adverse effects is high with 10% phenylephrine, but less with lower concentrations. Systemic reactions also increase with increased frequency of use and when phenylephrine is applied in a pledget. The package inserts for 10% phenylephrine in the USA and Australia require that the drug should not be used more often than once an hour. A large number of severe

© 2006 Elsevier B.V. All rights reserved.

systemic reactions, including death, have been reported in more than 20 articles in peer-reviewed ophthalmic journals. For this reason 10% phenylephrine eye-drops should be used with caution in patients with cardiac disease, significant hypertension, or advanced arteriosclerosis, and in frail elderly people.

It can never be emphasized enough that the eyes are a potential route for systemic drug administration. This has been illustrated by a British case of pulmonary edema in a child, apparently attributable to systemic absorption of phenylephrine eye-drops (1).

- An 8-year-old boy was admitted for unilateral retinal detachment surgery. Phenylephrine 2.5% and cyclopentolate 1% as premedication were prescribed but not given. In theatre the assistant surgeon administered 2–5 drops of 10% phenylephrine to the right eye. During the operation the boy developed bradycardia and was given glycopyrrolate, but shortly afterwards the systolic arterial pressure rose to 211 mmHg and the pulse rate to 160 beats/minute, with multifocal atrial and ventricular ectopic beats. Labetalol was given and the pulse and blood pressure fell to normal, but he then developed clinical and radiological signs of pulmonary edema, which resolved spontaneously.

The management of this case was subsequently criticized by correspondents in the same journal (2). They suggested that a lower ocular dose of phenylephrine should be used routinely, that oxymetazoline might in any case be safer, and that labetalol might have been hazardous, owing to its beta-blocking properties. In their reply the authors pointed out that they used the lowest concentration of phenylephrine available for ocular use, that oxymetazoline is not licensed for use as a mydriatic agent, and that the patient had tachycardia and ventricular extra beats, which made the beta-blocking properties of labetalol clinically desirable.

It is always wise to advocate nasolacrimal occlusion by digital compression of the lacrimal drainage system when using phenylephrine eye-drops in patients at risk or in patients in whom higher concentrations are necessary (3).

Organs and Systems

Cardiovascular

The FDA and the National Registry of Drug-induced Ocular Side Effects (Casey Eye Institute, Portland, Oregon) have received 11 reports of adverse systemic reactions to a single dose of topical ocular phenylephrine 10% applied in pledget form (4). There were eight men and three women, aged 1–76 years. Most of the patients noted systemic effects within minutes of applying phenylephrine, and the adverse systemic reactions included severe hypertension, pulmonary edema, cardiac dysrhythmias, cardiac arrest, and subarachnoid hemorrhage. Ophthalmologists should be warned not to apply phenylephrine in this way, which is believed to be contraindicated in ophthalmic surgery, especially when other medications may be used (SED-14, 1643).

A 10% solution of phenylephrine has sometimes caused extremely severe cardiovascular complications, including myocardial infarction.

In newborn infants the benefit of accurate assessment of gestational age by examination of the anterior vascular capsule of the lens and the value of funduscopic examination in ill premature babies must be weighed against the possible risks of the associated increase in blood pressure produced by the pupillary dilators. Since there is no increase in mydriatic effect with repeated instillation or increasing concentration, and their small body mass places premature neonates at increased risk of phenylephrine overdose, it is prudent to use the lowest possible concentration, as well as the most effective combination of mydriatics for indirect ophthalmoscopy in premature infants when such examination is absolutely necessary. The hypertensive effect is likely to be maximal at some time within the first 20 minutes, and whenever possible (or when risk factors are present) the blood pressure should be monitored.

- A child developed cardiac dysrhythmias, severe hypertension, and pulmonary edema after the intraoperative administration of ocular phenylephrine (1).
- A 2-month-old child given perioperative phenylephrine drops during cataract extraction developed ventricular extra beats, very severe hypertension, and pulmonary edema requiring intensive therapy (5). Extubation was possible within 3 hours, and she recovered with no untoward consequences.

The authors commented that changes in arterial blood pressure are well described with phenylephrine eye-drops, especially in infants. Clearly precise dosage is difficult in these very young patients and they suggested that microdrops might be a safer mode of administration.

Ear, nose, throat

When used as a nasal decongestant, phenylephrine can cause local nasal irritation and even perforation of the anterior nasal septum.

- A 69-year-old woman developed perforation of the nasal septum after overuse of a common over-the-counter nasal spray containing phenylephrine (6).

The authors attributed this effect to both vasoconstriction and physical irritation.

Nervous system

It has been suggested that sodium bisulfite, a preservative in phenylephrine solutions for injection, may have been responsible for transient neurological symptoms that have been observed in some patients (7). However, the original authors rejected this, since the dose of bisulfite was small and since there is uncertain evidence whether the compound is neurotoxic in any case. Another correspondent commented that tetracaine itself may be more toxic than other local anesthetics: the authors did not address this point in their reply (8).

Sensory systems

With phenylephrine, several cases of allergic blepharoconjunctivitis have been seen, even at low concentrations; the reaction begins 3–4 hours after drug application, persists for 12 hours, and regresses gradually within 72 hours

© 2006 Elsevier B.V. All rights reserved.

(9). Biopsy of the conjunctiva reveals marked infiltration with cells of various types; there is some evidence that a sensitization mechanism is involved.

However, blepharoconjunctivitis can occur (SEDA-17, 162), as can other complications.

- Acute periorbital dermatitis and conjunctivitis occurred in a 69-year-old man given phenylephrine 5% eye-drops for ophthalmological examination (10). Subsequent patch-testing was strongly positive for phenylephrine eye-drops.

There have been responses to last year's report of occurring after the addition of phenylephrine to tetracaine spinal anesthesia. It has been suggested that sodium bisulfite, a preservative in phenylephrine solutions for injection, may have been responsible for transient neurological symptoms that have been observed in some patients (7). However, the original authors rejected this, since the dose of bisulfite was small and since there is uncertain evidence whether the compound is neurotoxic in any case. Another correspondent commented that tetracaine itself may be more toxic than other local anesthetics: the authors did not address this point in their reply (8).

Skin

There have been a few reports of allergic contact dermatitis caused by phenylephrine, and little is known about cross-reactivity between the phenylephrine, adrenaline, and ephedrine.

- A 62-year-old man developed contact dermatitis after using phenylephrine eye-drops (Neosynerphin POS) (11). The inflammation affected both eyelids symmetrically and resolved rapidly on withdrawal of the eye-drops and application of topical glucocorticoids. Skin-testing confirmed hypersensitivity to phenylephrine but no cross-sensitization to ephedrine or adrenaline.

Immunologic

Phenylephrine was the drug that most often caused sensitization in patients with contact allergy after the application of mydriatic eye-drops. Since several eye-drops are often used in the same patient, it is always important to find out which drug or preservative is the allergen (10–13).

Long-Term Effects

Drug abuse

Abuse of alpha-adrenoceptor agonist nose-drops can cause a chronic rhinitis (14) and psychoses (15).

Susceptibility Factors

Phenylephrine should be used cautiously in elderly people and in patients with hypertension, coronary heart disease, aneurysms, and diabetic autonomic neuropathy (SEDA-21, 487).

Drug–Drug Interactions

Monoamine oxidase inhibitors

Patients taking monoamine oxidase inhibitors, anticholinergic drugs (such as tricyclic antidepressants), propranolol, reserpine, guanethidine, and methyldopa should be monitored closely if phenylephrine is used (SEDA-16, 542) (16).

Tetracaine

When phenylephrine was used together with tetracaine in spinal anesthesia, 10 of 80 patients developed transient dysesthesia (SEDA-22, 155). Provocation of myocardial ischemia (17), acute edema of the lung (18), and ischemic colitis (SEDA-22, 155) were not so clear-cut.

Phenylpropanolamine (norephedrine)

General Information

In the past, phenylpropanolamine was marketed extensively in over-the-counter products for a variety of indications, and dietary supplements were marketed with no premarket safety evaluation, at least by the Food and Drug Administration (FDA), since for dietary supplements that include an ingredient marketed in the USA before 15 October 1994 no FDA review is required. Because many of these products were promoted as foodstuffs, consumers may have assumed that they are safe (SEDA-21, 5). It has been used as an anorectic agent in doses of 3–25 mg/day.

However, adverse effects from therapeutic and toxic doses of phenylpropanolamine have often been reported (SEDA-9, 2) (SEDA-10, 3) (SEDA-11, 1), and recently it has been implicated as a cause of stroke and other neurological events. In November 2000, the US FDA asked all manufacturers to recall the product voluntarily.

Organs and Systems

Cardiovascular

Much of the concern over the free sale of phenylpropanolamine relates to its cardiovascular effects. Although the commonly recommended 75 mg dose has no significant effect on blood pressure in healthy volunteers, 150 mg causes significant albeit transient hypertension lasting several hours (1). Hypertensive crises have been reported, for example after a 600 mg overdose (SEDA-18, 158). However, field experience suggests that, because of individual variations in sensitivity, the risks to some patients are greater than these findings suggest. In single doses of 50 mg, phenylpropanolamine increased diastolic blood pressure to over 100 mmHg in 12% of adults.

Phenylpropanolamine can also, on occasion, cause cardiac dysrhythmias in mild overdosage.

A transient cardiomyopathy without hypertension occurred in a girl of 14 who had taken only a small overdose (2) and another in an adult woman (SEDA-17, 163).

A warning was issued by the Swiss Pharmaceutical Association that phenylpropanolamine can cause severe sympathomimetic adverse effects, including hypertensive crises, dysrhythmias, and tachycardia (3) (SEDA-5, 11) (SEDA-7, 12).

Nervous system

Although it has been thought to have relatively little stimulant effect on the central nervous system, phenylpropanolamine can produce restlessness, anxiety, insomnia, and tremor; its central stimulant effects are in practice often masked by manufacturers' practice of combining it with an antihistamine.

In a consecutive stroke registry since 1988, 22 patients (10 men and 12 women) had strokes associated with over-the-counter sympathomimetic drugs (4). There was intracerebral hemorrhage in 17, subarachnoid hemorrhage in 4, and ischemic stroke in 1. Stroke was associated with the use of phenylpropanolamine (75–675 mg) in 16 patients.

- Stroke occurred in an 8-year-old boy on chronic peritoneal dialysis after he took phenylpropanolamine (5). He developed occipital infarcts and was found to have extremely high concentrations of phenylpropanolamine in his blood and dialysis fluid. Although the voluntary recall was in effect, the family already had a bottle of phenylpropanolamine at home.

In a case-control study, 2078 men and women (702 patients and 1376 controls), age range 18–49 years, were recruited from 43 US hospitals if they had had a subarachnoid or intracerebral hemorrhage within 30 days before enrolment and no previously diagnosed brain lesion (6). For women, the adjusted odds ratio was 17 (95% CI = 1.5, 182) for the association between the use of appetite suppressants containing phenylpropanolamine and the risk of a hemorrhagic stroke. For men and women combined, the adjusted odds ratio was 16 (1.4, 184). The authors suggested that phenylpropanolamine in appetite suppressants is an independent risk factor for hemorrhagic stroke in women. There was a trend toward an increased risk of stroke with cough and cold remedies in women (OR = 3.1; CI = 0.9, 11).

- A 37-year-old woman took an over-the-counter formulation containing phenylpropanolamine 100 mg (7). About 90 minutes later she developed very severe bilateral headache resistant to analgesics. Her blood pressure was 180/100 mmHg but fell rapidly to 110/70 mmHg. A CT scan showed multiple small frontal and parietal hemorrhages, and angiography showed extensive segmental vasospasm. She was treated with nimodipine and prednisolone, followed by verapamil. She made an uneventful recovery, and there was angiographic resolution of the vascular lesions.

The authors reviewed a number of other case reports of phenylpropanolamine-induced cerebral vasospasm associated with hemorrhages and drew a parallel with similar effects of amfetamines.

Psychological, psychiatric

Psychosis has been attributed to phenylpropanolamine (8,9). Risk factors include symptoms or a history of

© 2006 Elsevier B.V. All rights reserved.

mood spectrum disorder, a history of psychosis, female sex, and a family history of psychiatric disorder.

Although irritability and insomnia are frequent in adults, behavioral disturbances (restlessness, irritability, aggressiveness, and sleep disturbances), seizures, and delirium with hallucinations have been most often observed in children (SEDA-11, 1) (10).

Immunologic

Phenylpropanolamine can give rise to severe allergic reactions with dyspnea, urticaria, and facial swelling (11).

Long-Term Effects

Drug abuse

As with several other sympathomimetics, phenylpropanolamine is often sold illegally in special packages as a look-alike for more euphoriant/alerting stimulants. Both the absolute increase in use and the changes in the type of user have been associated with many reports of overdose consequences, including hypertension, cardiac dysrhythmias (SEDA-9, 10, 11), cerebral hemorrhage (SEDA-11, 2) (12,13), neuropsychiatric symptoms, including agitation and acute psychosis, and seizures (SEDA-9, 4) (14).

Susceptibility Factors

Age

Children appear to be sensitive to therapeutic doses of pseudoephedrine in the development of hallucinosis as well as irritability and insomnia syndromes (15,16).

Drug–Drug Interactions

Caffeine

Pharmacokinetic and pharmacodynamic interactions between caffeine 250 mg and phenylpropanolamine 25 mg have been investigated in six healthy subjects in a double-blind, placebo-controlled study. Coadministration of caffeine and phenylpropanolamine produced an additive increase in blood pressure, not attributable to a pharmacokinetic interaction and despite the fact that phenylpropanolamine attenuated the responses of adrenaline and renin to caffeine (17).

However, in another study in 16 healthy subjects who took caffeine 400 mg plus phenylpropanolamine 75 mg, the peak plasma–caffeine concentration was significantly higher than after caffeine alone. There were greater increases in both systolic and diastolic blood pressures, and adverse effects were more frequent after the combination than after either drug alone or after placebo (18).

Indinavir

A hypertensive crisis has been reported in a patient receiving triple therapy for HIV prophylaxis, including indinavir (19).

- A 28-year-old female medical resident was given zidovudine, lamivudine, and indinavir after a needle-stick injury involving an HIV-positive patient. She had a long history of sinus complaints and was taking a phenylpropanolamine-containing formulation intermittently. Ten days after starting prophylactic therapy she took phenylpropanolamine, although the dose was not stated, and 6 hours later developed right-sided headache, weakness of the left arm, and a blood pressure of 220/120 mmHg. CT and MRI scans of the brain were normal. Her blood pressure and neurological signs resolved during treatment with nimodipine and aspirin, though the weakness returned briefly.

It seems very likely that the protease inhibitor indinavir inhibited the metabolism of phenylpropanolamine by cytochrome P450 (predominantly CYP3A4), increasing circulating concentrations, and causing systemic and cerebral vasoconstriction.

Indometacin

Severe systemic hypertension developed in a patient who took indometacin shortly after taking an appetite suppressant (Trimolets) containing phenylpropanolamine (20). The hypertension was attributed to inhibition of prostaglandin synthesis by indometacin, which exacerbated the sympathomimetic effects of phenylpropanolamine. However, in 14 young, healthy, normotensive women who were randomized double-blind to modified-release phenylpropanolamine 75 mg/day or placebo for 4 days, modified-release indometacin 75 mg bd had no significant effect on mean systolic or diastolic blood pressures (21).

Neuroleptic drugs

Neuroleptic malignant-like syndrome has been reported when phenylpropanolamine was combined with neuroleptic drugs (22).

Phenytoin and fosphenytoin

See also Antiepileptic drugs

General Information

Phenytoin is the only widely used hydantoin and, unless otherwise specified, effects discussed here refer to phenytoin. Other hydantoin derivatives include ethotoin (rINN), mephenytoin (rINN), and albutoin (rINN) (all of which are obsolete), and fosphenytoin (rINN). The latter is a water-soluble prodrug that is rapidly hydrolysed to phenytoin after intravenous or intramuscular injection. It causes fewer adverse reactions near the injection site (pain, phlebitis, tissue necrosis, purple hand syndrome) than phenytoin.

The effects of phenytoin have been studied in 39 patients with acute mania (1). One patient dropped out because of tachycardia and one required a dosage reduction because of nystagmus.

Comparative studies

Intravenous phenytoin and intravenous fosphenytoin have been compared in an open, randomized study in 256 emergency department patients who were given 279 doses (2). The mean phenytoin-equivalent dose was similar in the two groups. Adverse events occurred with similar frequencies, but slightly more often with fosphenytoin (phenytoin 9.1%, fosphenytoin 16%). The most common events were pruritus, pain on infusion, and paresthesia. Only one patient developed hypotension, with fosphenytoin. Thus, this study has not demonstrated obvious advantages of fosphenytoin.

General adverse reactions

Phenytoin can cause vestibulocerebellar, oculomotor, and cognitive dysfunction. It can also cause gingival hyperplasia, hirsutism, and acromegaly-like facial features. Movement disorders, symptoms of peripheral neuropathy, and endocrine changes are uncommon. Interstitial nephritis, interstitial pneumonia, and hepatotoxicity are rare. High intravenous doses are cardiotoxic.

Hypersusceptibility reactions

Hypersusceptibility reactions range from relatively common mild rashes to life-threatening Stevens–Johnson syndrome and toxic epidermal necrolysis. Hepatic, cardiac, muscular, pulmonary, hematological, reticuloendothelial, and renal reactions and systemic lupus erythematosus are uncommon.

Tumorigenesis

Pseudolymphoma and a condition resembling malignant lymphoma are very rare.

Organs and Systems

Cardiovascular

Intravenous phenytoin can cause cardiac dysrhythmias, hypotension, and potentially fatal cardiovascular collapse, especially if the highest recommended infusion rate (50 mg/minute or 1 mg/kg/minute in children) is exceeded. One case of hypersensitivity myocarditis was probably initiated by phenytoin, although carbamazepine may have contributed (SED-13, 142) (3).

After intravenous use, the most common vascular complication is the so-called purple-glove or purple-limb syndrome, defined as the progressive development of edema, discoloration, and pain in the limb; sequelae include soft-tissue necrosis and limb ischemia. Retrospective analysis of data from 152 patients treated with intravenous phenytoin identified nine (6%) who developed this syndrome: they had received a greater mean initial dose of phenytoin (500 versus 300 mg) and a larger dose over 24 hours (800 versus 500 mg), and they tended to be older (72 versus 49 years) than those without the complication (4). In one case surgical therapy was required; the others resolved conservatively within 1 month. Extravasation of intravenously injected phenytoin has caused tissue necrosis requiring amputation (SEDA-18, 67). Purple glove syndrome has generally been reported after intravenous phenytoin.

© 2006 Elsevier B.V. All rights reserved.

- In a 49-year-old otherwise healthy woman undergoing craniotomy for aneurysm clipping, inadvertent overdose with phenytoin (1500 mg) by rapid infusion caused intraoperative sinus arrest, which was managed successfully with standard resuscitative measures (5).

This report highlights the cardiovascular risk of intravenous phenytoin, particularly when high infusion rates are used.

However, the purple-glove syndrome can also occasionally occur after oral administration.

- A 10-year-old boy took phenytoin 100 mg/day and his seizures were well controlled (6). However, a pharmacist gave him about 1000 mg of phenytoin instead of the prescribed dose, and several hours later he became drowsy and his hands and feet turned dark purple with marked swelling. Phenytoin was withdrawn after 4 days and the swelling and discoloration of his hands and feet improved gradually and disappeared 11 days later.

The incidence of purple-glove syndrome associated with intravenous phenytoin has been assessed in a prospective review of 179 consecutive exposures (7). There were only three mild cases (1.7%).

However, the purple-limb syndrome was recorded in 20 of 67 patients who received intravenous phenytoin over a 5-month period (8). Affected cases tended to be older (median age 70 years versus 57 years in non-affected cases), and all resolved spontaneously within 3 weeks. These data suggest that the incidence of the syndrome may have been underestimated in the past, possibly owing to its delayed onset, frequent occurrence in patients with impaired communication abilities, and its usually mild self-limiting course.

In 775 patients who received intravenous phenytoin, valproate, or placebo, intravenous site reactions occurred in 25% of patients who received phenytoin (9). Most of the events (70%) occurred in the first intravenous site, and all occurred in peripheral administration sites. When patients who received the drug by central line were excluded, the estimated incidence was 30%. There were fewer adverse events when phenytoin was given alone than when it was given together with valproate.

Fosphenytoin-induced QT interval prolongation has been reported (10).

- A 23-year-old man was given intravenous fosphenytoin (equivalent to phenytoin 1500 mg or 20.5 mg/kg) over 85 minutes. He was normocalcemic before the infusion. During the infusion he had prolongation of the QT interval and reductions in the concentrations of total and ionized serum calcium. Plasma phenytoin concentrations were within the target range during the electrocardiographic changes, and the blood pressure was stable.

Fosphenytoin is metabolized by phosphatases to yield phenytoin plus inorganic phosphate. Binding of calcium by phosphate could have lowered the serum concentration of ionized calcium.

Respiratory

Interstitial pneumonitis is extremely rare with phenytoin (11). The clinical features are fever, dyspnea, hypoxemia, and bilateral radiographic infiltrates. It responds to withdrawal and corticosteroids. Bronchiolitis obliterans organizing pneumonia in the context of a severe hypersensitivity syndrome also improved rapidly with high-dose steroids (SEDA-22, 90).

Nervous system

Ataxia, dysarthria, fatigue, dizziness, tremor, and nystagmus are relatively common in patients with phenytoin intoxication. Sedation occurs only at high serum drug concentrations; however, toxic effects at relatively low serum concentrations can occur when drug binding to plasma proteins is impaired (SEDA-18, 67). Uncommon effects include seizure exacerbation (12), reversible monoplegia or hemiplegia (13), reversible spastic rigidity, hyper-reflexia and clonus, hyperkinetic disorders, choreoathetosis (14), hemiballismus (15), hemichoreiform movements, local dystonia in the foot, myoclonus (16), and reversible parkinsonism (SED-13, 143).

- A 13-year-old girl developed left partial motor status epilepticus with severe postictal hemiparesis (15). An MRI scan showed a right frontoparietal hyperintense T2-weighted signal. Treatment with phenytoin, carbamazepine, and phenobarbital caused the seizures to abate but left choreic-like flinging movements, consistent with hemiballismus, 2 days later. On phenytoin withdrawal, the symptoms gradually abated, with mild residual dystonia at 14 months.

The authors speculated that the lesion might have rendered the cortex more susceptible to phenytoin, causing unilateral toxicity.

Three patients with severe myoclonic epilepsy in infancy developed choreoathetosis after an increase in phenytoin dosage; it resolved when the phenytoin dosage was reduced (17). In one, an ictal SPECT showed reduced perfusion in the basal ganglia contralateral to the unilateral choreoathetosis. Polypharmacy, including carbamazepine and zonisamide, may have facilitated the onset of choreoathetosis.

Phenytoin can aggravate symptoms and worsen outcome in patients with Baltic myoclonic epilepsy (SED-13, 140) (18) and susceptibility to neurological complications can be increased in patients with organic brain disorders.

Long-term phenytoin can cause cerebellar degeneration, but this is probably rare (SED-13, 143) (19), (SEDA-19, 73); irreversible cerebellar atrophy after acute intoxication is extremely rare (SEDA-21, 73).

- Distal lower extremity paresthesia in stocking distribution and motor weakness with loss of the Achilles tendon reflex, associated with reduced sensory conduction velocity, occurred in an 18-year-old girl a few hours after the administration of phenytoin (7.5 mg/kg) (20). The condition regressed after phenytoin withdrawal.

Peripheral neuropathy is a known adverse effect of phenytoin, but this is the first report of an acute neuropathy within less than 1 week of treatment.

Cerebellar atrophy has been reported in association with phenytoin intoxication (21).

Pre-existing myasthenia gravis can be aggravated by phenytoin (SEDA-7, 78).

© 2006 Elsevier B.V. All rights reserved.

Sensory systems

Taste

- Ageusia occurred in a 52-year-old man within a few hours of an intravenous infusion of phenytoin 750 mg for the control of seizures (22). The condition persisted for 2 weeks during oral phenytoin treatment and cleared in about 1 week when phenobarbital was substituted.

The time course in this case strongly suggested that phenytoin was responsible.

Psychological, psychiatric

Phenytoin has been implicated in psychiatric adverse effects with or without other signs of toxicity, and at serum concentrations above or below the upper limit of the target range, but the actual incidence of these reactions is unknown (23).

- A 9-year-old boy with seizures developed intermittent complex visual hallucinations during therapy with fosphenytoin and, on a separate occasion, carbamazepine (24).

Five patients with Down's syndrome and dementia, aged 44–67 years, taking phenytoin had progressive cognitive decline (25). This resolved once the drug was withdrawn. Cognitive decline was not related to high serum concentrations. Older patients with Down's syndrome might be especially sensitive to the effects of phenytoin.

Endocrine

Phenytoin can cause a rise in growth hormone concentration (26).

Phenytoin can cause acromegaly-like facial features, possibly related to its osteogenic actions (SEDA-20, 65).

Hematologic

Megaloblastic anemia and pancytopenia have been rarely attributed to phenytoin (27,28), whereas aplastic anemia has been observed with mephenytoin (29).

Single cases of a hemophilia-like disorder (SED-13, 144) (30), hemolytic anemia associated with renal insufficiency (31), and pure red cell aplasia (SED-12, 129) (32), have been reported.

Mouth and teeth

Gingival hyperplasia is a well-known adverse effect of phenytoin. It occurs in at least one-third of patients, although it can be prevented by careful dental hygiene (SED-13, 144) (33), and does not occur in edentulous mouths. In one case generalized palatal hyperplasia occurred in a patient in whom retained roots and teeth were suspected of having perpetuated a pre-extraction lesion; a subsequently placed complete denture initiated a midpalatal hyperplasia (34).

In 114 patients, of whom 20% took phenytoin, 5 taking phenytoin had gingival hyperplasia (35), which can on occasion be extensive.

- A 17-year-old boy took phenytoin 300 mg/day unsupervised for 2 years and developed coarsening of the facial features, extensive gingival hyperplasia, and cerebellar ataxia (36). The gingival hyperplasia resolved within 3 months of withdrawal but the ataxia persisted.

Gastrointestinal

Phenytoin was implicated in a case of reversible hypertrophy of the submandibular salivary gland, but cause and effect were speculative (SEDA-18, 67).

Liver

Chronic hepatitis is rarely caused by phenytoin (SEDA-18, 67). When it occurs, the signs of hepatotoxicity usually appear after 1–8 weeks in acute cases, and after 4 months to several years in chronic cases (37). Among 16 acute cases, there was fever in 75%, rash in 63%, jaundice in 44%, hepatomegaly in 13%, and lymphadenopathy and splenomegaly in 60% (37). Less common symptoms included sore throat, malaise, chills, myalgia, and pruritus. The condition can be fatal.

- A 51-year-old woman developed hepatitis while taking phenytoin 300 mg/day (38).

The authors did not discuss the possible role of paracetamol, which was co-administered in a dosage of 4 g/day (see Paracetamol section under Drug–Drug Interactions in this monograph).

Urinary tract

There has been one report of autoimmune interstitial nephritis associated with tubular deposits of phenytoin and circulating antitubular basement-membrane antibodies (SED-13, 144) (39).

Skin

Acne and hirsutism are not uncommon in patients taking phenytoin. Of 61 women who had taken phenytoin 100–300 mg/day for 1–5 years, more than half had coarse facial features from a combination of several degrees of acne, hirsutism, and gingival hyperplasia (40).

Skin rashes occur in about 10% of patients. They are generally mild and their incidence varies seasonally (SED-13, 144) (41).

Diffuse fasciitis with eosinophilia (a variant of scleroderma) (42), reversible nodular cutaneous pseudolymphoma, acromelanosis (43), hypertrophic retroauricular folds, and severe forms of erythema multiforme (Stevens–Johnson syndrome and toxic epidermal necrolysis) (44,45) are all rare (SED-13, 144) (SEDA-22, 90) (33).

- Toxic epidermal necrolysis has been reported in a 28-year-old woman who had taken phenytoin for 20 days (46). Phenytoin was cytotoxic in vitro to the patient's lymphocytes.
- A 49-year-old man with post-traumatic epilepsy taking phenytoin developed severe rhinophyma; he also had gingival hyperplasia (47).

Nothing in the history of this case pointed definitively to a cause and effect association.

Subacute cutaneous lupus erythematosus has been reported in a patient taking phenytoin (48).

© 2006 Elsevier B.V. All rights reserved.

- A 73-year-old woman who had taken phenytoin for 5 years developed erythematous, macular, annular lesions over her upper chest, back, and arms. She was also taking propafenone and nifedipine. Routine hematology and biochemistry were normal, except for leukopenia and a raised gamma-glutamyltranspeptidase. There were no antinuclear antibodies, but antibodies against Ro, La, and histone proteins were detectable. A skin biopsy was consistent with subacute cutaneous lupus erythematosus. She was given topical steroids, and all medications, apart from phenytoin, were withdrawn. However, as her eruption persisted, the phenytoin was tapered and withdrawn. Her rash cleared within 6 months. Over the next year there was no photosensitivity or recurrence, but Ro and La antibodies remained positive.

Interpretation of this report is confounded by the presence of concomitant treatments and the lack of quick resolution of the symptoms on phenytoin withdrawal. Furthermore, the autoantibodies did not normalize at 6 months.

Reproductive system

- An 18-year-old man with heterozygous point mutation in the defective allele of CYP2C9 and CYP2C19 (two enzymes involved in phenytoin metabolism) developed gynecomastia about 1 month after phenytoin dosage was increased from 175 to 190 mg/day, resulting in a serum phenytoin concentration of 68 μmol/l (49).

Phenytoin has been rarely implicated in gynecomastia, and whether the cytochrome P450 genotype played a contributory role was unclear. The patient was also taking zonisamide, which has also rarely been associated with gynecomastia.

Immunologic

The phenytoin hypersensitivity syndrome ranges from a simple rash to a fulminant fatal illness with exfoliative dermatitis, vasculitis, and disseminated intravascular coagulation. Features include variable combinations of fever, eosinophilia, lymphadenopathy, hepatosplenomegaly, atypical lymphocytes, blood dyscrasias, serum sickness, hepatitis, and renal insufficiency.

Angioimmunoblastic lymphadenopathy, systemic lupus erythematosus, polymyositis, and serum sickness have been noted in individual cases (SED-13, 144) (50,51).

IgA depression is seen in about 10% of patients (52). There has been one report of deficiency of IgG2 and IgG4 (SEDA-17, 73) and one of panhypogammaglobulinemia (SEDA-16, 73).

- A 32-year-old man developed acute lung injury and renal insufficiency after 4 days of starting to take phenytoin (53). The symptoms mimicked a renopulmonary syndrome, and resolved completely after withdrawal of phenytoin and the addition of steroids.

Giant cell myocarditis has been reported in a patient taking phenytoin, phenobarbital, and mephobarbital and in one taking primidone (54).

Lupus-like syndrome has been attributed to phenytoin (55).

- A 67-year-old white man who had taken phenytoin 300 mg/day for about 15 years developed fever, pericarditis, severe abdominal pain, malaise, and weight loss. He had a positive antinuclear antibody in a titer of 1:80 in a homogeneous pattern, a strongly positive antihistone antibody test, a raised erythrocyte sedimentation rate (115 mm/hour), and a neutrophilia (21×10^9/l). All these abnormalities resolved within a few weeks of withdrawal. Rechallenge was not performed.

The long delay between the start of therapy in this case and the clinical presentation makes it highly likely that phenytoin was not implicated and that recovery was spontaneous.

There has been a report of hypersensitivity to phenytoin (which had been previously well tolerated) after a hypersensitivity reaction to carbamazepine (56).

- A 19-year-old man with partial epilepsy took phenytoin 300 mg/day for over 6 months. Carbamazepine was introduced and after about 6 weeks (while taking phenytoin 300 mg/day and carbamazepine 600 mg/day) he developed fever, anorexia, a sore throat, bloody diarrhea, a diffuse, erythematous, maculopapular rash and palatal petechiae, tender cervical lymphadenopathy, and mild splenomegaly. His liver enzymes were raised and he had a leukocytosis with eosinophilia. Phenytoin and carbamazepine were withdrawn, and he was given prednisone and sodium valproate 1000 mg/day. The rash resolved, as did other manifestations of what was thought to be a hypersensitivity reaction. About a year later, phenytoin was reintroduced starting at 100 mg/day. He developed a sore throat after taking the first dose and a widespread rash after the second dose. There was no evidence of hepatic or hematological dysfunction. Phenytoin was withdrawn and the rash resolved in 1 week.

Cross-sensitivity among aromatic antiepileptic drugs occurs in about 50% of patients with a hypersensitivity reaction. It has previously been described on first exposure to each of the offending drugs (57). However, this patient developed an allergic rash on his second exposure to phenytoin, having previously tolerated it for 6 months. This suggests that carbamazepine may have altered his response to phenytoin.

Long-Term Effects

Mutagenicity

Neuroblastoma has been rarely reported in association with the fetal hydantoin syndrome. Phenytoin can cause pseudolymphoma and rarely a condition resembling malignant lymphoma (SED-13, 142). Pseudolymphoma is usually characterized by lymphadenopathy, fever, and a diffuse erythematous macular skin eruption, although a presentation without fever and rash has been described (SEDA-20, 65).

Tumorigenicity

Pseudolymphomatous reactions, pseudomalignant histiocytosis, a reaction resembling mycosis fungoides, and

© 2006 Elsevier B.V. All rights reserved.

malignant lymphoma have been noted in individual cases (SED-13, 144) (58,59).

Susceptibility Factors

Genetic factors

- A 40-year-old man who developed toxic signs and a high serum phenytoin concentration (130 μmol/l) on a low dosage (187.5 mg/day) was found to be heterozygous for the Leu359 allele of CYP2C9 and for the *3 allele of CYP2C19 (60).

Phenytoin is metabolized by both cytochromes and the mutations probably explained the adverse reaction.

Other features of the patient

Patients receiving cranial irradiation and patients with malignant gliomas may be at particular risk of severe skin reactions to phenytoin (SEDA-18, 68) (SEDA-20, 58). Neurological adverse effects can be enhanced in patients with a recent history of severe traumatic brain injury.

Several reports have suggested that patients with brain tumors who undergo radiation therapy while taking phenytoin may be at increased risk of developing Stevens–Johnson syndrome. A 47-year-old black man (61) and four other patients, including one who died (62), were seen in a 24-month period in one department. A review of 20 similar reported cases showed no relation to the dosage of phenytoin or radiation therapy, or to the histological type of the tumor.

Drug Administration

Drug contamination

Phenytoin poisoning has been reported in a patient who took Chinese proprietary medicines containing phenytoin, carbamazepine, and valproate (63). The manufacturer's information leaflet did not mention any of these prescription drugs.

Drug administration route

Intravenous phenytoin has been associated with fatal hemodynamic complications and serious reactions at the injection site, including skin necrosis and amputation of extremities. Fosphenytoin, a phenytoin prodrug, has the same pharmacological properties but none of the injection site and cardiac rhythm complications after intravenous administration (64).

The extent of absorption and tolerability of intramuscular fosphenytoin has been assessed in a double-blind study in which patients received 10 mg/kg dose of intramuscular fosphenytoin in one gluteus muscle and intramuscular saline in the other (65). More than half the patients had serum concentrations in the target range at 30 minutes. There was no pain at either the fosphenytoin or saline injection sites in 46% of patients and no difference in pain at 60 minutes and thereafter.

Drug overdose

The saturable kinetics of phenytoin results in an increased half-life in overdose and a protracted clinical course, which can last a week or more (66). The most common initial finding in mild toxicity is nystagmus. As concentrations increase, ataxia, decreased coordination, hyperreflexia, slurred speech, and diplopia can occur. Progressive increases result in confusion, lethargy, and coma. Various attempts to increase elimination, including dialysis, hemoperfusion, diuresis, and plasmapheresis, have been ineffective and are not without risk. Meticulous supportive care, including ventilation if necessary, should provide a good clinical outcome. Multiple-dose activated charcoal may be helpful in shortening the duration of symptoms.

Severe poisoning in a hypoalbuminemic neonate responded unusually to peritoneal dialysis, possibly because of reduced phenytoin binding to plasma proteins (SEDA-16, 73).

Serum phenytoin concentrations in overdose have been studied in nine patients aged 20–66 years (67). The serum phenytoin concentrations were initially 136–230 μmol/l and fell linearly (that is with zero-order kinetics); the elimination rate varied from 19 to 41 μmol/l/day. In those with the highest serum concentrations at presentation there was a delay before the fall in concentrations began.

- The apparent effectiveness of charcoal hemoperfusion has been reported in a 19-year-old woman who took about 5 g of phenytoin (68). The plasma concentrations of total and unbound phenytoin fell rapidly, from 160 and 14 μmol/l to 65 and 6 μmol/l respectively, after 3 hours of hemoperfusion. The total phenytoin half-life was 3.9 hours. The protein-bound fraction was constant (91%) throughout.

Drug–Drug Interactions

Atorvastatin

In a 50-year-old woman with familial hypercholesterolemia and epilepsy, the addition of phenytoin caused a marked reduction in the lipid response to atorvastatin, an effect that was reversible after withdrawal of the anticonvulsant (69). It is likely that phenytoin reduced the efficacy of atorvastatin by inducing its metabolism.

Cimetidine

The combined use of cimetidine and phenytoin led to severe thrombocytopenia in four of 1512 neurosurgical patients (70).

Cyclophosphamide

In three patients treated with cyclophosphamide, phenytoin co-medication increased the formation of the *S*-enantiomer (but not the *R*-enantiomer) of the dechloroethylated cyclophosphamide metabolite (71). The findings also suggested that phenytoin increased the clearance of both *R*- and *S*-cyclophosphamide to 4-hydroxycyclophosphamide (the activation pathway). The clinical relevance of these findings is unclear.

© 2006 Elsevier B.V. All rights reserved.

Isradipine

Isradipine, an inhibitor of CYP450, provoked phenytoin intoxication in one patient (72).

Lamotrigine

Choreoathetosis is a rare adverse effect of some anticonvulsants, but has especially been associated with phenytoin. In a retrospective survey, three of 39 adults and one of 38 children developed choreoathetosis acutely when lamotrigine was added to phenytoin or vice versa (73). The effect was reversible by withdrawing one of the drugs. It was calculated that the risk of choreoathetosis is increased more than 50-fold when these drugs are combined, possibly owing to a pharmacodynamic interaction.

Losartan

The interaction of losartan with phenytoin has been studied in a randomized, crossover study in 16 healthy volunteers (74). Losartan, a CYP2C9 substrate, had no effect on the pharmacokinetics of phenytoin. However, phenytoin inhibited the CYP2C9-mediated conversion of losartan to its active metabolite, thus potentially reducing its efficacy.

Nelfinavir

In a 30-year-old man stabilized on phenytoin, the addition of nelfinavir was associated with a fall in serum phenytoin concentration and seizure recurrence (75). However, other drugs were also added or withdrawn during the observation period and the role of nelfinavir in this possible interaction is speculative.

Paracetamol

It has been proposed that phenytoin can exacerbate the hepatotoxic effects of paracetamol (76).

- A 55-year-old woman with a community-acquired pneumonia had unexplained moderate rises in hepatic enzyme activities while taking paracetamol 1300–6200 mg/day and phenytoin 350 mg/day. Paracetamol was withdrawn, and her chemistry normalized within 2 weeks.

The authors suggested that induction of CYP3A4 by phenytoin had encouraged the formation of a hepatotoxic metabolite of paracetamol.

Simvastatin

- In a 50-year-old woman with familial hypercholesterolemia and epilepsy, the addition of phenytoin caused a marked reduction in the lipid response to simvastatin, an effect that was reversible after withdrawal of the anticonvulsant (69).

It is likely that phenytoin reduced the efficacy of simvastatin by inducing its metabolism.

Ticlopidine

A careful study in six patients showed that ticlopidine 250 mg bd caused a two-fold increase in the Michaelis–Menten constant of phenytoin, indicating inhibition of phenytoin metabolism (77). These results are consistent with the known inhibitory activity of ticlopidine on CYP2C19, and suggest that phenytoin dosage requirements can be reduced by ticlopidine.

Valproate

The pharmacokinetic interaction of phenytoin with valproate is complicated (78–80). Initially, the total serum phenytoin concentration falls, because valproate displaces phenytoin from protein binding sites and so the unbound fraction increases, with a consequent increase in clearance. Because of the change in unbound fraction the total plasma concentration effect curve is shifted to the left, and a lower total concentration is as effective as the total phenytoin concentration was in the absence of valproate. However, valproate also inhibits the metabolism of phenytoin and so the serum phenytoin concentration then starts to rise and there is a risk of toxicity.

Phenytoin reduces serum valproate concentrations by inducing its metabolism (81). This may cause the formation of a hepatotoxic metabolite of valproate (82).

In 775 patients who received intravenous phenytoin, valproate, or placebo, intravenous site reactions occurred in 25% of patients who received phenytoin (9). Most of the events (70%) occurred in the first intravenous site, and all occurred in peripheral administration sites. When patients who received the drug by central line were excluded, the estimated incidence was 30%. There were more adverse events when phenytoin was given together with valproate than when it was given alone.

Food–Drug Interactions

The interaction of oral phenytoin with enteral feeding formulations has been reviewed (83). Four prospective, randomized, controlled trials in healthy volunteers showed no interaction. However, numerous anecdotal reports and studies have shown dramatic reductions in serum phenytoin concentrations in patients receiving enteral feeding formulations. The authors therefore concluded that this interaction occurs in patients but not in healthy volunteers.

Diagnosis of Adverse Drug Reactions

The usual target range for plasma concentrations is 40–80 μmol/l (10–20 μg/ml).

Phosphates

General Information

Sodium phosphates are considered to be dangerous (1), particularly because of their effects on electrolyte balance. An oral solution of sodium phosphates (dibasic sodium phosphate + monobasic sodium phosphate) is used as a laxative for the relief of occasional constipation and is used as part of a bowel-cleansing regimen in preparing patients for surgery or colonoscopy.

© 2006 Elsevier B.V. All rights reserved.

The FDA has limited the container size for oral solutions of sodium phosphates to not more than 90 ml in over-the-counter laxatives, because of reports of deaths associated with overdosage of oral solutions of sodium phosphates when the product was packaged in a larger container and a larger than intended dose was taken inadvertently. The agency has also required warning and direction statements to inform consumers that exceeding the recommended dose of oral and rectal sodium phosphates products in a 24-hour period can be harmful.

In 194 patients randomized to receive either sodium picosulfate or fleet phosphate soda before barium enema, there was no difference in the quality of bowel preparation, but picosulfate was easier to take and better tasting and it provoked less nausea and vomiting (2).

Organs and Systems

Endocrine

A 39-year-old woman with oncogenic osteomalacia caused by an osteosarcoma of the right scapula developed tertiary hyperparathyroidism after taking oral phosphate and vitamin D (3). The uniqueness of this case was the co-existence of hyperparathyroidism and oncogenic osteomalacia. All patients previously reported as having developed tertiary hyperparathyroidism with phosphate supplements had taken them for 10–14 years before diagnosis, but this patient had taken it for only 2 years. The proposed mechanism is that exogenous phosphate stimulates parathyroid activity through sequestration of calcium.

Electrolyte balance

From 1987 to October 31, 2001 the Canadian Adverse Drug Reaction Monitoring Program received 10 reports of serious electrolyte disturbances (hypocalcemia, hyperphosphatemia, hypernatremia, and hypokalemia), acidosis, dehydration, renal insufficiency, and tetany in patients who had taken more than 45 ml of the solution, in patients at risk of these complications, and/or in patients using multiple purgatives for bowel preparation (4). In view of these reports, Johnson & Johnson, Merck Consumer Pharmaceuticals, and Pharmascience Inc, in consultation with Health Canada, each issued a letter to all health professionals, giving information related to the safe use of sodium phosphates oral solution. The identification, characterization, and management of drug-related adverse events depend on the active participation of health care professionals in adverse drug reaction reporting programs. Health care professionals are asked to report any suspected adverse reactions in patients who have taken sodium phosphates oral solution.

The Austrian Adverse Drug Reactions Advisory Committee received three reports of severe electrolyte disturbances associated with an oral bowel-cleansing solution containing sodium phosphate solution (Fleet Phospho-Soda Buffered Saline Laxative Mixture), used as a bowel preparation for colonoscopy (5). Prescribers are advised to be aware of complications of the use of phosphate enemas, particularly in infants, elderly or debilitated patients, patients with congestive heart failure, and patients with impaired renal function.

Gastrointestinal

Four cases have suggested an association between oral sodium phosphate and microscopic focal cryptitis (6). The three men and one woman, aged 31–56 years, all had symptoms suggestive of irritable bowel syndrome and had not taken any antibiotics, NSAIDs, or immunosuppressive drugs before the onset symptoms. Colonoscopy was normal. There was no microbiological evidence of an infective cause, and routine biochemistry and hematology laboratory tests were normal. Histology was distinct from infective, ischemic, or inflammatory bowel disease. However, rebiopsy after withdrawal of the drug was not performed in any patient.

Rectal necrosis has been described in a child after phosphate enemas (7).

Susceptibility Factors

Age

Children

Although phosphate enemas are used in preparing children's bowels for colonoscopy and have been described as being safe and ideal for this purpose (8), in children under 5 years they carry risks of significant morbidity due to hyperphosphatemia, hypocalcemia, hypokalemia and dehydration (9). Phosphate toxicity associated with enteral sodium phosphate has been reported in more than 20 children (10,11). Two died, and one had severe neurological sequelae; these three children had either gastrointestinal or renal abnormalities, and one was very premature. Fatal phosphate toxicity has been reported in a 17-month-old child who had no apparent renal or gastrointestinal abnormality after a relatively small dose of hypertonic phosphate enema (12). Hypocalcemic tetany developed in children after the administration of phosphate enemas (10,11). The authors advised against the use of phosphate enemas in children under 2 years, and they recommend use only with extreme caution in children aged 2–5 years, especially when there is underlying bowel disease or renal dysfunction.

Elderly people

In elderly patients, phosphate enemas (Fleet Enema) have caused serious adverse effects.

- A 77-year-old patient with diverticular disease, who received phosphate enemas in preparation for a barium enema, developed hyperphosphatemia and hypocalcemic coma (13).

This case suggests that caution is required in administering phosphate enemas to patients with abnormal colonic mucosa.

- A Fleet Enema was given to a 91-year-old patient who lapsed into coma and died a few hours afterwards, despite treatment with phosphate binders and calcium (14).

Another similar case has been described (15).

Renal disease

Adults with normal excretory functions should not be at risk, but those with renal failure are likely to experience complications (SEDA-17, 425) (SEDA-18, 374).

© 2006 Elsevier B.V. All rights reserved.

Drug Administration

Drug overdose

A 46-year-old woman, with hepatic encephalopathy complicating cirrhosis due to hepatitis B and C infection, developed fatal hypernatremia, hyperphosphatemia, and hypocalcemia following the erroneous administration of a total of six sodium phosphate enemas (133 ml each) over 36 hours (16).

Phosphodiesterase type III, selective inhibitors of

See also Individual drugs

General Information

There is a range of bipyridines that are selective inhibitors of a specific isoenzyme of phosphodiesterase, F-III. These include amrinone, enoximone (fenoximone), milrinone, pimobendan, sulmazole, and vesnarinone. Their clinical pharmacology has been reviewed (1).

The pharmacology, clinical pharmacology, uses, therapeutic value, and adverse effects of positive inotropic drugs other than digitalis have been reviewed (2–6), as has the suggestion that their long-term use may be deleterious (6). Apart from the selective inhibitors of phosphodiesterase type III, these drugs include some beta-adrenoceptor agonists and partial agonists, such as dobutamine, dopamine, ibopamine, pirbuterol, prenalterol, and xamoterol, and calcium sensitizers.

The under-reporting of the results of clinical trials in patients with heart failure has been reviewed (7). Some trials that have been unpublished or published only in abstract or preliminary form have involved drugs with positive inotropic effects, such as the phosphodiesterase inhibitor vesnarinone (SEDA-23, 195), the beta-adrenoceptor partial agonist xamoterol, and the dopamine receptor agonist ibopamine.

Although the phosphodiesterase inhibitors are effective in the treatment of acute cardiac failure in various settings, overall mortality during long-term treatment of heart failure is increased, and these drugs should not be used for that purpose (8).

Photochemotherapy (PUVA)

General Information

Photochemotherapy, which consists of oral (and sometimes topical) administration of psoralens (the furocoumarins 5-methoxypsoralen, 8-methoxypsoralen, and trioxysalen) plus long-wave ultraviolet radiation, known as PUVA, is a well-established effective treatment for psoriasis, which has also been used for vitiligo (1), mycosis fungoides, alopecia areata, dyshidrotic eczema, atopic dermatitis, and certain other skin diseases. Guidelines for treatment have been recommended (2,3).

Bathwater delivery of psoralens ("Bath PUVA") is an attractive alternative to oral administration, since it virtually lacks systemic adverse effects and the rapid decline of photosensitivity after bath PUVA enables the patient to pursue daily activities without restrictions (4). Trioxysalen bath PUVA does not have carcinogenic effects (5).

Guidelines for topical PUVA therapy, including bath and local immersion PUVA therapy, have been published by the British Photodermatology Group (6).

Short-term reactions are not uncommon. They include erythema, burns, nausea, pruritus, headache, and dizziness. Hypersensitivity reactions, which are uncommon, include drug fever, skin rashes, and bronchial asthma. Long-term treatment increases the risk of non-melanoma skin cancers and possibly of cutaneous melanoma.

Organs and Systems

Cardiovascular

A rise in ambient temperature can have cardiovascular effects. In high-risk conditions, cardiovascular monitoring during treatment has been advised (SEDA-6, 148), although patients with cardiovascular disease and hypertension are also reported to tolerate PUVA therapy without evidence of cardiovascular stress (7).

Edema of the legs has been noted occasionally.

Respiratory

Bronchial asthma and coughing attacks have been attributed to methoxsalen allergy (8).

Nervous system

Dizziness, headache, and itching are well-known immediate adverse effects (SEDA-3, 132). Persistent skin pain can be serious (9).

Sensory systems

Although several cases of cataracts presumably or probably induced by PUVA have been reported (10,11), the risk appears to be small when recommendations to prevent ocular complications (12) are strictly adhered to (13).

Other ocular symptoms after PUVA include photophobia, conjunctivitis, keratitis, and dry eyes (SEDA-7, 166). Adequately protecting the eyes from the sun reduces the risk of acute toxic effects on the cornea and conjunctivae (14).

Visual field defects have been described in some patients (15).

Metabolism

Severe hyperlipidemia possibly related to PUVA has been observed once (SEDA-19, 155).

Hematologic

There have been reports of acute leukemia (SEDA-10, 125) and neutropenia (SEDA-5, 151) during PUVA and one dubious report of preleukemia (SEDA-4, 105). Transformation of stable chronic myelomonocytic leukemia to acute myeloid leukemia has been attributed to PUVA (SEDA-14, 124). These events may all have been purely coincidental and not causally related, as PUVA does not appear to increase the risk of non-cutaneous malignancies (16).

Gastrointestinal

Nausea and diarrhea sometimes occur (17).

Liver

Slight transient rises in liver enzymes have been reported during PUVA treatment, but they were usually attributable to pre-existing liver disease or the use of alcohol or other drugs. However, there have been two reports of liver damage clearly attributable to PUVA (18,19). It is rare for liver enzymes to rise after topical 8-methoxypsoralen (20).

Urinary tract

In 12 of 106 patients treated with PUVA an increase in serum creatinine to abnormal values was noted. In one patient a renal biopsy showed uncharacteristic glomerulonephritis (SEDA-5, 151).

Nephrotic syndrome has been reported in a patient treated with PUVA for polymorphic light eruption (SEDA-9, 132).

Skin

Phototoxicity with erythema, burns, localized edema, and blistering can occur in up to 11% of patients treated with PUVA (SEDA-22, 165) (21). Other cutaneous adverse effects that are related or possibly related to PUVA are listed in Table 1.

PUVA can cause pemphigus vulgaris, bullous pemphigoid, and pemphigus foliaceus. In one case intermittent flares continued for 2 years after the withdrawal of PUVA (22).

Immunologic

Concerns that PUVA therapy can cause systemic lupus erythematosus (SLE) and other connective tissue diseases, such as giant cell arteritis (SEDA-6, 147), have been raised by several reports (SED-12, 336) (30), (SEDA-15, 139) (SEDA-17, 183). There have been several studies of the incidence of serum antinuclear antibodies in patients who have received PUVA, with both

Table 1 Adverse effects of PUVA on the skin, hair, and nails

Acne (SEDA-3, 132)
Actinic lichenoid dermatitis (SEDA-12, 130)
Allergic contact dermatitis to methoxsalen (8-methoxypsoralen)
Allergic cutaneous vasculitis (SEDA-6, 146)
Bacterial infections, such as folliculitis and erysipelas
Bowen's disease and Bowenoid lesions
Bullous eruptions, including phototoxic bullae, acrobullous eruptions, and (rarely) bullous pemphigoid (SEDA-21, 160) (23)
Dermatomyositis (SEDA-19, 155)
Disseminated epidermolytic acanthoma (SEDA-12, 130)
Disseminated superficial actinic porokeratosis (SEDA-6, 147) (SEDA-11, 136)
Epidermal dystrophy
Exacerbation of polymorphic light eruption
Generalized exanthematous pustulosis (SEDA-20, 153)
Granuloma annulare (SEDA-4, 105)
Herpes simplex infection
Herpes zoster infection
Hirsutism (SEDA-6, 146)
Hypertrichosis
Kaposi's varicelliform eruption
Keratoacanthoma (SEDA-9, 131)
Lichen planus (SEDA-6, 147)
Lupus erythematosus (SEDA-15, 140) (SEDA-17, 183)
Lymphomatoid papulosis (SEDA-16, 151)
Mycosis fungoides, inflammatory flare-up (SEDA-20, 153)
Nail pigmentation (SEDA-8, 152)
Neurofibroma (SEDA-15, 142)
Papular phototoxic reaction
Pemphigus vulgaris (24)
Photoallergic dermatitis (SEDA-15, 141)
Photo-oncolysis (SEDA-3, 152) (SEDA-4, 105)
Pigment alterations, notably PUVA lentigines (SEDA-9,130); absence of PUVA lentigines may be an indicator of a lower risk of PUVA malignancy (25)
Psoriasis of the nails
Pustular psoriasis
PUVA keratoses (26)
Rosacea
Scleroderma-like changes
Seborrheic dermatitis of the face
Senile elastosis
Subungual bleeding
Suppression of induction and expression of delayed cutaneous hypersensitivity (27)
Urticaria (28)
Verruciform xanthoma (SEDA-20, 153)
Vitiligo (SEDA-22, 165) (29)

positive and negative results. Current evidence suggests that frequent evaluation of antinuclear antibodies during treatment of patients with uncomplicated psoriasis with an initially negative antinuclear antibody test and with no symptoms of connective tissue diseases is unnecessary (31).

Hypersensitivity reactions occur infrequently and have included drug fever, skin rashes, and bronchial asthma. Anaphylaxis to 5-methoxypsoralen has been reported (32).

- A 36-year-old woman had been treated for a polymorphic light eruption with two annual courses of PUVA, three times weekly for 6 weeks, plus oral 5-methoxypsoralen 60 mg, without any adverse effects. However, during the fourth course, 30 minutes after taking 5-methoxypsoralen 60 mg, she developed intense pruritus of the palms, spreading to the body. This was followed by erythema of the palms and symmetrical erythematous patches and urticarial lesions on the trunk. She had dizziness and slight difficulty in breathing. Her symptoms cleared within an hour after intravenous administration of an antihistamine and cortisone. Two months later skin prick tests with 5-methoxypsoralen were negative, but placebo-controlled oral provocation with 5-methoxypsoralen 20 mg resulted in symptoms similar to those she had experienced during PUVA.

Body temperature

Influenza-like symptoms have been attributed to psoralens (33).

- A 54-year-old man treated with photochemotherapy for disabling hand eczema developed flu-like symptoms, which lasted for 48 hours and occurred repeatedly within 2 hours after oral methoxsalen 50 mg. In addition to a fever up to 39°C, he had headache, nausea and vomiting, fatigue, dyspepsia, and muscle aches.

Although no attempt was made to isolate any viruses, the multiple positive rechallenges, in combination with a time-course compatible with methoxsalen pharmacokinetics, suggested a drug-related event.

Long-Term Effects

Tumorigenicity

Cutaneous carcinogenicity

In a review of the English language literature on the risk of non-melanoma skin cancer from photochemotherapy in the treatment of psoriasis (34) the following were the conclusions:

(a) PUVA is an independent dose-related carcinogen in humans and can initiate and promote the formation of squamous cell carcinoma (35). The relation of basal cell carcinoma to PUVA alone is not well established.
(b) The carcinogenic risk of PUVA is not simply dose-related and skin type; geographic location and other well-established co-carcinogenic risk factors must be taken into account.
(c) Three factors are important co-carcinogens with PUVA: a history of arsenic exposure, ionizing radiation therapy, and skin cancer. Other factors believed to be related to increased risk include skin types I and II.
(d) Factors that appear to be associated with little or no risk of PUVA-related carcinogenesis include methotrexate (although a study from Sweden (36) has suggested otherwise), topical tar, and ultraviolet B (UVB). Exceptions to this include simultaneous use of methotrexate and PUVA, and high exposure of the genital skin to UVB/tar. Retinoids may prove to be negatively correlated with skin cancer.
(e) The dose-related increased risk of cutaneous squamous cell carcinoma from PUVA is independent of

© 2006 Elsevier B.V. All rights reserved.

skin type (I–IV), although the absolute risk is much higher in skin types I and II.

(f) Men treated with PUVA without genital protection are at high risk of developing dose-related invasive squamous cell carcinoma of the penis and the scrotum (SEDA-15, 141).

(g) PUVA-induced squamous cell carcinoma is not biologically aggressive. Nevertheless, metastases have been observed in some patients, emphasizing the need for continued monitoring (37).

(h) There is no definitive degree of cumulative PUVA exposure above which carcinogenicity can be predicted. However, the risk of squamous cell carcinoma is less in patients with skin types II, III, and IV, no risk factors, and a cumulative exposure below 1000 J/cm^2. Of patients treated with over 2000 J/cm^2, even those without risk factors, at least 20% will develop squamous cell carcinomas and 50% atypical squamous keratoses (35). Patients with skin type I should be monitored more rigorously than others.

The following recommendations were made

(a) Whenever possible, exclude patients with a history of ionizing radiation therapy, skin cancer, or arsenic exposure.

(b) Shield the male genital skin at all times during PUVA treatment.

(c) Use the European dosage protocol (lower doses and less frequent irradiations than the US protocol) whenever possible.

(d) Reduce PUVA dosage by combining or cycling with other treatments. Avoid maintenance therapy if possible.

(e) Use PUVA in younger patients only when necessary.

(f) Monitor patients with skin type I closely.

(g) Monitor patients prospectively and at least annually for keratoses and cutaneous carcinoma, particularly after cumulative exposure of more than 1000 J/cm^2.

Risk of melanoma

The PUVA Follow up Study was a prospective evaluation of 1380 patients who started using PUVA for psoriasis in 1975 and 1976. There was a modest but significantly increased risk of malignant melanoma in PUVA-treated patients ($n = 822$), beginning 15 years after first exposure (SEDA-22, 166) (38,39). Incidence rates during 1996–1999 were 10-fold higher than those expected from incidence data in the general population (data available only for 1992–1996). There was a non-significant trend toward a higher incidence of melanoma in patients who had received more courses of PUVA (over 200). High degrees of exposure to PUVA, a period of at least 15 years from the time of the first exposure, or both are required before the risk of melanoma increases substantially. Despite the fact that melanoma is lethal if left untreated, this observation does not necessitate abandonment of PUVA (40). This risk should be weighed against the substantial efficacy of PUVA therapy in severe psoriasis. However, it does suggest that the guidelines for treating psoriasis with PUVA should be rigidly observed (41). Patients receiving long-term treatment should be carefully followed throughout their lives and those who are at increased risk of melanoma should not be given this treatment.

Non-cutaneous cancers

Long-term PUVA does not increase the risk of non-cutaneous cancer, including lymphomas or leukemia (16).

Second-Generation Effects

Pregnancy

Although PUVA therapy should not be begun during pregnancy or lactation, the theoretical mutagenic and teratogenic effect of PUVA does not carry any significant risk of abnormal delivery (42,43).

Susceptibility Factors

Relative contraindications to PUVA therapy include a history of arsenic intake, previous ionizing radiation, long-term use of cytostatic drugs, skin cancer, cataracts, and severe cardiovascular disease. In patients with photosensitive dermatoses and in patients who are using systemic photosensitizing drugs, PUVA should be administered with caution. The possible long-term adverse effects should be taken into consideration, especially when young patients are candidates for photochemotherapy. Uncontrolled use of psoralens may lead to life-threatening burns (27).

Drug–Drug Interactions

Emollients

The use of emollients before PUVA can significantly interfere with UV light transmission during photochemotherapy (44).

Phenytoin

Phenytoin can reduce the serum concentrations of methoxsalen, probably by inducing its metabolism (45).

Physical contraceptives—intrauterine devices

General Information

Intrauterine contraceptive devices (IUCDs) have been reviewed (1,2). Most are composed of bland synthetic materials or contain in addition a small amount of metallic copper. Others are designed to release either progesterone or a synthetic progestogen (for example levonorgestrel) (3,4). IUCDs that release levonorgestrel are somewhat more effective than copper-containing devices, while those that release progesterone are less effective (5).

© 2006 Elsevier B.V. All rights reserved.

Copper-containing IUCDs (6,7) became popular because local inflammatory reactions in the endometrium are more marked and the contraceptive effect is thus more pronounced (SEDA-21, 234) (8). In addition, copper ions released from IUCDs reach concentrations in the luminal fluids of the genital tract that are toxic to spermatozoa and embryos. The ability of copper to induce the generation of free radicals and the formation of malonaldehyde may be involved in its contraceptive effect.

Migration of IUCDs

Migration of IUCDs is relatively rare, although they have been found in the omentum, rectosigmoid, peritoneum, bladder, appendix, small bowel, adnexa, and iliac vein. Most authors have recommended removal of copper-containing devices, because of the potential for inflammatory reactions, which can cause bowel obstruction and perforation (9). Two cases of migration of IUCDs to the bowel have been reported.

- A 29-year-old woman who had had a Copper 7 IUCD inserted 3 years before developed amenorrhea (10). The intrauterine contraceptive was not in the uterine cavity and X-ray showed that it was positioned over the sacrum just to the right of the midline and outside the uterus. It later moved to the cecum and became completely embedded in the muscular layer after penetrating the serosal surface.
- A Copper-T IUCD migrated to the rectal lumen in a 36-year-old woman with menorrhagia for 3 month and a history of Copper-T insertion 6 years before (11).
- A 28-year-old pregnant woman developed an ileal perforation 4 weeks after the insertion of a Multiload-Cu 375 IUCD (12).

The last report documents the shortest interval between insertion and proven bowel injury by an IUCD.

Organs and Systems

Skin

Perimenstrual dermatitis has been attributed to a copper-containing IUCD (13).

- A 41-year-old woman had a 2-year history of a recurrent, self-healing skin rash associated with abdominal pain. She had had cholinergic urticaria since 1995 and had had a copper-containing IUCD inserted 12 years before. The eruption followed a cyclical pattern, invariably appearing 3–7 days before the menses and tending to improve spontaneously with the onset of bleeding. This non-itchy rash was associated with abdominal distension and cramps that followed a similar course. She had multiple non-itchy symmetrical erythematous papules on the upper trunk, neck, and arms. Patch-testing was positive for copper sulfate. The IUCD was removed and the abdominal symptoms subsided at the following cycle. Progressive resolution of the dermatitis was observed. No cutaneous eruption was observed after 8 months and no new lesions developed after a further 5 months.

Reproductive system

Although the effect of a progestogen in an IUCD is primarily local, the amounts released are sufficient to have some systemic effects. In particular, there are partial and variable effects on ovulation, which seem to cause a greater risk of functional ovarian cysts (14,15).

Menstrual disturbances

The authors of a balanced review of hormone-releasing intrauterine systems concluded that while with large-size devices that release high doses (for example 20 micrograms/day) pregnancy rates and the incidence of ectopic pregnancy are extremely low, users are more likely to have amenorrhea and device expulsion (16). Compared with users of a subdermal hormonal implant (Norplant-2), women who used LNG-20 were more likely to have oligomenorrhea but less likely to have prolonged bleeding and spotting.

The fibrinolytic activity of menstrual blood in wearers of Lippes loops exceeds that of patients with menorrhagia, while the values in users of the Cu-T (200) are in the same range as in normally menstruating and untreated women. In users of Lippes loops no fibrin was found in the endometrial stroma. This may explain the increased blood loss associated with the use of the Lippes loop, which can be severe enough to cause anemia (17).

Oligomenorrhea is a common adverse effect of IUCDs; during the first year after insertion; some 16% of users experience 90 days or more of amenorrhea, which is substantially more common than with a bland IUCD.

Early experience in 22 women who used a device releasing both copper and norgestrel ("Gynefix-Norgestrel") suggested that it was well tolerated and that the amount of menstrual bleeding was less than with the conventional copper-only "Gynefix" product (18).

In women who used a variant that released levonorgestrel 20 micrograms/day from a polymer cylinder covered with a membrane that controlled the rate of release, both the volume of menstrual blood loss and the number of bleeding days were reduced, and during the first year of use 20% of women developed amenorrhea (19). There was an initial increase in the mean number of bleeding and spotting days, but in 3–6 months the number of bleeding and spotting days was the same as observed in users of copper IUCDs. The variation between individuals was wide and unpredictable, but the method was claimed to be well accepted by users, with typical annual continuation rates above 80% in various studies. However, premature removal of the system was often required because of unwanted effects; in a nationwide study in Finland, the continuation rates at 1, 2, 3, 4, and 5 years were 93, 87, 81, 75, and 65% respectively (20). The symptoms most strongly associated with premature removal were excessive bleeding and spotting, infections, and pain. The risk of premature removal was markedly lower among women who had occasional or total absence of menstruation. Premature removal was less likely in the oldest age group. British experience showed a clear need to counsel women in advance about the possibility of early disruption of the bleeding pattern, including the chance of oligomenorrhea or amenorrhea, if they are not to become discouraged and abandon the treatment entirely (21).

© 2006 Elsevier B.V. All rights reserved.

The FibroPlant is a levonorgestrel-releasing device derived from the earlier GyneFix principle. Experience with two forms of this frameless "fibrous delivery system," which releases smaller doses (10 or 14 micrograms/day), suggested that it was as effective and well tolerated as other types of device (22). However, the irregular bleeding that can occur with devices of this type can complicate and delay the recognition of endometrial cancer (23).

Ectopic pregnancy

It is not known whether the risk of ectopic pregnancy is increased in women using an IUCD (24,25). The proportion of such pregnancies has been reported as 6–8%, or higher. Primary ovarian pregnancies also develop in IUCD users, suggesting that ovarian implantation is not fully prevented (26).

The proportion of pregnancies that are ectopic is higher with devices that release either levonorgestrel or progesterone than with copper IUCDs, although the rates vary inversely with the hormonal content; at the most common dosages, the ectopic pregnancy rate for progesterone-containing devices (releasing 65 mg/day) was three times that with IUCDs containing levonorgestrel (releasing 20 mg/day).

Use of a variant that released levonorgestrel 20 micrograms/day from a polymer cylinder covered with a membrane that controlled the rate of release resulted in extrauterine pregnancies in one per 5000 users per year (19).

Chronic inflammatory and degenerative changes

There is a positive correlation between high copper loss from an IUCD and the development of menorrhagia or pathological lesions, such as cervical dysplasia and endometrial cytopathology (27). Evidence of endometrial carcinoma was not found in endometrial aspirates from 189 women who had used Copper-T-200 devices for 1–10 years, but five cases of endometrial hyperplasia (2.67%) were encountered in women in the series, all of whom had worn copper devices for 6 years or more. Inflammatory changes in the endometrial cells were found in 12 cases (6.2%), 11 of 12 having worn the device for over 3 years. It is possible that constant exposure to copper may be responsible for persistence of chronic inflammatory changes in endometrial cells, which could be the precursors of hyperplastic changes. It is not clear whether the dissolved copper is also responsible for the temporarily increased predisposition to bacterial contamination and the somewhat increased risk of pelvic inflammatory disease, seen especially in young nulliparous women using this type of contraceptive method.

In endometrial specimens in which copper-containing IUCDs had been embedded there was evidence of severe, degenerative changes in abnormal cells on the surface of the device and also in the endometrium and occasionally also in the muscle layer of the uterus (28,29). These were characterized by pyknosis of the endometrial cells and altered intracellular components. There were relatively few microtubuli in the endometrial cells. Copper ions escaping to the surface of the device may have been responsible for local endometrial damage.

Uterine and extrauterine infections

Progesterone-releasing devices have to be replaced annually, and since there is always a risk of microbacterial contamination of the endometrium on IUCD insertion this brings with it some risk of pelvic inflammatory disease. The risk is less with an IUCD that releases levonorgestrel 20 mg/day, which remains effective for several years. There is even some evidence of an actual protective effect against pelvic inflammatory disease (30); in a comparative study, the 36-month rate of pelvic inflammatory disease was significantly lower for a levonorgestrel device (0.5 per 100 woman-years) than for a copper-releasing IUCD (2.0 per 100). The pregnancy rate in this study was also very significantly lower (0.3 for the progestogen device compared with 3.7 for the copper device), as was the rate of ectopic pregnancies (0.03 compared with 0.25). The rate of expulsion was similar, while the rates of removal because of amenorrhea and the hormonally related adverse effects were significantly higher with the levonorgestrel-releasing device than the copper IUCD.

If copper-containing fragments of IUCDs perforate the uterine wall and enter the peritoneal cavity, acute inflammatory reactions and peritoneal adhesions can occur. Laparoscopic removal is then not only as a rule impossible but may also be dangerous because of the marked peritoneal reaction surrounding the copper part of the device. Laparotomy has therefore been suggested as the primary measure in such cases. Whether copper devices result more commonly in perforation than non-copper devices is not entirely clear, nor is the question answered whether copper increases the risk of extrauterine pregnancies, although older evidence suggested this as a risk (SED-9, 371).

Immunologic

Immunological and hypersensitivity reactions beyond the uterus are uncommon, but they can occur. Rashes, including generalized urticaria and eczematoid eruptions, have occurred as a result of allergy to the copper released from IUCDs, although they are extremely rare (SEDA-11, 204) (SEDA-12, 186) (SEDA-21, 235). One woman who had worn a copper-containing device for 12 months developed widespread urticaria and angioedema of the eyelids and the labia majora and minora for about 6 months (31). She also had persistent symptoms of premenstrual and postmenstrual spotting and leukorrhea for about 6 months. A patch test was positive with 1% copper sulfate, as was an in vitro lymphocyte-stimulating test with copper. An endometrial biopsy showed vulvovaginitis, with hyperplasia of the cervical canal and T cell and eosinophilic granulocyte infiltration. Removal of the device caused complete remission.

The incidence of salpingitis and other pelvic inflammation is believed to be higher in users of IUCDs. A study of cervical smears in women using IUCD contraception compared with others using other methods of contraception showed that the incidence of cervical inflammation was higher in the former (32).

Genital tract actinomycosis has come increasingly to the fore (33,34). In one study in Britain, the pelvic smears of nearly one-third of women using plastic devices were positive for *Actinomyces*-like organisms, compared with

© 2006 Elsevier B.V. All rights reserved.

two of 165 women using copper-loaded IUCDs and none in a series of oral contraceptive users. There was a highly significant correlation between the presence of these organisms on smear and pain or other symptoms of pelvic inflammatory disease.

Current users of IUCDs suffer more often from acute rather than chronic pelvic inflammatory disease (1.51 compared with 0.54 times per 1000 woman-years). In ex-users the situation was reversed, chronic pelvic inflammatory disease being more common (0.95 compared with 0.48 times per 1000 woman-years) (35).

Second-Generation Effects

Fetotoxicity

Although copper-containing IUCDs are very effective, pregnancies do occur and the question of possible second-generation effects has to be considered. In one case the neonate showed significantly increased copper and ceruloplasmin concentrations, whereas maternal concentrations were within the reference range. Whether such exposure to copper can cause harm is not clear; because of the pharmacological effects of copper, it has been suspected of having mutagenic and carcinogenic potential. Until now, there is no clear evidence that harm is actually done. Five published cases scattered throughout the literature in which incomplete closure of the neural tube was found (36) could have been coincidental, bearing in mind the large number of pregnancies in which exposure to copper must occur in this way. In various species of animals which have been studied (rat, rabbit, hamster, sheep) no teratogenicity of intrauterine copper was detected (SED-11, 442).

Drug–Drug Interactions

Immunosuppressants

Two pregnancies (with normal outcomes) have been described in renal transplant patients using an IUCD. It seems that an intact immune system is needed for effective contraception by IUCD, and that immunosuppressive therapy can render an IUCD ineffective. Immunosuppressed patients should be advised to use another means of contraception (37).

Physical contraceptives—spermicides

General Information

Modern spermicides are produced in a variety of formulations, including gels, foams, creams, suppositories, pessaries, capsules, foaming tablets, and melting films. Spermicides are also used in conjunction with other methods, such as diaphragms, condoms, and sponges, but also with intrauterine contraceptive devices and methods based on fertility awareness (1).

Contraceptive sponges are controversial: do they act by delivering spermicides or as barriers? However, it has been shown conclusively that the newest forms of sponges, which provide not one but a combination of three active spermicides, act much more like spermicides than as simple vaginal barriers.

Spermicides are relatively inexpensive and widely available over the counter in most countries. All currently used formulations contain the non-ionic detergent nonoxinol-9, usually in a dose of 70–230 mg, but the newest formulations may contain octoxynol or benzalkonium chloride (2). All chemical agents used in spermicides disrupt the sperm cell membrane and finally rupture the cell.

Spermicides, especially in certain communities, have important advantages over the more modern methods of contraception: they are immediately reversible, are available over the counter without prescription, can be used by breastfeeding women, and are under direct female control.

However, spermicides also have adverse effects. They can cause local irritation in the woman or her partner, especially if they are used several times a day and can very rarely cause local allergic reactions in the woman or her partner.

Nonoxinols

Nonoxinols (ethoxylated alkyl phenols) are synthesized from alkylbenzene nonoxinol by reacting it with ethylene oxide to produce ethylene oxide polymers of various lengths. Each nonoxinol is followed by a number that indicates the approximate number of ethylene oxide groups it contains. In cosmetic products, nonoxinols are used as emulsifying, wetting, foaming, and solubilizing agents. They are used in hair and skin products, and in bath, shaving, and fragrance formulations (3). The non-ionic surfactant properties of nonoxinols allow them to be used in a wide variety of industrial, household, agricultural, and pharmaceutical products. Nonoxinol-9 and -10 are surface-active agents used in antiseptic formulations, such as Hibitane (chlorhexidine), Betadine (povidone-iodine), and Hexomedine (hexamidine). They are the most commonly used spermicidal contraceptives and have been recommended in the prevention of sexually transmitted diseases and in human immunodeficiency virus prophylaxis (4).

Carbomers

Carbomers are acrylic acid polymers that are used for a variety of purposes. They are used in pharmaceutical processes as suspending agents, gel bases, emulsifiers, and binding agents. They are also used as artificial tears. Carbomer 974P is a carbomer that is the major non-aqueous component (5% polymer, 94% water) of a proprietary formulation called BufferGel, which also contains dibasic potassium phosphate, magnesium sulfate, dibasic sodium phosphate, sorbic acid, monobasic sodium phosphate, and disodium EDTA. It is a buffering agent, a microbicide, and a spermicide. It is formulated in an aqueous gel at pH 3.9, which acidifies twice its volume of semen to a pH of 5 and maintains the protective acidity of the vagina. It is used vaginally as a spermicide that also protects against HIV infection and possibly other sexually transmitted diseases.

The safety of BufferGel has been evaluated in a high-dose tolerance trial in 98 women, of whom 91 (26 sexually abstinent and 65 sexually active) completed the study (5). Reasons for withdrawal included: an inability to adhere to the protocol ($n = 1$); breakthrough menstrual bleeding ($n = 2$); the presence of yeast on day 7 (two

© 2006 Elsevier B.V. All rights reserved.

asymptomatic cases and one symptomatic case); and refusal to continue ($n = 1$). The percentage of women with at least one sign or symptom judged by a clinician as potentially related to the product was 29% in India, 33% in Thailand, 35% in Malawi, and 33% in Zimbabwe. There were no differences in the proportions of sexually abstinent and sexually active women with at least one potentially product-related sign or symptom at each study site. In all, there were 45 potentially product-related signs and symptoms. Two were judged to be definitely related to the product (vaginal itching after product insertion) and 43 as possibly or probably related. All were categorized as mild (84%) or moderate (16%). Excluding participants who withdrew by day 7, 71% of the signs and symptoms resolved during the trial and 24% within 3 days of product withdrawal at the end of the trial; 5% persisted at the end of the trial (one woman was given treatment for a yeast infection and one was not re-evaluated for itching). Minor self-reported symptoms of irritation of limited duration accounted for 64% of reported signs and symptoms and were approximately equally distributed across study sites. They included vulvar and vaginal itching or burning, burning when urinating, and genital rash. The overall rate of symptoms of irritation for all sites combined was 0.58 events per woman-week of observation (95% CI = 0.3, 0.88). Other signs and symptoms included lower abdominal pain or backache, symptomatic yeast infection, and vaginal discharge.

Organs and Systems

Urinary tract

Urinary tract infections are quite common, although not very serious adverse effects of spermicides. For several years, the rate of urinary tract infections in young, sexually active women caused by the use of spermicides has been uncertain and has not been thoroughly evaluated. Since this phenomenon was observed, special surveys have been carried out and several have confirmed a higher risk of urinary tract infection among women who use a diaphragm with spermicides, compared with sexually active women who use other types of contraception (6). Finally, women who use spermicides are at higher risk of urinary tract infection than women who use other methods of contraception. Users of diaphragms and other barrier methods (including spermicide-coated male condoms) in conjunction with spermicides have increased degrees of introital and periurethral colonization with coliform organisms and *Staphylococcus saprophyticus*, leading to urinary tract infection (7).

In a large case control study in the USA, 96 sexually active young women with acute urinary tract infections caused by *S. saprophyticus* and 629 control patients without urinary tract infections were interviewed (7). Exposure to spermicide-coated condoms during the previous month was associated with a higher risk of urinary tract infections. Younger age, intercourse frequency, prior urinary tract infections and frequency of exposure to spermicide-coated condoms were independent predictors. Among women exposed to spermicide-coated condoms, 74% of urinary tract infections caused by *S. saprophyticus* were attributable to this exposure. The authors concluded that spermicide-coated condoms were associated with an increased risk of urinary tract infections caused by *S. saprophyticus*.

Skin

Contact dermatitis in patients exposed to nonoxinols was initially considered to result from irritation, but allergic reactions have also been reported (8). Nonoxinol contact allergy has been described in two patients who developed contact photosensitivity to nonoxinol-l0 in the antiseptic product Hexomedine transcutanée (hexamidine) (9). Among 32 control subjects, 13 had positive photopatch tests to Hexomedine transcutanée and four had positive photopatch tests to nonoxinol-10. Surprisingly, the authors observed that only undiluted nonoxinol was phototoxic, and in another study, nonoxinol-9 was found to be rarely sensitizing and compatible with latex and silicone lubricants used in condoms (10).

Second-Generation Effects

Teratogenicity

Use of spermicides in the year before pregnancy or during pregnancy has been associated with adverse reproductive outcomes, including spontaneous abortion and Down syndrome. In a preliminary analysis, an association was found between spermicide use at conception and tetraploid and hypertriploid conceptions (11). An association between the use of vaginal spermicides and birth defects has been suggested (12).

Spermicide use for more than a year at any time before conception was more common in cases aborting a trisomic conception than in controls. The association varied with maternal age, and was confined to women aged 30 years or older (13). However, it has since been concluded that there is no convincing evidence of an increased risk of fetal abnormalities in women who become pregnant while using spermicides, or in women who have used them before realizing that they were pregnant (14).

Phytolaccaceae

See also Herbal medicines

General Information

The genera in the family of Phytolaccaceae (Table 1) include pokeweed.

Phytolacca americana

Phytolacca americana (pokeweed) contains powerful mitogens (pokeweed mitogen), including phytolacain, used to study cell function.

Adverse effects

Severe emesis and diarrhea, accompanied by tachycardia, have been observed after ingestion of raw leaves and after drinking tea prepared from the powdered root of *P. americana* (pokeweed).

Table 1 The genera of Phytolaccaceae

Agdestis (agdestis)
Gisekia (gisekia)
Petiveria (petiveria)
Phytolacca (pokeweed)
Rivina (rivina)
Stegnosperma (stegnosperma)
Trichostigma (alpine clubrush)

In one case Mobitz type I heart block was associated with vomiting due to pokeweed, which resolved after intravenous promethazine (1). The authors suggested that the heart block had been due to increased vagal tone associated with severe gastrointestinal colic.

Reference

1. Hamilton RJ, Shih RD, Hoffman RS. Mobitz type I heart block after pokeweed ingestion. Vet Hum Toxicol 1995; 37(1):66–7.

Picenadol

General Information

Picenadol is a racemic mixture of an *N*-methyl-4-phenylpiperidine derivative. It has mixed agonist–antagonist properties, because the dextrorotatory isomer is a potent opioid agonist and the levorotatory isomer is an opioid antagonist. Picenadol also has anticholinergic activity. Its adverse effects include drowsiness, dizziness, and lightheadedness (SEDA-16, 90). In a double-blind comparison of the analgesic potency and adverse effects profiles of a single oral dose of picenadol 25 mg with codeine 60 mg and placebo, few adverse effects were reported. Drowsiness was the most frequent, with an incidence of 16% (1).

Picenadol 75 mg was reportedly distinguishable from morphine by sedation, dysphoria, and hallucinatory activity, probably due to anticholinergic activity; at lower doses it was morphine-like (SEDA-16, 90).

1. Brunelle RL, George RE, Sunshine A, Hammonds WD. Analgesic effect of picenadol, codeine, and placebo in patients with postoperative pain. Clin Pharmacol Ther 1988;43(6):663–7.

Picibanil

General Information

Picibanil (OK 432) is derived from *Streptococcus pyogenes* and has been used in the treatment of cancers, lymphangiomas, and viral infections. Low-grade fever, nausea and vomiting, and an inflammatory reaction at the injection site were commonly reported, whereas joint pain and mild liver dysfunction were seldom described.

© 2006 Elsevier B.V. All rights reserved.

Organs and Systems

Fluid balance

Hyponatremia due to the syndrome of inappropriate secretion of antidiuretic hormone (SIADH) has been attributed to picibanil (1).

- A 59-year-old woman with a previous history of squamous cell carcinoma of the esophagus developed a metastatic lung tumor 4 years later. A right lower lobectomy was performed, and intrapleural picibanil was instilled on postoperative days 4, 5, and 9 for pulmonary fistula with prolonged air leakage. On day 13 she had fatigue, nausea, and drowsiness. Her serum sodium concentration was 106 mmol/l and there was a 2.5-fold increase in serum antidiuretic hormone concentration. She recovered completely after fluid restriction and sodium supplementation.

The author thought that SIADH had resulted from severe pleurisy secondary to intrapleural administration of picibanil rather than to direct stimulation of antidiuretic hormone release.

Hematologic

Hemolytic anemia, presumably of immune origin, has been reported in a patient taking picibanil (2).

Picrotoxin

General Information

Picrotoxin is a non-nitrogenous plant derivative that is a powerful stimulant of all parts of the central nervous system, acting on the chloride ionophore–aminobutyric acid complex in a manner opposite to that of barbiturates (1). Its adverse effects resemble those of nikethamide; picrotoxin 20mg can cause severe poisoning.

1 Obata K. The inhibitory action of aminobutyric acid, a probable synaptic transmitter. Int Rev Neurobiol 1972; 15:167–87.

Piketoprofen

See also Non-steroidal anti-inflammatory drugs

General Information

Piketoprofen is an NSAID that has been used topically as the hydrochloride salt.

Organs and Systems

Skin

A photoallergic contact dermatitis followed topical administration of piketoprofen in a 46-year-old man after 3 days; photopatch testing for piketoprofen was positive (1).

Reference

1. Bujan JJ, Morante JM, Guemes MG, Del Pozo Losada J, Capdevila EF. Photoallergic contact dermatitis from piketoprofen. Contact Dermatitis 2000;43(5):315.

Pilocarpine

General Information

Pilocarpine is an antagonist at acetylcholine receptors (1). While it is mainly used in the eye in the treatment of glaucoma, pilocarpine is still occasionally used for other purposes, for example for treating salivary gland hypofunction and xerostomia. When used in this way, cardiovascular tolerance was good but there was a high incidence of sweating, flushing, increased frequency of micturition, increased nasal secretion, and lacrimation (SEDA-18, 174).

Pimecrolimus

General Information

Pimecrolimus is a non-steroidal ascomycin derivative with topical anti-inflammatory activity. In a 1% cream it is effective and safe in atopic dermatitis in infants, children, and adults (1–3), although its efficacy has been questioned (4).

© 2006 Elsevier B.V. All rights reserved.

Organs and Systems

Skin

The main adverse effect of pimecrolimus is local skin irritation, with a stinging or burning sensation, which occurs in 30% of patients. Typically, children have less skin irritation than adults. Adverse effects such as local immunosuppression and an increased risk of local bacterial and viral infections (notably eczema herpeticum) are less common than with topical glucocorticoids (5). In addition, there is a lack of skin atrophy (6,7). However, topical corticosteroids have the advantage of better skin penetration than pimecrolimus and will therefore continue to be used for more heavily keratinized skin such as in psoriasis (8).

Tinea incognito has been attributed to pimecrolimus (9).

- A 6-year-old boy developed a small, erythematous, slightly scaly, pruritic plaque near his right eye, which was treated with twice-daily pimecrolimus cream. After 2–3 days, the itching and erythema completely resolved, but a rough scaly plaque persisted. After 1–2 weeks, the itching gradually returned and the lesion began to increase in size. Multiple similar lesions appeared several centimeters from the initially affected area. Pimecrolimus was withdrawn and topical nystatin + triamcinolone ointment was prescribed. The eruption continued to spread, with multiple annular scaly papules and plaques with central clearing. There was excoriation and mild inflammation around all affected areas. A potassium hydroxide examination of the lesions showed numerous hyphae. The nystatin + triamcinolone was withdrawn and oral griseofulvin was prescribed. The eruption improved dramatically after 3 weeks and eventually cleared completely after 5 weeks of treatment. Topical 2% ketoconazole cream was applied twice a day during the final 2 weeks of treatment.

Pimobendan

See also Phosphodiesterase type III, selective inhibitors of

General Information

Pimobendan is an inhibitor of phosphodiesterase type III with calcium sensitizing properties in the myocardium. It has been associated with a worrisome albeit non-significant increase in mortality in patients with chronic congestive heart failure (1).

Reference

Pimozide

See also Neuroleptic drugs

General Information

Pimozide is a diphenylbutylpiperidine neuroleptic drug, structurally similar to the butyrophenones.

Organs and Systems

Cardiovascular

Pimozide can cause QT interval prolongation and torsade de pointes; a total of 40 reports (16 deaths) of serious cardiac reactions, mainly dysrhythmias, were reported to the Committee on Safety of Medicines in the UK from 1971 to 1995 (1).

Drug Administration

Drug overdose

In a study of overdosages of different neuroleptic drugs, pimozide had the lowest fatality index (the number of deaths divided by the number of prescriptions) (2).

© 2006 Elsevier B.V. All rights reserved.

Drug–Drug Interactions

Clarithromycin

In 12 healthy volunteers given oral pimozide 6 mg after 5 days of treatment with clarithromycin (500 mg bd) or placebo, pimozide significantly prolonged the QT_c interval in the first 20 hours in both groups (maximum changes in QT_c 16 and 13 ms respectively) (3).

Pipebuzone

See also Non-steroidal anti-inflammatory drugs

General Information

Pipebuzone is a combination of phenylbutazone with piperazine, produced in an unsuccessful attempt to improve the tolerance of phenylbutazone. Typical phenylbutazone reactions (abdominal, hematological, renal, allergic, and rectal irritation from suppositories) were common (SED-9, 145) (1–3).

Pipecuronium bromide

See also Neuromuscular blocking drugs

General Information

Pipecuronium bromide is a bisquaternary steroid analogue of pancuronium. In vitro pipecuronium reversibly inhibits both human red cell acetylcholinesterase and human plasma cholinesterase to an extent that might have clinical implications (1). Its potency is similar to that of pancuronium and its onset and duration are also approximately the same. Accumulation can occur (2), and maintenance doses should be one-quarter to one-sixth of the initial dose to achieve a similar effect, depending on the anesthetic technique used.

From animal investigations hepatic uptake appears to be a factor in the drug's total plasma clearance, but renal excretion seems to be the main route of elimination. Ligation of renal pedicles in dogs (3) resulted in reduced elimination of pipecuronium, with a four-fold increase in mean residence time and a four-fold increase in hepatobiliary elimination, which did not compensate for the loss of urinary excretion. In humans, about 40% of

© 2006 Elsevier B.V. All rights reserved.

pipecuronium is excreted unchanged in the urine together with another 15% as 3-hydroxypipecuronium in 24 hours (4). The half-life is around 135–160 minutes.

Organs and Systems

Cardiovascular

No histamine release has been reported with pipecuronium, and vagolytic or sympathomimetic effects are not seen in the usual dose range. Rarely, significant hypotension has been reported (2), but this was transient and occurred during an unstable phase of anesthesia. Bradycardia has also been seen (2) but is usually mild (5), and probably due to the vagotonic effects of co-administered drugs, as is seen with vecuronium and atracurium (that is a minor disadvantage of the relaxant's lack of vagolytic or sympathomimetic effects). Usually, no significant changes in heart rate or blood pressure are seen (6–8), even with doses up to three times the ED_{95} (9,10). Cardiovascular stability has also been reported in cardiac patients (11), including patients in ASA classes II and III about to undergo coronary artery bypass grafting who received doses up to 0.15 mg/kg (12) and those who received high-dose fentanyl anesthesia (13). The absence of tachycardia in these high-risk cardiac patients, in whom any increase in myocardial oxygen demand is unwanted, was considered an advantage of pipecuronium.

Susceptibility Factors

Renal disease

As expected, renal dysfunction is associated with an increase in volume of distribution, a decrease in plasma clearance (1.6 versus 2.4 ml/kg/minute), and an increase in half-life (263 versus 137 minutes) compared with patients with normal renal function (14). In the latter study there was no statistically significant prolongation of the mean duration of action of pipecuronium, but there was a much greater variation in those with renal insufficiency, with 25% recovery times (after 0.07 mg/kg) of 30–267 minutes (controls 55–198 minutes). These patients were also undergoing renal transplantation and most of the replacement kidneys would be expected to have some function and some glomerular excretion of pipecuronium. Prolongation of pipecuronium blockade should be expected in patients with renal insufficiency.

Drug–Drug Interactions

Barbiturates

Thiobutobarbital prolongs the duration of action of pipecuronium in dogs (15), but no interaction with barbiturates has been reported in man.

General anesthetics

In patients who have been exposed to volatile anesthetic agents for 30 minutes or so there is an increase in potency of pipecuronium to such an extent that doses can be reduced by about one-third with isoflurane (16) or enflurane (10) compared with those required for balanced anesthesia. Halothane appears to be associated with relatively minor changes in potency (16). When the same doses of pipecuronium are given, the duration of blockade is significantly longer during isoflurane anesthesia than during neuroleptanesthesia (17); halothane is also associated with a prolonged action but to a lesser extent.

Piperaceae

See also Herbal medicines

General Information

The family of Piperaceae contains three genera:

1. *Lepianthes* (lepianthes)
2. *Peperomia* (peperomia)
3. *Piper* (pepper).

Piper methysticum

The rhizome of *Piper methysticum* (kava kava) has been used for hundreds of years in the South Pacific islands as a recreational drug, the main constituents of which are non-alkaloidal pyrone derivatives. These compounds cause sedation and centrally induced muscle relaxation. Kava has also been marketed in the West as a herbal pharmaceutical for use in the treatment of anxiety, for which it seems to be effective (1). However, the formulation used indigenously is an aqueous extract, while the pharmaceutical formulation is prepared from a lipid extract. Thus, the formulation that has been used in the West may contain compounds that are not present in the drink that is commonly prepared in the South Pacific and may therefore have different adverse effects (2). This may explain the risk of liver damage that has been seen in the West, not having previously been reported.

Kava contains the pyridine alkaloid pipermethystine, the chalcone flavokavain, the norsesquiterpenoid dihydrokavain, and the pyran tetrahydroyangonin.

Adverse effects

The acute and chronic effects of kava were first described by the 19th-century German toxicologist Louis Lewin (3) in his book *Phantastica* (1924).

> A carefully prepared kava beverage taken in small quantity occasioned only slight and agreeable modifications of sensibility. In this form it is a stimulating beverage after the imbibition whereof hardships can be endured more easily. It refreshes the fatigued body and brightens and sharpens the intellectual faculties. Appetite is augmented, especially if it is taken half an hour before meals . . . After doses that are not too strong a state of happy carelessness, content, and well-being appears without any physical or mental excitation. It is a real euphoric state which is accompanied by an increased muscular efficiency. At the beginning speech is fluent and lively and the hearing becomes more sensible to subtle impressions. Kava has a soothing effect. Those who drink it are never choleric, angry, aggressive and noisy, as in the case of alcohol. Both natives and whites look upon it as a sedative in case of accidents. Reason and consciousness remain unaffected. After the consumption of greater quantities, however, the limbs become weary, the muscles seem out of control of the will, the gait is slow and unsteady, and the subject appears half drunk. An urgent desire to lie down manifests itself. The eye sees objects before it but is unable to identify them with exactness. In the same way the ears hear everything, but the individual is unable to account for what he hears. Everything becomes more and more diffuse. The drinker succumbs to fatigue, and experiences a desire to sleep which is stronger than all other impressions. He becomes somnolent and finally falls asleep. Many Europeans have themselves experienced this action of kava which paralyses the senses like magic and finally leads to deep sleep. Frequently a state of somnolent torpor accompanied by incoherent dreams and occasionally erotic visions remains without sleep supervening.
>
> The sleep is similar to that produced by alcohol, out of which the individual can be awakened only with difficulty. If moderate quantities have been consumed it occurs twenty to thirty minutes later, and lasts from two to eight hours according to the degree of habituation of the subject. If the beverage is concentrated, that is contains a large amount of the resinous components of kava, intoxication comes on much more rapidly. The drinkers are found lying in the very places where they have been drinking. Occasionally a short state of nervous trembling occurs before they fall asleep. No excitation precedes these symptoms.
>
> The kava drinker is incessantly tormented with the craving for his favourite beverage, which he cannot prepare for himself. It is a repugnant spectacle to see old and white-haired people, degenerate through prolonged abuse of the drug, going from house to house in order to beg for freshly prepared kava and often meeting with a refusal. Mental weakness has also been stated to follow from kavaism. It is said that old kava habitues have red, inflamed, bloodshot eyes, dull, bleary, and diminished in their functions. They become extremely emaciated, their hands tremble, and finally they cannot bring the drinking vessel to their mouths. Numerous cutaneous diseases of the natives of the South Seas, especially a kind of scaly eruption which results in a parchment-like state of the skin, have been attributed to the abuse of kava.

Nervous system

In a pilot study, 24 patients with stress-induced insomnia were treated for 6 weeks with kava 120 mg/day, followed by a 2-week washout period and then treatment with valerian 600 mg/day for another 6 weeks (4). Stress was measured in three areas, including social, personal, and life events, and insomnia was assessed by evaluating the time taken to fall

© 2006 Elsevier B.V. All rights reserved.

asleep, the number of hours slept, and waking mood. Total stress severity and insomnia were significantly improved by both compounds, with no significant differences. The most commonly reported adverse events were vivid dreams with valerian (16%) and dizziness with kava (12%).

In 24 patients treated with kava for generalized anxiety disorder for 4 weeks in an open, crossover, randomized trial, two dosage schedules were compared: 120 mg od and 45 mg tds (5). There were significant reductions in mean Hamilton Anxiety Rating Scale scores, irrespective of dose schedule, treatment order, or sex. The impact of adverse effects was relatively low, and only one patient had to withdraw from the study (tds schedule) because of nausea. There was daytime drowsiness in 33% of patients taking the thrice-daily regimen compared with 9% in those taking a once-daily dose.

Parkinsonism has been attributed to kava (6).

- A 45-year-old woman with a family history of essential tremor developed severe and persistent parkinsonism after taking kava extract for anxiety for 10 days. Her symptoms improved with anticholinergic drugs.

The authors concluded that kava derivatives can produce severe parkinsonism in individuals with a genetic susceptibility.

Liver

There have been reports of liver damage with lipid kava extracts (1), and it has therefore been banned in several countries.

- A 39-year-old woman had been treated for toxic hepatitis of unknown cause (7). When she represented with hepatitis-like symptoms and high liver enzymes, toxic hepatitis was diagnosed. Other causes for the liver pathology were excluded and it was noted that before both exacerbations, she had self-prescribed kava. When the kava was withdrawn, the liver pathology normalized and she made an uneventful recovery.
- A 60-year-old patient, who had taken no medications other than kava extract, developed liver and kidney failure and progressive encephalopathy (8). Viral, metabolic, and autoimmune causes were excluded. Liver biopsy was consistent with toxic liver damage. The patient eventually received an orthotopic liver transplant and made a good recovery.
- A 50-year-old man developed jaundice. He had noticed fatigue for a month, a "tanned" skin, and dark urine (9). The medical history was unremarkable, apart from slight anxiety, for which he had been taking three or four capsules of kava extract daily for 2 months. He took no other drugs and did not consume alcohol. Liver function tests showed very large increases in transaminases. He subsequently developed stage IV encephalopathy but made a good recovery after liver transplantation.
- A 34-year-old woman developed toxic hepatitis after taking kava-kava (10). Ultrasound showed an enlarged echogenic liver, and histology showed centrilobular necrosis and periportal inflammation. After withdrawal of the kava the changes resolved completely. This case illustrates the high hepatotoxic potential of kava-kava.
- A 33-year-old woman took a kava extract equivalent to 210 mg of kavalactones daily for 3 weeks (11). She developed malaise, loss of appetite, and jaundice. Her liver enzymes were raised 3-fold to 60-fold. Viral hepatitis was excluded and liver biopsy confirmed toxic hepatitis. Kava was withdrawn, and within 8 weeks the liver enzymes returned to normal. A lymphocyte transformation test showed strong concentration-dependent T cell reactivity to kava. Phenotyping of CYP2D6 activity showed that she was a poor metabolizer.

The authors of the last report concluded that the liver damage in this case was due to an immune-mediated reaction, possibly mediated by a reactive metabolite of kava, even though she was a poor metabolizer.

Kava has been associated with toxic liver damage in six cases reported from Switzerland (12). In one patient, the liver damage was so extensive that liver transplantation became necessary. Histological data from four patients were consistent with an allergic mechanism. In several cases, other medications with hepatotoxic potential had been taken concurrently. Symptoms generally occurred at between 3 weeks and 4 months and involved daily doses that contained kavapyrones 60–210 mg. Most instances involved acetone extracts. The leading kava extract, Laitan, was subsequently withdrawn from the Swiss market.

Australia's Therapeutic Goods Administration initiated a voluntary recall of all complementary medicines containing kava after the death of a woman who used a medicine containing kava (13). Sponsors and retailers were asked to remove all products containing kava from the market immediately. Consumers were advised to discard kava-containing products in their possession.

The Federal Institute of Germany has withdrawn all products that contain kava and kavaine from the German market because of the risk of hepatotoxicity and insufficiently proven efficacy. The regulation included homeopathic products with dilutions up to D4. The German regulation applies to all kava-containing pharmaceutical formulations. Moreover, following a provisional opinion from the UK Committee on Safety of Medicines (CSM), the Medicines and Healthcare products Regulatory Agency (MHRA) has consulted on a proposal to prohibit the sale, supply, or importation of unlicensed medicinal products containing kava in the UK. The CSM reviewed the issue of kava-associated liver toxicity following the emergence of safety concerns in Europe. At that time, stocks of kava were voluntarily withdrawn by the herbal sector while the safety concerns were under investigation. Currently the MHRA is aware of 68 cases worldwide of suspected kava-associated liver problems, including 6 cases of liver failure that resulted in transplant, and 3 deaths. In the UK there have been three reports of kava-associated liver toxicity. The CSM has advised consumers to stop taking medicinal products containing kava, and to seek medical advice if they feel unwell or have concerns about possible liver problems.

Finally, the FDA has advised consumers of the potential for liver injury by kava-containing dietary supplements. People who have liver disease or liver problems or who are taking medicines that can affect the liver have been advised to consult a physician before using kava-containing supplements (14). Consumers who use kava-containing dietary supplements and who have signs of illness associated with liver disease should also consult

© 2006 Elsevier B.V. All rights reserved.

a physician. The FDA has issued a letter to healthcare professionals informing them of the consumer advice and has urged consumers and healthcare professionals to report injuries that may be related to the use of kava.

The incidence of liver damage with kava seems to be less than one case per million daily doses (15). The mechanism of the effect is currently unclear. It has been suggested that supervised, monitored, short-term medication with kava would still do more good than harm (16). However, the FDA will continue to investigate the relation, if any, between the use of dietary supplements containing kava and liver damage.

Skin

Allergic skin reactions (17) and other adverse effects, including dermatological problems and neurological symptoms, have been described in individuals using such formulations. Heavy chronic consumption of kava-kava can lead to a pellagroid dermopathy that appears to be unrelated to niacin deficiency (18).

- A 36-year-old woman developed a generalized rash, severe itching with erythema, and papules 4 days after discontinuing a kava formulation (Antares), which she had taken in a dosage of 120 mg/day for 3 weeks (19). The condition improved with glucocorticoids and antihistamines, but the itching lasted several weeks. Patch tests with the kava extract were positive.

Musculoskeletal

Rhabdomyolysis has been attributed to kava (20).

- A 29-year-old man developed severe diffuse muscle pain and passed dark urine a few hours after taking a herbal combination product containing guaraná 500 mg, Ginkgo biloba 200 mg, and kava 100 mg. His blood creatine kinase activity and myoglobin concentration were raised and there were no signs of an underlying metabolic myopathy. His condition improved within 6 weeks.

The authors suggested that the methylxanthine-like effects of guaraná and the antidopaminergic and neuromuscular blocking properties of kava had caused the rhabdomyolysis in this patient.

Drug overdose

- A 34-year-old Tongan man complained of sore eyes, headache, generalized muscle weakness, and abdominal pain (21). He was disoriented and hallucinating. His family reported that he had been drinking large quantities of kava daily for about 14 years. Chronic kava intoxication was treated with intravenous Plasmalyte (a crystalloid solution) and he recovered within a day.

Piperaquine

General Information

Piperaquine is a synthetic 4-aminoquinoline with high blood schizonticidal activity, similar to that of chloroquine (SEDA-13, 810). There is some evidence that piperaquine is active against chloroquine-resistant *Plasmodium falciparum*, but laboratory studies suggest a degree of cross-resistance. Piperaquine 600 mg/month

© 2006 Elsevier B.V. All rights reserved.

was well tolerated. Its reported adverse effects included headache, dizziness, vomiting, and diarrhea.

Organs and Systems

Gastrointestinal

The novel combination (Artekin™) of dihydroartemisinin and piperaquine has been assessed in 106 patients (76 children and 30 adults) with uncomplicated *P. falciparum* malaria in Cambodia (1). The respective doses of dihydroartemisinin and piperaquine, which were given at 0, 8, 24, and 32 hours, were 9.1 and 74 mg/kg in children and 6.6 and 53 mg/kg in adults. All the patients became aparasitemic within 72 hours. Excluding the results in one child who died on day 4, there was a 97% 28-day cure rate (99% in children and 92% in adults). Patients who had recrudescent infections used low doses of Artekin. Adverse effects, most commonly gastrointestinal complaints, were reported by 22 patients (21%) but did not necessitate premature withdrawal.

Piperazine

General Information

Piperazine is an antihelminthic drug that selectively blocks the neuromuscular cholinergic receptors of worms. It is readily absorbed, but has a highly variable half-life. The adult oral dose of 4 g of piperazine hydrate has been used extensively in the treatment of ascariasis. A very old drug, it is still considered sufficiently safe for use, although in most developed countries it has been abandoned, primarily because of concerns about possible carcinogenicity and electroencephalographic changes (SEDA-12, 267).

General adverse effects

In most patients, piperazine is free of adverse reactions. Mild gastrointestinal disturbances may occur; neurotoxicity is rare. Eczematous skin reactions, lacrimation, rhinorrhea, joint pains, productive cough, and bronchospasm can develop after sensitization, especially with occupational exposure. Urticaria has also been reported. When hypersensitivity reactions occur it should be withdrawn and not used again in the same patient. Mononitrosylation of piperazine can occur in the stomach, releasing the potential carcinogen *N*-mononitrosopiperazine, but there is no direct proof of risk in human subjects.

Organs and Systems

Cardiovascular

Cardiac conduction defects have been described in patients taking piperazine (1).

Respiratory

Allergic respiratory reactions can occur in patients taking piperazine, resulting in cough and bronchospasm (2).

Nervous system

Headache, dizziness, and somnolence occur in a small proportion of individuals who take piperazine (3). More serious neurological reactions occur rarely, but tend to be reported in young children, in people with neurological or renal disease, or after overdosage. Symptoms in such cases include ataxia, paresthesia, undue clumsiness, myoclonus, and nystagmus. Choreiform movements and an electroencephalogram with prominent slow waves have been reported as well as an exacerbation of petit mal (4) and absence seizures (5). In a child, horizontal nystagmus and hypotonia have been reported after a normal dose (6).

- A previously well 23-month-old girl was given piperazine 65 mg/kg/day for 7 days for a suspected worm infestation and developed cerebellar ataxia after 8 days (7). Over the next 48 hours her symptoms gradually settled. She made a complete recovery 5 days later.

Sensory systems

Piperazine can cause a range of visual effects, including dry eyes, bulging eyes, difficulty in focusing, and double vision (8).

Reports of cataract after piperazine have not been authenticated (9).

Hematologic

One suspected case of hemolysis after piperazine treatment was published but it appeared as long ago as 1971 and the patient had G6PD deficiency (10).

A case of temporary thrombocytopenia has been described (11), probably due to prior sensitization by ethylenediamide (a stabilizer in some creams), with which piperazine cross-reacts.

Gastrointestinal

Nausea, vomiting, abdominal pain, and diarrhea can occur occasionally with piperazine (12).

Liver

A single incident resembling viral hepatitis after piperazine and recurring after further dosage has been reported (13).

Skin

Erythema and rarely allergic reactions can occur in patients taking piperazine (12).

© 2006 Elsevier B.V. All rights reserved.

Second-Generation Effects

Teratogenicity

There is no evidence that piperazine has any second-generation effects; it has been used extensively in pregnancy without untoward incidents, but as a precaution WHO advises against administration in the first trimester.

Drug–Drug Interactions

Chlorpromazine

High doses of piperazine can enhance the adverse effects of chlorpromazine and other phenothiazines (14,15).

Pyrantel

Piperazine can antagonize the antihelminthic efficacy of pyrantel and vice versa (16).

Piperidolate

General Information

Piperidolate is an anticholinergic drug that has been used to treat premature labor and digestive disorders (1). Doses of 50 mg are usual for treating pyloric spasm. The effects and adverse effects at this dose are both small.

Reference

1. Plancherel P. Klinischer Vergleich zwischen Dactil und Dactilase bei Verdauungsstorungen. [Clinical comparison of Dactil and Dactilase in digestive disorders.] Praxis 1969; 58(40):1275–8.

Piracetam

General Information

Piracetam is a so-called "nootropic" drug, one of a class of drugs that affect mental function (1). In healthy volunteers it improves the higher functions of the brain involved in cognitive processes, such as learning and memory. Its mechanisms of action are not known but may include increased cholinergic neurotransmission.

A meta-analysis of 19 double-blind, placebo-controlled trials in elderly patients with dementia or cognitive impairment showed significant improvement with piracetam (2).

Piracetam has also been used to treat fetal distress during labor, but there is insufficient evidence to assess its efficacy (3).

Organs and Systems

Nervous system

Piracetam 80–100 mg/day for 4 months has been evaluated in a randomized, double-blind, placebo-controlled, crossover study in 25 children with Down syndrome (4). Piracetam did not enhance cognition or behavior but was associated with adverse events: 18 children completed the study, 4 withdrew, and 3 were excluded at baseline. The adverse events were related to the nervous system and included aggression ($n = 4$), agitation/irritability ($n = 2$), sexual arousal ($n = 2$), poor sleep ($n = 1$), and reduced appetite ($n = 1$).

Pirazolac

See also Non-steroidal anti-inflammatory drugs

General Information

Pirazolac, a pyrazoloacetic acid derivative, caused heartburn, upper abdominal pain, cutaneous adverse effects (rashes, exacerbation of pre-existing eczema), and eosinophilia in early clinical studies (1). In two comparative studies it was withdrawn in 15–20% of patients, that is more often than the comparator NSAIDs (indometacin, sulindac) (SEDA-16, 111).

Pirenzepine

General Information

Pirenzepine is an anticholinergic drug with selective effects on muscarinic M_1 receptors. It therefore inhibits gastric acid secretion in the stomach. When it was introduced it was claimed that in the doses necessary to affect gastric acid secretion it would be almost entirely free of other muscarinic (atropine-like) effects. However, although muscarinic adverse effects, such as dry mouth and difficulty in accommodation, are less common with pirenzepine than with atropine, they can still occur in about half the patients who take the drug (1). Cardiac conduction effects resulting in sinus tachycardia, atrial fibrillation, and nodal tachycardia can also occur.

Granulocytopenia and thrombocytopenia are on record (SED-12, 944) (2).

Piretanide

See also Diuretics

General Information

Piretanide is a close relative of furosemide, with diuretic and kinetic properties very similar to those of furosemide and bumetanide (1,2). Its potency lies somewhere between the two. As with some other diuretics, attempts have been made to show specific advantages for piretanide, for example that it is a "potassium-stable" diuretic. However, there is no good evidence that it has such advantages (SEDA-10, 188) (SEDA-15, 213).

Piribedil

General Information

Piribedil is a piperazine derivative, a dopamine receptor agonist, which has been mainly used for the treatment of depression and Parkinson's disease. It has also been recommended for the treatment of patients with intermittent claudication, without convincing evidence.

Somnolence is a common adverse effect and can occur at low doses (SED-10, 346) (SEDA-10, 119). Among 50 patients with Parkinson's disease who had recently taken piribedil, 3 satisfied the clinical description of sleep attacks (1).

At higher doses gastrointestinal effects (anorexia and nausea) occur in 13% of patients taking a gradually increasing dose up to 120 mg/day (2). At very high doses (240 mg/day), changes in liver function tests occasionally occur. After intravenous administration (1.5–3.0 mg/hour for 6 hours) drowsiness, cold extremities, and spontaneous erections are common (SED-9, 317) (SEDA-2, 185) (SEDA-5, 207).

In 49 Filipino patients with Parkinson's disease and motor fluctuations the most common adverse effects of piribedil in a dosage of up to 150 mg/day were hallucinations (20%), dyskinesias (20%), dizziness (8%), and sleepiness (6%) (3).

Piridoxilate

General Information

Piridoxilate, an equimolar mixture of glyoxylic acid and pyridoxine, is marketed in a few countries (for example France) for peripheral arterial occlusive disease and functional venous disorders.

Organs and Systems

Urinary tract

A few reports have dealt with the occurrence of calcium oxalate renal calculi associated with long-term administration of piridoxilate.

- A 23-year-old man developed acute renal insufficiency due to hyperoxaluria and intratubular deposits of oxalate crystals after attempting suicide with an overdose of piridoxilate (SEDA-11, 180).
- An old woman developed end-stage chronic renal insufficiency and histological evidence of renal oxalosis ascribed to 10 years of piridoxilate treatment; renal function did not improve after withdrawal of the drug, and chronic hemodialysis was required (1).

1. Mousson C, Justrabo E, Rifle G, Sgro C, Chalopin JM, Gerard C. Piridoxilate-induced oxalate nephropathy can lead to end-stage renal failure. Nephron 1993;63(1):104–6.

Piritrexim

General Information

Piritrexim is a lipid-soluble analogue of methotrexate that has been used to treat methotrexate-resistant tumors (1). It is given with leucovorin (folinic acid) to minimize hematological toxicity. Myelosuppression is the major dose-limiting adverse effect. In 35 patients with urothelial carcinomas there was WHO grade 3/4 thrombocytopenia in four, granulocytopenia in one, and anemia in three; grade 3 non-hematological toxicity consisted of neuropathy in five patients, hepatotoxicity in two, nausea in two, and pulmonary toxicity and rash in one each (2). Piritrexim also causes facial flushing, periorbital edema, and pruritus, and anaphylactic shock has been reported (SEDA-18, 289).

Piroxicam

See also Non-steroidal anti-inflammatory drugs

General Information

Piroxicam was the first of the oxicam compounds, and is by far the most widely used. It is an inhibitor of prostaglandin synthesis and platelet aggregation. Its long half-life (36–48 hours) allows it to be given in a single daily dose. Adverse effects data from 46 trials in 3827 patients, 2716 on short-term treatment (less than 12 weeks), have been reviewed (SEDA-6, 1) (1). In 20 controlled trials in 816 patients, adverse effects occurred in 27%, causing withdrawal in 2.2%. However, an uncontrolled study registered adverse effects in only 16% of patients. Allowing for all analyses and reviews, the overall adverse effects profile of piroxicam seems to be qualitatively the same as that of other NSAIDs, with gastrointestinal complaints at the top of the list.

Reactions involving the gastrointestinal system occur in up to 40% of patients. The approximately 1% incidence of peptic ulcer appears to be dose-related, as it rises to 7% in patients who take dosages higher than 20 mg/day for several weeks (2). Nervous system reactions are the second most frequent types of adverse effect. Changes in laboratory findings (creatinine, aspartate transaminase, alanine transaminase) are frequent, but they have little clinical relevance. Hypersensitivity reactions do not seem to be a problem with piroxicam treatment, although skin or mucosal reactions have been reported. Shock has been described. Tumor-inducing effects have not been reported.

Cinnoxicam is the cinnamate ester of piroxicam; its adverse effects are similar. Gastrointestinal effects (81%), nervous system effects (4%), and cutaneous effects (4%) were most common in a multicenter post-marketing surveillance study of 2969 patients; 12% had adverse effects (SEDA-16, 113). Cinnoxicam cream can cause itchy erythema, edema, vesicles, and exudation (SEDA-20, 94).

Organs and Systems

Respiratory

In two cases piroxicam caused pulmonary infiltrates and eosinophilia (SEDA-19, 99).

Nervous system

Adverse effects in about 11% of patients include headache, dizziness, drowsiness, fatigue, and sweating (3).

Sensory systems

Eyes

Blurred vision and burning eyes have been described with piroxicam (SEDA-5, 107).

Ears

Permanent sensorineural hearing loss and tinnitus have been described with piroxicam (4).

Electrolyte balance

Severe hyponatremia, characterized by increasing confusion and disorientation, has been reported (SEDA-13, 83).

Hyperkalemia has often been linked to prolonged use of piroxicam, especially in the elderly (SEDA-8, 110) (SEDA-10, 87).

Hematologic

Piroxicam can cause thrombocytopenia, including a case of thrombocytopenic purpura due to an immunological mechanism (SEDA-13, 83). As an inhibitor of prostaglandin synthesis, piroxicam also inhibits platelet aggregation and prolongs bleeding time.

Leukopenia has been reported; the leukocyte count returned to normal after withdrawal (5). Agranulocytosis in a woman who took piroxicam for 3 days disappeared rapidly after withdrawal (SEDA-14, 95).

Aplastic anemia, which resolved fully after withdrawal, has been described (SEDA-17, 114).

Gastrointestinal

Gastrointestinal effects are the most frequent adverse effects of piroxicam. Although epigastric distress, nausea, abdominal pain, constipation, flatulence, and diarrhea have all been reported, they rarely interfere with treatment.

Esophageal lesions have been recorded in young healthy volunteers taking piroxicam (6).

An unusual case of gastrocolic fistula occurred in an old man who had taken piroxicam for 2 months (7).

Peptic ulceration and gastrointestinal bleeding were recorded in 1–1.4% of patients taking piroxicam 20 mg/day, and the incidence of ulceration increased to 6.9% at a dosage of 40 mg/day. A comparative study of gastrointestinal blood loss after aspirin 972 mg qds for 4 days versus different doses of piroxicam (20 mg od, 5 mg qds, and 10 mg qds) showed that piroxicam did not increase fecal blood loss, whereas aspirin did. Gastroscopic evidence of irritation was also greater with aspirin (8). The debate on the ulcerogenicity and relative safety of piroxicam continues, as new reports are published (SEDA-10, 85) (SEDA-11, 97) (SEDA-12, 91). As the perfect epidemiological study has yet not been carried out, the only thing that can be said is that piroxicam's ulcerogenicity increases with dosage and that 20 mg/day constitutes high-dose therapy, especially in elderly women.

Piroxicam can cause diaphragm-like strictures of the intestinal tract (9).

- A 65 year-old woman who had taken piroxicam for the previous 3 years presented with frequent episodes of abdominal bloating and cramping, sometimes associated with nausea and vomiting, and loss of weight. Small bowel examination showed several mid-ileal strictures associated with proximal dilated bowel.

Liver

Transient rises in aspartate transaminase and alanine transaminase can occur (10). Biopsy-proven hepatitis was noted in one patient who was also taking other medications (SEDA-5, 107). Cases of acute hepatitis have been described. Two elderly women developed acute hepatocellular injury, which progressed to fatal subacute hepatic necrosis (SEDA-12, 93) (11,12).

Urinary tract

Piroxicam reduces renal blood flow by inhibition of renal prostaglandins. It can cause transient and probably insignificant rises in urea or blood urea nitrogen, without increases in serum creatinine concentrations. Renal function should be monitored during long-term therapy and piroxicam should be avoided in renal insufficiency. An occasional patient develops edema and dysuria.

Hematuria with purpuric rash and Henoch–Schönlein purpura have been described (13).

Fatal acute renal insufficiency due to diffuse interstitial nephritis has been described in a young man (SEDA-14, 95).

Skin

Minor, often transient, skin rashes are relatively common, as with other NSAIDs. Light-induced skin eruptions have been reported to national ADR monitoring centers in several countries and generally occur only 1–6 days after the start of therapy. They are characterized by pruritic, papulovesicular, or bullous eruptions, usually restricted to exposed areas. Clinical, histological, and provocation studies are not conclusive in distinguishing the eruptions as photoallergic or phototoxic (SEDA-13, 76) (SEDA-15, 103) (14). Cross-reactivity between thiosalicylic acid and piroxicam supports the hypothesis that piroxicam-induced photosensitive reactions have a photoallergic mechanism and occur soon after starting therapy when patients have previously been sensitized to thiosalicylate (SEDA-16, 113) (15). The wide range of adverse skin effects include several types of rashes, urticaria, vasculitis, and life-threatening reactions (toxic epidermal necrolysis, erythema multiforme, and pemphigus) (SEDA-8, 110) (SEDA-11, 192) (SEDA-13, 77). Fixed drug eruptions have also been described (SEDA-16, 113).

- After piroxicam intake and sun exposure a patient with Sjögren's syndrome developed the typical cutaneous lesions and serological markers of systemic lupus erythematosus, despite drug withdrawal (16).

© 2006 Elsevier B.V. All rights reserved.

Susceptibility Factors

Renal disease

Reduced piroxicam excretion increases the risk of gastrointestinal adverse effects. Most reports of these effects refer to elderly women, since impaired renal function in the elderly can lower excretion of the drug by 33%. Dosages should be as low as possible, and certainly not above 20 mg/day in these patients.

Drug Administration

Drug formulations

The adverse effects profile of suppositories, soluble tablet formulations, and standard capsules are similar (SEDA-13, 83). A parenteral formulation of piroxicam caused somnolence more often than diclofenac in a double-blind study, but diclofenac provoked more gastric discomfort and nausea than piroxicam. Local adverse effects of both drugs were pain, burning, and induration at the site of injection (SEDA-15, 103).

In an attempt to reduce gastric toxicity, piroxicam has been complexed with cyclodextrins. In healthy volunteers piroxicam beta-cyclodextrin is less toxic than either piroxicam or indometacin; gastrointestinal adverse effects were the most frequent (SEDA-16, 113).

A fast-dissolving form of piroxicam that can be taken under the tongue infrequently causes local adverse effects, including stomatitis, mucosal erythema, and dysesthesia (SEDA-20, 95).

Drug–Drug Interactions

Furosemide

Furosemide natriuresis and kaliuresis can be reduced by short-term treatment with piroxicam in hypertensive patients with impaired renal function (SEDA-16, 113).

Lithium

Piroxicam can increase the risk of lithium toxicity (17).

Phenazone

The half-life of phenazone (antipyrine) was prolonged and its metabolic clearance significantly reduced in proportion to the dose of piroxicam administered to healthy young volunteers (SEDA-16, 113).

Pirprofen

See also Non-steroidal anti-inflammatory drugs

General Information

In an open, non-comparative trial in 1506 patients, the adverse effects of pirprofen were mainly gastrointestinal, and consisted mostly of epigastric pain. There were single cases of an attack of asthma, iron deficiency anemia, leukopenia, and an increase in serum transaminases to more than 10 times normal (1). In a long-term trial, 9.7% of over 3000 patients stopped treatment because of poor tolerability. The manufacturers decided to discontinue marketing it worldwide, saying that this was a commercial decision (SEDA-16, 111).

© 2006 Elsevier B.V. All rights reserved.

Organs and Systems

Liver

Laboratory signs of hepatic damage were documented in 37 patients, including three cases of hepatitis (2); pirprofen can definitely be considered hepatotoxic.

Pizotifen

See also Antihistamines

General Information

Pizotifen is a 5-HT receptor antagonist chemically related to the tricyclic antidepressants, with a five-membered third ring containing a sulfur atom. It has been suggested that pizotifen has effects and adverse effects resembling those of amitriptyline (1). However, it is pharmacologically similar to the antihistamine cyproheptadine and shares its adverse effects, including drowsiness and increased appetite. When used in migraine it causes increased weight; conversely, when it is used to improve appetite, sleepiness and dizziness are common.

Organs and Systems

Metabolism

In 47 patients with severe migraine unresponsive to clonidine, pizotifen 1.5 mg for 6 months more than halved the incidence of attacks in 30 patients and 12 became headache-free. Weight gain was a problem in some subjects (2). In an open, multicenter study of the use of pizotifen 1.5 mg at night to prevent migraine in 834 patients, the most frequent adverse effects were drowsiness, although in one-third of the affected patients this was transient, and weight gain, with an average increase of 0.7 kg over 2 months (3).

Long-Term Effects

Drug withdrawal

Severe weight loss has been reported after withdrawal of chronic pizotifen (4).

Drug Administration

Drug overdose

An acute overdose of 30 mg pizotifen caused pyrexia and anticholinergic effects, with resolution after 10 hours (5).

Placebo

General Information

Since the first paper in 1945 (1), thousands of papers have been published on placebos. However, little attention has been paid to data on placebos in clinical pharmacology studies. The conditioning model of placebo has been elegantly illustrated in a crossover study in hypertensive patients (2). The use of placebos has been reviewed (3).

The impact of experimental conditions on the results of 109 double-blind, placebo-controlled clinical pharmacology studies conducted in 1228 healthy volunteers has been reported (4). The subjects were young (aged 18–40 years) or old (65–80 years). The treatment was oral placebo (capsules, tablets, or suspension) and the adverse effects were spontaneously reported and/or observed by the investigators. The overall incidence of adverse effects was 19%, with an increased number of complaints in the elderly subjects. After single dosing of placebo, the most common events were headache, drowsiness, and weakness. After repeated dosing, there was an increased incidence of weakness, reaching 7% (compared with 2.5% after a single dose), while the incidences of the other major symptoms were unchanged. A lower overall incidence (7%) of adverse events has been reported after free interviews (5), while in another study there was a higher frequency (6).

Experimental conditions in phase I trials have been described as being potentially responsible for changes in serum transaminase activities (7,8), perhaps ascribable to dietary factors and rest.

Bed-rest experiments have previously shown changes in homeostasis (for example, glucose-induced insulin release) but no change in plasma catecholamine concentrations.

Plague vaccine

See also Vaccines

General Information

Plague vaccine is a suspension of the formaldehyde-killed encapsulated form of *Yersinia pestis*. Primary immunization involves three doses given intramuscularly.

The Working Group on Civilian Biodefense has developed consensus-based recommendations for measures to be taken by medical and public health professionals following the use of plague as a biological weapon against a civilian population (1). They concluded that an aerosolized plague weapon could cause fever, cough, chest pain, and hemoptysis, with signs consistent with severe pneumonia 1–6 days after exposure. Rapid evolution of disease would occur in the 2–4 days after the onset of symptoms and would lead to septic shock with a high mortality if early treatment was not instituted. They advised early treatment and prophylaxis with streptomycin or gentamicin or one of the tetracycline or fluoroquinolone classes of antimicrobials.

General adverse effects

General malaise, headache, fever, mild lymphadenopathy, or erythema and induration at the injection site have been reported following the administration of plague vaccine (10% of vaccinees); these effects are more common with repeated injections. Sterile abscesses and hypersensitivity reactions (urticaria, asthma) occur rarely (2).

Organs and Systems

Immunologic

Known allergy to any of the plague vaccine constituents (beef protein, soya, casein, phenol) contraindicates immunization. Severe local or systemic reactions following previous doses contraindicate revaccination (2).

Plantaginaceae

See also Herbal medicines

General Information

The family of Plantaginaceae contains two genera:

1. *Littorella* (littorella)
2. *Plantago* (plantain).

Plantago species

Plantago species have traditionally been used for many purposes in folk medicine (1,2). Plantain seeds are widely used as bulk laxatives under the names of "psyllium" (from *Plantago psyllium* or *Plantago indica*) and "ispaghula" (from *Plantago ovata*). They are covered in the monograph on laxatives.

Plasma products

General Information

Plasma products are used to substitute plasma proteins and in plasma exchange. Fresh frozen plasma is used as a source of coagulation factors in deficiency, if no purified factors are available.

Intensive plasma exchange has been studied in the treatment of numerous diseases, above all in Waldenström's macroglobulinemia, hypercholesterolemia, hyperviscosity syndrome, thrombotic thrombocytopenic purpura, systemic lupus erythematosus, myasthenia

gravis, hemolytic-uremic syndrome, Goodpasture's syndrome, Guillain–Barré syndrome, and several other autoimmune diseases. Its potential benefit is attributable to the removal of a variety of harmful substances from plasma, such as antibodies, antigens, immune complexes, toxins, or abnormal plasma components. If the circulating substance is a cause of the disease, the plasma exchange can be effective. However, its therapeutic potential in many diseases has not yet been precisely defined.

The performance of intensive plasma exchange (removal from an adult of 2–3 liters of plasma with substitution of fresh plasma to maintain the patient's blood volume) requires separation of plasma from cells, so that the patient's own cells can be returned. There are two methods of plasma separation: centrifugal flow separation and flow filtration (1,2).

Intensive plasma exchange is relatively safe. It is generally well tolerated, and only a few serious complications have been reported. The potential complications (3–5) include transient hypotension, nausea, urticaria, abdominal discomfort, fever, hypothermia, air or microaggregate embolism, hypocalcemia (citrate effect) with paresthesia, tetany, and cardiac depression, thrombocytopenia (often observed), coagulation factor depletion and depletion of various intravascular proteins, visual scotomata, hepatitis, vasovagal reactions, and reactions associated with phlebotomy (phlebitis, hematoma).

The fluid volume and protein removed by plasmapheresis must be replaced. Among the solutions available for replacement therapy are fresh frozen plasma and human albumin solutions.

Fresh frozen plasma

Fresh frozen plasma is defined as the fluid portion of 1 unit of human blood that has been centrifuged and separated and then frozen at −18°C (or below) within 6 hours of collection. It is used to reverse the effects of oral anticoagulants (for example during surgery or bleeding episodes) (6). Its use has increased considerably in most countries within the past 20–25 years (7), in spite of mounting evidence of its potential risks, such as the transmission of viral infections. Allo-immunization occurs infrequently, with the formation of Rh antibodies in response to contaminating stroma of red blood cells, and as with any intravenous administered fluid, hypervolemia and cardiac failure can occur (8). Anti-A and anti-B in the plasma can hemolyse the recipient's red cells if ABO-compatible fresh frozen plasma is not used (9). Other disadvantages of fresh frozen plasma are the large volume that needs to be given, the risk of viral transmission, and the variable quantities of clotting factors it contains. Quarantine fresh frozen plasma, when the unit is used after the next consecutive donation of the same donor has been found to be negative in virus screening assays, is a safe alternative.

Organs and Systems

Cardiovascular

Hypotension is a sometimes severe adverse effect of the administration of plasma proteins. It may be associated with the presence of a potent prekallikrein activator, the Hageman factor degradation product, which is thought to initiate the production of kinin from fibrinogen in the recipient's blood. The kinin then produces systemic hypotension.

In five of eight patients treated with fresh frozen plasma to achieve rapid correction of anticoagulation after warfarin-related intracranial hemorrhage, there were complications of fluid overload (10). In two of these patients congestive heart failure developed, resulting in myocardial infarction and renal insufficiency respectively. Two patients had supraventricular tachydysrhythmias and one developed pulmonary edema.

Respiratory

The incidence of transfusion-related acute lung injury is 0.16–0.24% per transfusion of blood products and is the cause of 15% of all fatal complications of blood transfusion (11). Specific antigen–antibody reactions involving donor antibodies specific for leukocyte antigens of the recipients cause activation of neutrophils and aggregation in small pulmonary vessels (11). The complement and cytokine cascade is activated, leading to capillary leakage.

- In a 58-year-old man transfusion of a unit fresh frozen plasma resulted in acute lung injury, caused by antibodies of the donor specific for the neutrophil antigen NB1 (11).

NB1 has a phenotype frequency of 97%.

Immunologic

Immunological adverse effects of the administration of plasma range from mild urticaria and flushing to fatal anaphylaxis. Such reactions can occur either during the infusion or some minutes after. Mild reactions often start locally and have a tendency to spread. In more severe cases dyspnea, arthralgia, and fever occur. Stabilizers or other additives in plasma protein preparations may be of significance in provoking these reactions. In addition, protein aggregates in the preparations may participate in anaphylactoid reactions, including acute pulmonary injury. Severe reactions have occasionally been encountered.

Development of an antibody response

The development of an antibody response against a deficient or genetically different protein can cause post-transfusion complications. The main problems are antibodies against antihemophilia factors, for example directed against factor VIII or factor IX, which may be produced in hemophiliacs after repeated transfusions and inhibit the therapeutic effect. Another problem arises when antibody formation occurs in IgA-deficient subjects who receive IgA-containing products and produce anti-IgA antibodies. Inhibitors of coagulation proteins and antibodies to IgA are described in the monographs on coagulation proteins and immunoglobulins.

Body temperature

Fever can occur 10–15 minutes after the start of an infusion of plasma. It is often accompanied by headache,

© 2006 Elsevier B.V. All rights reserved.

nausea, and shivering. These symptoms often disappear when the infusion is discontinued.

Platelet glycoprotein IIb/IIIa antagonists

General Information

Platelet membrane glycoprotein IIb/IIIa receptor inhibitors have been approved in various countries for the treatment of patients scheduled for percutaneous transluminal coronary angioplasty or coronary atherectomy to prevent ischemic complications (1). They are antagonists at an adhesion receptor on the platelet membrane, the glycoprotein IIb/IIIa, which binds some ligands implicated in platelet aggregation, fibrinogen, and von Willebrand factor, and is involved in the common final pathway whereby various stimuli cause platelet activation. They therefore reduce platelet aggregation regardless of the mechanism by which the platelet is activated, and are currently the most powerful inhibitors of platelet aggregation available.

The first drug to be developed in this family was the monoclonal antibody abciximab, which is covered in a separate monograph. Other GP IIb/IIIa blockers include peptides (eptifibatide) or small molecules such as tirofiban and lamifiban. Other small molecules that are orally active are in development (2).

For the drugs so far used in major clinical trials (eptifibatide, tirofiban, lamifilan, roxifiban, and sibrafiban) the available data suggest that the commonest adverse events are episodes of bleeding, mostly minor and essentially at the vascular access site, without an excess of intracranial hemorrhage. There is also a low incidence of thrombocytopenia with these non-antibody drugs; two cases were reported in a study of the use of roxifiban in 98 patients with chronic stable angina pectoris (3).

Platinum-containing cytostatic drugs

See also Cytostatic and immunosuppressant drugs

General Information

Although the main platinum-containing cytotoxic drugs, cisplatin (rINN), carboplatin (rINN), and oxaliplatin (rINN), share some structural similarities, there are marked differences between them in therapeutic uses, pharmacokinetics, and adverse effects profiles (1–4). Compared with cisplatin, carboplatin has inferior efficacy in germ-cell tumors, head and neck cancers, and bladder and esophageal carcinomas, whereas the two drugs appear to have comparable efficacy in ovarian cancer, extensive small-cell lung cancers, and advanced non-small-cell lung cancers (5–7).

Oxaliplatin belongs to the group of diaminocyclohexane (DACH) platinum compounds. It is the first platinum-based drug that has marked efficacy in colorectal cancer when given in combination with 5-fluorouracil and folinic acid (8,9).

Nedaplatin has been registered in Japan, whereas other derivatives, like satraplatin (JM216, which is the only orally available platinum derivative), ZD0473, BBR3464, and SPI-77 (a liposomal formulation of cisplatin), are still under investigation (10–13).

Other platinum-containing compounds under investigation include dexormaplatin, enloplatin, eptaplatin, iproplatin, lobaplatin, miboplatin, miriplatin, ormaplatin, picoplatin, sebriplatin, spiroplatin, and zeniplatin.

The adverse effects of platinum compounds have been reviewed (14).

© 2006 Elsevier B.V. All rights reserved.

Mechanism of action

Although the precise mechanism of the cytotoxic action of the platinum-containing compounds has not been fully elucidated, they are thought to act by causing interstrand and intrastrand cross-links in DNA, particularly including two adjacent guanine or two adjacent guanine-adenine bases (15–18). In comparison with cisplatin- or carboplatin-induced DNA lesions, diaminocyclohexane (DACH) platinum DNA adduct formation has been associated with greater cytotoxicity and inhibition of DNA synthesis. In addition, there appears to be a complete lack of cross-resistance between oxaliplatin and cisplatin, which may be related to the bulky DACH carrier ligand of oxaliplatin, hindering DNA repair mechanisms within tumor cells (8,9).

Pharmacokinetics

There are significant pharmacokinetic differences among cisplatin, carboplatin, and oxaliplatin. Cisplatin is the most highly protein-bound (>90%), followed by oxaliplatin (85%) and carboplatin (24–50%).

The negligible nephrotoxicity of oxaliplatin and carboplatin compared with cisplatin may be related to their slower rates of conversion to reactive species. As a result, intensive hydration is not warranted during carboplatin or oxaliplatin infusion, in contrast to cisplatin (1,8–10). In the case of macromolecular platinum-protein complex formation, decomposition proceeds rather slowly, which may explain why the urinary excretion of total platinum is increased for a long time after treatment, particularly in patients who have been given cisplatin (19,20).

In contrast to cisplatin, carboplatin is primarily eliminated (about 75%) by glomerular filtration, whereas tubular secretion appears to be of minor importance (2–4). It has therefore been recommended that the dose of carboplatin be adjusted according to the individual glomerular filtration rate, in order to avoid high plasma drug concentrations when the dose is calculated according to body surface area (21–23). Individualized carboplatin therapy helps to avoid abnormally high drug concentrations in patients with renal dysfunction and subtherapeutic concentrations in patients with an unexpectedly high glomerular filtration rate (24,25).

Pharmacokinetic-pharmacodynamic correlations between AUC, response rates, and the extent of myelosuppression have been examined retrospectively in patients with advanced ovarian carcinoma (21,24). AUC values below 4 minutes/mg/ml and exceeding 7 minutes/mg/ml cannot be recommended; the former is associated with low response rates and the latter is associated with more pronounced neutropenia and thrombocytopenia without higher response rates. Doses of carboplatin are generally calculated by the Calvert formula (26):

$$\text{Carboplatin dose} = \text{AUC (minutes.mg/ml)} \times (\text{GFR} + 25)$$

However, it is still debatable which method most accurately predicts individual values of glomerular filtration rate or creatinine clearance. Whereas the Cr-EDTA method is the most accurate method of estimating glomerular filtration rate, most clinicians do not use it routinely, and prefer to collect urine for estimation of creatinine clearance. Alternatively, the use of special formulae has been proposed, for example Wright's formula and the formulae of Cockcroft & Gault or Jelliffe (27–29). However, calculation of the glomerular filtration rate or creatinine clearance using such formulae has been associated with some bias in different ranges, regardless of which formula has been used.

After intravenous administration of oxaliplatin, about 33% and 40% of the dose is bound to erythrocytes and plasma proteins. The half-life averages 26 days, which is in accordance with the normal life expectancy of erythrocytes (12–50 days). Oxaliplatin undergoes rapid non-enzymatic biotransformation to form a variety of reactive platinum intermediates, which bind rapidly and extensively to plasma proteins and erythrocytes. The antineoplastic and toxic properties appear to reside in the non-protein bound fraction, whereas platinum bound to plasma proteins or erythrocytes is considered to be pharmacologically inactive. Biotransformation produces DACH-platinum dichloride, 1,2-DACH-platinum dicysteinate, 1,2-DACH-platinum diglutathionate, 1,2-DACH-platinum monoglutathionate, and 1,2-DACH-platinum methionine. The erythrocyte contains only thiol derivatives, whereas all derivatives can be recovered from the plasma.

The platinum-containing metabolites of oxaliplatin are predominantly excreted in the urine (about 50% of the dose within 3 days), whereas drug excretion via the feces is of minor importance (about 5% of the dose after 11 days). The mean total platinum half-life averages 9 days after oxaliplatin administration (130 mg/m^2 intravenously) (8,9). There is a strong negative correlation between the mean plasma concentration of unbound oxaliplatin and renal function; however, moderate renal impairment does not increase the risk of acute toxicity associated with oxaliplatin (30).

General adverse effects

The comparative toxicity and mutagenic effects of platinum anticancer drugs have been reviewed (31).

Of the clinically established platinum compounds, cisplatin has the most toxic effects on organs like the nervous system, the organ of Corti, and the kidneys in a dose-dependent fashion. The dose per cycle has therefore usually been limited to 100–120 mg/m^2 intravenously, in order to avoid drug-induced irreversible organ dysfunction (12,13). The complete spectrum of late or long-term adverse effects of cisplatin in survivors of testicular cancer has been reviewed (32).

In contrast to cisplatin, myelotoxicity represents the most prominent adverse effect of carboplatin. Based on its lower organ toxicity and its better predictable pharmacokinetic behavior, carboplatin has extensively replaced cisplatin in combination chemotherapy for the treatment of ovarian cancer and extensive small cell and non-small cell lung cancer. For other indications, one has to weigh the possibly inferior efficacy of carboplatin against the more pronounced undesirable adverse effects of cisplatin, which may limit its long-term use. Based on its marked organ toxicity, high-dose cisplatin-containing regimens

© 2006 Elsevier B.V. All rights reserved.

are not feasible, in contrast to carboplatin, which is part of several dose-intensified combination chemotherapy regimens (12,13).

Like carboplatin, oxaliplatin does not usually cause nephrotoxicity. In addition, both drugs are only moderately emetogenic, in contrast to cisplatin. The most important dose-limiting adverse effect of oxaliplatin is a sensory peripheral neuropathy, which has two different forms:

1. a unique acute peripheral sensory (and motor) toxicity that often occurs during or within hours after drug infusion and which is rapidly reversible and aggravated by cold;
2. a peripheral sensory neuropathy related to the cumulative dose, which is generally moderate and slowly reversible, in contrast to the forms that have been described after cisplatin administration.

BBR3464

BBR3464 is the first congener of a novel group of platinum compounds, the so-called cationic trinuclear platins. It binds to DNA more rapidly than cisplatin, which results in long-range interstrand and intrastrand cross-links. It is more potent than cisplatin, and very low dosages were effective in phase I trials. With a 1-hour intravenous infusion of 1.1 mg/m^2 every 28 days, diarrhea (preceded by abdominal cramps), nausea/vomiting, and neutropenia were the most prominent drug-related adverse effects. There were no signs of drug-related nephrotoxicity, neurotoxicity, or lung dysfunction (12,13,33).

Heptaplatin

Heptaplatin (cis-malonate[(4*R*,5*R*)-4,5-bis(aminomethyl)-2-isopropyl-1,3-dioxolane]platinum(II), SKI-2053*R*, Sunpla) has high antitumor activity against various cancer cell lines, including cisplatin-resistant tumor cells. Preliminary results suggested that it is less nephrotoxic than cisplatin. However, a comparative trial showed that intravenous heptaplatin 400 mg/m^2 was more nephrotoxic than intravenous cisplatin 60 mg/m^2 in terms of uremia and proteinuria, which occurred despite the use of hyperosmolar mannitol and appropriate concomitant hydration (fluid intake at least 3500 ml/day) (34,35).

Nedaplatin

Nedaplatin (cis-diammineglycolatoplatinum, CDGP, 254-S) has some structural similarities to cisplatin and carboplatin. Since 1995 it has been available for therapeutic use in Japan. In phase II trials, it had promising antineoplastic activity in patients with head and neck cancers, non-small cell lung cancers, esophageal cancer, testicular tumors, and cervical cancer. A distinct number of patients with ovarian cancer have responded to nedaplatin (for example 100 mg/m^2 intravenously) even after relapsing following treatment with cisplatin/carboplatin and cyclophosphamide. Its pharmacokinetic behavior is similar to that of carboplatin. It causes less nephrotoxicity than cisplatin, but hematological toxicity is dose-limiting. Other adverse effects include nausea/vomiting and mild peripheral neuropathy (12,13,36). Although nedaplatin is less nephrotoxic than cisplatin, incidental cases of severe nephrotoxicity have occurred. In addition, ototoxicity, similar to that observed after cisplatin, has been documented. Nedaplatin is excreted primarily unchanged by glomerular filtration, and there is a formula for predicting the clearance of unbound platinum after its administration (37).

Satraplatin

Satraplatin (bis-acetato-ammine-dichloro-cyclohexylamine-platinum, JM 216, BMS-182751) is the first oral platinum compound among the third-generation platinum complexes with activity in platinum-sensitive and some platinum-resistant preclinical models. Adverse effects were generally modest (grades I and II), including nausea, fatigue, anorexia, diarrhea, and altered taste. In addition, myelosuppression and rare cases of grades II and III increases in serum creatinine were reported. During phase II trials satraplatin was given in a dose of 120 mg/m^2/day for 5 consecutive days every 3 weeks in untreated patients with lung cancer or 30 mg/m^2/day for 14 consecutive days every 5 weeks in patients with metastatic squamous cell carcinoma. There was no nephrotoxicity or neurotoxicity (38–40). Pharmacokinetic studies showed that very little intact parent compound reached the systemic circulation after oral administration, perhaps because of extensive metabolic biotransformation or rapid reaction of platinum(II) species with DNA or other compounds. One of the intermediate compounds released during biotransformation is JM118, which has a longer half-life than the parent compound. Its particular role in the overall activity of satraplatin is still being investigated (41).

SPI-77

SPI-77 is a stealth liposomal dosage form of cisplatin. One of the main features of stealth liposomes is that they are pegylated on the liposomal surface. Compared with conventional liposomes (for example DaunoXome or Myocet) the half-life of the liposome and its embedded drug in plasma is significantly increased by this modification, because degradation by cells of the mononuclear phagocytic system is impaired; the cells are thereby, as it were, tricked. Liposomal encapsulation of cisplatin has been suggested to reduce systemic drug exposure and may help to increase drug delivery into tumor tissue. Pharmacokinetic studies have shown a slow rate of release of cisplatin from the liposomes, resulting in low systemic exposure to unbound drug. In contrast to conventional cisplatin, the incidence of gastrointestinal toxicity after SPI-77 was low, and so prophylactic antiemetics could be avoided. In addition, renal toxicity has not been observed, which also makes hydration before or after chemotherapy unnecessary. Extensive neurological measurements did not show any adverse effects. In conclusion, the toxicity profile of SPI-77 is encouraging compared with conventional cisplatin. However, despite its favorable pharmacokinetic behavior, enhanced platinum accumulation in tumor tissue has not yet been detected (42–44).

© 2006 Elsevier B.V. All rights reserved.

Tetraplatin

The further development of the third-generation platinum derivative tetraplatin (ormaplatin, *trans*-D, L-1,2-diaminocyclohexane tetrachloroplatinum) has been abandoned, because drug-induced severe motor and sensory peripheral neuropathy occurred even at low cumulative doses. The high neurotoxic potential of tetraplatin may be associated with its pharmacokinetics: it is rapidly metabolized to 1,2-DACH-platinum dichloride, which was 3.8 times more neurotoxic than oxaliplatin in a neurite outgrowth assay (45).

ZD0473

ZD0473 (formerly AMD473, JM473) was developed in order to overcome acquired or intrinsic (de novo) resistance to cisplatin. Based on the steric bulk of its methyl-substituted pyridine moiety, thiol substitution and drug inactivation is hindered compared with cisplatin. In several in-vitro studies, ZD0473 was active even in cisplatin-refractory tumor cells, whose key mechanism of resistance was based on thiol substitution. In addition, ZD0473 is also active in cisplatin-resistant tumor cells, in which resistance is based on altered drug transport mechanisms or enhanced DNA repair.

Based on encouraging preclinical results, ZD0473 entered clinical phase I/II trials in several solid tumors, including non-small cell lung cancers, mesothelioma, head and neck cancers, and ovarian carcinoma. Its most prominent adverse effects included myelosuppression and nausea/vomiting. Thrombocytopenia and neutropenia were the dose-limiting adverse effects at intravenous doses of 130–150 mg/m^2. In contrast to cisplatin, neurotoxicity, ototoxicity, and renal toxicity have not yet been reported during or after treatment with ZD0473 (12,13,33,36).

Organs and Systems

Cardiovascular

Asymptomatic sinus bradycardia (for example 30–40/minute) is observed within 30 minutes to 2 hours after the start of cisplatin infusion. When cisplatin is withdrawn normal rhythm is restored. Because patients who receive platins are not routinely monitored, drug-induced sinus bradycardia may not be detected in practice. However, several case reports have included heavily pretreated patients, which makes a direct relation between cisplatin administration and the onset of cardiotoxic symptoms much more difficult to assess. In conclusion, no dosage adjustment appears to be warranted in patients with cisplatin-induced sinus bradycardia; however, attention should be paid to patients with resting bradycardia or those using medications known to slow the heart rate (46,47).

- A 60-year-old woman with a squamous cell lung carcinoma developed a paroxysmal supraventricular tachycardia during administration of cisplatin 20 mg/m^2 and etoposide 75 mg/m^2. The dysrhythmia appeared to be related to cisplatin since normal rhythm was restored after cisplatin was withdrawn (48).

Orthostatic hypotension was reported in "several" of 126 patients given cisplatin 50 mg/m^2 on days 1, 8, 29, and 36 as part of treatment for lung cancer in combination with etoposide and chest radiotherapy (49).

There have been 21 reports of life-threatening disease affecting large arteries in patients treated with cisplatin, bleomycin, and vinblastine in combination for germ cell tumors (50,51). Five patients died during or after therapy, three from acute myocardial infarction, one from rectal infarction, and one from cerebral infarction. Other patients who developed major vascular disease, including coronary artery and cerebrovascular disease, have been reported. Symptoms occurred acutely in some (within 48 hours of starting therapy), and after months or years had elapsed in others.

Reduced peripheral circulation, Raynaud's phenomenon, and polyneuropathy have been described after the combined use of cisplatin, bleomycin, and vinblastine for testicular tumors. Of eight cases with polyneuropathy that were investigated, it was not possible to confirm a causative association between Raynaud's phenomenon and the chemotherapy (52).

Platinum compounds have rarely been described to cause phlebitis after intravenous administration (53).

Respiratory

Seven patients died from irreversible respiratory failure after receiving combined cisplatin plus bleomycin chemotherapy; five had raised serum creatinine and all received cisplatin before the bleomycin (54). The authors recommended extreme caution with this combination, and suggested that bleomycin should precede the cisplatin infusion.

Ear, nose, throat

- A 67-year-old white woman with a small cell lung cancer was given six courses of cisplatin and etoposide once every 4 weeks and after the last course developed acute shortness of breath, hoarseness, and stridor, due to bilateral vocal cord paralysis (55).

Nervous system

The neurotoxicity of platinum-containing compounds has been reviewed (56,57), as has the prevention of cisplatin-associated neurotoxicity (58). In experimental measurements of sensory nerve conduction velocity: oxaliplatin caused the most impairment, followed by cisplatin, carboplatin, and satraplatin (JM216) (59). The cumulative incidence of grade 2 peripheral sensory neuropathy with oxaliplatin was 19% (60).

Conventional dosages of carboplatin have been associated with the lowest risk of peripheral neuropathy (for example mild paresthesia) among the approved platinum compounds. It has been estimated that about 4–6% of patients who receive carboplatin develop a peripheral neuropathy. Patients over 65 years of age or patients pretreated with other neurotoxic agents may be at a slightly higher risk (61).

A 47% incidence of peripheral neuropathy of all grades has been reported with cisplatin (62), and a 31% off-therapy deterioration of peripheral neuropathy presenting as muscle cramps and demyelination syndromes has been described (63). Cisplatin causes a well-recognized reversible sensory

© 2006 Elsevier B.V. All rights reserved.

peripheral neuropathy, starting with depressed deep tendon reflexes and loss of vibration sense, progressing to a sensory ataxia (64). This may be age-related, as the use of high-dose cisplatin in children with neuroblastoma has not been associated with peripheral neuropathy (65). Motor nerves are spared (66). There have also been case reports of cerebral herniation and coma, severe encephalopathy, tonic-clonic seizures with concomitant visual disturbances and changed mental state, insomnia, anxiety, and parkinsonian symptoms. The symptoms generally resolved within several weeks (67–71). In some studies, the nervous system effects were the consequence of cisplatin-induced electrolyte disturbances (for example hyponatremia, hypocalcemia, or hypomagnesemia), rather than a direct action of the platinum derivative in the nervous system (72–74). For example, mental status improved in one patient who was given 3% sodium chloride in order to increase the serum sodium from 118 to 128 mmol/l, whereas diazepam, phenytoin, phenobarbital, and dexamethasone were ineffective (75).

Presentation

In about 90% of patients, oxaliplatin is associated with acute neurosensory toxicity, including dysesthesia and paresthesia. Neurosensory toxicity affects the fingers, toes, perioral and oral regions, and the pharyngolaryngeal tract (in about 1–2% of cases), which is generally induced or aggravated by coldness. As a result, patients should be instructed to avoid exposure to cold. Such symptoms can occur during or shortly after the first course of oxaliplatin. The symptoms are commonly mild and disappear within a few hours or days. Some patients also develop muscle cramps or spasms. The risk of acute neuropathy appears to be lower if oxaliplatin is given in a dosage of 85 mg/m^2 every 2 weeks rather than 130 mg/m^2 every 3 weeks. A further strategy to reduce the risk of acute recurrent pseudolaryngospasm is to increase the infusion duration from 2 to 6 hours during subsequent cycles (76,77). The prophylactic use of infusions containing calcium and magnesium sulfate before and after oxaliplatin can prevent acute neurotoxic symptoms (78).

- A woman developed bilateral blindness and lumbosacral myelopathy within 1 month of having received an autologous bone marrow transplant, cisplatin 55 mg/m^2, carmustine 600 mg/m^2, and cyclophosphamide 1875 mg/m^2 (79).

In addition to the acute neurotoxic symptoms caused by oxaliplatin, about 10–15% of patients develop a moderate neuropathy, particularly after cumulative intravenous doses of 700–800 mg/m^2. The symptoms of cumulative neuropathy include non-cold-related dysesthesia, paresthesia, superficial and deep sensory loss, and eventually sensory ataxia and functional impairment, which persists between treatment cycles. Most of these symptoms usually resolve a few weeks or months after oxaliplatin withdrawal. Lower cumulative doses (for example 510–765 mg/m^2) and higher cumulative doses exceeding 1020 mg/m^2 have been associated with incidences of cumulative grade 3 neurotoxicity of 3.2% and 50% respectively (8,9,76,77). In addition, higher cumulative doses, exceeding 1000 mg/m^2, have been associated with severe, atypical neurotoxic symptoms, such as micturition disturbances and Lhermitte's sign, mimicking cord disease. However, these signs have been observed in only a few patients so far (3.3% in phase 3 trials). Both symptoms appear to be reversible after oxaliplatin withdrawal (80). In some patients oxaliplatin treatment is feasible for as long as 18 months (for example cumulative oxaliplatin dose over 3000 mg/m^2) with no signs of dysesthesia or paresthesia causing functional impairment, indicating high interindividual variability with respect to sensitivity to oxaliplatin-induced cumulative neuropathy (76,77). Whether cumulative sensory neuropathy can occur as a result of accumulation of dichloro-DACH-platinum, a biotransformation product of DACH-platinum, in the axonal and dorsal root ganglia neurons, needs further investigation (45).

Persistent Lhermitte's sign (an electric-like sensation induced by flexion of the neck) suggestive of irreversible spinal cord toxicity has been reported in a patient taking cisplatin and etoposide (81). Of four patients with oxaliplatin neurotoxicity, two presented with Lhermitte's sign, one had urinary retention, and one had both (82). All had received cumulative doses of 1248–2040 mg/m^2, which is more than the generally accepted neurotoxic threshold for oxaliplatin (1000 mg/m^2).

Peripheral paresthesia has been reported 5 years after adjuvant cisplatin-based treatment for stages I and II testicular cancer (83).

Four of eight children developed acute neurological toxicity. Three had seizures and one had transient blindness after high-dose cisplatin (200 mg/m^2) given by continuous infusion over 5 days, followed 10 days later by a further 2 days with 40 mg/m^2/day. These children had the greatest deterioration in renal function, and they may have had impaired clearance of and increased exposure to cisplatin (84).

Peripheral neuropathy with clinical signs and/or symptoms was found in 80% of patients who had received a cumulative dose of 576 mg/m^2 of cisplatin. There was a dose-related reduction in sensory action potential amplitudes (85). The clinical and neurophysiological time progression of the severity of cisplatin polyneuropathy during and after treatment with cisplatin up to a cumulative dose of 600 mg/m^2 has been described (86).

The paraneoplastic neuropathy experienced by women with epithelial ovarian cancer receiving cisplatin has been attributed in certain cases to the drug (87).

- A woman with cancer of the ovary and a man with oat cell carcinoma both developed paresthesia of all four limbs, reduced control of fine movements, and unstable gait after receiving a cumulative dose of 500 mg/m^2 of cisplatin (88). There was distal hypesthesia, with conservation of temperature and pain sensation, areflexia, and sensory ataxia. The woman also had continuous pseudoathetosis. Neurophysiological studies showed absence of peripheral and central sensory potentials and of H-reflexes, normal electromyography, normal motor conduction, and normal mixed silent period.

The target organ in cisplatin neurotoxicity is the dorsal root ganglion. This patient had a syndrome that clinically and neurophysiologically suggested diffuse neuropathic involvement of the dorsal ganglion, in which absence of sensory and H-reflex potentials showed that the small

© 2006 Elsevier B.V. All rights reserved.

myelinic cells were not altered, consistent with the preservation of pain and temperature sensation.

- A woman developed bilateral blindness and lumbosacral myelopathy within 1 month of having received an autologous bone marrow transplant, cisplatin 55 mg/m^2, carmustine 600 mg/m^2, and cyclophosphamide 1875 mg/m^2 (79).

Encephalopathy has also been reported.

- A 50-year-old woman with carcinoma of the cervix was treated with radiotherapy and six courses of cisplatin (75 mg/m^2 every 3 weeks; total dose 810 mg) (89). The therapy was completed with no obvious acute complications, but 12 weeks after the last course, she developed sudden blindness associated with occipital headache. She had mild global cognitive deficits and intermittent myoclonic jerking of both arms. Her visual acuity was limited to light perception in both eyes; her pupils were symmetrical with no afferent pupillary deficit. Anterior segment examination and dilated fundoscopy were normal; no ocular movements were elicited when a large plain mirror was held in front of her. The rest of the neurological examination was normal. Serum magnesium was reduced to 0.1 mmol/l (reference range 0.7–1.2 mmol/l). Electroencephalography showed diffuse slowing confirming an encephalopathy.
- An 84-year-old woman with adenocarcinoma of the ovary had two fully reversible episodes of non-convulsive encephalopathy, each following a course of cisplatin-based chemotherapy, confirming a causal relation (90). She developed acute confusion, a partial left homonymous hemianopia and a left extinction hemiparesthesia 7 and 10 days after treatment. Brain MRI showed long-standing cerebral microvascular changes and an electroencephalogram showed right-sided parieto-occipital periodic lateralized epileptiform discharges over a generalized background slowing of activity.

In view of the similarity to posterior leukoencephalopathy, the second case suggests regional endovascular injury rather than direct cerebral toxicity as the initial event in the evolution of encephalopathy.

Strokes have been reported in patients receiving cisplatin.

- A 21-year-old woman with a mixed germ cell tumor of the left ovary was given intravenous chemotherapy including etoposide 100 mg/m^2 on days 1–5, cisplatin 20 mg/m^2 on days 1–5, and bleomycin 30 units on days 2, 8, and 15, all of which she tolerated very well (91). Three weeks later she received a second cycle, which was complicated by an episode of dizziness on day 8. The following day she had an episode of transient dysphasia for 10 minutes. Her third course was uneventful until day 7, when she collapsed with a severe right-sided hemiparesis and dysphasia. Left-sided total anterior circulation infarction was confirmed on MRI scan.
- A 31-year-old man with a seminoma had an orchidectomy, followed by chemotherapy with cisplatin, etoposide, and bleomycin (92). A day after the end of the second course of chemotherapy he became comatose with a heart rate of 150/minute and a systolic blood pressure of 80 mmHg. Cranial angiography showed a thrombosis of the basilar artery and a cranial CT scan showed cerebellar infarction but no brain metastases.

However, the use of other drugs in these patients makes it difficult to assign causality to cisplatin.

Infusions of cisplatin into the axillary artery have led to a bronchial plexopathy rather than the more commonly described lumbosacral nerve plexus lesion (93).

In five patients cerebral herniation followed cisplatin therapy (94). However, all had evidence of an intracerebral tumor with mass effect and the herniation of the brain was thought to be multifactorial rather than directly attributable to cisplatin.

Auditory brainstem responses have been used to detect ototoxicity from cisplatin and carboplatin when used in combination therapy (95).

Mechanism and susceptibility factors

The mechanism of cisplatin-induced neurotoxicity has not been fully explained. Cisplatin appears to affect neurons in the dorsal root ganglia. It has also been suggested that it can act as a calcium channel blocker, altering intracellular calcium homeostasis and leading to apoptosis of exposed neurons, such as those of the dorsal root ganglia. Cisplatin-induced sensory neuropathy is predominantly characterized by symptoms such as numbness and tingling, paresthesia of the upper and lower extremities, reduced deep-tendon reflexes, and leg weakness with gait disturbance. The first symptoms are often observed after a cumulative dose of 300–600 mg/m^2. Risk factors include diabetes mellitus, alcohol consumption, or inherited neuropathies. Advanced age has not been identified as an independent risk factor when there is no co-morbidity (67–70).

The acute neurotoxic effects of oxaliplatin may result from drug-related inhibition of voltage-gated sodium currents (96). It has been suggested that oxalate ions, which are released during oxaliplatin metabolism, might be responsible for the inhibitory effects on the voltage-gated sodium channels, because of their calcium-chelating activity. Whether there are calcium-sensitive, voltage-gated sodium channels that can be affected by oxalate-induced calcium depletion or whether an indirect effect through changes in intracellular calcium-dependent regulatory mechanisms contributes to oxaliplatin-induced sensory neuropathy needs further investigation (97).

The risk of oxaliplatin-induced neurosensory toxicity may be increased after surgery. Of 12 patients with metastatic colorectal cancer, seven reported immediate postoperative aggravation of pre-existing neurotoxicity. Before surgery, they had only acral paresthesia without any functional impairment, whereas after surgery they complained of major worsening of symptoms, including loss of hand grip strength, leading to dependence in dressing, eating, and use of the toilet, or loss of sensitivity, interfering with walking, which could persist for several months (98). The authors speculated that perioperative hemolysis had caused an increase in unconjugated bilirubin and the release of ultrafilterable oxaliplatin, which had previously been confined to the intraerythrocytic compartment. In addition, diffusion of ultrafilterable

© 2006 Elsevier B.V. All rights reserved.

oxaliplatin out of erythrocytes into the plasma during hemodilution can contribute to the undesirable perioperative increase in unbound oxaliplatin in the plasma.

There is a correlation between the total dose of cisplatin and the vibratory perception threshold of the hand (99).

Dose-relatedness

When three different schedules of cisplatin were evaluated with regard to the drug's neurotoxicity, using the same dose of 450 mg/m^2 for each of the schedules, it was found that cisplatin-induced peripheral neuropathy depended on both total-dose and single-dose intensity (100).

Neurotoxicity in 22 adolescents was related to the prior cumulative dose of cisplatin that had been received; the relative risk increased 3.2-fold up to a dose of 600 mg/m^2, and 4.1-fold up to a dose of 1340 mg/m^2 (101).

By comparing 50 mg/m^2 weekly with 75 mg/m^2 3 times weekly, using detailed neurological and neurophysiological examination, it has been concluded that cisplatin neuropathy is either of sensory or axonal type, and that both are related to total and single doses (102). However, others have suggested that cisplatin-induced peripheral neurotoxicity is related to dose intensity rather than to the total dose received (103).

A 4-year follow-up of comparison of a combination of cyclophosphamide with cisplatin either 50 mg/m^2 or 100 mg/m^2 in ovarian cancer has been reported (104). Peripheral neuropathy was dose-limiting and persistent. Ten of 31 patients had significant toxicity in the high-dose group compared with one of 24 in the low-dose group.

High-dose cisplatin therapy

The use of aggressive hydration using hypertonic saline and sodium thiosulfate, with dose-scheduling, reduces the risks of dose-limiting nephrotoxicity of cisplatin, and this has made possible the use of high-dose cisplatin (over 200 mg/m^2/course). However, such doses can cause severe chronic peripheral neuropathy, ototoxicity, and myelosuppression, although these effects can be reduced by lengthening the infusion time of cisplatin (65). Peripheral neuropathy is the commonest manifestation of cisplatin neurotoxicity; with high-dose administration the incidence and severity increase with the total dose, and it appears to be age-related. It was not seen in 47 children treated with high-dose cisplatin (40 mg/m^2/day for 5 days) for neuroblastoma (105). Autonomic neuropathy, motor neuropathy, and denervation changes in muscles occur occasionally.

In a clinical and electrophysiological study of eight patients treated with high-dose cisplatin (800–1400 mg) plus etoposide and bleomycin, all developed a peripheral sensory neuropathy (106). A reduction in vibratory sensation was the earliest manifestation of the neuropathy and the findings were compatible with primary damage to the dorsal root ganglia with a central-distal axonopathy. No motor nerve abnormalities were detected, apart from one patient with carpal tunnel syndrome, but two patients had prolonged brain-stem auditory-evoked potentials, indicating a central transmission defect. In another clinical and electrophysiological study of seven patients treated with cisplatin, the sensory neuropathy was also axonal, with considerable involvement of proprioception (107). Postmortem study in one case showed degeneration of the posterior columns of the spinal cord and evidence of neuronal loss in the lumbar spinal ganglion.

Eleven patients referred for neurological evaluation after cisplatin infusion into the internal or external iliac arteries for pelvic or lower limb tumors all developed symptoms within 48 hours of nerve or plexus dysfunction within the territory supplied by the cannulated artery (108). The lumbosacral plexus was affected in nine patients, the femoral nerve in one, and the peroneal nerve in one. The doses of cisplatin ranged from 50 to 160 mg/m^2 and they did not correlate with the severity or course of the neuropathy. Small-vessel injury and infarction or a direct toxic effect are likely explanations.

Time-course

In a study of the time-course and prognosis of cisplatin-induced neurotoxicity (for example sural nerve sensory action, conduction velocity, and vibration threshold in the left big toe) in 29 patients with metastatic germ cell tumors, the onset of paresthesia was delayed (109). After completion of chemotherapy (3–4 cycles) only 11% of the patients had neurotoxic symptoms, whereas 3 months later the proportion was 65%. Cisplatin-induced neurological disorders should therefore be evaluated at 1–4 months after the end of weekly cisplatin administration, because during this time the most severe form of cisplatin neurotoxicity is to be expected. There was resolution of symptoms in most of the patients over the next 12 months, suggesting that in some individuals a long period of regeneration is required to restore axonal sensory function. In patients with mild signs of cisplatin-related neuropathy, retreatment is generally feasible after several months (110,111).

Management

Among several thiol compounds, glutathione may provide neuroprotection in patients treated with cisplatin without altering its antineoplastic activity. This protective role may be based on blockade of the accumulation of p53 protein in response to platinum in dorsal root ganglia, thereby hindering platinum-based apoptosis (57,112).

The melanocortin Org 2766, an ACTH analogue, which is not yet available for clinical use, alleviates neurotoxicity due to vinca alkaloids and cisplatin, perhaps by enhancing neural repair. However, whereas preliminary results suggested some neuroprotection in women with ovarian cancer treated with cisplatin, these results were not confirmed in a randomized, multicenter, double-blind, placebo-controlled dose-finding study, even with higher doses of Org 2766 (113).

There is evidence that amifostine can reduce the frequency of cisplatin-induced peripheral neuropathy, allowing higher mean cumulative doses to be used. However, some of the results should be interpreted with caution, because the studies included patients who differed in respect to treatment regimen, disease states, and pretreatment status. The underlying protective effect of amifostine may be based on its capacity to scavenge

© 2006 Elsevier B.V. All rights reserved.

free radicals and prevent cisplatin DNA adduct formation in several organs, including the dorsal root ganglia (57).

In a pilot study in 15 patients, subcutaneous amifostine was given 20 minutes before oxaliplatin, in order to counteract oxaliplatin-induced peripheral neurosensory toxicity. In 10 patients, this regimen reduced the severity of cumulative neuropathy without compromising antitumor efficacy; the amifostine was well tolerated (114).

There is increasing evidence that acute oxaliplatin-induced neurotoxicity can be improved by intravenous infusion of calcium gluconate 1000 mg and magnesium sulfate heptahydrate 1000 mg before and after oxaliplatin. It has recently been shown that this strategy could reduce the incidence of acute neurotoxic symptoms, including laryngopharyngeal dysesthesia. Of 101 patients with advanced colorectal cancers who received folinic acid (leucovorin), 5-fluorouracil, and oxaliplatin (85 mg/m^2/2 weeks, 20 patients; 100 mg/m^2/2 weeks, 22 patients; 130 mg/m^2 /3 weeks, 59 patients), 63 received infusions of calcium and magnesium (1 g each) before and after oxaliplatin administration (treatment group); 38 patients (control group) did not receive infusions of calcium + magnesium. The median cumulative dose of oxaliplatin was 910 (range 255–2340) mg/m^2 in the calcium/magnesium group and 650 (range 255–1450) mg/m^2 in the control group. At the end of treatment, 27% had neuropathy (any grade) compared with 75% in the control group; 1.6% and 26% had pharyngolaryngeal dysesthesia; and 5% and 24% had grade 3 neuropathy. However, further studies are warranted before this regimen can be generally recommended for reducing the risk of acute neurosensory symptoms associated with oxaliplatin infusion (77,115).

Carbamazepine is a potent sodium channel blocker and has therefore been studied in the prevention of oxaliplatin-induced neuropathy (116). The doses of carbamazepine were adjusted to produce serum concentrations in the range 30–60 μg/ml. None of the patients who took carbamazepine reported symptoms of peripheral neurotoxicity; however, two patients (one who forgot to take carbamazepine and one who stopped taking it because he felt tired) developed grade-1 peripheral sensory neurotoxicity. These symptoms were abolished when carbamazepine was restarted. One can therefore speculate that the concomitant use of carbamazepine may allow the use of a higher cumulative dose of oxaliplatin without the occurrence of grade-4 neuropathy. However, a multicenter trial is warranted to confirm these encouraging preliminary results (117).

In 15 patients with metastatic colorectal cancer who were given gabapentin (100 mg bd or tds) if neuropathic symptoms developed with oxaliplatin, the symptoms disappeared in all patients, even in those who received up to 14 courses of oxaliplatin. Withdrawal of gabapentin resulted in recurrence. However, a controlled trial is required to verify these encouraging preliminary results.

It has been suggested that chronomodulated delivery of oxaliplatin might reduce the incidence of platinum-induced neurotoxicity (118,119). In a randomized, multicenter trial in patients with previously untreated metastases from colorectal cancer, 93 patients were assigned chronotherapy and 93 were assigned constant-rate infusion (120). Chronotherapy reduced the rate of severe mucositis five-fold and halved the rate of functional impairment from peripheral sensitive neuropathy. Median and 3-year survival times were similar in the two groups.

Preliminary results have suggested that glutathione may be neuroprotective in patients receiving oxaliplatin (121).

Sensory systems

Eyes

Ocular effects, including optic neuritis, papilledema, and retrobulbar neuritis, are uncommon adverse effects of cisplatin-containing cancer chemotherapy. The risk of retinal toxicity is restricted to high-dose cisplatin therapy (for example 200 mg/m^2 over 5 days) and can result in blurred vision and altered color perception, which can persist for several months. In contrast to cisplatin, carboplatin is seldom involved in drug-induced visual disturbances. In two cases there was a relation between the administration of carboplatin (800–1200 mg/m^2) and the occurrence of clinical cortical blindness (122). However, both patients had impaired renal function before the start of therapy with carboplatin.

- Ocular toxicity of cisplatin has been reported in a 47-year-old woman who experienced rapid uncontrollable eye movements associated with hypomagnesemia and hypocalcemia in the presence of renal tubular damage (123).

Ears

Cisplatin is ototoxic (95).

Frequency

In serial audiometric testing in 66 patients receiving cisplatin 100 mg/m^2 per course, of 39 evaluable patients, 54% had no or mild hearing loss, 36% developed early hearing loss and 10% had late loss. If early hearing loss occurred and treatment was nevertheless continued, the speech frequencies were eventually affected in 71% of patients (124).

Dose-relatedness

Tinnitus and bilateral high-frequency hearing loss (threshold 3000 Hz) have been observed in up to 31% of patients treated with initial intravenous doses of cisplatin of 50 mg/m^2. There is considerable individual variation in susceptibility to cisplatin-induced ototoxicity, and both peak plasma concentrations and cumulative dose are important. Transient reversible tinnitus occurs commonly, even after low doses, but hearing impairment is more dose-dependent and affected by age, renal function, preexisting inner ear damage and concomitant loop diuretic and/or aminoglycoside treatment. In in-vitro studies, selective damage to hair cells in the cochlea and in the supporting cells in the cochlear and vestibular parts of the labyrinth has been shown, with arrest of morphogenesis and cytodifferentiation. Morphological changes in the stria vascularis have been noted (125).

An attempt has been made to quantify the ototoxic effects of cisplatin in children by cumulative platinum dose and decibel hearing loss at certain predetermined frequencies. The findings provide useful insight into this

© 2006 Elsevier B.V. All rights reserved.

toxicity (126). In a study of cisplatin ototoxicity in children it was concluded that 77% experienced ototoxicity with a median cumulative dose of 360 mg/m^2 (127). However, when cisplatin was given by continuous infusion rather than bolus administration in 39 children with germ cell tumors, only one, who had received a total cumulative dose of 500 mg/m^2, had evidence of significant ototoxicity over 6 years after diagnosis (128).

In a series of 154 audiograms, ototoxicity increased with cumulative dosage of cisplatin and low-dose or monthly regimens caused the lowest toxicity (129). Patients who were given high doses over short periods of time, or who developed tinnitus and hearing loss in the speech frequencies, were at the highest risk. In a small series of patients it was confirmed that pretreatment hearing loss does not increase the risk of cisplatin ototoxicity (130). It has been postulated that cisplatin ototoxicity is inversely related to the patient's age (131). A 600 mg/m^2 plateau dose of cisplatin, beyond which hearing loss shows no apparent further deterioration in children and adolescents, has been described (132).

Presentation

Progressive hearing loss develops as a result of repeated administration of cisplatin, until a threshold plateau is reached at 3000–8000 Hz (133). Hearing loss greater than 20 dB with frequency as 5% at 1000 Hz, 31% at 2000 Hz, 59% at 4000 Hz, and 95% at 8000 Hz is described (132). This is the result of damage to the organ of Corti. The ototoxicity is bilateral, symmetrical, progressive, and irreversible. Following one course of cisplatin (150–225 mg/m^2) the mean hearing loss recorded was 27 dB at 8000 Hz, 21 dB at 6000 Hz, and 11 dB at 4000 Hz. Development of hearing loss is independent of pretreatment hearing function (134). Sudden bilateral deafness without tinnitus has been described after a single course of cisplatin at a dose of 120 mg/m^2; the patients showed only slight improvement after 4 weeks (135).

Of 186 women receiving cisplatin 50 mg/m^2 4-weekly for gynecological cancers, 40 developed significant hearing loss of at least 15 dB, but there was no significant loss in the speech frequency range (125). Prior hearing acuity did not influence the incidence or extent of the deterioration.

Susceptibility factors

Susceptibility factors include young age, previous cranial irradiation, pre-existing renal dysfunction or inner ear damage, and the concomitant use of other potentially ototoxic agents, such as aminoglycosides, loop diuretics, or tirapazamine (129,136–142). Previous use of an aminoglycoside increases the risk of ototoxicity. Younger patients and patients who had undergone prior cranial irradiation are more particularly susceptible to audiological changes, which progress in severity with increasing dose (143).

Mechanisms

The mechanisms of cisplatin-induced damage to the outer hairy cells of the cochlea may include the formation of highly reactive oxygen radicals and depletion of glutathione (144). The role of amifostine and glutathione in preventing cisplatin-induced ototoxicity has therefore been studied (145,146). The data are not sufficient to support the use of glutathione in this indication. In contrast, there is some evidence that amifostine may provide protection (147). No ototoxicity developed in 18 patients who received amifostine over 15 minutes, 15–20 minutes before the intravenous administration of cisplatin 50–120 mg/m^2 over 20 minutes. There was transient hearing loss and mild persistent audiometric abnormalities in only 30% of the patients who received cisplatin 150 mg/m^2.

Animal experiments show that cisplatin is only weakly vestibulotoxic (148), and clinical vestibular toxicity is found less often than hearing loss. Of 10 patients who received 80–550 mg cisplatin, clinical features of vestibulotoxicity were analysed in addition to hearing, and patients underwent audiometry, body sway, caloric, and optokinetic and pendular rotation testing (149). Four patients sustained significant hearing loss, five had tinnitus, and three complained of dizziness, giddiness, and/or unsteadiness rather than vertigo. These symptoms were transient, and they occurred usually after several weeks of administration; they were not consistently dose-related. Spontaneous nystagmus was observed in seven and positional nystagmus in six. Caloric and body sway tests were abnormal in the early stages in several patients. The findings were suggestive of a cumulative toxic effect.

In an in-vitro study of the adverse effect of cisplatin on hair cells and other inner ear structures, aimed at determining whether selective damage occurs in inner ear hair cells and whether morphogenesis and cytodifferentiation are influenced by low cisplatin concentrations, even at low cisplatin concentrations (0.1 μg/ml) there was selective damage to hair cells. Incubation at a cisplatin concentration of 1 μg/ml caused morphological damage in the supporting cochlear and vestibular cells, and 10 μg/ml caused total collapse of the membranous labyrinth. Drug exposure arrested morphogenesis as well as cytodifferentiation (150).

Auditory brainstem responses have been used to detect ototoxicity from cisplatin and carboplatin when used in combination therapy (95). The method can detect early high frequency damage due to these drugs up to two or three cycles earlier than conventional audiometry.

The ototoxicity of cisplatin has been studied using distortion-product otoacoustic emissions (DPOAEs) and conventional pure-tone audiometry (151). Cisplatin ototoxicity was detected on average one cycle earlier with DPOAEs than with pure-tone audiometry. The authors suggested that this was because DPOAEs are more sensitive to outer hair cell damage.

Carboplatin and oxaliplatin

In one study only 1.1% of evaluable patients taking carboplatin had ototoxic symptoms, such as tinnitus, or subclinical audiographic changes (152). However, in a series of closely monitored patients there was an incidence of 27% (129). It has also been estimated that 19% of patients receiving carboplatin have significant hearing loss greater than 30 dB; the hearing loss is cumulative and maximum at 8000 Hz; the authors reported two of these patients with hearing loss greater than 10 dB at

© 2006 Elsevier B.V. All rights reserved.

1000 Hz. The overall conclusion is that with low-dose, short-schedule, carboplatin therapy, routine audiometry is not justified (152).

After otoacoustic emission testing in 19 children who received cisplatin the authors suggested that this is better at detecting the early cochlear damage associated with cisplatin ototoxicity than traditional pure-tone audiometry, particularly in children, in whom early detection is of the utmost importance (153). In patients who receive high-dose carboplatin, preliminary results suggest that there may be a correlation between the risk of ototoxicity and carboplatin serum concentrations (AUC) during the first course. Patients with high-grade ototoxicity had higher median carboplatin AUCs than patients without any symptoms (122,154).

In another study, carboplatin-induced ototoxicity was reported in 32% of exposed patients. This was similar to cisplatin ototoxicity, although at a lower frequency (4000–8000 Hz) than the often-quoted 6000–8000 Hz for cisplatin. The extent of otic damage was proportional to the dose of carboplatin (155).

Audiological testing has been recommended for patients receiving high-dose carboplatin therapy, following hearing problems in a series of 10 patients with ovarian cancer (156).

There is no evidence that oxaliplatin causes ototoxicity (157).

Smell

About 30% of patients treated with cisplatin have been reported to have some degree of anosmia, which in 1% is severe or complete; the sense of smell returns to normal within 3–4 months of completing cisplatin therapy (158).

Endocrine

The endocrine effects of cisplatin-based chemotherapy were studied in 22 men 9–24 or more months after completion of treatment for germ cell tumors (159). Mean basal FSH and stimulated LH and FSH concentrations were increased but serum testosterone concentrations were similar to untreated controls. Younger patients (under 25 years old) appeared more resistant to these effects of chemotherapy, and the hormonal abnormalities recovered with time.

The long-term effects on Leydig cell function of chemotherapy in 244 patients with germ cell tumors have been studied by measuring concentrations of sex hormone-binding globulin, luteinizing hormone, and follicle-stimulating hormone at least 74 months after chemotherapy (160). The population was divided into groups by cumulative cisplatin exposure (above and below 400 mg/m^2). Low-dose cisplatin exposure had no effect on Leydig cell function, but cumulative high-dose chemotherapy caused persistent impairment.

Metabolism

- Hyperosmolar non-ketotic hyperglycemia occurred in a 61-year-old patient 6 days after a first cycle of cisplatin therapy (161). The patient recovered with conventional conservative management.

Electrolyte balance

Hyponatremia is rare, and persistent hyponatremia very rare in patients taking cisplatin (162). In a detailed description of the biochemical abnormalities that can result from renal tubular dysfunction after cisplatin therapy, it was noted that hypocalciuria is more common than hypomagnesemia, and that there tends to be a state of reduced serum bicarbonate. The most severe renal tubular damage caused by cisplatin is characterized by hypocalciuria, total body magnesium deficiency, and hypokalemic metabolic alkalosis (163).

Other electrolyte disturbances induced by cisplatin include hypocalcemia, hypophosphatemia, hyponatremia, and hypokalemia (164,165). However, these changes are rarely associated with symptoms (166,167).

Metal metabolism

Magnesium

About 75% of patients treated with cisplatin develop hypomagnesemia (serum concentrations below 1.5 mmol/l), which appears to be associated with drug-induced renal tubular damage (168–171). The symptoms include tetany, muscular weakness, tremulousness, dizziness, personality changes, and perioral and peripheral paresthesia (172). Magnesium supplementation is generally recommended during treatment courses with cisplatin (168,170). Sometimes, hypomagnesemia resolves rather slowly and can last several weeks. A significant reduction in serum magnesium and other effects associated with progressive renal dysfunction appear to correlate with high cumulative doses of carboplatin (for example a median cumulative dose of 2590 mg/m^2 in children or in adults undergoing high-dose chemotherapy with peripheral blood stem cell support).

Renal magnesium wasting is the main mechanism responsible for the hypomagnesemia associated with cisplatin (172), and it can be associated with enhanced tubular reabsorption of calcium and consequent hypocalciuria (173). This dissociation in the renal handling of calcium and magnesium is similar to what is found in Bartter's syndrome. The site of the renal tubular defect in these conditions is not known, but there is evidence that active renal tubular transport systems are disrupted.

In a prospective study of 28 patients who received a total of 82 doses of cisplatin, hypomagnesemia occurred in all patients and was associated with significant and prolonged dose-related magnesium wasting. Serum magnesium was 1.8 mg/dl after the fourth dose. Examination of the urine sediment 2–4 days after each dose of cisplatin showed renal tubular epithelial cells, suggesting that cisplatin directly injures the tubules, leading to reduced tubular reabsorption of magnesium, renal magnesium wasting, and hypomagnesemia (174). In another study, patients receiving cisplatin and concomitant magnesium supplementation developed significantly less renal tubular damage, as assessed by urine *N*-acetyl-β-D-glucosaminidase (175). No patient developed clinical signs of hypomagnesemia when intravenous or oral supplementation of magnesium was given as soon as the serum magnesium fell to or below 0.45 mmol/l. In patients receiving intracavitary cisplatin in high doses (100–200 mg/m^2), together with

© 2006 Elsevier B.V. All rights reserved.

intravenous thiosulfate, there was a lower incidence of hypomagnesemia as a result of the thiosulfate; thiosulfate probably inactivated cisplatin before it reached the kidney, by complex formation (176).

Hypomagnesemia secondary to cisplatin administration can be severe enough to present as generalized seizures (172). It more commonly presents with muscular weakness, tremulousness, peripheral paresthesia, tetany, and personality changes. It is dose-related and schedule-related. Loss of magnesium can be prevented by prophylactic magnesium infusion before and during cisplatin administration (177), but this is not universally recommended because of the risk of acute uremia (178).

Zinc

Hyperzincuria and hypozincemia can occur concurrently in patients treated with cisplatin, due to variable excretion of zinc in these cases (179).

Hematologic

Compared with cisplatin and oxaliplatin, carboplatin has the highest myelotoxic potential. Carboplatin-induced myelosuppression is dose-related and results in thrombocytopenia and neutropenia. At conventional doses (AUC 4–7 minutes/μg/ml) about 20–40% of patients develop thrombocytopenia (platelet counts below 50×10^9/l). In contrast, severe neutropenia is less pronounced with conventional doses; about 16–21% of patients develop neutrophil counts less than 1×10^9/l. The lowest leukocyte and platelet counts usually occur at 14–28 days after drug administration. The hemoglobin concentration was below 11 g/dl in 71–91% of patients and below 8 g/dl in 8–21% (155). The severity of drug-induced thrombocytopenia is inversely correlated with the endogenous formation and release of thrombopoietin, which is an important cytokine for de novo platelet formation in the bone marrow. In contrast to conventional dosages, high-dose chemotherapy containing carboplatin is generally associated with severe and life-threatening forms of hematological toxicity, requiring the prophylactic use of recombinant hemopoietic growth factors, such as G-CSF, and peripheral blood stem cell support (180).

Underlying risk factors, which predispose patients to more severe forms of myelosuppression, include lower initial blood cell counts, renal impairment, poor performance status, extensive prior chemotherapy, and advanced age. There is a strong correlation between carboplatin pharmacokinetics and the severity of myelosuppressive adverse effects; an AUC-adapted dosage of carboplatin is therefore highly recommended during conventional dose chemotherapy (22,23,155).

Cisplatin belongs to the most important causative agents for the induction of treatment-related anemia requiring the prophylactic use of erythropoietin or intermittent transfusion of erythrocytes, whereas drug-induced leukopenia and thrombocytopenia are generally mild and transient (180,181). In a pharmacokinetic study, non-protein-bound platinum concentrations in patients with significant falls in hemoglobin (3 g/dl or more) were significantly higher (mean 53 ng/ml) than in patients who did not have significant falls in hemoglobin. The authors suggested that early and simple platinum pharmacokinetic control on the day after first drug administration might be useful in targeting patients who are likely to develop more severe forms of cisplatin-related anemia (182).

Myelosuppression caused by oxaliplatin is generally mild. Grade 3/4 anemia, neutropenia, and thrombocytopenia are observed in only 2–3% of patients. In combination with fluorouracil/folinic acid, the frequency is slightly higher, depending on the dose of fluorouracil (8,9).

Cisplatin causes an increase in erythropoietin, but anemias associated with platinum therapy are independent of this mechanism (183).

Forty patients with lung cancer, treated with a combination of cisplatin, mitomycin, vinblastine, doxorubicin, cyclosphosphamide, and methotrexate, had a significant post-treatment increase in fibrinopeptide A and a fall in fibrinolytic activity, reflected by a fall in functional tissue activator; this appeared to be cumulative, depending on the extent of drug exposure (184).

Gastrointestinal

Of the approved platinum compounds, cisplatin has the greatest emetogenic potential (185). Whereas about 65–94% of patients who receive conventional dosages of carboplatin complain of mild to moderate nausea or vomiting, more than 90% of those who receive cisplatin can have more than 10 vomiting episodes within the first day of administration in the absence of effective antiemetic therapy. An emetogenic episode occurring within 24 hours after drug administration is usually classified as acute emesis; nausea and vomiting that occur thereafter are classified as delayed emesis and may persist over several days. There appears to be a correlation between the time of cisplatin administration and the severity of drug-induced vomiting (186). When cisplatin was given in the morning (0500 hours) vomiting was greater than when it was given in the evening (1700 hours). However, the prophylactic use of a 5-HT_3 receptor antagonist reduced the time-of-day dependency. 5-HT_3 receptor antagonists, such as dolasetron, granisetron, ondansetron, palonosetron, or tropisetron, particularly in combination with dexamethasone, reduce the severity of acute emesis occurring within the first 24 hours after cisplatin. In contrast, the satisfactory prevention of delayed emesis remains a challenge. There is increasing evidence that the introduction of a novel class of antiemetic agents, the neurokinin-1-receptor antagonists, such as MK869 (aprepitant), may be associated with additional benefit in combination with a 5-HT_3 receptor antagonist in reducing cisplatin-induced nausea and vomiting, both acute and delayed (187).

Nausea, vomiting, and diarrhea are common adverse effects of oxaliplatin and carboplatin, but they are generally mild to moderate, and both are less emetogenic than cisplatin. However, patients who have previously received cisplatin may be at greater risk of vomiting with carboplatin or oxaliplatin (1,8,9).

In an endoscopic study of the acute gastroduodenal toxicity of intravenous cisplatin 10 mg/m^2 and etoposide 107 mg/m^2 (mean dose) given for three doses, a significant number of patients developed gastroduodenal lesions, several of which progressed (188).

© 2006 Elsevier B.V. All rights reserved.

Liver

Mild reversible increases in liver function tests can occur in patients who have received platinum compounds (189). However, the platinum compounds are generally not classified as hepatotoxic drugs.

Urinary tract

Cisplatin

Of the approved platinum compounds, cisplatin has the greatest nephrotoxic potential, and the nephrotoxicity is often dose-limiting (190). If dosages exceed 100 mg/m^2 per course or per day, nephrotoxicity is the most severe drug-related adverse effect. It is mainly due to proximal tubular dysfunction (191), with hydropic degeneration, necrosis, and occasional tubular atrophy. Fragments of distal tubular cells have been demonstrated in the urine of patients receiving chemotherapy that included cisplatin (192). The risk is reduced by adequate hydration, which lowers drug concentrations in the renal tubules. Impaired renal function can persist for at least 6 months after treatment has been withdrawn. Indicators of cisplatin-related renal tubular toxicity include changes in creatinine clearance or in urinary alanine aminopeptidase and *N*-acetyl-*β*-D-glucosaminidase activities. Blood urea nitrogen and serum creatinine are poor indicators of early renal damage. The nephrotoxicity of cisplatin is primarily tubular, although changes in renal blood flow and glomerular filtration also occur, and hypomagnesemia is common (SEDA-12) (193,194).

The mechanisms of cisplatin-induced nephrotoxicity have not been fully elucidated. Like several nephrotoxic heavy metals (for example mercury), cisplatin can accumulate in the kidney, where it can interact with sulfhydryl compounds, resulting in increased membrane fragility and depletion of intracellular glutathione. There is some evidence that cisplatin can induce apoptosis and necrosis of kidney cells dose-dependently. In vitro studies have suggested that the constitutive expression of antiapoptotic proteins (for example *bcl*-X) might be inversely correlated with the sensitivity of renal tubular cells (146,195–197).

Cisplatin-induced nephrotoxicity can be detected by a rise in blood urea or by a fall in creatinine clearance. Tubular dysfunction can cause hyponatremia (72), hypokalemia, hypomagnesemia (173), and hypophosphatemia. Inappropriate ADH secretion may be partly responsible for hyponatremia (191).

In experiments in mice, the trace element selenium, which interacts with heavy metals, reduces the renal, intestinal, hepatic, and hematological toxicity of cisplatin without affecting its antitumor activity (198).

Regarding prolongation of infusion, it has been suggested that there is a correlation between higher plasma platinum concentrations and the risk of cisplatin-induced nephrotoxicity. If platinum concentrations exceed 6 μg/ml, more patients develop nephrotoxicity. These drug concentrations were measured shortly after the end of infusion (for example 5 minutes after intravenous infusions of 100–120 mg/m^2), suggesting that high blood concentrations rather than trough concentrations may be predictively important. As a result, prolongation of cisplatin infusion (for example 6 hours) has been proposed to reduce the risk of cisplatin-induced renal insufficiency (147,199). However, in practice, a 1-hour infusion remains the common standard.

In 35 children who had taken cisplatin for a maximum of 2 years, nephrotoxicity was not related to total dose but was less severe in children who received cisplatin in doses below 40 mg/m^2/day (200). During follow-up for 2 years there was partial but significant recovery of renal function.

The effect of age on nephrotoxicity after treatment with ifosfamide or cisplatin has been studied (201). Children aged 5 years or less had more severe proximal tubular toxicity associated with ifosfamide than older patients. They also had significantly lower plasma phosphate concentrations and a higher fractional excretion of glucose. There was no evidence of glomerular or distal renal tubular damage after ifosfamide and there was no difference between the older and younger children in any other aspect of renal function. In general, age predicts independently the likelihood and severity of genitourinary toxicity caused by cisplatin in combination chemotherapy (202).

Several supportive measures have been proposed in order to circumvent cisplatin-induced nephrotoxicity. These include:

- adequate hydration before and during cisplatin administration and afterwards, in combination with an osmotic diuretic such as mannitol (the current standard method);
- prolongation of the infusion time (for example 6 hours instead of 2 hours);
- fractionation over several days;
- the use of a chronomodulated schedule;
- the use of nephroprotective agents, such as organic thiosulfate compounds.

Sodium thiosulfate protects against cisplatin-induced nephrotoxicity by reacting covalently with cisplatin in the renal tubules. Other protectors include probenecid, orgotein, fosfomycin (203), amifostine (2-[3-aminopropyl) amino]ethylphosphorothioic acid, WR-2721, ethyofos), and anthiol. Experimental study drugs that may be useful in renal protection include BNP7787 (dimesna), selenium, and silibinin (146,204–212). The beneficial role of furosemide is uncertain.

Amifostine is an organic thiophosphate. It is a prodrug, because dephosphorylation by tissue-bound alkaline phosphatase is necessary to form its active metabolite, WR-1065. It protects normal tissues against the toxic effects of radiation, cisplatin, and alkylating agents in animals, perhaps through free radical scavenging, hydrogen ion donation, and the prevention or removal of DNA platinum adducts (213). Amifostine has been used in the pretreatment of patients with metastatic melanoma before administration of cisplatin 60–150 mg/m^2 in an uncontrolled trial of 36 patients (214). There was a response rate of 53% and a low incidence of nephrotoxicity; transient nephrotoxicity occurred in 4% of 82 courses of amifostine given with cisplatin 120 mg/m^2.

In a randomized study, 242 patients with advanced ovarian cancer received intravenous cisplatin 100 mg/m^2 and cyclophosphamide 1000 mg/m^2 once every 3 weeks with or without amifostine 910 mg/m^2. Besides a

© 2006 Elsevier B.V. All rights reserved.

significant reduction in chemotherapy-induced neutropenia and thrombocytopenia, amifostine produced significant protection against cisplatin-induced nephrotoxicity. Creatinine clearance fell by more than 40% in 60% of the control group compared with 12% of those in the treated group. In addition, the incidence of cisplatin-related hypomagnesemia was less pronounced in the patients who received amifostine.

Dose fractionation over several days has been associated with less kidney damage. The glomerular filtration rate was maintained in patients who received cisplatin 20 mg/m^2/day over 5 consecutive days (215,216). However, patients still had a significant increase in sensitive urinary markers, such as low molecular weight proteins, *N*-acetyl-β-D-glucosaminidase (NAG), and α–1-microglobulin, showing that conventional approaches can reduce but not completely prevent nephrotoxicity (146,195).

Chronomodulated administration of cisplatin can also reduce drug-induced organ toxicity, for example nephrotoxicity (217,218). Administration of cisplatin in the evening caused markedly less nephrotoxicity and neurotoxicity than morning administration. There is also increasing evidence that all platinum-based anticancer drugs are better tolerated if they are given in the late afternoon or early evening, with less frequent and severe nephrotoxicity, thrombocytopenia, and cumulative peripheral neuropathy after cisplatin, carboplatin, and oxaliplatin. As chronomodulated scheduling appears to affect the adverse effects of all platinum compounds, the mechanism may be based on circadian variation in renal tubular excretion and plasma filtration of platinum compounds, increased plasma protein binding, and reduced tissue susceptibility at about 1600 hours (217–219).

In several studies, intravenous amifostine (910 mg/m^2) preserved glomerular filtration rate when it was co-administered with cisplatin-containing regimens (213). Even after two cycles containing intravenous cisplatin 50 mg/m^2 plus intravenous ifosfamide and etoposide or paclitaxel, glomerular filtration rate can fall by more than 30%, but concomitant use of amifostine prevented this. Even lower dosages of intravenous amifostine (for example 740 mg/m^2) may be effective (220,221).

Because preclinical results suggested that intracellular glutathione may be involved in the modulation of cisplatin-induced toxicity, several trials (two uncontrolled and two randomized) have been conducted to evaluate the efficacy and tolerability of standard doses of cisplatin with concomitant glutathione. In some studies, glutathione reduced cisplatin-related toxicity without impairing its antineoplastic activity (113). However, a cisplatin dose-escalation study with concomitant administration of glutathione had to be terminated prematurely because of unacceptable ototoxicity. Glutathione has not yet received FDA approval for chemoprotection.

Carboplatin

When carboplatin is used in doses that cause similar hematological toxicity to cisplatin, it has negligible renal, neurological, and auditory toxicity (222,223). In combination with other cytotoxic agents, the maximum tolerated dose is less than normal because of the risk of myelosuppression (224). However, if the dose is increased, as in acute non-lymphocytic leukemia, high-tone hearing loss and renal impairment can occur (225). In this study, all but one patient who developed these adverse effects had also received aminoglycoside antibiotics.

Concomitant intravenous hydration and monitoring is not needed when carboplatin is given in conventional dosages. However, during dose-intensified treatment with carboplatin, the risk of impaired renal function increases. In addition, other nephrotoxic drugs, such as ifosfamide, are often part of those high-dose combination regimens. During a study of the use of high-dose carboplatin (1500 mg/m^2/day or more) on 3 consecutive days, the nephrotoxic profile was comparable to a standard single dose of cisplatin (216).

Ultra-high-dose carboplatin can be safely administered as long as clinicians individualize and adjust the therapy to renal function using ^{51}Cr-EDTA glomerular filtration rate; there was only one death attributed to carboplatin in 31 patients who died of acute renal insufficiency (226).

Mild to moderate reduction in creatinine clearance with rises in serum urea and creatinine were reported in 14% of patients receiving carboplatin in a dose of 400 mg/m^2 for gynecological malignancies. Of the patients who received carboplatin 400 mg/m^2 with vincristine but without hydration for lung cancer, 19% developed renal changes.

During a 2-year follow-up of 23 children receiving carboplatin there were falls in both glomerular filtration rate to 22 ml/minute and serum magnesium concentration to 0.17 mmol/l (166). The authors thought that the fall in glomerular filtration rate, although statistically significant, was not clinically significant, but they were unsure about the long-term clinical effects of the low magnesium.

Intensified carboplatin-containing regimens can predispose patients to drug-induced renal dysfunction when cisplatin has previously been used or when renal function is already impaired (167,227).

In a randomized study of the prophylactic use of amifostine during dose-intensified chemotherapy including carboplatin and ifosfamide, patients in the control arm had a median loss of glomerular filtration rate of 37% compared with baseline after one cycle, and 35% of these patients had glomerular filtration rates below 60 ml/minute on day 10 after treatment. In patients who received amifostine during dose-intensified chemotherapy, the glomerular filtration rate fell only by a median of 10% and no patient developed a glomerular filtration rate below 60 ml/minute by day 10 (228).

Oxaliplatin

Oxaliplatin, when given alone or in combination with fluorouracil, is considered not to be nephrotoxic (166,167,227). There has been a single case of acute tubular necrosis probably caused by oxaliplatin and not related to dehydration or pre-renal insufficiency (229).

Skin

Even in cases of accidental extravasation, the risk of skin ulceration is low. Severe cisplatin-related extravasation injury appears to be primarily restricted to the use of

© 2006 Elsevier B.V. All rights reserved.

high concentrations (for example 0.75 mg/ml) and infusion over a short time. In such circumstances it is advisable to give a local injection of isotonic thiosulfate solution (0.16 mol/l). Since carboplatin is more slowly activated than cisplatin to active DNA binding moieties and is more water-soluble, there have been no reports of severe carboplatin extravasation and no antidote is necessary (230,231).

- Accidental subcutaneous administration of oxaliplatin resulted in a red-brown painful swelling and sclerosis of the skin within 8 days (232). The symptoms were worst 1 week after extravasation and lasted for about 5 weeks, but the patient, a 52-year-old woman, recovered fully. Acute intervention included local fluid instillation to dilute the extravasation, removal of the cannula, cold packs, and a gel containing aescin and diethylamine salicylate.

Two other cases of oxaliplatin extravasation have been reported (233). Both occurred when the intraport needle disconnected. The initial symptoms were swelling and tenderness at the port site. The patients developed severe inflammation after 3 days. Treatment included local cool packs, diclofenac ointment, and oral indometacin, morphine, or dexamethasone. The authors avoided saline instillation because sodium chloride and oxaliplatin may be incompatible in combination (119). Both patients recovered without any sign of local necrosis and long-term sequelae (233)

Sexual function

Sexual function in men can be compromised by cisplatin + vinblastine + bleomycin chemotherapy. Of 54 patients, 29 had disorders of sexual function 2 years after completion of treatment (234). Ejaculatory dysfunction was tentatively linked to chemotherapy in 30% of those affected. There was reduced libido, usually reversible, in 40 at the time of chemotherapy.

Reproductive system

A cumulative dose–response toxic effect of cisplatin affects gonadal function when the drug is used in children around puberty; this damage is reversible in girls, but not in boys (235).

Immunologic

Cisplatin can cause anaphylactic shock, asthma, or urticaria (236). Hypersensitivity reactions, probably of type I, have also been reported after the administration of cisplatin, carboplatin, and oxaliplatin (237–243). Life-threatening allergy to cisplatin has also been reported after 16 doses of cisplatin 20 mg/m^2/week (244). These allergic reactions can include respiratory dysfunction (for example wheezing, dyspnea), gastrointestinal discomfort (for example abdominal cramps, diarrhea), and rashes (for example pruritus, urticaria, facial erythema, and swelling). The risk of exfoliative dermatitis is very low. In most patients, the first signs of hypersensitivity reactions usually occurred after the administration of multiple intravenous courses containing platinum compounds. Whether patients who are hypersensitive to one platinum compound also react to another cannot be excluded, since some case reports have suggested possible cross-reactions among platinum compounds (245). Sometimes, successful retreatment may be feasible through premedication with glucocorticoids and antihistamines (240).

The frequency of carboplatin-induced hypersensitivity reactions is 2–9%. Of more than 200 patients 16 had allergic reactions to carboplatin (246). According to one retrospective analysis, mild carboplatin-related hypersensitivity reactions, with itching and mild erythema, occurred in 20 of 194 patients, whereas 12 patients developed severe forms of reactions, including diffuse erythroderma, rigor, facial swelling, throat and chest tightness, tachycardia, bronchospasm, and hypertension or hypotension (243). The most important interventive measures in patients with severe forms of hypersensitivity reactions include intravenous adrenaline, glucocorticoids, and antihistamines.

Severe anaphylaxis has been reported in five patients who had already received several cycles (5–12) containing oxaliplatin 100 mg/m^2 every 2 weeks (241). The predominant symptoms included reduced systolic blood pressure, flushing, sweating, headache, tachycardia, and respiratory distress. If retreatment with the causative platinum compound is required in such cases, premedication with a glucocorticoid and antihistamine may prevent recurrence. However, symptoms can occur despite premedication, making drug withdrawal necessary.

There was a 12% incidence rate of hypersensitivity reactions in 205 women who received carboplatin as part of their treatment for gynecological malignancies (247). In trying to characterize these reactions, the authors noted that in about half of the patients, the reaction developed after more than half of their carboplatin had been infused, with a median number of exposures to carboplatin of eight cycles before the reaction.

An effective carboplatin desensitization protocol has been reported in a child with hypersensitivity, allowing additional months of carboplatin treatment (248). After premedication with diphenhydramine, ranitidine, and methylprednisolone, eight dilutions of carboplatin (0.01–50.0 mg) were given intravenously at 15-minute intervals at a rate of 1 mg/minute. Subsequently, carboplatin 600 mg was given as a continuous infusion over 3 hours without adverse effects. Whether desensitization is generally suitable for overcoming allergic adverse events should be tested prospectively (249).

The term "oxaliplatin-induced hypersensitivity reaction" can refer to:

1. acuteneurosensory symptoms;
2. a cytokine release syndrome related to increased plasma concentrations of interleukin-6 and tumor necrosis factor alfa;
3. an immunological reaction involving antibody formation and histamine release (238).

In order to prove an underlying allergic disorder, an intradermal skin test with commercial formulations of the platinum compound in different concentrations (for example 0.003–1 mg/ml) can be done (250).

© 2006 Elsevier B.V. All rights reserved.

Body temperature

Oxaliplatin is generally well tolerated. Some patients develop fever, which appears to be related to a transient increase in cytokines, particularly interleukin-6 and tumor necrosis factor alfa. In one study the oxaliplatin-induced increase in body temperature correlated with a marked increase in interleukin-6 serum concentrations (peak 133 pg/ml) (251). Interleukin-6 is a proinflammatory cytokine, which stimulates acute phase proteins and B lymphocytes. Premedication with metamizol, dexamethasone, and clarithromycin, which interferes with interleukin-6, did not prevent the fever. The roles of interleukin-6 and tumor necrosis factor alfa in the development of fever is strengthened by the observation that their serum concentrations fell during resolution of the fever (252).

Death

- Fatal acute tumor lysis syndrome has been reported in a 74-year-old woman who received cisplatin (50 mg/m^2 on day 1) and fluorouracil (1000 mg/m^2 by continuous infusion for 5 days) for vulvar carcinoma (253).

Whilst this is a well known complication of chemotherapy, particularly with hematological tumors, it is extremely rare as a complication of neoadjuvant chemotherapy for gynecological tumors.

Long-Term Effects

Tumorigenicity

There is some evidence that platinum compounds are mutagenic in bacteria and can cause chromosomal aberrations in animal cells in tissue culture (254). The risk of secondary leukemia in 28 971 patients with ovarian cancers receiving platinum-based chemotherapy has been evaluated; 96 developed a secondary leukemia (255). The authors concluded that the risk of developing a secondary leukemia while receiving a platinum-based protocol may be increased four-fold. The relative risks for carboplatin and cisplatin were estimated at 6.5 and 3.3 respectively. The relative risks of leukemia after cumulative doses of platinum of less than 500, 500–749, 750–999, and 1000 mg were 1.9, 2.1, 4.1, and 7.6 respectively. The delay between the start of platinum-containing chemotherapy and the occurrence of secondary malignancies was 2.8–7.7 years. In children who received an average cumulative dose of cisplatin of 600 mg/m^2, the estimated incidence of chemotherapy-induced leukemia was 1.5% (256). Concomitant radiation therapy or administration of other carcinogenic agents increases the risk.

Second-Generation Effects

Fertility

There is experimental evidence that several anticancer drugs can cause abnormalities of sperm chromosomes. Preliminary data have suggested that after platinum-containing chemotherapy for testicular cancer, penetration of oocytes can be severely impaired. Cytogenetic study of the spermatozoa has shown that many of the abnormalities correspond to structural aberrations that may not have a pathogenic effect in the production of abortions or children with chromosome abnormalities (257).

In men receiving chemotherapy, the sperm count will return to normal within 2 years of discontinuing chemotherapy in 78% of cases; however, intensive treatment, such as with doses of cisplatin in excess of 500 mg/m^2, reduces the probability of full recovery of normal spermatogenesis (258).

A Danish study group has reported a fertility problem of 53% in patients with unilateral germ cell tumors, but there was no significant difference between orchidectomy and cisplatin-based chemotherapy or subdiaphragmatic irradiation (259). Eight patients remained infertile despite evident recovery of spermatogenesis, and all 22 children conceived post-treatment were born normal and without malformations.

Gonadal function was evaluated in 59 men and 31 women after successful treatment of germ-cell tumors with the POMB/ACE regimen (cisplatin, vincristine, methotrexate, and bleomycin + dactinomycin, cyclophosphamide, and etoposide) (260). Most of the patients recovered fertility; 81% of the men who did not receive para-aortic radiotherapy, whose original tumor bulk was less than 5 cm in diameter, and whose duration of chemotherapy was less than 6 months recovered, compared with 32% who had larger tumors or who received longer courses of chemotherapy, or both. Fertility and pregnancies were undisturbed in 24 women with invasive trophoblastic tumors treated with methotrexate alone, with methotrexate and dactinomycin in combination, or with other combination chemotherapy (261). There were nine subsequent pregnancies, with the birth of eight healthy babies, and one woman requested a termination of pregnancy.

The long-term prognosis for sperm counts after chemotherapy with and without radiation in 71 males treated for non-Hodgkin's lymphoma on the CHOP-Bleomycin combination has been studied (262). Pelvic radiotherapy and cumulative cyclophosphamide dosages of greater than 9.5 g/m^2 are associated independently and in combination with a greater risk of permanent sterility.

Teratogenicity

Cisplatin and related compounds cross the placenta and can therefore cause fetal damage. Cisplatin is teratogenic in mice and embryotoxic in mice and rats. The platins should only be used during pregnancy in life-threatening situations. The patient should be informed of the potential hazard to the fetus (263).

Drug Administration

Drug administration route

There have been several reports of local neurotoxicity after intra-arterial cisplatin. In 63 patients pretreated with low-dose cisplatin given by arterial infusion for head and neck cancer (up to 25 mg/day for 1–10 days), before definitive local treatment, cranial nerve palsies developed on the same side as the cannulated artery in

© 2006 Elsevier B.V. All rights reserved.

four cases (264). There was ipsilateral involvement of the 9th, 10th, 11th, and 12th cranial nerves in two patients, and the 7th and 12th nerves alone were affected in the other two patients. The palsies appeared at the end of treatment or up to 10 days later and only the 12th nerve palsy in one of the patients with multiple cranial nerve involvement recovered completely. In each patient, no other cause for paresis was found and CT scans showed that the nerves were not infiltrated by tumor. The cumulative dose of cisplatin administered to these four patients was less than that received by the unaffected 59 patients (median 200 mg, range 160–250; compared with 250 mg, range 160–400).

Drug overdose

Irreversible renal insufficiency has been described after accidental overdosage with cisplatin.

- In a 68-year-old woman who received an accidental overdose of cisplatin (480 mg), there was severe vomiting and myelosuppression, irreversible renal insufficiency, and deafness; other effects included seizures, hallucinations, loss of vision, and hepatotoxicity (265).

Drug–Drug Interactions

Antiepileptic drugs

Plasma concentrations of antiepileptic drugs (for example carbamazepine, valproic acid, phenytoin) should be measured more frequently during cisplatin-containing cancer chemotherapy (266,267).

- Cisplatin caused subtherapeutic carbamazepine and valproic acid concentrations in a 38-year-old woman with epilepsy undergoing cytotoxic cancer chemotherapy with doxorubicin and cisplatin, resulting in tonic-clonic seizures; the mechanism was not clear (266).

Etoposide

- A 52-year-old patient with glioblastoma developed severe ocular and orbital toxicity after receiving intracarotid etoposide phosphate and carboplatin (268). Acutely non-pupillary block angle-closure glaucoma developed secondary to uveal effusion in the ipsilateral eye. Four days later, severe orbital inflammation resulted in reduced visual acuity, proptosis, optic neuropathy, and total external ophthalmoplegia.

Fluorouracil

The combination of cisplatin 100 mg/m^2 with 5-fluorouracil 1000 mg/m^2 for 7 days caused angina and ischemic electrocardiographic changes, suggesting synergistic cardiotoxicity (269). There have also been cases of arterial occlusive events (270) and myocardial infarction (271,272), in some cases with evidence of coronary vascular spasm (273,274).

In 39 patients given low-dose continuous fluorouracil and cisplatin 20 mg/m^2/week for 8 weeks, there was a very low incidence of renal toxicity, although electrolyte abnormalities, particularly hyponatremia and hypomagnesemia, were as expected (244).

Irinotecan

The concomitant use of irinotecan as a 1-hour infusion immediately following a 2-hour infusion of oxaliplatin resulted in more severe hypersalivation and abdominal pain than irinotecan monotherapy (275). Acute intervention with atropine alleviated these adverse effects. When the drugs were separated by 1 day, the cholinergic symptoms were not exacerbated. The authors postulated that oxaliplatin might have some acetylcholinesterase inhibitory activity.

Lithium

Some data have suggested that cisplatin-containing chemotherapy can alter lithium clearance through impaired renal function, and lithium therapy should be closely monitored during treatment with cisplatin-containing regimens (276).

Mesna

Platinum agents are combined with ifosfamide in the treatment of cancer. The possibility that mesna may interfere with the anticancer effects of platinum agents has been investigated using cultured malignant glioma cells (277). Mesna protected tumor cell lines from the cytotoxic effect of the platinum agents. This in-vitro study emphasizes the importance of specifying in detail the infusion schedules of mesna and platinum agents.

Methotrexate

A patient with no other risk factors developed irreversible nephrotoxicity after four cycles of carboplatin 300 mg/m^2 and methotrexate 50 mg/m^2 (278). This appears to have been an additive effect of drugs that are not individually nephrotoxic until much higher doses.

Nephrotoxic drugs

Based on its considerable nephrotoxic potential, cisplatin should be given after, rather than before, other anticancer drugs and other drugs with a low therapeutic index (for example aminoglycoside antibiotics or bleomycin) that are primarily excreted in the urine in unchanged form. Concomitant use of potentially nephrotoxic agents (for example conventional amphotericin, tacrolimus) with cisplatin should be avoided (279,280).

Neurotoxic drugs

The concomitant or previous use of potentially neurotoxic drugs (for example paclitaxel, vinca alkaloids, or hexamethylmelamine) can increase the risk of peripheral neuropathy due to platinum compounds (68,69).

Paclitaxel

There is some evidence that there is a clinically significant pharmacokinetic interaction of paclitaxel with cisplatin. When cisplatin was given before paclitaxel, the clearance rate of paclitaxel was 25% less than when the two drugs were given in the opposite sequence. In consequence, neutropenia was more profound with the former schedule (281). In addition, in experimental studies, cytotoxicity increased when human ovarian carcinoma cells were

© 2006 Elsevier B.V. All rights reserved.

exposed to paclitaxel before cisplatin, whereas the interaction was antagonistic when a 1-hour exposure to cisplatin was followed by a 20-hour exposure to taxol, or when the cells were exposed to cisplatin and taxol for 1 hour concurrently (282). The biochemical basis of this interaction has not been elucidated. The pharmacodynamic interaction may be related to cisplatin-induced alterations in cell-specific and non-specific binding sites for paclitaxel (283). In view of these results, paclitaxel should be given before cisplatin (284). There does not appear to be a similar interaction of paclitaxel with carboplatin (285).

Both cisplatin and paclitaxel are neurotoxic, the toxicity being dose-limiting and cumulative; neurotoxicity due to the combination has been suggested to be synergistic; after five cycles of chemotherapy, 96% of 44 patients had grade 1 toxicity and 52% grade 2 toxicity; 18% with grade 2 or 4 toxicity were withdrawn (286).

Vincristine

In 86 patients treated with cisplatin-based chemotherapy for testicular cancer, cumulative exposure (over 400 mg/m^2) and a previous history of noise exposure were significant susceptibility factors for irreversible ototoxicity; high doses of vincristine (greater than 6 mg/m^2) significantly increased the risk of reversible ototoxicity (287).

Pneumocandins

General Information

The pneumocandins are a class of anti-*Pneumocystis* agents, thought to act by inhibiting the synthesis of beta-1,3-glucan, a component of the *Pneumocystis jiroveci* cyst wall. Chemical modification of the poorly water-soluble pneumocandins resulted in L-693,989, which can be given by aerosol. In rats, this compound prevents *P. jiroveci* pneumonia after daily or weekly administration, without evidence of toxicity. Since there is no counterpart for beta-1,3-glucan synthesis in humans, there are no obvious reasons to suspect mechanism-based toxicity with this class of compounds. More effective compounds are being studied (1).

Pneumococcal vaccine

See also Vaccines

General Information

Two types of pneumococcal vaccine are available, polysaccharide vaccine and conjugated polysaccharide vaccine.

Pneumococcal vaccine is composed of a saline solution containing the purified capsular polysaccharides of 23 types of *Streptococcus pneumoniae*. The improved 23-valent vaccine, which replaced a 14-valent vaccine at the beginning of the 1980s, contains antigens to pneumococcal types that are responsible for about 85% of bacteremic pneumococcal pneumonia.

Pneumococcal vaccines produced by different manufacturers are currently available, for example "Pneumovax 23" produced by Merck Sharp & Dohme and "Pnu-Imune 23" produced by Lederle Laboratories. Each vaccine dose (0.5 ml) contains 25 μg of each polysaccharide antigen. Immunization is recommended for people who are at increased risk of developing pneumococcal disease because of underlying chronic health conditions and for older people. About 50% of vaccinees develop mild adverse effects, such as erythema and pain at the injection site. Fever, myalgia, and severe local reactions have been reported in under 1% of vaccinees. Severe systemic reactions, such as anaphylaxis have been rarely reported.

Incidental case reports relate to small vessel vasculitis after combined pneumococcal-influenza immunization (1), severe febrile reactions with leukocytosis (2), Sweet's syndrome (3), thrombocytopenia (4,5), and keratoacanthoma at the injection site (6).

Patients with AIDS have an impaired antibody response to pneumococcal vaccine. Adverse effects in symptomatic and asymptomatic HIV-infected vaccinees were not different from those in HIV-negative persons (7).

Note on abbreviations

DtaP = Diphtheria + tetanus toxoids + acellular pertussis
DTwP = Diphtheria + tetanus toxoids + whole cell pertussis
Hib = *Haemophilus influenzae* type b
OPV = oral poliovirus vaccine
PPV = pneumococcal polysaccharide vaccine

Pneumococcal polysaccharide vaccine

The question of whether revaccination with 23-valent pneumococcal polysaccharide vaccine (PPV) at least 5 years after the first vaccination is associated with more frequent or more serious adverse events than those after the first vaccination has been studied in patients aged 50–74 years who had never been vaccinated with PPV ($n = 901$) or who had been vaccinated once at least 5 years before enrolment ($n = 513$) (8). After one dose of PPV, local injection site reactions and prevaccination concentrations of type-specific antibodies were measured. Those who were re-vaccinated were more likely than those who received their first vaccinations to report a local injection site reaction of at least 10.2 cm (4 in.) in diameter within 2 days of vaccination (55/513 versus 29/901, or 11 versus 3%). The reactions resolved by a median of 3 days after vaccination. The highest rate was among revaccinated patients who were immune competent and did not have chronic illnesses: 15% (33/228) compared with 3% (10/337) among comparable patients receiving their first vaccinations. The risk of these local reactions correlated significantly with prevaccination geometric mean antibody concentrations. The authors concluded that physicians and patients should be aware that self-limited local injection site reactions occur more often after revaccination compared with a first vaccination; however, this risk does not represent a contraindication to revaccination with PPV in recommended patients.

Pneumococcal conjugated polysaccharide vaccines

Pneumococcal polysaccharides are not immunogenic in infants, but improved immunogenicity of polysaccharide-protein conjugates has been demonstrated. One of the major problems in developing a successful vaccine against *S. pneumoniae* is the large number of different serotypes involved. More than 83 serotypes of the bacterium are known to cause disease, although about 10 of these account for up to 70% of disease in young children. The frequency of the serotypes can vary from year to year, from one age group to another, and on a geographical basis. Various conjugated vaccines that include different serotype variations are already licensed (the heptavalent conjugated vaccine Prevnar/Prevenar), under development or undergoing clinical trial (9- and 11-valent

© 2006 Elsevier B.V. All rights reserved.

conjugated vaccines). If the vaccines prove to be successful, it is estimated that their use could reduce child deaths from pneumococcal pneumonia by up to 25%, saving over 250 000 lives a year worldwide. The development of conjugate pneumococcal vaccines has also been driven by the high incidence of inner ear infections and the severity of meningitis due to *S. pneumoniae* in industrialized countries. The results of some clinical trials with different vaccines of this type have been reviewed (SEDA-22, 344).

The immunogenicity of 7-valent pneumococcal-conjugate vaccine plus 23-valent pneumococcal vaccine in 11 children has been compared with the immunogenicity of 23-valent vaccine alone in 12 children up to 2 years of age with sickle cell disease (9). IgG pneumococcal antibody concentrations were higher with combined administration, with no increase in adverse effects after immunization with 23-valent vaccine.

In 2000, the first heptavalent conjugated pneumococcal vaccine, Prevnar, which contains polysaccharides of pneumococcal serotypes 4, 6B, 9V, 14, 19F, and 23F, and oligosaccharide of serotype 18C, conjugated to the protein carrier CRM 197 (non-toxic variant of diphtheria toxin), was licensed in the USA (covering 90% of pneumococcal serotypes found in young children in the USA) and in all EU member states, as well as in selected other countries in 2001. In a randomized, double-blind study, 302 healthy infants in the Northern California Kaiser Permanente Health Plan received either the pneumococcal vaccine or meningococcal group C conjugate vaccine as a control at 2, 4, and 6 months of age and a booster at 12–15 months of age (10). The immunogenicity and safety of simultaneous administration of vaccines used in the routine immunization program of children (DTwP or DTaP, Hib and OPV or hepatitis B vaccine) were also evaluated. Local reactions after pneumococcal, DTwP-Hib, and DTaP plus Hib vaccine were statistically less severe at the pneumococcal vaccine site than at the DTwP-Hib sites (Table 1). There were 12 emergency room visits and 8 hospitalizations that occurred soon after immunization (otitis, febrile illness, urinary tract infection, burns), but none was thought to be related to the vaccine. One hypotensive-hyporesponsive episode 15 minutes after pneumococcal vaccine, DTwP-Hib/HB, and OPV, with complete recovery within 1 hour, was considered to have been vaccine-related. After the booster dose of pneumococcal vaccine, the geometric mean titers of all seven serotypes increased significantly (compared with the values after dose 3 and before dose 4) to antibodies considered as protective. When vaccine was administered at the same time as the booster dose of DTaP and Hib vaccines, there were lower antibody titers for some of the antigens than the antibody response when the pneumococcal vaccine was given separately. Because the geometric mean titers of the booster responses were all generally high and all subjects achieved similar percentages above predefined antibody titers, these differences were considered to be probably not clinically significant. Summarizing their results the authors concluded that the pneumococcal vaccine was safe and immunogenic.

Table 1 Local reactions within 48 hours of injection in infants given conjugated pneumococcal, DTwP-Hib, and DtaP + Hib vaccines

Reaction	Number of children	Infants		Toddlers

Dose 4	110	16		9.8

A comprehensive technical overview on the epidemiology and prevention of pneumococcal disease, including the use of polysaccharide and conjugate vaccines has been provided (11).

Further results of field trials on the efficacy, safety, and immunogenicity of heptavalent conjugated pneumococcal vaccine have appeared. Between October 1995 and August 1998, 37 868 infants were included in a double-blind trial (12). At 2, 4, 6, and 12–15 months of age they were randomly assigned to receive either the pneumococcal conjugate vaccine or meningococcal conjugate vaccine. More than 95% of pneumococcal vaccine recipients developed = 0.15 μg/ml antibodies against all serotypes included in the vaccine. As of April 1999, a vaccine efficacy of 97% (prevention of invasive pneumococcal disease caused by vaccine serotypes) was calculated; in addition, there was a significant impact on otitis media. Data on reactogenicity of the conjugate pneumococcal and meningococcal vaccines are provided in Table 2 and Table 3. Local reactions were analysed separately for children who had received DTaP and DTwP vaccine simultaneously. Local and systemic reactions were generally relatively mild with either vaccine, and more severe local and systemic reactions were uncommon and self-limiting. There were significant differences in outpatient clinic visits for seizures (11 pneumococcal vaccine recipients versus 23 controls), but none of the subcategories of seizure (febrile seizures, epilepsy, afebrile seizures) was significantly different. There were four cases of sudden infant death syndrome (SIDS) (0.2/1000) in the pneumococcal vaccine group and eight in the controls (0.4/1000). This rate is similar to the rate of 0.5/1000 children observed in the general infant population of California.

Recent advances in conjugated pneumococcal vaccines selected from current literature have been reviewed, including studies with experimental tetravalent and pentavalent conjugated vaccines and vaccines conjugated to various proteins (13).

23-valent pneumococcal polysaccharide vaccine

The efficacy of polysaccharide vaccine in preventing invasive pneumococcal disease, pneumonia, and death has been assessed in a double-blind, randomized, placebo-controlled trial in 1392 HIV1-infected adults in Uganda (14). The vaccine was well tolerated. However, it was ineffective and is not recommended for use in HIV1-infected individuals. Reassessment of recommendations for polysaccharide vaccine immunization may be necessary in some countries. The authors suggested that the vaccine causes destruction of polysaccharide-responsive B cell clones.

In another clinical trial the immunogenicity and safety of polysaccharide vaccine has been assessed in 21 renal transplant recipients (15). Protective antibody titers were reached at 6 and 12 weeks after immunization in all recipients, bar one. No local or systemic adverse effects were observed.

Organs and Systems

Immunologic

Arthus reactions and systemic reactions have commonly been reported after booster doses of polysaccharide vaccine and are thought to result from antigen–antibody reactions involving antibodies induced by the previous immunization (16). Data on revaccination of children are not yet sufficient to provide a basis for recommendation.

An allergic reaction has been described to 23-valent polysaccharide pneumococcal vaccine (17).

- A 2-year-old child developed bronchospasm and cutaneous and laryngeal edema immediately after the injection of a 23-valent polysaccharide pneumococcal vaccine. The symptoms resolved within 1 hour of treatment with antihistamines, glucocorticoids, and aerosols. Skin tests and specific IgE tests showed that the pneumococcal antigens were responsible for the anaphylaxis.

Susceptibility Factors

Age

In an evaluation of simultaneous immunization in 85 elderly subjects, pre-immunization pneumococcal antibodies were

© 2006 Elsevier B.V. All rights reserved.

associated with more reactions, both local and systemic, after vaccination (18). A rise in temperature (9% of vaccinees), and pain at the injection site (5% of vaccinees) were significantly associated with raised preimmunization pneumococcal polysaccharide antibody concentrations.

Other features of the patient

The immunogenicity and safety of pneumococcal polysaccharide vaccine have been studied in renal allograft recipients, dialysis patients (19), children and adolescents with sickle-cell anemia (SED-11, 682) (SEDA-12, 277), people with diabetes mellitus (SED-11, 682), and children with nephrotic syndrome (20). When comparing the results with healthy persons there were no significant differences.

The problems connected with pneumococcal disease and its prevention in HIV-infected individuals have been reviewed (21). Pneumococcal disease occurs significantly more often in HIV-infected individuals, with pneumococcal pneumonia rates 5.5–17.5 times greater than population-based estimates in the USA, and the increasing rate of penicillin-resistant strains of *S. pneumoniae* highlight the need for improved prevention strategies. Studies of pneumococcal disease in HIV infection have repeatedly shown that over 85% of the isolates from bacteremic patients, in both the USA and Africa, are of serotypes included in the 23-valent vaccine. However, the proportion of HIV-positive individuals who respond to 23-valent pneumococcal polysaccharide vaccine has been shown in some but not all studies to be slightly reduced compared with age-matched controls but comparable to other high-risk groups, such as elderly people, in whom clinical efficacy has been established. Some studies have suggested a trend toward a lower response rate as the CD4 cell count falls. The reason for concern about the safety of pneumococcal immunization in HIV-infected individuals is the reported association between immunization and increasing HIV virus load.

Much of this concern arises from extrapolation from published data on influenza immunization. However, there are some data on pneumococcal immunization alone. In 32 HIV-positive patients with a median CD4 cell count of 242×10^6/l, who received Pneumovax and tetanus toxoid there was no change in plasma HIV-1 RNA at 20–56 days after immunization (22). In contrast there were marked increases in plasma viral RNA (1.6–586 times) reported in 12 asymptomatic HIV-positive individuals (mean CD4 cell count 374×10^6/l). More recently, a study of patients with more advanced disease found that HIV-1 RNA and DNA were unaffected by either conjugate or polysaccharide pneumococcal vaccine up to 309 days after immunization (23). In summary, the authors of the review (21) recommended that HIV-infected individuals be immunized with pneumococcal vaccine and that immunization should be carried out as early as possible in the course of HIV infection.

Drug–Drug Interactions

Influenza vaccine

In a study of the interaction between 23-valent pneumococcal polysaccharide vaccine and influenza vaccine, 152 adults with chronic respiratory disease were randomized to receive both vaccines either simultaneously or at an interval of 1 month (24). There were no significant differences in serological responses between the groups. The incidence and severity of both local and systemic adverse effects were also similar: there were mild local reactions in 38 and 36% and systemic reactions in five and three of the vaccinees respectively.

General Information

The genera in the family of Poaceae (Table 1) include bamboo, barley, cane, fescue, lawn grass, oats, pappus, and rice.

Anthoxanthum odoratum

Anthoxanthum odoratum (sweet vernal grass) contains anticoagulant coumarins, which cause bleeding in cattle that consume the grass.

Adverse effects

In 125 Turkish patients with rhinitis and/or symptoms of asthma reactivity to *Dermatophagoides* as an indoor

Podophyllum derivatives

General Information

Podophyllum is a powerful skin irritant and antimitotic agent, widely used in the topical treatment of condylomata acuminata. The anticancer topoisomerase inhibitors, tenoposide and etoposide, are podophyllotoxins.

The signs and symptoms of systemic toxicity (1,2) (SED-9, 240) include:

- cyanosis, tachycardia, electrocardiographic changes;
- stertorous respiration;
- polyneuritis, ataxia, coma, agitation, delirium, confusion, lethargy, muscular weakness, paresthesia;
- leukopenia, leukocytosis, thrombocytopenia, anemia;
- nausea, vomiting, abdominal pain, paralytic ileus;
- raised liver enzymes;
- oliguria, anuria, hematuria;
- urticaria;
- fever.

Intrauterine death and teratogenicity have not been demonstrated convincingly.

Podophyllum emodi (Indian podophyllum)

Proresid (mitopodozide), a mixture of more than 20 derivatives of *Podophyllum emodi*, has been used for many years in some countries as a disease-modifying agent in rheumatoid arthritis. A microtubulin antagonist, it is comparable with colchicine and griseofulvin. Its use has been limited because treatment is often complicated by severe diarrhea, abdominal pain, nausea, and vomiting. Leukopenia and thrombocytopenia have been reported (3,4).

Etoposide and teniposide are semisynthetic derivatives of podophyllin, which was originally isolated from the root of the Indian podophyllum plant. They inhibit topoisomerase II and are dealt with in a separate monograph.

Podophyllum peltatum (American mandrake)

The resin prepared from the dried rhizome and roots of *Podophyllum peltatum* contains podophyllotoxin, α-peltatin, and β-peltatin. When applied topically, it is a strong irritant to the skin and mucous membranes and can lead to poisoning because of systemic absorption. When taken by mouth, it has a drastic laxative action and produces violent peristalsis. Ingestion of large doses can result in

severe neuropathic toxicity (SEDA-11, 426). The oral and local use of the resin should be avoided during pregnancy, as this has been associated with teratogenicity and fetal death.

- A 31-year-old man took an unknown amount of *Podophyllum peltatum*, thinking it to be *Mandragora officinarum*; he developed severe nausea and vomiting and recovered uneventfully (5).

Dysosma pleianthum (bajiaolian)

Dysosma pleianthum (bajiaolian), a species of mayapple, has been widely used for thousands of years in China as a general remedy and for the treatment of snake bite, weakness, condyloma acuminata, lymphadenopathy, and tumors. Podophyllotoxin is one of its main ingredients. Five people who drank infusions of bajiaolian developed nausea, vomiting, diarrhea, abdominal pain, thrombocytopenia, leukopenia, abnormal liver function tests, sensory ataxia, altered consciousness, and persistent peripheral tingling or numbness (6).

Long-Term Effects

Tumorigenicity

Etoposide and teniposide are prominent causes of secondary malignancies, particularly secondary myeloid and lymphoid leukemias. The risk appears to be related to both the schedule and the cumulative dose, and it may be aggravated by addition of alkylating agents and/or radiotherapy (7,8). There are differences between the chromosomal abnormalities and the subsequent acute myeloid leukemia associated with the alkylating agents and those following topoisomerase inhibition by epipodophyllotoxins (9). The alkylating agents cause abnormalities of chromosomes five and seven, singly or together, and the epipodophyllotoxins damage the 11q23 chromosome locus (10).

Second-Generation Effects

Teratogenicity

Podophyllum is likely to be teratogenic (11,12) because of its effects on topoisomerase.

- A woman who applied podophyllum resin five times for a duration of 4 hours from the 23rd to the 29th week of pregnancy gave birth to a child with a simian crease on the left hand and a preauricular skin tag (11).

Drug Administration

Drug overdose

Fatal podophyllum toxicity has been reported.

- When a 59-year-old man took 10 g of podophyllum in a fatal suicide attempt he did not develop symptoms until 10 hours later, with loss of reflexes, coma, and marked lactic acidosis; there were nuclear and cytoplasmic changes in circulating leukocytes (1). Despite hemoperfusion, he died after 39 hours.

Poldine methylsulfate

General Information

Poldine methylsulfate is an anticholinergic drug that has been used to reduce gastric acid secretion in patients with peptic ulceration (1) and has been administered by iontophoresis in the treatment of palmar and plantar hyperhidrosis (2). Its adverse effects are those expected of an anticholinergic drug.

Poliomyelitis vaccine

See also Vaccines

Note on abbreviations

DTP = Diphtheria + tetanus toxoids + pertussis
DtaP = Diphtheria + tetanus toxoids + acellular pertussis
Hib = *Haemophilus influenzae* type b
IPV = inactivated poliomyelitis vaccine
OPV = oral poliovirus vaccine
PRP-T-Hib = conjugated Hib vaccine (tetanus toxoid linked to Hib capsular polysaccharide)

General Information

There are two types of poliomyelitis vaccines available. One is prepared from polioviruses that as a rule have been inactivated by formaldehyde. Inactivated poliomyelitis vaccine (IPV) is given parenterally. The second group of polio vaccines comprises attenuated strains of live polioviruses (oral poliomyelitis vaccine, OPV), which are given orally; these live vaccines are the most widely used.

Inactivated poliomyelitis vaccine

Inactivated poliomyelitis vaccine produced by improvements in manufacturing technology (potency-enhanced IPV-eIPV was licensed in 1987) is used for routine immunization in an increasing number of countries (for example in Finland, France, Germany, Iceland, the Netherlands, Norway, Sweden, and certain provinces of Canada) and is recommended in other countries for certain specific purposes, for example for persons with underlying immunological disorders or non-immunized adults exposed to high risk. A few countries (for example Denmark, Hungary, Italy, Lithuania, and Israel) use a mixed schedule, starting primary immunization with IPV followed by OPV.

The US 2000 childhood immunization schedule, proposed by the Advisory Committee of Immunization Practices (ACIP), the American Academy of Pediatrics, and the American Academy of Family Physicians, recommended an all-IPV schedule for routine use in the USA, aimed at the elimination of the rare vaccine-associated paralytic poliomyelitis (1). Since 1 January 2000, all children have received four doses of IPV at ages 2 months, 4 months, 6–18 months, and 4–6 years.

Some other industrialized countries that use OPV in their routine immunization programs, and which had no wild poliomyelitis cases for many years but some vaccine-associated poliomyelitis, are reassessing their immunization strategy. They are considering new concepts of shifting from OPV to IPV or from OPV to mixed schedules. This change could help to prevent vaccine-associated poliomyelitis mostly occurring after the first dose of OPV immunization.

Serious adverse effects after IPV immunization have not been documented (2). Because IPV contains streptomycin and neomycin, there is a possibility of allergic reactions in those who are sensitive to these antibiotics. Although it has been postulated that IPV, like some viral infections, might trigger Guillain–Barré syndrome, there is inadequate evidence to accept or reject such an association (3); in this respect it may differ from the oral vaccine.

Oral polio vaccine

In contrast to IPV, OPV causes important problems, including vaccine-associated polio and prolonged polio virus excretion.

Combination vaccines

The safety, immunogenicity, and lot consistency of five-component pertussis combination vaccine (DtaP + IPV + PRP-T-Hib) in infants have been compared to those of a whole-cell pertussis combination vaccine (DTwP + IPV + PRP-T-Hib), as have separate and combined injections of DTP + IPV and Hib. The combination vaccine DtaP + IPV + Hib were comparable or superior regarding safety and immunogenicity to the combination vaccine containing the whole cell pertussis component. There was no interaction between acellular pertussis and PRP-T-Hib, a feature that distinguishes this combination vaccine from some others, which depress anti-PRP responses. The combination vaccine DtaP + IPV + Hib produced significantly lower rates of local and systemic reactions than did the combination vaccine containing the whole-cell pertussis component. Local reactions, such as redness, swelling, and tenderness occurred two to three times more often after combination vaccine containing whole cell pertussis than after combination vaccines with acellular pertussis components. Fever was three times more common after whole cell combination vaccine. Fever over 40°C was rare in all vaccinees, because of the use of paracetamol prophylaxis. Systemic reactions, such as fussiness, crying, reduced activity, and anorexia, were about twice as frequent with whole cell vaccine as with acellular pertussis vaccine. Both local and systemic reactions persisted longer after whole cell vaccine than after acellular pertussis vaccine. There were no significant differences between reaction rates among infants given DtaP + IPV vaccine combined with PRP-T-Hib vaccine in the same syringe compared with those given separate injections, except for local redness after the first dose (4).

Hexavalent immunization

The Hexavalent Study Group has compared the immunogenicity and safety of a new liquid hexavalent vaccine against diphtheria, tetanus, pertussis, poliomyelitis, hepatitis B and *Haemophilus influenzae* type b (DTP + IPV + HB + Hib vaccine, manufactured by Aventis Pasteur MSD, Lyon, France) with two reference vaccines, the pentavalent DTP + IPV + Hib vaccine and the monovalent hepatitis B vaccine, administrated separately at the same visit (5). Infants were randomized to receive either the hexavalent vaccine ($n = 423$) or (administered at different local sites) the pentavalent and the HB vaccine ($n = 425$) at 2, 4, and 6 months of age. The hexavalent vaccine was well tolerated (for details see the monograph on Pertussis vaccines). At least one local reaction was reported in 20% of injections with hexavalent vaccine compared with 16% after the receipt of pentavalent vaccine or 3.8% after the receipt

© 2006 Elsevier B.V. All rights reserved.

of hepatitis B vaccine. These reactions were generally mild and transient. At least one systemic reaction was reported in 46% of injections with hexavalent vaccine, whereas the respective rate for the recipients of pentavalent and HB vaccine was 42%. No vaccine-related serious adverse event occurred during the study. The hexavalent vaccine provided immune responses adequate for protection against the six diseases.

Polio vaccines as a possible cause of AIDS

There is a hypothesis that the HIV virus might have jumped the species barrier from monkey to people via a contaminated polio vaccine because the vaccine was manufactured in primary monkey kidney tissue known to be sometimes contaminated with monkey viruses. The existing evidence, including tests of poliovirus seed stocks, more than 20 vaccine lots, and serum samples from vaccine recipients makes this hypothesis highly improbable (6,7).

Contamination of polio vaccines with simian papovavirus 40 (SV40)

The problem of early polio vaccines produced in the 1950s and early 1960s, and, in some instances, contaminated with the monkey virus SV40 (simian virus 40) has been discussed (8). From 1954 to 1962, millions of people were immunized with polio vaccines, which during that period contained SV40 as an unrecognized contaminant. Some studies sought to investigate possible causation between the receipt of the vaccine and the development of tumors. The results were not convincing (SEDA-15, 355) (SED-12,821). At a workshop in 1997 some of the scientific questions concerned were again considered (9). The presentations by polio vaccine manufacturers and the UK National Institute for Biological Standards and Control provided convincing evidence that currently used polio vaccine was free of SV40.

Critical assessment of virological and epidemiological data suggests a probable causative role for SV40 in certain human cancers, but that additional studies are necessary to prove etiology (8). To help answer these issues, the World Health Organization has provided the following statement (10): "Investigations from several medical research institutions have detected the presence of simian virus 40 (SV40) genome in certain rare human tumors, notably mesotheliomas, osteosarcomas, and brain tumors. SV40, which is known to induce tumors in laboratory rodents, is a polyomavirus identified in 1960 as a contaminant of some batches of primary rhesus monkey kidney cells used to produce polio vaccine in the 1950s. Soon after its discovery, measures to exclude the virus from polio and other vaccines were rapidly introduced into WHO Requirements for the Manufacture and Quality Control of Polio Vaccines, and these have been rigorously applied by vaccine manufacturers. For over 30 years now, polio vaccines made in primary monkey kidney cells have been shown to be free of live SV40."

The use of new and highly sensitive polymerase chain reaction (PCR) techniques for the detection of the SV40 genome in batches of oral polio vaccines from several manufacturers has confirmed that the measures taken have been effective in excluding SV40 from vaccines. There is no doubt that the early batches of polio vaccine that were used between 1955 and 1963 contained SV40. Epidemiological studies between 1960 and 1974 failed to show an association between exposure to SV40-contaminated vaccines and human tumors. More recent epidemiological data from tumor registers, involving more than 60 million person years of observation, have likewise found no differences in tumor incidence that could be attributable to SV40-contaminated polio vaccines. The latest data published in the Journal of the National Cancer Institute, USA, suggest that SV40 may be present in humans more commonly than had previously been thought, and raises the possibility of transmission of the virus among humans. Whether the antibodies that have been detected are due to exposure to SV40 or to cross-reacting human polyomaviruses is not known. Neither is it certain that SV40 strains now present in the human population originated from the use of the early polio vaccines. Despite almost 40 years of observation, there is still no evidence that SV40 contamination of some early batches of polio vaccine has had any adverse effect on human health.

"The River" by Edward Hooper

The hypothesis that oral polio vaccine played a key role in the current AIDS epidemic was raised again by Edward Hooper, who has worked many years for the BBC and the UN in Africa and some years ago wrote a book called "Slim," in which he described the AIDS epidemic in East Africa. His book "The River. A journey to the source of HIV and AIDS," published in 1999 (11), raised great public attention and was discussed in BBC Press Releases and in the New York Times. Leading experts in virology and AIDS research published comments in Science and other scientific journals. "The River" is a thoroughly researched, well-written book and deserves to be taken seriously. Hooper carefully collected data and events describing the first phases of HIV infection and AIDS, as well as the early development and implementation of polio vaccines. His book reflects some hundreds of interviews, including the leading researchers in the related fields, and he has documented more than 4000 references.

The hypothesis is based on the following facts and assumptions. In 1957 and 1958, Koprowski, from the Wistar Institute in Philadelphia, was administering oral polio vaccine in Africa (pre-licensure field trials in Burundi, Rwanda, and the North-East Congo) near Stanleyville (now Kisangani) in Congo. Not far from the base, chimpanzees for use in medical research were housed in Camp Lindi and might have carried a primate immunodeficiency virus (PIV). Chimpanzee kidneys for hepatitis research were shipped from Camp Lindi to the Virological Department of the Children Hospital in Philadelphia in 1958 and 1959. Hooper suggests that "it could be that [kidneys from these chimpanzees] ended up at the Wistar", the laboratory in Philadelphia where polio vaccines were manufactured, where they contaminated vaccines with PIV. The polio vaccine that was supposed to be contaminated with PIV was then used in the Congo, transmitting the virus that evolved into HIV-1, the starting point of the worldwide HIV-1 epidemic. Over

© 2006 Elsevier B.V. All rights reserved.

the next 20 years, infected humans progressed to AIDS, and the disease became visible in central Africa in the mid-to-late 1970s.

Does Hooper prove his hypothesis beyond a shadow of doubt? No, but he makes a powerful case for soberly and squarely addressing the issue.

There are also strong arguments against the hypothesis. Polio vaccines were first propagated in kidney cultures of rhesus and cynomolgus macaques, and later in African green monkeys. Plotkin and Koprowski categorically stated in a letter to the editor of the New York Times (7 December 1999) that no chimpanzee tissues were used in the Wistar Institute for polio vaccine production. They added that two independent analyses of the probable timing of the crossover of HIV from chimpanzees into humans give dates earlier than 1957–59, the years in which the Wistar polio vaccine was used in the Congo (12). It should also be mentioned that the vaccine manufactured in Wistar at that time was not only used in Africa but also in Sweden, Poland, and the US. One vial of Wistar's oral polio vaccine stored in Stockholm has already tested negative. Garrett and colleagues in England experimentally examined the survival of human and simian immunodeficiency viruses in oral polio vaccine formulations; no live retrovirus came through the procedure. Wistar declared that they would release lab specimens from a polio vaccine project carried out at the end of the 1950s in Africa for examination in two independent laboratories, in order to dispel claims that Wistar scientists inadvertently caused the AIDS epidemic.

It should be mentioned that the majority of scientists believe that the AIDS epidemic began after the simian immunodeficiency virus was transmitted from chimpanzees to humans during the slaughter of chimpanzees as early as the 1930s (13–16).

Finally, it is worth repeating the statement of the US Centers for Disease Control and Prevention, issued in 1992 but still valid (17): "The suggestion that HIV, the AIDS virus, originated as a result of inadvertent inoculation of an HIV-like virus present in monkey kidney cell cultures used to prepare polio vaccine is one of a number of unsubstantiated hypotheses. The weight of scientific evidence does not support this idea and there is no more reason to believe this hypothesis than many other which have been considered and rejected on scientific grounds."

Nevertheless, there are important lessons to be learned from Hooper's book. For many years, virologists and regulatory authorities have been worried that using permanent cell lines for vaccine virus propagation may somehow transfer cancer-causing properties and animal viruses. African green monkey kidneys are still used as the main cell substrate for oral polio vaccine. Millions of doses have been made from simian immunodeficiency virus (SIV)-positive monkeys before screening was introduced. Now there are well-tested non-oncogenic cell substrates, and it is time to reopen the debate on the use of primary cells versus cell lines for live attenuated virus vaccines. There is also a need to strengthen research on the sources of AIDS. However, the main focus of AIDS research should be prevention and treatment.

Global eradication of poliomyelitis and immunization

Using oral vaccine, the global campaign to eradicate polio achieved a more than 90% reduction in the number of polio cases worldwide in the 11 years since it was launched, and is on track to eradicate polio (18). It is to be expected that in a few years both poliomyelitis and polio vaccines will be confined to history books and science museums. Polio immunization will stop for good. When the final goal of global eradication is achieved, a decision on when and how to stop polio immunization will be necessary. Such a decision has not yet been prepared. Different scenarios are under discussion: continuation of universal immunization programs, sequential removal of one or two of the Sabin strains of OPV, change to an all-IPV program, and discontinuation of OPV immunization simultaneously worldwide or selectively country by country (19). The Technical Consultative Group for the World Health Organization on the Global Eradication of Poliomyelitis has the task of elaborating a proposal for final approval by the World Health Assembly (20).

Organs and Systems

Cardiovascular

Myopericarditis has been attributed to Td-IPV vaccine (21).

- A 31-year-old man developed arthralgia and chest pain 2 days after Td-IPV immunization and had an acute myopericarditis. He recovered within a few days with high-dose aspirin.

The authors discussed two possible causal mechanisms, natural infection or an immune complex-mediated mechanism. Infection was excluded by negative bacterial and viral serology and a favorable outcome resulted within a few days without antimicrobial drug treatment.

Nervous system

Vaccine-associated poliomyelitis

There is no doubt that OPV can cause poliomyelitis in a minority of recipients and their contacts. The risk is very low, but the seriousness of such a complication is evident. Various case reports and national surveys of vaccine-associated poliomyelitis, as well as studies quantifying this risk for OPV, have been published (SED-12, 820) (SEDA-16, 390) (SEDA-18, 336). The main conclusions from the field study that WHO conducted over a period of 15 years in 13 countries were as follows:

- The type 1 strain is almost never implicated in vaccine-associated poliomyelitis cases.
- The type 2 strain is an occasional cause of paralysis, commoner in contacts of the vaccine than in recipients.
- Most of the very small number of cases that do occur are due to type 3, both in vaccine recipients and in contacts.

In general, the risk of vaccine-associated poliomyelitis is less than one per million children immunized. The type 1 strain has been confirmed to be as safe and effective as any biological substance can be. The type 2 strain is safe for recipients of the vaccine but on rare occasions can

© 2006 Elsevier B.V. All rights reserved.

cause paralysis in contacts, so that any contact whose immunization status is doubtful should be immunized at the same time as the original vaccinee. The type 3 strain is much less stable genetically than the two strains and requires constant monitoring in the laboratory and in the field (22).

Frequency

The risk of vaccine-associated poliomyelitis has remained exceedingly low but stable since the mid-1960s. In all, 260 cases of vaccine-associated poliomyelitis were reported in the USA between 1961 and 1989. Cases of vaccine-associated poliomyelitis appeared to occur randomly in time and space. One potential cluster of vaccine-associated poliomyelitis consisting of six cases occurring over an 18-month period in Indiana was investigated during the period 1980–89. These cases were not shown to be epidemiologically related.

Using the total number of 80 vaccine-associated poliomyelitis cases in the USA from 1980 to 1989 as a numerator, the overall risk of vaccine-associated poliomyelitis was one case per 2.5 million doses of trivalent OPV distributed. The overall risk of vaccine-associated poliomyelitis was 9.7 times greater after the first dose of OPV than after all subsequent doses. The overall risk of recipient vaccine-associated poliomyelitis was one case per 6.8 million doses. The risk among OPV recipients was 29.0 times higher after the first dose than after subsequent doses. Comparing the first dose of OPV to subsequent doses, the lowest relative risk was found in immunologically abnormal persons. Whereas the average annual rate of vaccine-associated poliomyelitis for the period 1980–89 was 0.34 cases per million population, the annual incidence of vaccine-associated poliomyelitis among immunologically competent infants, who were used as the reference group, was 7.6 cases per 10 million population. Children under 1 year of age with a primary immunodeficiency were at highest risk of vaccine-associated poliomyelitis (annual rate of 16 216 cases per 10 million population, or 0.16%), which is more than 2000 times higher than the rate in the reference group. Among household contacts of children below 6 years of age, the annual rate of contact vaccine-associated poliomyelitis was 0.45 cases per 10 million population. For the remaining US population, the annual rate of vaccine-associated poliomyelitis was 0.14 cases per 10 million population. Summarizing their experience (23), the authors of the 1980–89 study distinguish three groups at risk of vaccine-associated poliomyelitis:

- recipients of OPV, especially infants receiving their first dose of OPV;
- persons in contact with OPV recipients, mostly unimmunized or inadequately immunized adults;
- immunologically abnormal individuals.

There has been a retrospective cohort study of cases of acute flaccid paralysis reported to the Ministry of Health in Brazil between 1989 and 1995 (24,25). For the first dose of OPV the estimated risk was one case of vaccine-associated paralytic poliomyelitis per 2.39 million doses; for total doses of OVP the risk was one case in 13.03 million doses. Most of the cases of vaccine-associated paralytic poliomyelitis were in children with a mean age of 1 year. Paralysis of the lower limbs caused by poliovirus type 2 was dominant.

Poliomyelitis caused by vaccine-derived polioviruses Between 12 July and 18 November 2000, a total of 19 people (aged between 9 months and 21 years) with acute flaccid paralysis were identified in the Dominican Republic; one case occurred in Haiti (August 2000) (26). The case in Haiti and three of the cases in the Dominican Republic were laboratory-confirmed with poliovirus type 1 isolates. All cases were either unimmunized or incompletely immunized. The outbreak was unusual, because the virus is derived from oral polio vaccine virus, with 97% genetic similarity to the parental OPV strain. Normally, vaccine-derived isolates are more than 99.5% similar to the parent strain. In contrast, wild polioviruses normally have less than 82% genetic similarity to OPV. The differences in nucleotide sequences suggest that the virus causing the outbreak has been circulating for about 2 years in the area in which immunization coverage is very low, and that the virus had accumulated genetic changes that restored the essential properties of wild poliovirus. A mass immunization with OPV brought the outbreak under control.

Causative strains

In an outbreak in Egypt during 1988–93, 32 cases of polio were associated with vaccine-derived poliovirus type 2 (27). Nucleotide sequence analysis performed during 1999 showed that all isolates were related (93–96% similarity) to the OPV 2 vaccine strain. The isolates were not related (less than 81% similarity) to the wild poliovirus type 2 that had been indigenous in Egypt. OPV was probably low in the affected communities.

Between 15 March and 26 July 2001, three cases of acute flaccid paralysis associated with vaccine-derived polioviruses type 1 were reported in the Philippines (28). There was a 3% genetic sequence difference between OPV type 1 virus and the vaccine-derived isolates.

Mechanism

The molecular biological findings connected with the occurrence of vaccine-associated poliomyelitis have been summarized (29). There is convincing evidence that the Sabin 2 and 3 viruses themselves can revert to a neurovirulent phenotype on passage in man. The authors report that a point mutation in the 5′-non-coding region of the genome of the poliovirus type 3 vaccine consistently reverts to the wild type in viruses isolated from cases of vaccine-associated poliomyelitis.

Prolonged poliovirus excretion

Molecular studies of poliovirus isolates have suggested that viral replication of vaccine-related polioviruses may have persisted for as long as 7 years in a patient with vaccine-associated paralytic poliomyelitis, in whom common variable immunodeficiency syndrome had previously been diagnosed (SEDA-21, 336).

DTP injections

The risk of DTP injection in provoking paralytic poliomyelitis during a large poliomyelitis outbreak in Oman

© 2006 Elsevier B.V. All rights reserved.

has been evaluated (30). Health center immunization records for 70 children aged 5–24 months with confirmed poliomyelitis and 692 control children were reviewed. A significantly higher proportion of case-patients received a DTP injection within 30 days before onset of paralysis compared with controls (43 versus 28%). All the patients for whom this information was available had paralysis of the injected limb. This study, which provided the first quantitative estimate in this respect, confirmed that injections are an important cause of provocative poliomyelitis and stressed the recommendation to avoid unnecessary injections during poliomyelitis outbreaks.

Multiple injections

Studies in 1994–95 in Romania produced evidence that multiple (unnecessary) injections may actually increase the risk of vaccine-associated poliomyelitis (SEDA-19, 302).

Between 1976 and 1985, seven cases of neurological disease were reported to have occurred in Germany among young children after simultaneous administration of oral poliovirus vaccine and diphtheria–tetanus toxoids or diphtheria–tetanus–pertussis vaccine (31). However, the virological data were incomplete; only one case was confirmed by the isolation of a vaccine-like polio virus, and in three cases the clinical symptoms did not correspond to poliomyelitis. The author concluded that in some cases the simultaneous administration of injectable vaccines cannot be excluded as a cause for paralysis.

Acute disseminated encephalomyelitis

Acute disseminated encephalomyelitis associated with polio vaccine has been reported (32).

- A 6-year-old girl developed acute disseminated encephalomyelitis, and polio vaccine virus type 2 was isolated from her cerebrospinal fluid and pharynx. The virus was sequenced throughout the 5′ non-coding region of the genome by polymerase chain reaction and was determined to have undergone various mutations at nucleotides 481, 500, 795, and 1195. The clinical signs of disease had completely disappeared 2 months later.

Guillain–Barré syndrome

Coincident with the mass nationwide campaign of OPV immunization that interrupted the transmission of wild poliovirus in Finland in 1985, with 4.5 million doses of OPV being administered, there was an unexpected rise in the occurrence of Guillain–Barré syndrome. In 10 cases of Guillain–Barré syndrome with onset of symptoms within 10 weeks after OPV immunization, no specific agents were found (33). The authors concluded that live attenuated polioviruses might trigger Guillain–Barré syndrome.

The authors of a report of the Institute of Medicine concluded that the evidence favored a causal relation between OPV and Guillain–Barré syndrome, but considered the evidence inadequate to accept or to reject a causal relation between OPV and transverse myelitis (SEDA-18, 325) (3).

The available reports on a possible association between polio vaccine and Guillain–Barré syndrome have been reviewed (34). The conclusion of a 1994 US Institute of Medicine committee that the evidence favored acceptance of a causal relation was mainly based on two reports from Finland (35,36). An earlier study of Guillain–Barré syndrome and oral polio vaccine has been extended to include hospital reports from the whole of Finland for 1981–6, during which time an oral polio vaccine campaign was carried out to control an outbreak of poliomyelitis (37). The rise in the numbers of cases of Guillain–Barré syndrome started before the immunization campaign. Because there had also been an influenza epidemic during that time, the researchers acknowledged that the increase in the incidence of Guillain–Barré syndrome could also have been associated with influenza. Data from the Americas are also not supporting an association between oral polio immunization campaigns and Guillain–Barré syndrome (38).

Sensory systems

Optic neuritis has been attributed to Td-IPV vaccine (39).

- Ten days after receiving Td-IPV vaccine a 56-year-old woman developed acute unilateral optic neuritis. Complete remission occurred within 6 weeks of prednisolone treatment. No other causes were found.

Gastrointestinal

Intussusception probably causally related to rotavirus vaccine (SEDA-23, 354) prompted studies to answer the question of whether polio vaccine could also cause intussusception. A workshop held in Atlanta on 15–16 June 2000 brought together experts from various fields with the primary investigators of the studies. The participants concluded that the available evidence favored rejection of a causal relation between OPV and intussusception (40).

Skin

Bullous pemphigoid has been attributed to DTP-IPV vaccine (41).

- A previously healthy 3.5-month-old infant developed bullous pemphigoid 3 days after receiving a first dose of DTP-IPV vaccine. *Staphylococcus aureus* was isolated from purulent bullae. The lesions resolved rapidly after treatment with antibiotics and methylprednisolone.

The authors mentioned 12 other cases of bullous pemphigoid, reported during the last 5 years, that had possibly been triggered by vaccines (influenza, tetanus toxoid booster, and DTP-IPV vaccine).

Second-Generation Effects

Pregnancy

Pregnancy is not a contraindication to the use of IPV. Although there is no convincing evidence documenting adverse effects of OPV on the developing fetus, and some evidence points to safety, it is widely considered prudent to avoid immunizing pregnant women, especially during the first 4 months of pregnancy. However, if immediate protection against poliomyelitis is needed, poliomyelitis immunization is recommended (42,43).

© 2006 Elsevier B.V. All rights reserved.

In order to interrupt poliovirus transmission during an outbreak of wild poliomyelitis in Israel in 1988, some 90% of the population, including pregnant women, were immunized with trivalent OPV. In a study of the abortions that occurred within 4 months of immunization compared with figures from a similar period in the previous year, the number of spontaneous abortions did not differ between women immunized during the first trimester of pregnancy and the controls (44). The authors concluded that OPV administered during early pregnancy has no adverse effect on the embryo or placenta that would cause increased fetal deaths or spontaneous abortions, nor does it seem to cause a higher rate of congenital anomalies.

An analysis of the OPV mass campaign in Finland suggested that OPV during early pregnancy had no harmful effects on fetal development (45). There were no significant deviations from the baseline prevalence for all malformations. However, when the vaccine is administered later in pregnancy the prospects may be different.

- Irreparable damage to the anterior horn cells of the cervical and thoracic cord occurred in a 20-week-old fetus whose mother was immune to poliomyelitis before conceiving but who was inadvertently given OPV at 18 weeks gestation (46).

Susceptibility Factors

There are no known contraindications to the use of IPV. OPV should not be given to persons who are immunocompromised due to immunodeficiency diseases, leukemia, lymphoma or generalized malignancy or who are immunosuppressed due to therapy with glucocorticoids, alkylating drugs, antimetabolites, or radiation. If poliomyelitis immunization is indicated in such persons, IPV should be used. OPV should also be avoided when immunizing household contacts of immunocompromised patients.

In the view of the WHO, live vaccines should in general not be given to immunocompromised individuals, but in developing countries, the risk of poliomyelitis in nonimmunized infants is high and the risk from these vaccines, even in the presence of symptomatic HIV infection, appears to be lower (47).

The Immunization Advisory Committees of many developed countries recommend that OPV should not be given to children and young adults who are immunocompromised due to AIDS or other clinical manifestations of HIV infection. OPV can be given to asymptomatic infected persons. However, because family members may be immunocompromised due to AIDS or HIV infection, it seems prudent to use IPV (48).

Polyacrylonitrile

General Information

Polyacrylonitrile is a constituent of dialysis membranes (1).

Organs and Systems

Immunologic

Non-IgE-mediated anaphylactic reactions to polyacrylonitrile membranes have been reported (2,3). The effects are enhacing in those using ACE inhibitors (4,5), perhaps because of an effect of bradykinin (6), which is released by the membranes (2,8,9) and whose metabolism is inhibited by ACE inhibitors. The effects also occur to a lesser extent in those taking angiotensin receptor antagonists (7) and in those with C1 esterase inhibitor deficiency (10). Treating the membranes with polyethyleneimine prevents bradykinin release (11).

The FDA has issued a safety alert about life-threatening anaphylactoid reactions associated with the concurrent use of angiotensin converting enzyme (ACE) inhibitors and polyacrylonitrile dialyzers (12). The warning was followed by increased reports in the literature and to the FDA of severe, sudden and sometimes fatal reactions. Symptoms include nausea, abdominal cramps, burning, angioedema, and shortness of breath, leading rapidly to severe hypotension. When these symptoms are recognized, dialysis should be stopped immediately and aggressive treatment for anaphylactoid reactions begun. Antihistamines do not relieve the symptoms. The mechanism of this interaction has not been

© 2006 Elsevier B.V. All rights reserved.

established, and the incidence and scope of the problem are unknown.

Polygeline

General Information

Polygeline is a plasma volume expander used as a 3.5% solution with electrolytes in the management of hypovolemic shock. It is also used in extracorporeal perfusion fluids, as a perfusion fluid for isolated organs, as fluid replacement in plasma exchange, and as a carrier solution for insulin.

Organs and Systems

Urinary tract

The effects of two modified gelatin preparations (Plasmion and Haemaccel) on renal function have been studied in 15 patients (1). In both groups proteinuria appeared as soon as perfusion began, with a peak as high as 6 g/l at the third hour. At the same time, low-molecular weight proteinuria (<30 kDa) was observed. $Beta_2$-microglobulinuria was significantly increased. The authors suggested that proteinuria was due either to inhibited tubular reabsorption of filtered protein, caused by gelatin, or to the amino acids, arginine and lysine, which are released as a result of gelatin hydrolysis. The pathological significance of this finding is unexplained.

Immunologic

Anaphylactic reactions associated with parenteral gelatin products are relatively common. The number of reports to the UK licensing authority now approaches 300, involving 127 patients, with 7 deaths. Most of these reactions are associated with multiconstituent gelatin-containing products, such as Gelofusine. An anaphylactic reaction due solely to the use of Gelofusine in a patient with non-hemorrhagic hypovolemia has been reported (2).

- A 57-year-old man presented with a 3-day history of lower abdominal pain and vomiting. He was hemodynamically stable but febrile, with tenderness and guarding in the lower abdomen. He was given intravenous fluids and antibiotics and mini-laparotomy was performed. Although 6 liters of crystalloids were given, his urine output was minimal, so 500 ml of Gelofusine was prescribed. Within 10 minutes he developed an urticarial rash, with wheals on his face and chest and difficulty in breathing. The infusion was stopped and replaced with crystalloids via a new administration set. Intravenous chlorphenamine and hydrocortisone improved his condition and the operation was completed without further complications.

Anaphylactic reactions to gelatins occur in about 0.1% of patients. Such reactions are more common in atopic patients and men and often occur within 10 minutes of starting the infusion. The authors recommended the use of allergy identification jewellery in such individuals, to reduce the possibility of life-threatening reactions.

The allergic reactions that have been described in association with polygeline are thought to be caused by direct histamine release as a result of allergenic stimulation of mast cells. These cases raise the questions of whether polygeline is appropriate for bronchoreactive patients and whether such patients should be protected by histamine receptor blockade.

- A 46-year-old man with diabetes mellitus and a history of allergy to penicillin, seafood, and soap had spinal anesthesia, and his systolic blood pressure fell to 90 mmHg (3). He was given 500 ml of gelafundin. Within minutes, he complained of pruritus along the drip site. There was no rash or urticaria, but the infusion was stopped immediately. He became restless, had copious oral secretions, complained of dyspnea, quickly

© 2006 Elsevier B.V. All rights reserved.

lost consciousness, and was bradycardic and hypotensive, with a systolic blood pressure of 65 mmHg. He was given Hartman's solution, Haesteril 6%, adrenaline, and atropine. He had a markedly raised IgE concentration (16 000 IU/ml). He eventually recovered.

The authors suggested that the sequence of events strongly suggested an anaphylactic reaction to gelafundin, and they concluded that while polygelines are useful volume substitutes they should be used carefully in atopic individuals or those with previous drug allergies. Etherified starch is considered a safer alternative in such patients.

- Suspected polygeline-induced anaphylaxis occurred in an 83-year-old woman within 1 minute of receiving an infusion of about 10 ml (exact dose not stated) of polygeline after induction of anesthesia for left thoracotomy (4). Her arterial blood pressure fell to 30 mmHg and there were no palpable pulses and no detectable cardiac output, but she was successfully resuscitated. About 1 month later she showed a strongly positive reaction to polygeline on skin testing. It is believed that modification of the manufacturing process of polygeline has reduced the incidence of associated adverse reactions, although there have been no large-scale studies to estimate the current incidence.

Three cases of acute anaphylactoid reactions to polygeline have been described from Australia. The reactions were serious and the explanation for them was unclear. All three patients were either normovolemic or mildly hypovolemic at the time of the event (5).

In a comparison of 4% human albumin solution, gelatin, and dextran 40, given as replacement fluids during plasma exchange, the gelatin solution induced two immediate allergic reactions and one delayed reaction (among 37 patients exposed). There was no cross-reactive allergy between the two colloids. Dextran 1000 injections were well tolerated. Gelatin infusions were associated with 10 times more episodes of hypovolemia (5.6 compared with 0.62%). This difference is probably explained by the faster elimination of gelatin from the vascular compartment, and it suggests that a larger volume of gelatin is required compared with dextran 40 for the same volume of plasma exchanged (6).

An IgE-mediated anaphylactic reaction to polygeline (Haemaccel, Hoechst Marion Roussel) has been reported (7).

- A 33-year-old woman with supraventricular tachycardia and a history of cadaveric renal transplantation for end-stage renal insufficiency, who was taking an immunosuppressant, enalapril, and simvastatin, was given intravenous adenosine and polygeline 500 ml. After 30 minutes she developed generalized urticaria. Promethazine and hydrocortisone did not ameliorate her symptoms and an hour later she developed angioedema of the lips and tongue, but no airway obstruction, bronchospasm, or hypotension. The reaction resolved with subcutaneous adrenaline. Skin prick tests 2 weeks later showed hypersensitivity to polygeline but not to latex (a possible contaminant).

The authors suggested that the positive skin prick reaction showed that the cause was an IgE-mediated anaphylactic reaction, rather than an anaphylactoid reaction, although this was not confirmed by independent tests.

Susceptibility Factors

Patients with underlying bronchial asthma and pheochromocytoma are thought to be particularly at risk of acute histamine release due to polygeline.

- A 45-year-old woman, who had used salbutamol and budesonide inhalers and oral theophylline for asthma and who had developed bronchospasm during induction of general anesthesia 6 weeks before, was readmitted for surgery under spinal anesthesia (8). During the procedure she developed two episodes of hypotension, which was corrected with fluids and intravenous mephentermine 6 mg. When blood loss reached 750 ml she was given an infusion of polygeline 3.5%, and 10 minutes later complained of respiratory difficulty and developed severe respiratory distress. Polygeline was withdrawn and she was given 100% oxygen with halothane by face mask. The oxygen saturation fell by more than 80% and she developed severe bradycardia and ventricular fibrillation. She was resuscitated.

The authors concluded that the severe reaction in this case had been due to polygeline, despite careful preparation of the patient with glucocorticoids and antihistamines. They recommended that polygeline should be avoided in any patient with reactive airway disease. Preoperative antihistamines and glucocorticoids may not prevent reactions induced by polygeline administration in such patients.

Drug Administration

Drug formulations

Using a computer-aided model for the prediction of pseudoallergic reactions from prospective data collected from 581 patients in a controlled clinical trial with an outdated formulation of polygeline, accurate prediction of 86% of the patients who had a systemic reaction was possible (9). The data were handled by multivariate analysis using the independence Bayes model. The predictive accuracy of other reactions was poor. A history of allergy was recorded in 26% of the patients who had systemic reactions and in 12 and 13% of the patients with no systemic or skin reactions. However, these differences were not statistically significant.

Polygonaceae

See also Herbal medicines

General Information

The genera in the family of Polygonaceae (Table 1) include buckwheat and rhubarb.

Table 1 The genera of Polygonaceae

Antenoron (antenoron)
Antigonon (antigonon)
Aristocapsa (spiny cape)
Brunnichia (buckwheat vine)
Centrostegia (centrostegia)
Chorizanthe (spineflower)
Coccoloba (coccoloba)
Dedeckera (July gold)
Dodecahema (spineflower)
Emex (three-corner jack)
Eriogonum (buckwheat)
Fagopyrum (buckwheat)
Gilmania (golden carpet)
Goodmania (spine cape)
Hollisteria (hollisteria)
Homalocladium (homalocladium)
Koenigia (koenigia)
Lastarriaea (lastarriaea)
Mucronea (spine flower)
Muehlenbeckia (maidenhair vine)
Nemacaulis (cottonheads)
Oxyria (mountain sorrel)
Oxytheca (oxytheca)
Polygonella (jointweed)
Polygonum (knotweed)
Pterostegia (pterostegia)
Rheum (rhubarb)
Rumex (dock)
Stenogonum (buckwheat)
Systenotheca (spineflower)

Polygonum species

Some species of *Polygonum* (knotweed) contain stilbene phytoestrogens, including resveratrol. *Polygonum tinctorium* contains indirubin, an isomer of indigo, which inhibits interferon-gamma production by human myelomonocytic HBL-38 cells and interferon-gamma and interleukin-6 production by murine splenocytes with no effect on the proliferation of either cells (1). *Polygonum multiflorum* contains compounds that inhibit calmodulin-depleted erythrocyte calcium-dependent ATPase (2). *Polygonum pennsylvanicum* contains vanicosides, glycosides that inhibit protein kinase C (3).

Adverse effects

Hepatitis has been attributed to *P. multiflorum* (4).

- *Polygonum multiflorum* (Shou wu Pian) was prescribed by a Chinese herbalist for a 46-year-old woman with graying hair (5). After taking it for 2 weeks she developed signs and symptoms of hepatitis. The history revealed no plausible cause for hepatitis and viral infection was ruled out. After withdrawal of the *P. multiflorum* her liver enzymes normalized and she recovered fully.
- A 31-year-old pregnant Chinese woman developed hepatitis after consuming Shou wu Pian; tests for viral hepatitis were negative and there was no evidence of other systemic disease (6).

Rheum palmatum

Rheum palmatum (rhubarb) contains the anthranoids sennosides and rhein. In a study of patients taking regular doses of rhubarb-containing Kampo medicines (extracts or decoctions) and patients taking excess doses there was tolerance to initial stimulant pain in the abdomen during excess use (7). The authors proposed that the absence of tenderness on pressure over the umbilical region could predict increasing or excess use of rhubarb.

In 14 616 patients who used various Kampo medicines, some of which contained rhubarb, there was no association between the use of rhubarb and the development of gastric carcinoma (8).

Polyhexanide

See also Disinfectants and antiseptics

General Information

Polyhexanide is a polymerized form of chlorhexidine, used as a disinfectant (1).

Organs and Systems

Immunologic

Severe anaphylaxis occurred in an 18-year-old woman and a 15-year-old man when polyhexanide was used to clean surgical wounds (2). Immediate-type hypersensitivity to polyhexanide was suggested by positive skin prick tests. Both patients had previously been exposed to chlorhexidine, but skin tests with chlorhexidine were negative.

Polymyxins

General Information

The polymyxins are antibacterial agents that are produced from different strains of *Bacillus polymyxa*. Because of their poor tissue distribution and their substantial nephrotoxicity and neurotoxicity, they are mainly restricted to topical use. However, they can be considered for serious systemic infections caused by multidrug-resistant Gram-negative bacteria (1–4).

The polymyxins that are used clinically are polymyxin B (rINN) and colistin (pINN, formerly known as polymyxin E). Colistimethate sodium (rINN, also called colistin methanesulfonate and colistin sulfomethate sodium) is prepared from colistin.

The polymyxins are cationic, basic, and amphipathic polypeptides that interact with lipopolysaccharides in the outer membrane of bacilli. They potently neutralize endotoxin, reduce blood endotoxin concentrations in patients with septic shock during direct hemoperfusion over immobilized polymyxin B fibers, and are bactericidal for many Gram-negative rods, even in resting bacteria. Alteration of the cell wall is also thought to be the mechanism of damage to renal epithelia and to the nervous system.

The polymyxins are effective against Gram-negative bacteria, with the exception of *Proteus* and *Neisseria* (*Branhamella*). They have in the past been used particularly to treat infections due to *Pseudomonas*, including inhalation therapy in patients with cystic fibrosis (5). They are prescribed in mg or units; 1 mg of polymyxin B corresponds to 10 000 units and 1 mg of colistin corresponds to 20 000–30 000 units.

After intravenous colistimethate (5 mg/kg/day) the CSF concentration was 25% of the serum concentration in a patient with meningitis (6). For life-threatening meningitis due to such organisms, polymyxins can also be given intrathecally as adjunctive therapy (7). Polymyxins are also used in regimens of selective decontamination of the digestive tract (8).

Observational studies

In a randomized study of the effects of a triple antibiotic ointment (polymyxin B + bacitracin + neomycin) and simple gauze-type dressings on scarring of dermabrasion wounds, the ointment was superior to the simple dressing in minimizing scarring; the beneficial effect on pigmentary changes was especially pronounced (9).

General adverse effects

Even in patients with normal renal function, adverse reactions have occurred in up to 25%, contributing to death in 5% (10). At therapeutically equivalent doses, suggestions of differences in nephrotoxicity or neurotoxicity between polymyxin B and colistin are not convincing. In view of their potential for adverse effects, the polymyxins have now been largely replaced by other antibacterial drugs.

Organs and Systems

Respiratory

The polymyxins are bronchial irritants, probably by histamine release (11). This reaction can be very rapid and resistant to bronchodilators.

In 58 children with bronchoconstriction in response to nebulized colistin, FEV_1 was significantly reduced for 15 minutes (12). In 20 children the reduction was greater than 10% from baseline FEV_1 and was still at that level in five children after 30 minutes. Subjective assessment, baseline FEV_1, and serum IgE did not distinguish susceptible children.

In 62 children with cystic fibrosis there was increased dyspnea in seven and pharyngitis in three in response to nebulized colistimethate (80 mg dissolved in 3 ml of preservative-free isotonic saline, by inhalation twice daily for 4 weeks) (13).

© 2006 Elsevier B.V. All rights reserved.

Nervous system

During treatment with any of the polymyxins, neurotoxicity can occur in up to 7% of patients with normal renal function. Circumoral paresthesia, vasomotor instability, ataxia, dizziness, convulsions of varying severity, and apnea have been reported. Of 31 patients with cystic fibrosis 21 had one or more adverse effects attributed to colistin (14). The most common reactions involved reversible neurological effects, including oral and perioral paresthesia ($n = 16$), headache ($n = 5$), and lower limb weakness ($n = 5$). All of these effects, although bothersome, were benign and reversible. There was no relation between the occurrence of any colistin-associated adverse effect and plasma colistin concentration or colistin pharmacokinetics.

Meningeal irritation rarely occurs in daily doses of 50 000 units (5 mg) given intrathecally, but higher doses can cause a stiff neck with CSF pleocytosis (15).

In animals the polymyxins can cause neuromuscular blockade similar to that observed with the aminoglycosides, aggravated by curare, ether, and suxamethonium, and antagonized by calcium. This can be noted first as fatiguability 1–26 hours after dosing, and can progress to severe muscular weakness, including respiratory paralysis (11). This complication has been reported both in neurologically normal subjects exposed to high plasma concentrations of the polymyxins, and also in some individuals with concentrations that were considered to be in the target range. Particularly at risk are patients with myasthenia gravis, who may require increased doses of neostigmine.

In patients with chronic pulmonary disease, polymyxin-induced neuromuscular block can result in fatal apnea. Finally, after anesthesia involving muscle relaxants the polymyxins can cause relapse of muscle weakness and inadequate ventilation (16).

Effective treatment of polymyxin-induced neuromuscular blockade requires awareness of the complication, with appropriate supervision and immediate ventilatory support, if required. Calcium gluconate and neostigmine are not of proven efficacy and should not be relied on (11).

Sensory systems

The polymyxins are occasionally ototoxic (17).

Electrolyte balance

Hyponatremia, hypokalemia, and hypocalcemia, with corresponding clinical manifestations, have occurred in patients treated for 3 weeks with doses of polymyxin B over 2 g/m^2 body surface (18,19). These abnormalities were interpreted as consequences of polymyxin-induced nephrotoxicity. Hyperchloremia and a negative anion gap seem to result from the polycationic properties of polymyxin B (20).

Urinary tract

Adverse reactions involving the kidneys occur in about 20% of patients receiving polymyxins (10). The potential for kidney damage seems to be related to age. Whereas in neonates and young infants colistimethate 20 mg/kg may be well tolerated, children over 2 years should not receive more than 10 mg/kg/day and adults even less.

Nephrotoxicity occurs more often in patients with preexisting impairment of renal function. Doses must be adjusted in patients with renal insufficiency, because colistin is excreted principally by the kidneys, and raised blood concentrations can further impair renal function (21).

Intermittent proteinuria was observed on urinalysis in 14 of 31 patients with cystic fibrosis, and one patient developed reversible, colistin-induced nephrotoxicity (14). There was no relation between the occurrence of any colistin-associated adverse effect and plasma colistin concentration or colistin pharmacokinetics.

Skin

Topical polymyxin B was the predominant allergen in patients who underwent patch-testing for evaluation of eczema of the external ear canal (22).

Immunologic

Compared with their toxic effects, allergic reactions to the polymyxins are relatively unimportant. Nevertheless, drug fever and maculopapular eruptions and other skin lesions have been observed in few patients (23,24).

In 145 patients with eczema of the external ear canal, allergic contact dermatitis was diagnosed in one-third; topical therapeutic agents, especially neomycin sulfate and probably polymyxin B, were the dominating allergens (22).

Long-Term Effects

Drug resistance

The Gram-negative organism *Burkholderia pseudomallei* is the pathogen that causes melioidosis. This bacterium is intrinsically resistant to the killing action of cationic antimicrobial peptides, including polymyxins. An in vitro study has now identified genetic loci that are associated with resistance to polymyxins in a virulent clinical isolate (25). In patients with cystic fibrosis *Pseudomonas aeruginosa* synthesized specific lipid A structures containing palmitate and aminoarabinose, which were associated with resistance to cationic antibiotics and increased inflammatory responses (1).

A two-component regulatory system has been characterized that is involved in the resistance of *P. aeruginosa* in response to external magnesium concentrations (26). Similarly, the PmrA/PmrB two-component system of *Salmonella enterica* that mediates modifications in the lipopolysaccharide, resulting in resistance to polymyxins, has been characterized in more detail (27). The pqaB locus affected polymyxin B resistance in *Salmonella typhi* (28).

All hemolytic and cytotoxic *Aeromonas* species that have been isolated from water samples from various sources were resistant to polymyxin B (29). Resistance to polymyxin B was also found in *Vibrio vulnificus* (30).

Resistance to colistin has been analysed in 44 adults with cystic fibrosis treated with inhaled colistin. Five developed polymyxin resistance (31). After therapy *P. aeruginosa* became sensitive to polymyxins within a few months, enabling the reintroduction of colistin for antibacterial treatment.

© 2006 Elsevier B.V. All rights reserved.

Second-Generation Effects

Teratogenicity

Colistin, and probably also polymyxin B, crosses the placenta (32). Although there is no evidence that the polymyxins are teratogenic, they should be avoided in pregnancy.

Drug Administration

Drug formulations

A food additive (flavored BMI-60) may help to mask the bitter taste of polymyxin B sulfate tablets (33).

Drug administration route

Bolus intravenous colistin (160 mg in 10 ml of saline tds) has been studied in a phase I open study during acute respiratory exacerbations in adults with cystic fibrosis and chronic *P. aeruginosa* infection; patients without total indwelling venous access systems had mild to moderate injection-like pain (34).

Intramuscular injection of the sulfates of polymyxin or colistin often causes pain at the site of injection; with sodium colistimethate this adverse reaction is largely absent (35).

In a study of the intrathecal administration of colistin adverse events were not reported (36). This may be an effective alternative treatment of bacterial meningitis caused by multidrug-resistant Gram-negative rods.

During sepsis, toxins (for example released from bacteria) can cause shock, disseminated intravascular coagulation, multiorgan dysfunction, and death. Apheresis may be a way of reducing the amounts of toxins and other harmful compounds in the circulation, and polymyxin B may serve as an adsorber. In three patients with septic shock, direct hemoperfusion using a polymyxin B-immobilized fiber column was carried out after antibacterial and antishock therapy. As a result, cardiovascular instabilities improved without increasing the supply of catecholamines (37). Furthermore, in seven patients with endotoxic shock after laparotomy undergoing hemoperfusion with the polymyxin B-immobilized fiber, there was an early increase in urine volume, attributable to increased glomerular filtration independent of systemic hemodynamic factors (38).

Drug overdose

If patients have high plasma concentrations of polymixins, neither hemodialysis nor peritoneal dialysis is effective in eliminating them (39). Exchange transfusion has been proposed (40,41).

Drug–Drug Interactions

Neuromuscular blocking drugs

There may be difficulty in reversing neuromuscular blockade if polymyxin is given in combination with neuromuscular blocking drugs (42).

Polystyrene sulfonates

General Information

Polystyrene sulfonic acid has been used as sodium, potassium, and calcium salts. Sodium polystyrene sulfonate has been used to treat hyperkalemia in patients with renal insufficiency and as an adjuvant during hemodialysis. It can be given orally or rectally in all age groups (1). It has also been added to feeding formulae and nutritional supplements to reduce their potassium contents and so prevent hyperkalemia; however, the reduction in potassium content was more than balanced by a concomitant increase in sodium content, presumably because of exchange of the sodium with calcium and magnesium (2,3). The uses and adverse effects of sodium polystyrene sulfonate have been reviewed (4,5).

Potassium polystyrene sulfonate has been used to treat hypercalciuria and renal calculi. Calcium polystyrene sulfonate has been used to treat hyperkalemia, particularly in patients who cannot tolerate the extra sodium that would be provided by the sodium salt.

A confection containing sodium polystyrene sulfonate resin 5.0 g per piece was used to treat six chronic dialysis patients with predialysis serum potassium concentrations of 5.2 mmol/l or more (6). Over 2 weeks the mean serum potassium fell by 0.7 mmol/l. However, the effectiveness of sodium polystyrene sulfonate in lowering serum potassium concentrations in patients with renal insufficiency has been questioned (7). A cathartic alone (phenolphthalein) in six patients caused an average fecal potassium output of 54 mmol. The addition of sodium polystyrene sulfonate had no further significant effect on total potassium output. With placebo the average serum potassium concentration increased slightly (0.4 mmol/l) during 12 hours. This rise was attenuated by sodium polystyrene sulfonate, perhaps in part because of extracellular volume expansion caused by the absorption of sodium. Phenolphthalein was associated with a slight rise in serum potassium concentration (similar to placebo), perhaps because of extracellular volume contraction

© 2006 Elsevier B.V. All rights reserved.

produced by a sodium-rich diarrhea and acidosis secondary to bicarbonate loss. None of the regimens reduced the serum potassium concentration, compared with baseline.

Organs and Systems

Respiratory

Pneumonitis has been reported in a woman taking sodium polystyrene sulfonate (8).

Electrolyte balance

Sodium polystyrene sulfonate can cause hypokalemia, hypocalcemia, and hypernatremia (4,5).

Calcium polystyrene sulfonate can cause hypokalemia and hypercalcemia (4,5).

Acid–base balance

Cation-containing antacids and laxatives (for example magnesium hydroxide, calcium carbonate) can reduce the effect of polystyrene sulfonate and metabolic acidosis can develop. This has been reported in both children (9,10) and adults.

- A patient with end-stage renal disease undergoing long-term maintenance hemodialysis developed moderately severe metabolic alkalosis in the absence of vomiting or gastric drainage (10). The cause of the acid–base disorder was the oral administration of exogenous alkali, in the form of "non-absorbable" antacids (aluminium hydroxide and magnesium hydroxide), neutral phosphate, and sodium polystyrene sulfonate.
- In a patient with chronic renal insufficiency, chronic hypocalcemia plus severe metabolic alkalosis due to combined administration of sodium polystyrene sulfonate and magnesium hydroxide caused a generalized tonic-clonic seizure (11).

Hematologic

Thrombocytopenia has been attributed to sodium polystyrene sulfonate (Kayexalate) (12).

- An 84-year-old man with diabetes mellitus and hypertension had gradually worsening renal insufficiency with hyperkalemia and was given oral sodium polystyrene sulfonate (Kayexalate). After 7 days he developed gradually worsening thrombocytopenia, and 12 days later his platelet count, which had initially been 207×10^9/l, fell to 86×10^9/l. The thrombocytopenia rapidly improved after withdrawal of the sodium polystyrene sulfonate. At a later date readministration of sodium polystyrene sulfonate for the treatment of hyperkalemia again caused thrombocytopenia. Bone marrow aspiration biopsy showed normal numbers of nucleated cells and megakaryocytes with no increase in blast count. No other disorders which could have caused thrombocytopenia were seen in this patient.

Gastrointestinal

After oral administration the polystyrene sulfonates commonly cause anorexia, nausea, vomiting, and constipation (4,5).

Esophagus, stomach, and duodenum

Upper gastrointestinal damage associated with sodium polystyrene sulfonate in sorbitol is reported far less often than colonic damage. However, endoscopic appearances were markedly abnormal in 11 patients with crystals of sodium polystyrene sulfonate in biopsies from the esophagus ($n = 7$), stomach ($n = 6$), and duodenum ($n = 2$), in some cases closely mimicking other diagnoses, including esophageal carcinoma, *Candida* esophagitis, and gastric bezoar (13). There was histological and/or endoscopic evidence of mucosal injury in the form of an ulcer or erosion in nine patients, and in four patients with mucosal injury, no other cause could be identified.

Esophageal ulceration has occasionally been attributed to sodium polystyrene sulfonate (14).

- An 83-year-old man with septic shock and renal insufficiency after prostatectomy was given sodium polystyrene sulfonate for hyperkalemia and developed a 3 cm esophageal ulcer. Crystals of sodium polystyrene sulfonate were found in a biopsy.

In five infants of extremely low birth weights, who were given either sodium polystyrene sulfonate or calcium polystyrene sulfonate orally for hyperkalemia, masses were palpable in the left upper quadrant of the abdomen and visible radiographically as opaque masses in the stomach (15). At autopsy, the palpable mass was identified as a solid chalk-like concretion and X-ray diffraction showed that the material was Brushite. The authors suggested that oral exchange resins should not be used in critically ill, extremely low birth-weight infants.

Small bowel

In 15 patients who were given sodium polystyrene sulfonate (Kayexalate) in sorbitol as an enema or orally to treat hyperkalemia, sodium polystyrene sulfonate crystals were observed in specimens from gastrointestinal surgical resections ($n = 9$) or endoscopic biopsies ($n = 7$) (16). There was necrosis in seven of eight surgical resection specimens and three of five endoscopic biopsy specimens; four also had necrosis of the small intestine. Four patients with colonic necrosis in the initial resection specimen developed progressive necrosis of the small intestine or rectum, and five died within 1 day to 6 weeks. There were sodium polystyrene sulfonate crystals in upper gastrointestinal tract specimens from four patients, including one with hemorrhagic gastritis.

The incidence of intestinal necrosis has been estimated in 752 hospitalized patients who had received sodium polystyrene sulfonate, of whom 117 were exposed within 1 week of surgery (17). There were two cases of intestinal necrosis, both in patients who had received oral sodium polystyrene sulfonate in sorbitol. Based on these two cases, the postoperative incidence of intestinal necrosis associated with sodium polystyrene sulfonate was 1.8%. In 862 patients, who had undergone hemodialysis, renal transplantation, or cardiac transplantation, but had not received sodium polystyrene sulfonate, there were no cases of idiopathic intestinal necrosis.

With high doses, intestinal impaction can occur and this has been associated with perforation (18).

- A 650-g, 24-week-old neonate with hyperkalemia was given sodium polystyrene sulfonate enemas and

© 2006 Elsevier B.V. All rights reserved.

developed cecal impaction and perforation. Abdominal radiographs showed radiodense impacted resin outlining the bowel. Pathological examination showed sodium polystyrene sulfonate crystals in a cecal abscess.

Large bowel

After rectal and oral administration, intestinal ulcers and necrosis have occurred (13,19). Several cases affecting the large bowel have been reported and critically ill and uremic patients are at particular risk.

- A 67-year-old man underwent laparotomy for a ruptured abdominal aortic aneurysm (20). Postoperatively he was treated with hemodialysis because of acute renal insufficiency. Hyperkalemia was treated with sodium polystyrene sulfonate, after which he developed ulceration of the colon and required a hemicolectomy because of intractable blood loss.
- Two patients, who had died after cardiac surgery, were in renal insufficiency, and had received sodium polystyrene sulfonate in sorbitol, had colonic luminal crystals of sodium polystyrene sulfonate associated with underlying mucosal necrosis, submucosal edema, and transmural inflammation (21).
- In a patient who developed near-total colonic necrosis shortly after renal transplantation, the onset of symptoms was temporally related to the administration of sodium polystyrene sulfonate plus sorbitol enemas (Kayexalate) for hyperkalemia (22).
- In another case, colonic necrosis presented as an acute abdomen within 24 hours of administration of sodium polystyrene sulfonate in sorbitol (23). After prompt surgical resection of the necrotic transverse colon there was rapid recovery of bowel function.
- A 53-year-old woman took sodium polystyrene sulfonate 15 g twice, 8 days apart, and 15 days later developed colonic necrosis and perforation; there were crystals of sodium polystyrene sulfonate in the inflammatory debris (24).
- An 81-year-old woman with chronic renal insufficiency, who had taken sodium polystyrene sulfonate 2 spoons/day, developed a 3–4 cm ulcer at 45 cm from the anal margin, with crystals of sodium polystyrene sulfonate in the biopsy (25).
- A 74-year-old woman with chronic renal insufficiency, who had taken sodium polystyrene sulfonate 1–2 spoons/day, developed cecal ulceration, with crystals of sodium polystyrene sulfonate in the biopsy (25).
- A giant diverticulum in the sigmoid colon has been attributed to inflammation due to sodium polystyrene sulfonate crystals in a 44-year-old man who had taken 15 mg/day for 2 years (25).

Colonic perforation has been attributed to calcium polystyrene sulfonate in a premature infant (26).

- A boy delivered at 28 weeks was given calcium polystyrene sulfonate 0.2 mg rectally for hyperkalemia (7.1 mmol/l). His abdomen, already distended, became larger with abdominal wall discoloration. An X-ray showed distended loops of bowel and at laparotomy he was found to have a perforation at the rectosigmoid junction.

While crystals of sodium polystyrene sulfonate, which are purple, irregular, and jagged, can be an incidental finding and are not known to cause injury, they are a helpful histological clue to the possibility that sorbitol has been administered (16). Five cases of extensive mucosal necrosis and transmural infarction of the colon have been reported after the use of sodium polystyrene sulfonate (Kayexalate) and sorbitol enemas to treat hyperkalemia in uremic patients (27). The authors also studied the effects of Kayexalate sorbitol enemas in normal and uremic rats and concluded that sorbitol was responsible for colonic damage and that the injury was potentiated in uremic rats. When sorbitol alone or Kayexalate sorbitol was given, extensive transmural necrosis developed in 80% of normal rats and in all the uremic rats. Because uremia and the concomitant use of sorbitol appear to be common denominators in the pathophysiology of this complication, some have suggested that Kayexalate enemas be avoided in renal transplant patients (22). Following reports of colonic necrosis, the Pharmaceutical Affairs Bureau of Japan revised the product information for enemas of polystyrene sulfonate cation exchange resin suspension in sorbitol solution for potassium removal (28).

Two other cases of neonatal bowel opacification secondary to oral and rectal sodium polystyrene sulfonate have been reported (29). Abdominal radiography showed a faint homogeneous increase in density within the bowel lumen.

Hematochezia in a neonate who had been given sodium polystyrene sulfonate enemas prompted a review of the use of such enemas in 20 of 2317 patients (30). Of these 20 patients, four had evidence of hematochezia temporally related to the use of the enemas. There were no episodes of bleeding in infants who were older than 29 weeks or over 1250 g birth weight. In one case, an autopsy performed within 2 days of the enema showed extensive vascular congestion in the mucosa and submucosa, with focal areas of hemorrhage. Sorbitol 20% (1098 mosm/l) was the vehicle for suspension of the sodium polystyrene sulfonate, and the authors thought that the hyperosmolarity of sorbitol had contributed to the colonic damage in these children.

Drug Administration

Drug formulations

Drugs that have similar names are not infrequently confused. The name of Sanofi-Synthelabo's brand of sodium polystyrene sulfonate, Kayexalate, could be confused with the names of proprietary brands of potassium chloride, such as Kay-Cee-L and Kay-Ciel. Furthermore, some formulations of potassium chloride are formulated in packaging that resembles that of Kayexalate. There have been two deaths when potassium chloride was given instead of sodium polystyrene sulfonate for hyperkalemia (31).

Drug–Drug Interactions

Iron

It has been suggested that sodium polystyrene sulfonate might be useful in treating iron overdose, since it binds iron in vitro with high affinity (32). However, in a placebo-controlled crossover study in six healthy adults

© 2006 Elsevier B.V. All rights reserved.

sodium polystyrene sulfonate 30 g had no significant effect on the kinetics of an oral dose of elemental iron 10 mg/kg (33).

Lithium

Sodium polystyrene sulfonate binds lithium in vitro (34); it is more effective than charcoal, but has a higher affinity for potassium (35). In healthy volunteers who took a single dose of lithium carbonate 600 mg, sodium polystyrene sulfonate 30 g reduced the area under the lithium serum concentration-time curve by 11%, reduced the mean C_{max} by 0.07 mmol/l, and delayed the t_{max} by 2.04 hours (36). In six young healthy volunteers who took lithium carbonate 0.5 mmol/kg (18.5 mg/kg), sodium polystyrene sulfonate 857 mg/kg in 4 ml of water/g taken 1 hour later reduced the mean AUC by 15% and the C_{max} by 0.20 mmol/l (37). There was no significant difference in 24-hour urine lithium excretion or in serum sodium and potassium concentrations. Both of these results suggest that sodium polystyrene sulfonate reduces the absorption of lithium. Furthermore, sodium polystyrene sulfonate increased the clearance of oral lithium in a volunteer when given 30 minutes after each dose of lithium (38). For these reasons it has been used to treat lithium overdose (39,40). However, it can cause hypokalemia and is not currently recommended as routine therapy (41).

Tetracyclines

Since calcium salts can bind tetracyclines, leading to reduced absorption (SED-14, 910), an interaction of this kind might be expected with calcium polystyrene sulfonate, but it does not seem to have been reported.

Polytetrafluoroethylene

General Information

Polytetrafluoroethylene (Polytef) is widely used in industry. "Teflon" is used in household appliances to avoid sticking of food. Polytef paste is used for a variety of medical purposes, including replacement grafts in vascular surgery, vocal cord or fold augmentation, and correction of vesicoureteric reflux and urinary incontinence.

The use of polytetrafluoroethylene has become controversial because of reports of granulomatous reactions and distant migration of the material. Foreign body giant cell responses to the polytetrafluoroethylene implant ("teflonoma") have become a serious complication, and animal models have clearly shown a classic foreign body reaction with multinucleated giant cells, granuloma formation, and migration of Teflon into surrounding muscle after Teflon injection (1). Teflon-related granuloma occurred in 1.3% of a series of 155 patients with trigeminal neuralgia treated by microvascular decompression using Teflon (2). Such granulomas can cause compression syndromes at various locations after varying periods of time.

- A patient who had previously undergone suboccipital microvascular decompression for hemifacial spasm presented 3 years postoperatively with a progressive asymmetric sensorineural hearing loss. At surgery a granuloma was found displacing the structures of the internal auditory canal. Histologically, there was evidence of a Teflon fiber-induced giant cell granuloma (3).

Postoperative failure after Teflon sling repair of a rectal prolapse is probably due to poor technique (4).

Organs and Systems

Cardiovascular

Teflon injected in a young woman for urinary incontinence migrated to the pulmonary vascular system (5).

Particles of Teflon can detach from cardiac valve prostheses, producing embolic complications (6).

Nervous system

Periureteral injection of Teflon has been linked to stroke in a previously healthy child 1 year after the procedure (7).

Urinary tract

Refluxing ureters can be treated endoscopically with subureteric injection of polytetrafluoroethylene paste (Polytef), the "STING" procedure. However, ureteric obstruction has been described as a complication (8). Urinary incontinence has also been treated by periurethral or submucosal injections of Polytef, but reports of urinary obstruction (9,10) and poor long-term success (11,12) have limited the range of indications for this treatment. Other reported complications of Teflon injection for stress urinary incontinence include periurethral abscess, urethral diverticulum, Teflon granuloma with urethral wall prolapse (13), and microembolization (14).

Skin

Skin migration following periurethral polytetrafluoroethylene injection for urinary incontinence has been reported (15).

© 2006 Elsevier B.V. All rights reserved.

Musculoskeletal

Interposition of Teflon-Proplast implants for internal derangement of the temporomandibular joint has been used, although cases of osseous destructive changes have been reported (16).

Polyurethanes

General Information

Polyurethanes are organic polymers that are formed by reacting a polyol (an alcohol with more than two reactive hydroxyl groups per molecule) with a diisocyanate or a polymeric isocyanate in the presence of suitable catalysts and additives. Flexible polyurethane forms are used in upholstery, mattresses, chemical-resistant coatings, adhesives, sealants, and packaging. Rigid foams are used in insulation for buildings, water heaters, refrigerated transport, and commercial and residential refrigerators.

In medical practice, polyurethane is used in implants. Complications of polyurethane implants are not uncommon, mainly due to foreign-body reactions (1), such as with microporous polyurethane (Mitrathane) cardiac patch implants and with breast implants.

Long-Term Effects

Tumorigenicity

In a study of the mortality (1958–98) and cancer morbidity (1971–94) in a cohort of 8288 male and female employees from 11 factories in England and Wales engaged in the manufacture of flexible polyurethane foams, mortality from lung cancer in female employees was significantly increased (standardized mortality ratio 181) (2). There was no excess among male employees (standardized mortality ratio 107). There were no significantly increased cause-specific standardized mortality ratios among the subcohort ($n = 1782$) with some period of isocyanate exposure.

Polyvidone

See also Disinfectants and antiseptics

General Information

Polyvidone (polyvinylpyrrolidone, povidone) is a variable-weight polymer of the monomer *N*-vinylpyrrolidinone. When it enters the body, it causes histologically characteristic reactions in tissues with which it comes into contact (1,2).

Polyvidone co-polymers are used in cosmetics as antimicrobials, antistatics, binding compounds,

© 2006 Elsevier B.V. All rights reserved.

stabilizers of emulsions, and film-forming, viscosity-controlling, hair-fixing, skin-conditioning, and skin-protective agents. It is used as a component of hair sprays and as a retardant for subcutaneous injections. It was formerly used as a plasma expander (3) and has been inappropriately used for intravenous injection as a "blood tonic," especially in Asian societies. Some products intended for parenteral administration contain polyvidone as an excipient. Polyvidone is widely used as a suspending and coating agent in tablets, for its film-forming properties in eye drops, and as a carrier molecule for iodine in disinfectants. About 20% of all tablets on the market contain polyvidone. It is also used in the cosmetics industry as a dispersing agent and as a lubricant in ointments.

Povidone-iodine

Povidone-iodine is a macromolecular complex (poly-I(I-vinyl-2-pyrrolidinone)) that is used as an iodophor. It is formulated as a 10% applicator solution, a 2% cleansing solution, and in many topical formulations, for example aerosol sprays, aerosol foams, vaginal gels, ointments, and mouthwashes. Because it contains very little free iodine (less than 1 ppm in a 10% solution), its antibacterial effectiveness is only moderate compared with that of a pure solution of iodine.

Systemic absorption

The extent of systemic absorption of povidone-iodine depends on the localization and the conditions of its use (area, skin surface, mucous membranes, wounds, body cavities).

Healthy skin

Repeated surgical skin antisepsis and hand washing did not increase serum iodine concentrations, but produced a small increase in iodine content in the 24-hour urine (4).

Burns

The use of povidone-iodine for the treatment of burns, for peritoneal lavage in the treatment of purulent peritonitis, or as a rinsing solution for body cavities can increase serum iodine concentrations associated with increased urinary excretion of iodine. In people with burns, the extent of iodine absorption depends on the extent of the burned body surface. It is not uncommon for serum iodine concentrations to rise to more than 1000 μg/ml. If renal function is intact, iodine elimination in the urine can be adequate. The serum iodine concentration returns to normal about 1 week after the last application.

The penetration of povidone-iodine has been studied in vivo in rabbits (5). The penetration from third-degree burns on the back was measured autoradiographically in tissues, blood, urine, and bandages. The results showed that about 20% of iodine is absorbed through fresh necrosis, whereas only 5% is absorbed through a clean wound or 24-hour-old necrosis. The passage through burn necrosis was faster than through vital tissue.

In repeated topical use on burns, the extent of absorption seems to decrease with the treatment time.

Wounds

Povidone-iodine inhibits leukocyte migration and fibroblast aggregation in wounds. The effect on the wound healing process has been studied in 294 children undergoing surgery, 283 of whom had undergone appendectomy (6). In a first series using 5% povidone-iodine aerosol for preoperative disinfection, the postoperative wound infection rate was 19% in the test group and only 8% in the controls. When a 1% povidone-iodine solution was used, only 2.6% of the patients were infected (control group 8.5%). Using a drain with a cellulose viscose sponge, 5% povidone-iodine by aerosol inhibited leukocyte migration, but no cell aggregates or fibroblasts were detected. A 5% solution allowed better cellular movement and attachment to the framework, polymorphonuclear leukocytes predominating. The excipients in the aerosol formula must be more toxic to the cell than those in the solution. If a 1% povidone-iodine solution was absorbed by the sponge, the aggregation phenomenon was only slightly averted and cell morphology was similar to that of the saline control.

Povidone-iodine reduced the number of wound infections only in patients with appendicitis in whom neither peritonitis nor a periappendicular abscess had yet developed (SEDA-11, 489).

Mucous membranes

The effect of a povidone-iodine mouthwash on thyroid function has been studied in 16 medically healthy volunteers. After they had used the mouthwash four times daily for a period of 14 days, all thyroid tests were significantly changed, but there was no suppression of thyroid function. However, this was not to be expected, considering the short test period.

Body cavities

When povidone-iodine is used as a rinsing solution in body cavities, absorption of the whole macromolecular complex is possible. The complex has a molecular weight of about 60 000 and cannot be eliminated by the kidneys or metabolically. It is filtered by the reticuloendothelial system (4,7,8).

Although povidone-iodine is no longer used in dialysates, a povidone-iodine-containing cap is used to seal the Tenckhoff catheter during the day. Iodine-induced hypothyroidism occurred in a 3-year-old boy and an 18-month-old girl, in both cases due to the sealing cap (9). The povidone-iodine inside the cap diffused into the catheter and flushed into the peritoneal cavity at the next dialysis session.

Intravaginal administration

Systemic iodine absorption can occur after intravaginal administration of povidone-iodine (10). There were increases in serum iodine, protein-bound iodine, and inorganic iodine, but not serum thyroxine, after a 2-minute vaginal administration of povidone-iodine in non-pregnant women (11).

Guidelines for the safe use of povidone-iodine complexes

In 1985, a working group of the Federal German Medical Association issued a number of recommendations for the

© 2006 Elsevier B.V. All rights reserved.

safe use of povidone-iodine complexes (12). They remain valid and can be summarized as follows:

1. The application of povidone-iodine formulations cannot be recommended for surgical hand disinfection, since active iodine-free formulations are available.
2. The activity of povidone-iodine in preoperative skin disinfection in adults is well proven.
3. Povidone-iodine is appropriate for skin disinfection before an incision, a puncture, with use of intravenous or arterial catheters, and for the prophylaxis of iatrogenic *Clostridia* infections.
4. In the case of superficial wounds, povidone-iodine can be applied occasionally or repeatedly in spite of increased iodine absorption through the broken skin surfaces.
5. Lavage of wound and body cavities with povidone-iodine or its instillation is not indicated because of increased iodine absorption.
6. Routine body washing of patients in intensive care units is not cost-beneficial.
7. Vaginal administration of povidone-iodine is not recommended.
8. Povidone-iodine is contraindicated in premature babies and neonates; this also applies to prophylactic disinfection of the umbilical stump.
9. The clinical usefulness of povidone-iodine in the treatment of burns is well proven.
10. Local mouth antiseptics serve no therapeutic purpose; this is also true for povidone-iodine.

Organs and Systems

Nervous system

- A 62-year-old man, treated with continuous mediastinal irrigation with a 1:10 solution of povidone-iodine, developed seizures on the fifth day of drainage (13). After the seizure, his serum iodine concentration was raised (120 μg/ml). Renal insufficiency developed at the same time. The electroencephalogram showed no evidence of epileptic activity or other abnormalities. The povidone-iodine irrigation was replaced by continuous irrigation with a solution of neomycin and polymyxin B. Renal function improved and the creatinine concentration returned to normal 3 days after the seizure.

Endocrine

Extensive iodine absorption can cause transient hypothyroidism, or, in patients with latent hypothyroidism, the risk of destabilization and thyrotoxic crisis (SEDA-20, 226) (SEDA-22, 263). Especially at risk are patients with an autonomous adenoma, localized diffuse autonomy of the thyroid gland, nodular goiter, latent hyperthyroidism of autoimmune origin, or endemic iodine deficiency (4).

Povidone-iodine-induced hyperthyroidism is rarer than hypothyroidism (SEDA-20, 226), but a history of long-term use of iodine-containing medications should be considered when investigating the cause of hyperthyroidism (14).

- A 48-year-old woman developed palpitation and insomnia. The clinical history, physical examination, and laboratory tests supported hyperthyroidism. Since July 1994, she had been combating constipation by improper use of an iodine-containing antiseptic cream for external use only. She had inserted povidone-iodine into her rectum by means of a cannula. The iodine-containing cream was withdrawn and she was given a beta-blocker. The palpitation resolved within 2 weeks and her plasma thyroid hormone concentrations normalized within 1 month.

Hyperthyroidism in this patient was probably triggered by improper long-term use of an over-the-counter iodine-containing cream.

Thyrotoxicosis related to iodine toxicity in a child with burns occurred after alternate-day povidone-iodine washes (15).

- A 22-month-old boy was admitted to a pediatric intensive care unit after partial and full thickness burns over 80% of his body surface area. After debridement he was given alternate-day povidone-iodine (Betadine) washes. He became increasingly tachycardic, hypertensive, and hyperpyrexic, with sweating, agitation, and diarrhea and developed neutropenia. Daily sepsis screens were negative. Thyroid function tests showed evidence of iodine-induced thyrotoxicosis. He was given propranolol and carbimazole, and chlorhexidine was substituted for povidone-iodine. His tachycardia, hypertension, and diarrhea slowly improved and his neutropenia resolved. By day 42 his free thyroxine concentration was normal and he was given thyroxine. On day 63 the carbimazole, propranolol, and thyroxine were withheld. However thyroid function tests 1 week later showed hypothyroidism, and thyroxine was restarted. Repeat plasma and urine iodine concentrations on day 57 (a month after withdrawal of povidone-iodine) continued to show marked urinary excretion of iodine (urine concentration 65 μmol/l, reference range 0.39–1.97) with high but falling plasma iodine concentrations (5.9 μmol/l, reference range 0.32–0.63).

Hematologic

Severe neutropenia occurred in a patient in whom deep, second-degree burns, involving about 50% of the body surface, were being treated with Betadine Helafoam twice a day (16).

Liver

There have been reports of liver damage from polyvidone (17).

Urinary tract

Povidone-iodine sclerosis has been suggested to be safe and effective in treating lymphoceles after renal transplantation, with only minor complications of the procedure, such as pericatheter cutaneous infections. However, a case of acute renal tubular necrosis has been reported (18).

- In a 23-year-old woman, a kidney allograft recipient with recurrent lymphoceles treated with povidone-iodine irrigations (50 ml of a 1% solution bd for 6 days), a metabolic acidosis occurred and renal function

© 2006 Elsevier B.V. All rights reserved.

deteriorated. After a few days, despite suspension of irrigation, the patient developed oliguria, and dialysis was needed. A renal biopsy showed acute tubular necrosis.

Iodine-induced renal insufficiency has also been reported after the use of topical povidone-iodine on the skin and after intracavity irrigation.

- A 65-year-old man with second- and third-degree burns covering 26% of his body was given intravenous lactated Ringer solution and topical silver sulfadiazine in addition to debridement and skin grafting (19). However, he developed a wound infection with *Pseudomonas aeruginosa*, which was treated successfully with topical povidone-iodine gel. Persistent nodal bradycardia with hypotension, metabolic acidosis, and renal insufficiency occurred 16 days later. Iodine toxicosis was suspected and the serum iodine concentration was 206 μg/ml (reference range 20–90 μg/ml). The povidone-iodine gel was therefore withdrawn immediately. His family refused hemodialysis and he died 44 days after admission.
- A 57-year-old man developed renal insufficiency after triple coronary bypass grafting, 7 days after povidone-iodine mediastinal irrigation and required 3 days of renal replacement therapy (20). Complete resolution occurred within 8 days and followed a short non-oliguric phase (4 days).

Although other common causes of acute renal insufficiency were present in the second case, the only significant change in management at the time of onset of renal insufficiency was the use of povidone-iodine.

Skin

Povidone-iodine causes concentration-dependent damage to cells and clusters. The effect is most pronounced for isolated cells, but it is also detectable in more complex tissues. Clinical experience with burn victims cannot rule out the possibility that the healing process may be slightly retarded. However, this deficiency may be balanced by an appropriate microbicidal effect on the healing edge (21).

Polyvidone storage disease

Polyvidone molecules that weigh less than 20 kD can be excreted by a normally functioning kidney, whereas larger polymers are phagocytosed and permanently stored in the mononuclear phagocytic system, causing so-called polyvidone storage disease. Polyvidone storage disease occurs in patients who have received polyvidone for prolonged periods of time. The large polymers deposit in the histiocytes and cause them to proliferate and infiltrate histiocytes in the reticuloendothelial system, including osteocytes. There is generally no significant damage to these organs, except that prolonged administration can cause bone destruction, skin lesions, arthritis, and polyneuropathy.

The first cutaneous case of polyvidone storage disease, reported in 1964 (22), was caused by local injection of polyvidone-containing posterior pituitary extracts for the treatment of diabetes insipidus. Similar cases, including those following local injection of porcine polyvidone to treat neuralgia, were documented, mostly in European reports (23,24). Localized cutaneous polyvidone storage disease was then known as Dupont-Lachapelle disease (25).

Five cases of polyvidone storage disease with cutaneous involvement have been documented (26). Two patients presented with skin eruptions mimicking collagen vascular disease and chronic pigmented purpuric dermatosis. In one, polyvidone was found in a metastatic tumor and in the other in a pemphigus lesion. The fifth case was seen in a blind skin biopsy specimen taken to exclude Niemann-Pick disease after examination of a bone marrow smear. The latter patient and the patient with a collagen vascular-like disease also had severe anemia and serious orthopedic and neurological complications due to massive infiltration of polyvidone-containing cells in the bone marrow, with destruction of the bone.

Polyvidone storage disease can easily be diagnosed by its histopathological features. Skin biopsy specimens show a variable number of characteristic blue–gray vacuolated cells around blood vessels and adnexal structures, and stain positively with mucicarmine, colloidal iron, and alkaline Congo red and negatively with periodic acid Schiff and Alcian blue.

Musculoskeletal

Pathological fractures of several bones and destructive lesions seen radiologically in other bones have been reported in patients who had received repeated intravenous injections of polyvidone for many years (27,28). Biopsies of the fracture sites showed both intracellular deposits of polyvidone and mucoid changes in the affected cells. If of sufficient severity, this may cause a virtual "melt down" of osseous tissue.

Immunologic

Polyvidone has been reported to cause anaphylaxis (29).

- A 32-year-old man took paracetamol (in Doregrippin) for flu-like symptoms and about 10 minutes later developed generalized urticaria, angioedema, hypotonia, and tachycardia, and became semiconscious. His symptoms were rapidly relieved by intravenous antihistamines and steroids. This was the first time he had taken Doregrippin, but he had previously taken paracetamol-containing formulations, which had been well tolerated. He was not taking any regular medications. Subsequent testing of the various constituents of the analgesic tablets identified polyvidone as the cause of the anaphylactic reaction.

This report demonstrates a rare case of a type I allergic reaction toward a commonly used ingredient of tablets and widely used disinfectants.

In principle, all forms of the well-known iodine-induced allergic reactions, such as iododerma tuberosum, dermatitis, petechiae, and sialadenitis are possible with povidone-iodine, but the incidence seems to be very low (SEDA-11, 489) (SEDA-12, 586) (4,30,31).

- A severe anaphylactoid reaction occurred immediately after the instillation of a 10% solution of povidone-iodine into a hydatid cyst cavity during surgery. Severe bronchospasm developed immediately and was

© 2006 Elsevier B.V. All rights reserved.

followed by a coagulopathy and subsequent liver and renal insufficiency (32).

There have been only a few reports of contact allergy to povidone-iodine, despite its widespread use. In two cases there were positive patch test reactions on days 2, 3, and 7 to povidone-iodine (5% aqueous) and iodine (0.5% in petrolatum), but negative reactions to povidone itself (33).

Second-Generation Effects

Pregnancy

Routine vaginal douching with povidone-iodine during pregnancy causes maternal iodine overload and markedly increases the iodine content in amniotic fluid and of the fetal thyroid, as soon as the trapping mechanism of iodine by the thyroid has started to develop. Vaginal use of povidone-iodine is therefore not recommended during pregnancy (34,35) and labor (36).

The fetal thyroid starts to store iodine between the 10th and 13th weeks of gestation, and to secrete thyroid hormone between the 18th and 24th weeks. Especially after intravaginal administration during pregnancy, povidone-iodine can cause congenital goiter and hypothyroidism in newborn infants. However, hyperthyroidism can also occur.

In 99 of 9320 newborns, TSH concentrations were above the reference range (20 mU/ml) on the fifth day of life, but between the 10th and 21st day, all these infants had normal TSH concentrations and normal thyroid function (37). In 76 of the newborns with hyperthyrotropinemia, urinary iodine excretion was significantly raised (above 16 μg/ml). Most of them were born in obstetric departments where iodophores were routinely used for disinfection during labor.

In 66 mothers and their infants, povidone-iodine was given during labor and delivery as a 1 or 2% solution pumped intravaginally through a plastic catheter until delivery (for 5–30 hours), urinary iodide concentrations on the first and the fifth day, and serum iodine concentrations at birth were significantly raised in the mothers as well as in the neonates (38). At birth, the TSH concentrations in the mothers and infants were no different from those in the controls, but on the third and fifth days they were significantly higher. Thyroxine concentrations were significantly lower in the exposed mothers and infants (at birth and on the third and the fifth days). One-fifth of the infants had high TSH concentrations (above 20 μU/ml) and low thyroxine values (below 7 μg/ml), which is suggestive of hypothyroidism. However, none of the infants developed clinical symptoms, and on the 14th day the values were normal again. In the iodine-exposed mothers and infants, tri-iodothyronine (T3) concentrations were significantly reduced at birth, but not thereafter. The concentrations of reverse T3 did not differ from the controls at birth, but were significantly lower on succeeding days. This reduction in reverse T3 in the iodine-exposed infants was probably due to reduced thyroxine concentrations, causing a lack of substrates for monodeiodination to reverse T3.

Iodine concentrations in breast milk and in random urine in neonates and the serum concentrations of neonatal TSH and free thyroxine on day 5 after delivery were measured after the use of povidone-iodine for disinfection after delivery (36). Iodine concentrations in the breast milk and neonatal TSH were significantly raised.

Perinatal iodine exposure causes transient hypothyroidism in a significant number of neonates, in whom careful monitoring and follow-up of thyroid gland function are needed. It is better to avoid the use of iodine-containing antiseptics in pregnancy and neonates, especially if follow-up cannot be guaranteed.

Susceptibility Factors

Age

Neonates

Hypothyroidism in neonates has been related to the use of small doses of iodine as an antiseptic. The high vulnerability of the neonatal thyroid is a reason for avoiding povidone-iodine for care of the umbilical stump or omphaloceles (SEDA-11, 488) (SEDA-12, 585) (39).

Serum TSH and thyroxine concentrations have been measured 57 days after birth in 365 healthy newborns whose umbilical stump had been treated with 10% povidone-iodine (40). The prevalence of high TSH concentrations was significantly higher in this group than in the general population (3.1 versus 0.4%), as was the rate of transient hypothyroidism (2.7 versus 0.25%). All the children were normal when retested 1 week later.

Transient hypothyroidism due to skin contamination with povidone-iodine occurred in a neonate with an omphalocele (41).

The postnatal iodine overload, measured as urinary iodine concentration, has been studied in ill neonates after the cutaneous application of povidone-iodine (0.96% I_2; Betadine) (SEDA-11, 488) (39). The mean iodine overload was 1297 μg/day in one povidone-iodine group and 1253 μg/day in a second group; in the control group, 64% of the newborns had iodinuria of less than 100 μg/day, and of the 10 others (mean ioduria 1212 has been studied in ill neonates) three were born by cesarean section: in these cases the mothers received an iodine-containing curariform agent. There were 12 cases of hypothyroidism among the neonates exposed to iodine-containing antiseptics, but none in the control group.

Very low birth weight infants admitted to a neonatal intensive care unit who had been given chlorhexidine-containing antiseptics ($n = 29$) were compared with infants in a comparable unit who had been given iodinated antiseptic agents ($n = 54$) (42). The latter had an up to 50-fold higher increase in urinary iodine excretion than the controls. The median serum TSH concentration was significantly higher in the iodine-exposed infants (4.6 mU/ml) than in the control infants (2.4 mU/ml). On day 14, TSH concentrations in nine of the 36 iodine-exposed infants were above 20 mU/ml, their mean thyroxine concentration was significantly lower (44 nmol/1) than the mean thyroxine concentrations (83 nmol/l) in both the exposed infants with normal TSH concentrations and the controls.

Renal disease

Since iodine is eliminated by the kidneys, renal insufficiency increases the risk of toxicity, and the risk may be further increased by metabolic acidosis (43,44).

Drug Administration

Drug contamination

Bacterial contamination of povidone-iodine formulations has been reported. *Pseudomonas cepacia* was discovered in the blood cultures of 52 patients in four hospitals in New York over 7 months, and of 16 patients in a Boston hospital over a 10-week period in 1980 (45). A contaminated povidone-iodine solution produced by one manufacturer was implicated as the source of the bacteria. It is not clear why this solution was contaminated, whereas other marketed povidone-iodine solutions containing equivalent amounts of available or free iodine remained sterile.

Interference with Diagnostic Tests

Povidone-iodine gives a positive reaction with an orthotoluidine reagent used to detect blood in the urine, for example Hematest reagent tablets or dipsticks (SEDA-11, 488) (46).

Povidone-iodine used for skin disinfection before skin puncture blood was taken altered serum concentrations of potassium, phosphate, and uric acid.

Posaconazole

See also Antifungal azoles

General Information

Posaconazole is similar in structure to itraconazole. It was well tolerated and as effective as fluconazole 100 mg in two large randomized comparisons in HIV-infected patients with oropharyngeal candidiasis. In a salvage study in patients with a variety of invasive fungal infections, there were response rates of 44–80% in patients with aspergillosis, fusariosis, cryptococcosis, candidiasis, and pheohyphomycoses after 4–8 weeks of therapy (1,2).

Potassium chloride

General Information

Oral potassium chloride is used to prevent or correct potassium depletion due to diuretic use or other conditions. Potassium chloride is available not only for medicinal purposes but also as a food supplement and salt substitute.

The main adverse effects of oral potassium salts are hyperkalemia, particularly when they are used in combination with potassium-sparing drugs, such as spironolactone and ACE inhibitors, and gastrointestinal ulceration and perforation, particularly with modified-release formulations. The problems surrounding enteric-coated potassium chloride tablets are unresolved. Despite recommendations that they be withdrawn, some are still available. The risks seem to be less with slow-release potassium chloride tablets.

Simple dietary measures provide adequate potassium intake, and it is questionable whether for most patients potassium supplementation in any pharmaceutical form is necessary, as opposed to the use of potassium-sparing drugs.

Organs and Systems

Cardiovascular

When potassium chloride is given by intravenous infusion for the treatment of potassium depletion (for example in diabetic ketoacidosis) there is a risk of cardiac dysrhythmias if the infusion is too rapid. The rate of infusion should be no greater than 20 mmol/hour.

Electrolyte balance

Hyperkalemia is a risk of potassium chloride administration whether medicinal or not. The wide availability of potassium salts can contribute to accidental fatal hyperkalemia. Hyperkalemia has been reported after ingestion of salt substitutes (1,2) and over-the-counter potassium supplements (3).

Gastrointestinal

Potassium chloride is irritating to the gastrointestinal tract, even to the extent of causing perforation (4). In a retrospective study at surgical clinics in Stockholm County there were 22 cases of small-bowel ulceration in which a connection with slow-release potassium chloride tablets was probable (5). Most of the ulcers had caused stenosis of 1–2 cm of gut, and in four cases there was also perforation of the bowel wall. Five patients had perforation without signs of stenosis. Mortality was 27%. The pathology of the ulcers was similar to that described after use of enteric-coated potassium chloride tablets. The frequency of potassium-induced ulceration is low (about 3 cases per 100 000 patient-years of slow-release tablet use), but this complication can be serious.

Susceptibility Factors

Renal disease

The risk of hyperkalemia from potassium chloride is increased in patients with renal insufficiency (6).

Drug Administration

Drug formulations

Microencapsulated potassium chloride tablets have been reported to be less irritating to the gastrointestinal tract than other forms of potassium chloride. In a comparison of a microencapsulated potassium chloride formulation and a wax-matrix formulation in 48 healthy volunteers, the latter were associated with a higher incidence of upper gastrointestinal lesions determined by endoscopy after 1 week (7). The lesions were not accompanied by epigastric symptoms. Glycopyrrolate, given to some volunteers to reduce gastric emptying, aggravated the effects of potassium chloride.

Drug–Drug Interactions

Potassium-sparing drugs

The risk of hyperkalemia with potassium chloride formulations increases when they are given in combination with drugs that are potassium sparing (8), such as ACE inhibitors and angiotensin II receptor antagonists (9), canrenone, spironolactone (10), amiloride, and triamterene (11).

Potassium perchlorate

General Information

Potassium perchlorate is a thyrostatic drug that is still used (in a dose of 1000 mg/day or more) as an alternative to the thionamides, especially in cases of allergy. It has also been used to treat the iodine-induced form of thyrotoxicosis, such as type 1 hyperthyroidism due to amiodarone (qv).

Compared with the thionamides, potassium perchlorate has two disadvantages:

1. treatment cannot be directly changed to radioiodine therapy, since perchlorate elimination lasts for some weeks;
2. brief high-dose iodine therapy cannot be used as a preoperative thyrostatic measure.

Potassium perchlorate produces goiter, as do the thionamides, but its effects on the hematological system are the main reason for using it sparingly.

Organs and Systems

Hematologic

Agranulocytosis and aplastic anemia have been described in patients taking potassium perchlorate (SED-8, 897) (1). Deaths have been recorded as a result (2,3).

© 2006 Elsevier B.V. All rights reserved.

Skin

Erythema nodosum associated with lupus erythematosus cells has been described as an adverse effect of potassium perchlorate (SED-8, 897) (1).

Practolol

See also Beta-adrenoceptor antagonists

General Information

Practolol is a highly cardioselective beta-adrenoceptor antagonist with partial agonist activity.

Although practolol has long been withdrawn from general oral use (because of the oculomucocutaneous syndrome and sclerosing peritonitis) (1), it is still available for intravenous administration in some countries. The practolol syndrome included a psoriasiform rash, xerophthalmia due to lacrimal gland fibrosis, secretory otitis media, fibrinous peritonitis, and a lupus-like syndrome (SED-8, 444) (SEDA-3, 161) (SEDA-2, 170). The pathogenesis of this adverse effect is unknown, but it appears to be unique to practolol.

Pramipexole

General Information

Pramipexole is a non-ergot dopamine agonist similar to bromocriptine, used in the management of Parkinson's disease as an adjunct to levodopa.

In a systematic review of randomized controlled trials of pramipexole and ropinirole, dizziness, nausea, hypotension, hallucinations, and somnolence were common adverse effects (1). In 306 patients adverse events secondary to pramipexole that occurred in over 10% included dyskinesias, asymptomatic orthostatic hypotension, dizziness, insomnia, and hallucinations (2).

Organs and Systems

Cardiovascular

Orthostatic hypotension is common during oral pramipexole therapy (2).

Peripheral edema has occasionally been described as an adverse effect of dopamine agonist therapy and has been reported in 17 of 300 patients treated with pramipexole (3). The mean dose at onset of edema was 1.7 mg/day and the time after initiation of therapy was 2.6 months. In all cases the edema disappeared after the drug was withdrawn but reappeared on rechallenge. Although the condition was dose-dependent in affected individuals its occurrence was idiosyncratic with no obvious predisposing features. Response to diuretics was minimal.

Nervous system

Drowsiness, dizziness, and insomnia are relatively common adverse nervous system effects of pramipexole in patients with early Parkinson's disease (2).

Worsened dyskinesia is the most common outcome in patients with advanced disease taking concomitant levodopa therapy. In a systematic review of four randomized, placebo-controlled trials of pramipexole in 669 patients with idiopathic Parkinson's disease and long-term complications of levodopa therapy, there were no significant changes in a dyskinesia rating scale, but dyskinesia as an adverse event was reported more often with pramipexole (4).

Eight men aged 54–83 years, who had taken pramipexole 1–4.5 mg/day for Parkinson's disease for an average of 7 months, all fell asleep while driving, resulting in accidents but no injuries (5). They described sudden irresistible sleepiness, with virtually no warning, and four had had similar episodes during other activities. In six patients pramipexole was withdrawn, and in the other two the dose was reduced.

However, doubt has been cast on the existence of sleep attacks, that is acute episodes of sleep that occur without warning, with the newer dopamine receptor agonists (6). In the view of the authors of this review underlying somnolence is always present, even if the patient is not aware of it. They did not attempt to differentiate the risk associated with different agents, but noted that pramipexole doses below 1.5 mg/day are usually adequate and much less likely to cause this problem than higher doses. In general they stressed the importance of keeping doses of all the agents as low as possible and of warning patients about the risk, particularly when driving. They also commented that the possibility of an underlying sleep disorder should be considered in these circumstances.

A study of the effects of pramipexole was generally in agreement with these conclusions (7). In a double-blind study 22 patients were randomized to pramipexole monotherapy (mean 4.4, range 1.5–6, mg/day) and 18 to placebo. Six patients taking pramipexole reported somnolence (one moderate, five mild), compared with two patients taking placebo (one moderate, one mild).

© 2006 Elsevier B.V. All rights reserved.

In an open extension of the study, 21 of 37 patients reported somnolence, including 11 with moderate and 3 with severe symptoms. The onset of symptoms occurred at a mean dosage of 4 mg/day and patients had been taking treatment for 10 months on average at the time of the worst symptoms. Of the 14 patients with moderate to severe symptoms, 12 were interviewed in detail; 7 reported falling asleep while driving and 2 had been involved in minor accidents. Most of the patients reported continuous drowsiness as a background, but three said that they experienced sudden waves of irresistible sleepiness, although with some prodromal symptoms. The symptoms resolved on drug withdrawal or dosage reduction (though details of this were not given), and the comments on dosage from the previous paper are surely relevant. In patients taking pramipexole patient education is clearly of vital importance.

The pathophysiology of the restless legs syndrome is poorly understood, but it often responds well to dopaminergic therapy. However, augmentation of symptoms has also been described, especially with levodopa. Of 60 patients (mean age 58 years) with this syndrome who were treated with pramipexole (0.25–1.0 mg/day) 5 had augmentation of symptoms over a period of at least 6 months during continuous treatment and 4 had what was described as a secondary syndrome, in other words with co-existing and possibly causative neurological disease (8). There was no relation to the initial severity of the syndrome or to the dosage of drug, although the authors suggested that the very low dose of 0.25 mg/day is probably optimal.

Psychological, psychiatric

Hallucinations occur in about 10% of patients with Parkinson's disease, regardless of the stage of disease (2).

Fluid balance

Peripheral edema and weight loss have been reported occasionally during pramipexole therapy. Of 300 patients taking pramipexole, 17 had mild to severe peripheral edema attributable to the drug (3). The mean dosage was 1.7 (range 0.75–3.0) mg/day when the edema first appeared and 2.6 (range 1.5–3.0) mg/day when it was at its worst. In all cases, the edema rapidly abated on withdrawal, and rapidly returned on rechallenge.

Gastrointestinal

Gastrointestinal symptoms have tended to be more frequent in patients with early Parkinson's disease compared with those with advanced disease during pramipexole therapy. In patients with early disease, the most common effects have been nausea (up to 20% of patients), dry mouth (up to 10%), and constipation (7%), whereas less frequent ones, such as dyspepsia, anorexia, dysphagia, and flatulence, have been observed (9). In patients with advanced disease, the overall incidence of adverse gastrointestinal effects is usually 5% or less, and includes constipation, dry mouth, and flatulence (10). Abdominal pain and vomiting occasionally occur.

Hair

Hair loss has been attributed to dopamine receptor agonists.

- Two women in New York, aged 66 and 68 years, took pramipexole 15 and 3.5 mg/day (11). Both developed progressive hair loss 2–12 months later. When pramipexole was withdrawn, there was partial regrowth of hair. Ropinirole and levodopa did not provoke hair loss in these women.

The authors noted that this problem appears to be confined to women, at least according to published reports. The mechanism is unknown.

Pranlukast

See also Leukotriene receptor antagonists

General Information

Pranlukast is a leukotriene receptor antagonist. It was developed primarily for the Japanese market and there is little international experience of it. To date, adverse events have occurred in under 1% of patients and gastrointestinal effects were the most common, accounting for 4.7% of reported adverse events (1).

© 2006 Elsevier B.V. All rights reserved.

Organs and Systems

Respiratory

Lung injury with interstitial pneumonitis has been attributed to pranlukast (2).

- A 62-year-old woman with severe asthma took oral pranlukast 450 mg/day and oral prednisolone 80 mg/day for a severe asthmatic attack. After oral prednisolone was tapered and subsequently withdrawn by day 35, she was maintained on pranlukast only and 5 days later had fever, deteriorating pulmonary symptoms, hypoxemia, and bibasal reticulonodular pulmonary infiltrates on chest CT. A transbronchial biopsy was consistent with drug-related interstitial pneumonitis. A lymphocyte stimulation test was positive for pranlukast. Her fever abated and her pulmonary symptoms markedly improved 3 days after withdrawal of pranlukast, and 5 months later the pulmonary infiltrates had completely resolved.

Immunologic

The association of cysteinyl leukotriene receptor antagonists with eosinophilic conditions, especially Churg–Strauss syndrome, has generated widespread interest. However, evaluation of the few data is hampered by poor understanding of the underlying pathophysiology of the syndrome as well as by the limited knowledge of the effect that cysteinyl leukotriene has on the immune response and the possibility of interacting genetic polymorphisms (3).

- A 26-year-old asthmatic woman had severe acute necrotizing eosinophilic endomyocarditis while taking pranlukast, inhaled beclomethasone, and oral theophylline (4). Oral prednisolone had been replaced by pranlukast 9 months before the event. Cardiac injury was accompanied by peripheral eosinophilia, cardiogenic shock, and pulmonary infiltrates, suggesting atypical Churg–Strauss syndrome. She recovered after intensive treatment, steroid pulse therapy, and withdrawal of pranlukast.
- A 53-year-old asthmatic woman developed p-ANCA-positive vasculitis while taking pranlukast 450 mg/day (5). Inhaled beclomethasone dipropionate had previously been tapered from 1200 to 800 µg/day over the previous 17 months. She had a mononeuritis multiplex, eosinophilia, and sinusitis. A lymphocyte stimulation test was negative for pranlukast.

In the second case, because p-ANCA had been positive before the patient started to take pranlukast, the authors suggested that her Churg–Strauss syndrome had occurred either through unmasking of a previously unrecognized forme fruste, through tapering the inhaled corticosteroid, or had been coincidental with the natural course of a pre-existing progressive Churg–Strauss syndrome.

In an NIH workshop summary report on the relation between asthma therapy and Churg–Strauss syndrome, the authors concluded that no one compound or class of antiasthmatic agents was solely implicated. An association was found for pranlukast, montelukast, zafirlukast, the 5-lipoxygenase inhibitor zileuton, inhaled corticosteroids, and salmeterol. As corticosteroids constitute the principal therapy of Churg–Strauss syndrome, tapering of these agents may allow incipient Churg–Strauss syndrome to become manifest. In patients who develop Churg–Strauss syndrome and do not receive corticosteroids (6–8), these various antiasthmatic medications might be used to treat asthmatic symptoms but not the underlying Churg–Strauss syndrome (3).

Pranoprofen

See also Non-steroidal anti-inflammatory drugs

General Information

Pranoprofen is an arylalkanoic acid NSAID (1).

Respiratory

Acute eosinophilic pneumonia has been attributed to pranoprofen in a 48-year-old man (2).

Gastrointestinal

Multiple small bowel ulcers and massive bleeding occurred in a patient taking oral pranoprofen and rectal indometacin (SEDA-17, 113).

Urinary tract

Hemolytic urenic syndrome has been reported in a 25-year-old woman on two separate occasions (3).

Pravastatin

See also HMG Co-A reductase inhibitors

General Information

In a placebo-controlled study of 1142 hypercholesterolemic patients treated with pravastatin for 8–16 weeks, the numbers of "adverse drug experiences" were similar in the treated and untreated individuals (1). Rash was the only adverse clinical event that was different (4.0 versus 1.1%). However, in the same patients withdrawal of therapy during follow-up was thought to be necessary in 3.2% of those given pravastatin alone. Myopathy was observed in one instance only, and increases in creatine kinase activity in those taking pravastatin did not differ significantly from controls. There were marked persistent increases in transaminases in 1.1%, with no cases of symptomatic hepatitis. Pravastatin is believed to have a particularly low potential for nervous system-related adverse effects, as it has not been shown to enter the cerebrospinal fluid, and clinical experience suggests that muscle toxicity occurs less often with pravastatin than with lovastatin (2).

Organs and Systems

Respiratory

- A 41-year-old man, who had been taking pravastatin for 2 years, developed a hypersensitivity pneumonitis with eosinophilia; the symptoms gradually resolved after withdrawal of pravastatin (3).

Metabolism

- After short-term treatment with pravastatin, a 77-year-old woman transiently developed symptoms diagnosed as porphyria cutanea tarda (4).

Liver

Acute cholestatic hepatitis occurred after 7 weeks of pravastatin 20 mg/day. There was no evidence of allergy (5). It is possible that pravastatin enhances the toxicity of simultaneously administered drugs, for instance, metoprolol in the present case.

- A 64-year-old woman who was twice treated with pravastatin had cholestasis on both occasions with minimal hepatocellular injury (6).

Musculoskeletal

Although myopathy is rarely seen with pravastatin in clinical trials, it does occur.

- Rhabdomyolysis was suspected in a 67-year-old obese man with an acute myocardial infarction (7).
- A 37-year-old man with sarcoidosis developed marked myotonia during several years while he was taking pravastatin 20 mg/day (8). On drug withdrawal his symptoms improved after 2 months.

This association does not prove a causal relation. The authors of the second report pointed to previous observations of myotonia both in sarcoidosis and during the administration of various drugs.

Reproductive system

- A man taking pravastatin 20 mg/day for 3 months reported gynecomastia, which regressed after withdrawal of the drug; he was also taking allopurinol (9).

Drug–Drug Interactions

Fibrate

Rhabdomyolysis can occur when pravastatin is combined with a fibrate (SEDA-21, 460) (10).

Warfarin

With concurrent administration of warfarin and pravastatin there was no evidence of an interaction as assessed by prothrombin time (11).

Praziquantel

General Information

Praziquantel, initially introduced as a veterinary cesticidal drug, was found to have efficacy against all the human species of schistosomes (including cerebral forms), fasciolopsiasis, cysticercosis, paragonimiasis (lung fluke), *Clonorchis sinensis* (oriental liver fluke), and *Opisthorchis viverrini* infections. It is used in a single oral dose of 40 mg/kg, except in infestations with *Schistosoma japonicum*, *Clonorchis*, and *Paragonimus*, for which more prolonged administration is required, doses varying from 40 to 70 mg/kg/day depending on the infecting species. Evaluation of the result of praziquantel treatment has shown a lower laboratory rate of success than reported for clinical response (SEDA-16, 311).

Praziquantel is effective in human cysticercosis in doses of 10–100 mg/kg for 3–21 days (1). Initially, longer courses of praziquantel were advocated, but even shorter treatment regimens are equally effective: a complete course can be administered in a single day with comparable efficacy as conventional therapy of 15 days. Praziquantel was originally introduced as a racemic mixture; there is evidence that the levorotatory isomer is relatively more effective, but has the same incidence of adverse reactions (2).

Praziquantel is well absorbed and penetrates cyst walls, but it undergoes first-pass metabolism, especially when given together with glucocorticoids and anticonvulsants.

Observational studies

Echinococcosis

The management and operative complications in 70 patients with hydatid disease aged 10–78 years have been studied retrospectively to assess the impact of albendazole and praziquantel compared with surgery (3). In all, 39 patients received albendazole and praziquantel in combination and 19 received albendazole alone; none was treated with praziquantel alone. The combined use of albendazole and praziquantel preoperatively significantly reduced the number of cysts that contained viable protoscolices.

Neurocysticercosis

Praziquantel is generally used to treat neurocysticercosis in an oral dose of 50 mg/kg/day (divided into three doses) for 15 days. Sedation can be marked and driving should be avoided. Liver enzymes sometimes increase. Ocular cysticercosis should not be treated with praziquantel, because destruction of the parasite within the eye can cause irreparable lesions.

A one-day intensive course of praziquantel has been used experimentally, but results vary, and when there are multiple brain cysts present the outcome is poor (4). When used for this purpose in a dose of 25 mg/kg at 2-hour intervals, adverse effects included mild headache, dizziness, nausea, and vomiting. All the adverse effects remitted with analgesics or dexamethasone 0.2 mg/kg/day and continued for 2 days.

Paragonimiasis

Paragonimiasis is a food-borne parasitic disease common in Southeast Asia, especially in Japan, Korea, The Philippines, Taiwan, and parts of China. In Japan, paragonimiasis is caused by either *Paragonimus westermani* or *Paragonimus miyazakii*. Traditionally biothionol was used to treat paragonimiasis, a food-borne zoonosis that is endemic in limited areas of the world. However, owing to the need for long-term administration and moderate to severe adverse effects, such as nausea and diarrhea, biothionol has been replaced by praziquantel. At a dose of 75 mg/kg/day for only 2–3 days, praziquantel has the advantage of an easier dosing schedule in combination with excellent therapeutic efficacy. Adverse effects of praziquantel in paragonimiasis, if any, are mild and transient (5). In patients with pleural effusion, pleural fluid must be drained before starting chemotherapy; insufficient drainage often causes complications, such as chronic empyema or insufficient inflation of the lungs. Praziquantel is also effective for cutaneous, cerebral, or any form of extrapulmonary paragonimiasis.

The radiological features and treatment of paragonimiasis have been described in 13 patients (10 men, three women, aged 25–77 years) (6). All were treated with praziquantel 75 mg/kg/day for 2–3 days. One patient with empyema was also given bithionol. There was mild urticaria in two patients and no serious adverse effects.

Tenia infections

In a report from India the efficacy and safety of treatment of niclosamide-resistant *Tenia saginata* infections with praziquantel 10 mg/kg orally has been confirmed in 185 consecutive patients (7). Follow-up stool examinations at 4 and 12 weeks showed a cure rate of 96%. Eleven patients were lost to follow-up, and eight still produced proglottides at the end of 12 weeks. None passed the worm in their stools, since praziquantel destructs the worm, after which the scolex and worm are digested. Thirty patients (16%) reported minimal adverse effects, such as nausea ($n = 4$), abdominal discomfort ($n = 10$), and giddiness ($n = 16$).

Comparative studies

Praziquantel 100 mg/kg in three divided doses has been compared with albendazole 15 mg/kg/day for 1 week in the treatment of neurocysticercosis in 20 patients (8). In the patients treated with albendazole the number of cysts fell from 64 to 7 and in the patients treated with praziquantel it fell from 59 to 24. The difference was not

© 2006 Elsevier B.V. All rights reserved.

statistically significant. All the patients were concomitantly treated with high doses of glucocorticoids. Nine of the ten patients treated with praziquantel had seizures, headache, and dizziness, and two had hemiparesis before treatment. A few hours after the last dose of praziquantel six patients had adverse reactions, including headache and vomiting in five patients, seizures in one patient, and worsening of the pre-existing motor deficit in one. Analgesics and antiemetics improved the symptoms in four patients. In two patients treatment with mannitol was needed to relief symptoms of increased cranial pressure. The results suggested that single-day treatment with praziquantel of neurocysticercosis may be a useful option. The observed adverse effects were considered to be the result of the inflammatory reaction following the dying of worms and not a toxic effect of the drug itself.

Placebo-controlled studies

In a double-blind, randomized, placebo controlled trial of praziquantel in 42 patients with clonorchiasis and an open study in 32 patients, the adverse effects of praziquantel were transient and included nausea and vomiting (15%), vertigo (12%), hepatomegaly (4.5%), headache (1.5%), rash (1.5%), and hypotension (1.5%) (9). Of 20 patients who received placebo, one developed a transient skin rash, fever, and chills. There were minor and transient, albeit statistically significant, changes in hemoglobin and serum concentrations of total protein, uric acid, cholesterol, and bilirubin.

General adverse effects

Although adverse effects are common they tend to be mild and it is rarely necessary to withdraw praziquantel for this reason; even when used in relatively high doses, as in schistosomiasis, praziquantel has, according to the *British National Formulary* (September 2005), "the most attractive combination of effectiveness, broad-spectrum activity, and low toxicity [of all antihelminthic drugs]." The most common problems relate not so much to direct adverse effects of the drug as to allergic and inflammatory reactions in the host to the presence of dying parasites. Fever, headache, meningism, and exacerbation of neurological symptoms have all been noted; these symptoms tend to be more severe when the pretreatment parasitic infection is widespread and intense (SEDA-20, 282) (SEDA-21, 318). The main direct adverse effects of praziquantel are abdominal discomfort, diarrhea, nausea and vomiting, dizziness, and somnolence (SED-13, 837) (10), (SEDA-16, 310). Among children somnolence was seen in 11%. Headaches, skin rashes, and fever are less common (SED-13, 837). Non-specific effects observed in a minority of patients taking praziquantel include generalized weakness, swelling of the legs, epigastric area, scrotum, or more generally, fatigue (SEDA-16, 354).

Organs and Systems

Respiratory

Acute respiratory failure with exudative polyserositis has been reported in a patient taking praziquantel (11).

Nervous system

An important aspect of drug treatment in neurocysticercosis is the simultaneous use of glucocorticoids with cysticidal drugs (12,13). This combination has been recommended to avoid the secondary effects of treatment due to destruction of parasites within the brain parenchyma. However, these reactions are usually mild and transient and may be ameliorated with analgesics or antiemetics, questioning the need for corticosteroids in every case. Glucocorticoids are currently indicated for patients who develop intracranial hypertension during treatment with cysticidal drugs. This can be anticipated in patients with multiple lesions. However, some forms of neurocysticercosis should not be treated with cysticidal drugs (12,13). Both albendazole and praziquantel can exacerbate the syndrome of intracranial hypertension observed in patients with cysticercotic encephalitis, and are contraindicated during the acute phase of the disease (1). In patients with mixed forms of neurocysticercosis, including hydrocephalus and parenchymal brain cysts, cysticidal drugs should only be used after prior ventricular shunt placement to avoid a further increase in intracranial pressure after treatment. When this precaution is not taken, a further increase in intracranial pressure precipitated by praziquantel can prove fatal (14).

- A 66-year-old man with neurocysticercosis treated with glucocorticoids and praziquantel developed headache and confusion. He did not have a ventricular shunt inserted. A contrast-enhanced CT scan showed multiple focal enhancing lesions with mild edema. An MRI scan of the head was reported as being most consistent with neurocysticercosis. He was given dexamethasone 2 mg bd and praziquantel 50 mg/kg/day. A few days later his headache worsened, with nausea and drowsiness. After 2 weeks he became stuporose and had to be ventilated. A CT scan showed multiple areas of deep subcortical focal edema near the areas of previously enhancing cysts, a striatocapsular stroke, and obstructive hydrocephalus. Two weeks after the last dose of praziquantel and despite a ventriculostomy tube he died.

The authors reported that deaths related to praziquantel in neurocysticercosis are rare. However, this case had characteristics suggestive of a high risk of post-treatment complications. Death was attributed to a sudden increase in intracranial pressure, with multiple foci of edema, meningeal inflammation, and stroke, and occurred despite the concomitant use of glucocorticoids.

In patients with neurocysticercosis treated with praziquantel in increasing doses of 10–50 mg/kg/day for the first week and maintenance therapy during the second week, 27 (60%) presented with adverse effects, three requiring interruption of therapy. Increased intracranial pressure occurred in two cases (one fatal). Exacerbation of CSF pleocytosis was recorded in 26 patients (57%) (SEDA-16, 311).

A delayed reaction, with central nervous system involvement, has been described in patients with cerebral cysticercosis; papilledema, hemorrhages, focal seizures, motor weakness (SEDA-13, 242), and in one case hemiplegia from a vasculitic infarct occurred (SEDA-14, 243). The possibility that this reaction is caused by a

© 2006 Elsevier B.V. All rights reserved.

massive inflammatory response was discussed (SEDA-14, 243). If this hypothesis is correct, glucocorticoid treatment could be contemplated. A review has suggested that the use of glucocorticoids, although still controversial, is generally accepted as a means of alleviating inflammatory complications; however, simultaneous use of a glucocorticoid seems to reduce the plasma praziquantel concentration significantly. According to one group of investigators, no delayed reaction was seen in patients with cerebral schistosomiasis (SED-13, 837).

Dose-dependent dizziness is a recognized effect in some 14% of cases at higher doses of praziquantel (SEDA-12, 267). Patients predisposed to epilepsy may develop convulsions, probably as a reaction to the death of the parasite (15). Headache (40%) and drowsiness (25–40%) have been common in some studies and the manufacturers warn against driving or operating machinery while taking praziquantel.

Most patients treated for neurocysticercosis with praziquantel develop an early cerebrospinal fluid reaction; a similar late reaction, some 2 weeks after treatment has finished, has also been described (16). In both cases clinical signs and symptoms can include papilledema, headache, nausea, vomiting, neck stiffness, and even focal seizures. Glucocorticoids can usually prevent or relieve both the early and late reactions, but they can also reduce efficacy by lowering plasma concentrations of the drug by some 50% (17).

There is a risk that if patients treated with praziquantel for a disease other than neurocysticercosis do in fact also have neurocysticercosis, serious neurological reactions (notably seizures) can occur as the parasite is killed and toxins are released (18).

Sensory systems

Praziquantel should not be used in ocular cysticercosis, because of the risk of inoperable lesions from destruction of the parasite within the eye (19).

Gastrointestinal

Praziquantel can cause dose-related nausea, vomiting, heartburn, and abdominal pain. For example, at doses of 30 mg/kg in schoolchildren there was stomachache in some 16% (SED-12, 775), while in a study with 40 mg/kg 35% of users had abdominal pain (20).

Bloody diarrhea occurs in some patients, but it can be difficult to distinguish this as an adverse effect from pretreatment symptoms; one Ethiopian study of the use of praziquantel in suspected schistosomiasis found that before treatment there was blood in the stool in 55% of cases, diarrhea in 61%, and abdominal discomfort in 80%, and the figures recorded the next day after treatment were not very different (21).

The efficacy and adverse effects of treatment with a single oral dose of praziquantel 40 mg/kg, in relation to egg counts and morbidity, have been studied in 611 primary schoolchildren infected with *Schistosoma mansoni* in Northeastern Ethiopia (22). Before treatment 40% of the patients had no symptoms and 30–40% complained of nausea, abdominal cramps, and/or bloody diarrhea. The symptoms before treatment were not related to nutritional status, intensity of *S. mansoni* egg excretion, or the presence of concomitant intestinal parasites. In the first 4–6 hours, 90 children (15%) developed severe gastrointestinal symptoms, with vomiting, abdominal cramps, and/or bloody diarrhea. They had higher mean pretreatment egg counts than the children who did not have these symptoms. The day after treatment 529 children (87%) were reviewed. Adverse effects were reported by 92% and consisted of abdominal cramps (87%), bloody diarrhea (50%), dizziness (31%), and vomiting (29%). Skin rashes and edema were observed in four individuals. The combination of abdominal cramps with vomiting, bloody diarrhea, and general weakness was significantly more common in the malnourished children and in the children with higher pretreatment egg counts. The overall cure rate after treatment with praziquantel was 83% after 5 weeks, but this rate fell with increasing pretreatment egg counts. These findings confirm that praziquantel is effective in the treatment of *S. mansoni* infections but that treatment may be associated with severe abdominal adverse effects, which may reduce drug compliance in population chemotherapy.

This point has been further evaluated in a larger double-blind, placebo-controlled study of the concurrent administration of albendazole and praziquantel in over 1500 children with high prevalences of schistosomiasis and other helminthic diseases in China and the Philippines, including two strains of *S. japonicum*, and two different areas of Kenya, one each with *S. mansoni* or *Schistosoma hematobium* (23). There was no difference in the rate of adverse effects after treatment with albendazole compared with placebo, but after treatment with praziquantel the children had significantly more nausea, abdominal pain, and headache. These adverse effects, although considered mild, were more common in children with schistosomiasis, which suggests a reaction to dying schistosomes rather than a toxic effect of the drug itself. There was a very high rate of complaints in Kenya, but both the history and the reactions after placebo suggested that many of the adverse effects reported after treatment reflected complaints before treatment.

Liver

It has been suggested that praziquantel can cause hepatomegaly and splenomegaly in children with schistosomiasis (22), but hepatomegaly and splenomegaly have also been described as complications of the disease in these young patients, and they regress with effective treatment (24).

Immunologic

Allergic reactions to praziquantel can be due to parasite death and include fever, urticaria, pruritic skin rashes, and eosinophilia. In one violent reaction there was marked eosinophilia, pleuritic chest pain, cardiac effusion, and ascites, pointing strongly to an exudative polyserositis (11).

Long-Term Effects

Drug tolerance

Diminished susceptibility to praziquantel of *S. mansoni* was reported in an area in Northern Senegal (25).

© 2006 Elsevier B.V. All rights reserved.

Second-Generation Effects

Lactation

Praziquantel is excreted in the breast milk, and mothers should not breastfeed for 72 hours after a dose (26).

Drug–Drug Interactions

Cimetidine

Praziquantel is well absorbed after oral administration and undergoes extensive first-pass metabolism, especially when it is given simultaneously with corticosteroids and anticonvulsants (1). Cimetidine significantly increases praziquantel serum concentrations by inhibiting its first-pass metabolism (27). The concurrent administration of cimetidine with praziquantel in neurocysticercosis allows simplification of the effective praziquantel regimen from 50 mg/kg/day for 2 weeks to a one-day regimen of three doses of 25 mg/kg at 2-hour intervals; this regimen increases the time over which the parasite is exposed to high drug concentrations and produces similar benefits, and also reduces the cost, length of treatment, and total dose used (28). It has also been proposed that simultaneous administration of praziquantel and cimetidine could improve the efficacy of single-day therapy with praziquantel for cysticercosis and other parasitic diseases, such as schistosomiasis (29).

Grapefruit juice

A single dose of grapefruit juice 250 ml significantly increased the AUC and C_{max} of a single dose of praziquantel without changing the t_{max} or half-life, suggesting increased systemic availability (30).

Food–Drug Interactions

Serum praziquantel concentrations increase when a carbohydrate-rich diet is administered (1).

Prazosin

See also Alpha-adrenoceptor antagonists

General Information

Prazosin is an alpha$_1$-adrenoceptor antagonist.

Organs and Systems

Cardiovascular

Postural hypotension and reflex tachycardia, particularly on standing, are features of the first-dose response to prazosin, but adaptive receptor responses lead to resetting of the reflex mechanisms within the first few days of treatment, and there are therefore generally no significant changes in heart rate during long-term treatment. An orthostatic component to the hypotensive response persists during long-term treatment, and this may be significant and symptomatic if high dosages are used. It is less frequent with modified-release prazosin.

Metabolism

Prazosin and other quinazolines are associated with small but significant changes in plasma lipid profiles. Generally these are potentially beneficial changes, with reductions in LDL cholesterol, total cholesterol, and triglycerides, and increases in HDL cholesterol.

Urinary tract

Blockade of alpha$_1$-adrenoceptors in the urinary tract leads to smooth muscle relaxation and improvement in urinary flow, and this pharmacological action has been used to ameliorate the urinary symptoms of benign prostatic hyperplasia. Prazosin can occasionally lead to urinary incontinence, particularly stress incontinence in women (1).

© 2006 Elsevier B.V. All rights reserved.

Sexual function

There is some evidence that male sexual dysfunction occurs less often with alpha-blockers than with other types of antihypertensive drugs (2). For example, in a comparison of the effects of prazosin and hydrochlorothiazide on sexual function in 12 hypertensive men, plethysmographic measurements and subjective assessments showed less dysfunction with prazosin than with hydrochlorothiazide (3). There is no evidence that this effect can be used therapeutically, but cases of priapism have been reported: for example, a 55-year-old man presented with priapism having taken prazosin 7.5 mg tds for 4 months. After a further 3 months, prazosin was discontinued and erectile function became normal (4).

Drug–Drug Interactions

Alcohol

In a well-controlled study in 10 Japanese patients with mild hypertension, the blood pressure reduction caused by alcohol 1 ml/kg was significantly increased by concurrent treatment with prazosin 1 mg tds (5). At 2–4 hours after ingestion the blood pressure fell by 18/12 mmHg without prazosin and by 24/18 mmHg with prazosin. These results raise the possibility that heavy drinking may cause symptomatic hypotension in patients taking prazosin.

Prenalterol

General Information

Prenalterol has dobutamine-like positive inotropic effects and has been used in severe heart failure (1). It can cause cardiac dysrhythmias (SEDA-6, 135).

Reference

1. Kendall MJ, Goodfellow RM, Westerling S. Prenalterol—a new cardioselective inotropic agent. J Clin Hosp Pharm 1982;7(2):107–18.

Prenylamine

See also Calcium channel blockers

General Information

Prenylamine is a coronary vasodilator that depletes myocardial catecholamine stores and has some calcium-channel blocking activity. It has been used in the treatment of angina pectoris, but it often causes ventricular dysrhythmias and has been superseded by less toxic drugs.

Organs and Systems

Cardiovascular

Ventricular tachycardia associated with QT prolongation (torsade de pointes) has often been described with prenylamine (1,2).

Drug–Drug Interactions

Iothalamate

Ventricular tachycardia has been reported after the intravenous administration of sodium iothalamate in a patient taking prenylamine (3). Both drugs can prolong the QT interval.

Preservatives

General Information

Preservatives that are often found in cosmetics include formaldehyde, quaternium-15, imidazolidinyl urea, diazolidinyl urea, parabens mix, 5-chloro-2-methyl-4-isothiazolin-3-one + 2-methyl-4-isothiazolin-3-one (MCI/MI, Kathon CG), and methyldibromoglutaronitrile (MDBGN, Euxyl K400). Polyhexamethylenebiguanide, a biocide structurally related to hexamidine, is added to cosmetics as a preservative.

Organs and Systems

Immunologic

Preservatives are important causes of allergic contact dermatitis in cosmetics. In a 10-year analysis in 16 centers in 11 countries, 73 818 consecutive patients were patch-tested for the preservatives listed above. There were several cases of contact allergy to formaldehyde and MCI/MI. These preservatives are currently avoided in cosmetics. However, the frequency of positive reactions to MDBGN has risen, from 0.7% in 1991 to 3.5% in 2000. The authors suggested that the concentration of this preservative should be reduced in leave-on cosmetic products (1).

DMDM hydantoin is a preservative that is used mainly in cosmetics. In 1808 consecutive patients DMDM hydantoin was patch-tested in a concentration of 2% in petroleum, and in a further 34 321 patients it was tested in a concentration of 2% in water. The proportion of positive reactions was 0.39–0.65%, with no evidence of a significant time trend. In the 180 positive cases cosmetics (30%) or topical drugs (22%) were considered causal (2).

Hexamidine (0.15% petrolatum) (SEDA-10, 128) has rarely been reported to cause a contact allergic reaction (3,4). Of 1554 patients tested with polyhexamethylenebiguanide 2.5% in aqua, 6 (0.4%) had a positive reaction, indicating a very low sensitization rate (5).

Prilocaine and Emla

See also Local anesthetics

General Information

Prilocaine is an aminoamide local anesthetic. It can be used on its own, but it is also included in Emla in a eutectic combination with lidocaine (25 mg/ml each), which is widely used as a local anesthetic in topical administration for, for example, superficial surgery and venepuncture.

© 2006 Elsevier B.V. All rights reserved.

Emla cream causes minor local adverse effects, such as itch, burning, and localized purpura (SEDA-19, 131) (SEDA-20, 127) (SEDA-22, 140). A meta-analysis of the use of Emla cream in the elderly (over 65) showed that the technique is generally safe, with only mild transient effects (pallor, redness, and edema) at the application site; there were no systemic effects (1).

However, if large amounts are applied, particularly under occlusion, it can be sufficiently well absorbed to cause systemic effects. Three of 1648 children who received measles vaccination with Emla 1 g had adverse reactions 10–20 minutes later; all required adrenaline for similar symptoms of weakness and dizziness with a cold clammy skin and no pulse or a weak pulse (2). One went on to wheeze markedly and had peripheral cyanosis and shivering, improving with hydrocortisone. The authors proposed that these unusual reactions could have been due to a biphasic local reaction to Emla, with vasodilatation leading to increased absorption and further toxicity.

Organs and Systems

Nervous system

Particular care must be taken with Emla in children, since seizures can occur.

- A 5-year-old child had 35 g of Emla applied under an occlusive dressing to eczematous skin in preparation for cryotherapy for molluscum contagiosum (3). Within 1 hour, the child had a generalized seizure that lasted 10 minutes. The plasma concentrations of lidocaine and prilocaine 30 minutes later were 5.5 and 2.0 μg/ml, respectively, and 6 hours later, the methemoglobin concentration was 19%. The child was given vitamin C 500 mg intravenously, and 2 days later had a methemoglobin concentration of 0.3%.

Errors by pharmacists or parents continue to contribute to severe complications, such as seizures, after overdose of Emla cream in children (4).

- A 21-month-old girl had four generalized tonic-clonic seizures after inadvertent overuse of Emla before curettage of skin lesions of molluscum contagiosum. Because of a pharmacy error, 30 g tubes of Emla were dispensed instead of 5 g tubes. The toddler's mother applied 75 g under occlusive dressing, covering about 350 cm^2 of the child's surface area. This dose significantly exceeds the recommendations for a 14 kg child—maximum 10 g on a maximum area of 100 cm^2. Two doses of intravenous lorazepam (0.1 mg/kg) did not control the seizures, which stopped only after phenobarbital (20 mg/kg) was given. The child then required intubation and ventilation for respiratory depression. The lidocaine concentration 4 hours after the first application of Emla was 2.5 μg/ml and the methemoglobin concentration was 8%.

Seizures have also been reported in adults.

- An 84-year-old woman had three generalized tonic-clonic seizures after repeated applications of Emla (17 applications of 10 g over 23 weeks) (5,6).

Sensory systems

Emla cream can cause severe eye irritation (7).

- Emla cream 30 g was applied to both periorbital and proximal nasal sidewall areas for laser treatment in a 20-year-old woman. Despite the use of a right eye shield for corneal protection, the next day she developed right eye pain and blurred vision and remembered that Emla cream had accidentally entered her right eye before treatment. This caused immediate discomfort, which subsided and then recurred several hours later. She had severe conjunctival injection with loss of epithelium from over 90% of the surface of her cornea, in a pattern more suggestive of chemical than mechanical damage. Treatment with a bandage contact lens and prophylactic antibiotics was effective and her visual acuity returned to baseline.

Hematologic

Methemoglobinemia as an adverse effect of prilocaine (8) has been reported more often than with any other local anesthetic. It is caused by a metabolite and is a particular problem in neonates, who have an immature methemoglobin reductase system and residual fetal hemoglobin, increasing the risk of symptomatic methemoglobinemia.

Neonates and small children who have penile block with prilocaine, for circumcision can develop severe methemoglobinemia (9,10). A report has emphasized the severity of methemoglobinemia in infants especially if premature, when even a small dose of prilocaine is used for infiltration (11).

- A 1.3 kg premature neonate of 30-week gestation, having required ventilation over the first 3 days for respiratory distress syndrome, required reintubation on day 12 of life for recurrent apnea. He developed a pneumothorax requiring an intercostal drain; 0.5 ml of 1% prilocaine was used for infiltration, after which his oxygen requirements overnight went from 28 to 100%; his SpO_2 was 90% and he turned pale gray. His PaO_2 was 23 kPa (170 mmHg) and his methemoglobin concentration was 15%. He was given methylthioninium chloride, and within 8 hours, his methemoglobin concentration was 0.5% and his SpO_2 96%.

Methemoglobinemia can occur with overdosage of prilocaine (SEDA-20, 129) and after inadvertent intravenous administration, particularly in neonates and children (SEDA-11, 221) (12).

- In a 6-year-old boy, 10 ml of a 2% solution given for bilateral percutaneous nephrostomy produced a degree of cyanosis that demanded methylthioninium chloride treatment (13).

In adults, even those with anemia, the shift in methemoglobin concentrations from prilocaine, while measurable, is not of clinical significance (SEDA-12, 257) (14).

Despite concerns that Emla cream can cause methemoglobinemia in neonates and preterm babies, a French study of 116 infants in neonatal intensive care, who were treated with small amounts of Emla once a day before skin puncture, showed that methemoglobin concentrations never exceeded 5% and were not related to

© 2006 Elsevier B.V. All rights reserved.

gestational age or duration of application (SEDA-20, 127). Two other studies on the use of Emla as analgesia for neonates and low birth weight infants showed localized pallor, but no evidence of methemoglobinemia (SEDA-22, 140).

However, high doses of Emla have been responsible for two cases of methemoglobinemia in neonates. In one, 3.5 g of Emla was used before circumcision, and in the other 25 g of cream had been applied to a buttock hemangioma by the parents before laser therapy (SEDA-22, 140).

- A 3-year-old girl with multiple lesions of molluscum contagiosum had Emla applied to the lesions before curettage (15). She became lethargic and hypoactive 2 hours later, with periorbital discoloration and cyanosed lips. Her SaO_2 was 85%, systolic blood pressure 185 mmHg, pulse 144/minute, and her methemoglobin concentration 21%. Her caregiver had applied about 25 g of cream to her entire torso, a massive dose of prilocaine (about 625 mg).

This report reinforces previously described problems arising from carers' lack of understanding of instructions when using Emla in children or babies.

- A 4-day-old boy developed methemoglobinemia (16%) after the application of Emla cream to his penis before circumcision (16).
- A 7-month-old girl was ventilated with inhaled nitric oxide 40 ppm and developed methemoglobinemia after the application of Emla to an 8 cm^2 area of skin for 5 hours (17). Shortly after removal she developed cyanosis, with a methemoglobin concentration of 16%, which resolved with two doses of methylthioninium chloride.

In these cases, the prolonged duration of Emla application was thought to be the cause, but concomitant use of inhaled nitric oxide may have contributed.

Skin

The adverse effects of Emla include localized blanching or erythema, burning or itching sensations, irritant and allergic reactions, and purpura (18).

In 29 children with atopic dermatitis who were given Emla cream before curettage of molluscum contagiosum, there were no adverse reactions, apart from mild transient application site reactions, such as pallor, redness, and edema. No systemic reactions were reported, but the authors emphasized that Emla can be rapidly absorbed through atopic skin, and they therefore recommended that when Emla is applied under occlusive dressing, the maximum dose should be 10 g for 30 minutes (19).

The analgesic effects of single and repeated applications of Emla over six consecutive days have been studied in 11 patients with post-herpetic neuralgia (20). There was no evidence of systemic adverse effects, but four patients developed mild erythema at 30 minutes, which may have been due to the occlusive dressing, and one patient had pruritus on day 7.

Two children developed petechial eruptions after the application of Emla for treatment curettage of molluscum contagiosum (21). Neither became systemically unwell, and subsequent reapplication of Emla in one child did not elicit a petechial eruption.

There has been a report of hyperpigmentation following the use of Emla cream (22).

- A 12-year-old black child developed a patch of hyperpigmentation on his forehead where Emla cream had been used for cutaneous anesthesia before local infiltration with lidocaine for removal of a nevus. This persisted, although fading, for at least 4 months. No other cause could be found.

Hypopigmentation has also been reported with Emla (23).

Contact dermatitis was reported in three hemodialysis patients who used Emla cream repeatedly as analgesia for AV fistula cannulation (SEDA-21, 136).

- A 6-year-old boy developed contact dermatitis following the application of Emla for a skin biopsy to diagnose graft-versus-host disease (24). The histopathological features of the contact dermatitis were similar to graft-versus-host disease.

The use of Emla to provide topical anesthesia should be documented in order to avoid misdiagnosis.

Primaquine

General Information

The 8-aminoquinolines were the first synthetic antimalarial drugs to be introduced into medicine. Pamaquine (Plasmochin) was the first to be marketed in 1926, but primaquine proved to have the highest chemotherapeutic index of the many compounds tested.

Primaquine is rapidly absorbed, extensively distributed, and predominantly cleared by non-renal elimination. Its principal metabolite is carboxyprimaquine. While primaquine itself is rapidly eliminated from the plasma, the drug is effective when given once daily or even once weekly (SEDA-13, 810). The pharmacokinetics in children, pregnant women, and patients with renal or hepatic dysfunction are unknown.

Primaquine is mainly used to eradicate the exoerythrocytic stages of *Plasmodium vivax* and *Plasmodium ovale*, which if untreated cause late relapse (SEDA-18, 287). There is growing concern about primaquine resistance in *P. vivax* (SEDA-21, 296).

Observational studies

Primaquine base 0.5 mg/kg/day in the prophylaxis of *Plasmodium falciparum* and *P. vivax* malaria for a year did not cause noteworthy adverse effects. General complaints were less than in the placebo group but about the same as in those treated with chloroquine. None of the volunteers (smokers or non-smokers) had a methemoglobin concentration greater than 13% (1).

A randomized, placebo-controlled trial of supervised malaria prophylaxis with primaquine (30 mg/day for 20 weeks) in 97 non-immune adults with normal glucose-6-phosphate dehydrogenase (G6PD) concentrations in Papua New Guinea showed 93% protective efficacy of primaquine against malaria (95% CI = 71, 98%) (2). The most common adverse events were headache, abdominal pain, cough, and nausea, but these were not more frequent than with placebo. Transient rises in methemoglobin concentrations (mean 3.4% on the last day of prophylaxis, resolving by day 18) were asymptomatic.

Supervised treatment of *P. vivax* malaria with chloroquine (600 mg on day 1, 450 mg on days 2 and 3) and primaquine (15 mg/day for 14 days) has been studied in 50 patients in a non-endemic area of Brazil in a prospective open trial (3). G6PD status was not checked. The relapse-free cure rate at 6 months was 86%. There were no important adverse events. Risk factors for relapse included lower doses of primaquine. In patients over 60 kg in weight, the dose of primaquine can fall short of recommendations (0.25–0.3 mg/kg/day), and this can contribute to the risk of relapse.

Combination therapy

Primaquine + clindamycin

Primaquine on its own has some effect against *Pneumocystis jiroveci*, but in dosages of 0.25 or 0.5 mg/kg, primaquine alone was ineffective in rats, confirming earlier clinical experience. Clindamycin alone was also ineffective. The combination was effective both in vitro and in animals for treatment and prophylaxis.

Intravenous clindamycin, 900 mg every 8 hours, with oral primaquine 26.3 mg, was effective in a number of patients with active disease. A maintenance oral dose of clindamycin 150 mg four times daily plus primaquine 26.3 mg/day was adequate. The drugs are thought to be synergistic. In a second study, clindamycin 600 mg qds was used intravenously, with a maintenance dose of 300–400 mg orally and primaquine base orally, 15 mg/day. Tolerance was reasonably good; the most frequent adverse effect, in half the patients, was a generalized maculopapular rash after 10–12 days. Rash was accompanied by fever in three cases. Other adverse effects were leukopenia ($n = 2$), nausea ($n = 2$), and diarrhea ($n = 1$) (SEDA-12, 703) (4). In a third study with higher doses of primaquine, methemoglobinemia was a major adverse effect. In a fourth study, clindamycin was given 900 mg tds with primaquine 30 mg/day, except in three of 28 episodes of *P. jiroveci* pneumonia treated in a total in 26 patients, who received primaquine 15 mg/day (two) or 30 mg on alternate days (one). In 11 episodes the patients had been intolerant of standard therapy, in 13 episodes conventional therapy had failed, and in four episodes there had been treatment failure and intolerance. Of the 28 episodes, 24 were successfully treated with clindamycin/primaquine, the most common adverse effect being rash (5). With the use of higher doses of clindamycin, gastrointestinal effects, especially diarrhea and colitis,

© 2006 Elsevier B.V. All rights reserved.

can be expected. The primaquine component can cause hemolytic anemia and methemoglobinemia. Patients should be screened for G6PD deficiency.

Organs and Systems

Psychological, psychiatric

Severe mental depression and confusion was reported in one patient who had been treated with chloroquine beforehand; all the symptoms disappeared on withdrawal (SEDA-11, 588).

Hematologic

Mild anemia, methemoglobinemia, and leukocytosis have been mentioned occasionally, as well as a very occasional case of agranulocytosis, usually associated with overdosage (6).

Primaquine and its congeners can cause hemolytic anemia in people with G6PD deficiency. The effects are more pronounced in the B type (the Mediterranean type) than in the A type. In a 28-year-old Thai soldier, who developed a hemolytic anemia, G6PD deficiency was not mentioned (SEDA-16, 308), but four patients reported in Vanuatu in 1992 had G6PD deficiency; all developed acute intravascular hemolysis resulting in anemia, hemoglobinuria, and systemic illness after a single dose of the drug (SEDA-17, 328).

Gastrointestinal

The most common adverse effects of primaquine are gastrointestinal: mild to moderate abdominal cramps and occasional gastric distress. In those without G6PD deficiency, primaquine is well tolerated as a prophylactic at doses of 15 mg/day (7), with only 1/106 patients withdrawing because of gastrointestinal upset in one study.

Liver

Primaquine can cause dose-dependent hepatotoxicity, as illustrated by a case of acute liver failure (with spontaneous recovery) caused by accidental overdosage (1260 mg on the second day of treatment for *P. vivax*) (8).

Drug–Drug Interactions

Dapsone

The combination of primaquine with clindamycin is used as second choice in the treatment or prevention of *P. jiroveci* pneumonia. If the patient has been treated immediately beforehand with dapsone, methemoglobinemia can result, especially in patients infected with HIV (SEDA-21, 296).

Primidone

See also Antiepileptic drugs

General Information

Primidone, a deoxybarbiturate, is partly metabolized to phenobarbital, which is responsible for most of its pharmacological effects. During chronic dosing, the adverse effects of primidone are identical to those of phenobarbital. However, at the start of treatment, primidone can cause a transient intolerance reaction with malaise, dizziness, nausea, vomiting, headache, and other symptoms.

Primidone can cause various idiosyncratic reactions, including systemic lupus erythematosus, a syndrome resembling diabetes insipidus, lymphadenopathy, toxic epidermal necrolysis, thyroid enlargement, and edema.

The use and adverse effects of primidone in the treatment of essential tremor has been reviewed (1). Acute reactions include vertigo, nausea, and unsteadiness; chronic reactions include worsening of depression.

At the start of treatment, primidone can cause a transient intolerance reaction with malaise, dizziness, nausea, vomiting, headache, and other symptoms. To minimize this problem, which is more prominent in patients not exposed to other anticonvulsants, primidone should be started in a low dosage (for example 62.5 mg/day) and increased slowly according to response.

Pretreating patients with phenobarbital can reduce the impact of adverse events when primidone is introduced. Of 30 patients with intractable partial epilepsy pretreated with phenobarbital before starting primidone (500 mg/day increasing by 125–250 mg/day every

© 2006 Elsevier B.V. All rights reserved.

3 weeks until adverse events or a seizure-free state was reached), 26 tolerated the introduction of primidone with minimal or no adverse events (2). Only one patient had to discontinue primidone during the initial 4 weeks because of severe dizziness. Three other patients had dizziness severe enough to interfere with their activities and this disappeared in two patients after the dose was lowered.

Organs and Systems

Immunologic

Giant cell myocarditis has been reported in a patient taking phenytoin, phenobarbital, and mephobarbital and in one taking primidone (3).

Susceptibility Factors

Like phenobarbital, primidone should not be given to patients with acute intermittent porphyria (4).

Drug Administration

Drug overdose

After overdosage, massive crystalluria can occur, due to overload of the urine with hexagonal primidone crystals (SED-13, 154) (4).

Probenecid

General Information

Probenecid is a uricosuric agent. It is generally well tolerated. Soreness of the gums, gastrointestinal irritation, skin rashes, pyrexia, and the nephrotic syndrome have been reported (1).

Drug interactions with probenecid arise, because it is an inhibitor of the renal tubular secretion of acids and bases (2).

Drug–Drug Interactions

Antibiotics

Probenecid inhibits the renal tubular secretion of various penicillins (3–6) and many cephalosporins (6–20). Ceforanide is not affected (21).

Aspirin

In low dosages (up to 2 g/day), aspirin reduces urate excretion and blocks the effects of probenecid and other uricosuric agents (22,23). However, in 11 patients with gout, aspirin 325 mg/day had no effect on the uricosuric action of probenecid (22). In higher dosages (over 5 g/day), salicylates increase urate excretion and inhibit the effects of spironolactone, but it is not clear whether these phenomena are of importance.

Chloroquine

Probenecid may increase the risk of chloroquine-induced retinal damage (24).

Dapsone

Probenecid increases plasma dapsone concentrations by inhibiting its renal clearance (25).

Indometacin

Interactions with indometacin have been documented through inhibition of renal tubular excretion (26,27). In 17 patients with rheumatoid arthritis, probenecid 500 mg bd improved the therapeutic response to indometacin 25 mg tds over 3 weeks (28). There were changes in the pharmacokinetics of indometacin, which the authors attributed to a reduction in the non-renal clearance of indometacin, possibly because of reduced biliary clearance.

Methotrexate

Probenecid reduces the renal tubular secretion of methotrexate, enhancing its effect (29) and may reduce its plasma protein binding (30).

Sulfinpyrazone

Probenecid reduces the renal tubular secretion of sulfinpyrazone but there is no change in the uricosuric effect (31).

Zidovudine

Probenecid reduces the renal tubular secretion of zidovudine (32,33).

Probucol

General Information

The adverse effects of probucol have been reviewed (1). As the Probucol Quantitative Regression Swedish Trial (PQRST) showed no improvement in lumen volume of the femoral artery in patients given probucol plus colestyramine, as compared with those given colestyramine alone, doubt has been raised about its efficacy (2).

Organs and Systems

Cardiovascular

Prolongation of the QT interval has been seen and 16 cases of tachydysrhythmias, especially torsade de pointes, have been reported in association with probucol, 15 cases in women (SEDSA-13, 1331) (3,4).

Gastrointestinal

According to long-term studies covering 7–9 years, probucol seems to be well tolerated with a reasonably low incidence of adverse effects. All the documented adverse effects were concentrated in the gastrointestinal tract. The incidence of diarrhea fell from 19% in the first year to 5% in the next. Only in some 3% of cases do symptoms such as diarrhea or abdominal pain lead to withdrawal of treatment. Diarrhea and flatulence, which resolve after a few months, are common.

Procainamide

See also Antidysrhythmic drugs

General Information

In a prospective study of 488 inpatients there were adverse reactions in 45 cases (9.2%), thought to have been life-threatening in 7 (1.4%), none of whom died (1). The seven patients all had cardiovascular effects. Common adverse effects included gastrointestinal upsets (19 cases) and fever (8 cases). Reactions were more common at daily dosages of 3 g and more.

Comparative studies

The adverse effects of intravenous procainamide (400 mg up to three times infused over 10 minutes) have been reported in 60 adults with atrial flutter or fibrillation in a comparison with ibutilide (2). The adverse effects were headache in 11%, hypotension in 11%, flushing in 3.1%, dizziness in 3.1%, and hypesthesia in 3.1%. The mean fall in systolic blood pressure was about 20 mmHg and occurred at 30–35 minutes after infusion; the corresponding fall in diastolic blood pressure was 10 mmHg. However, in seven patients there was severe hypotension, with a fall in diastolic blood pressure of up to 67 mmHg; in three cases withdrawal of the infusion was required and these patients were treated with intravenous fluids, dopamine, or both. In the severe cases the hypotension occurred during or immediately after the infusion of procainamide.

A comparison between procainamide and propafenone in 62 patients, who had undergone coronary artery bypass grafting or valvular surgery within 3 weeks and developed sustained atrial fibrillation, showed that both drugs converted the dysrhythmia to sinus rhythm in up to 76% of cases, but that propafenone did it more quickly (3). Symptomatic arterial hypotension occurred more frequently with procainamide (nine of 33 patients) than with propafenone (two of 29 patients). Other adverse effects of procainamide were nausea ($n = 2$) and junctional escape rhythm ($n = 2$).

General adverse effects

The adverse effects of procainamide are predominantly on the heart. It causes reduced myocardial contractility and hypotension, and prolongs the QT interval, with consequent dysrhythmias and conduction defects. The lupus-like syndrome most commonly causes polyarthralgia, myalgia, fever, and pleurisy. Neutropenia has been relatively commonly reported in patients taking modified-release formulations. Other adverse effects are uncommon; these include muscle weakness, ataxia, mental confusion, cholestasis, and skin rashes. Hypersensitivity reactions include fever and hematological reactions, including neutropenia, pancytopenia, and pure red cell aplasia. Tumor-inducing effects have not been reported.

Organs and Systems

Cardiovascular

Procainamide has a negative inotropic effect and can cause hypotension after both intravenous and oral administration (4,5). When given intravenously it should therefore be infused slowly, at no more than 20 mg/minute. In patients with poor cardiac function procainamide can worsen heart failure, and it may reduce survival after myocardial infarction (6).

Procainamide prolongs the QT interval (7) and can cause dysrhythmias. It can also impair cardiac conduction and can cause bradycardia and heart block (1). In the sick sinus syndrome it can alter sinus node recovery time (8), although the clinical significance of this is not clear.

Pericarditis and tamponade have been reported as rare complications of procainamide-induced lupus-like syndrome (9).

Respiratory

Procainamide can cause lung damage in the context of a lupus-like syndrome (SEDA-17, 226).

Nervous system

Procainamide rarely causes nervous system effects. Acute confusion (10), cerebellar ataxia (11), tremor (12), and muscle weakness (13–16) have all been occasionally reported. In high dosages procainamide has anticholinergic effects (17).

Procainamide has been reported to cause a chronic inflammatory demyelinating polyradiculoneuropathy (18).

- A 68-year-old man took procainamide 500 mg qds for 3 years and developed distal paresthesia and dysesthesia in the legs, followed by progressive muscle weakness, mainly affecting the legs. His gait became unsteady and was wide-based. He had antinuclear antibodies directed against histones in a titer of 1:320, but no antibodies to double-stranded DNA. He had a circulating lupus anticoagulant. The serum procainamide concentration was 3.3 μg/ml (target range 4–8). Nerve conduction studies showed a reduction in sensory nerve action potential amplitudes, a mild reduction in sensory nerve conduction velocity, prolongation of distal motor latencies, and reduced conduction velocities, but no conduction block or temporal dispersions. Electromyography was normal. A left sural nerve biopsy showed perivascular inflammation around a single vessel, without evidence of vasculitis. Myelinated

© 2006 Elsevier B.V. All rights reserved.

nerve fibers were reduced, and scattered nerve fibers showed thin myelin sheaths. About 30% of the fibers showed randomly distributed demyelinated or remyelinated segments. Procainamide was withdrawn and prednisone was given in combination with six plasma exchanges over 2 weeks; after 1 month there was clinical improvement.

This case of polyneuropathy was attributed to a lupus-like effect of procainamide.

Sensory systems

Scleritis has been reported as part of a procainamide-induced, lupus-like syndrome (19).

Psychological, psychiatric

Acute psychosis has been attributed to procainamide (20).

- A 45-year-old woman developed an acute psychosis within 72 hours of starting to take procainamide 75 mg intravenously, followed by a continuous infusion of 2 mg/minute for atrial fibrillation. The plasma procainamide concentration was 8.2 μg/ml and the plasma concentration of the main acetylated metabolite, acecainide, was 4.6 μg/ml. She was then given oral procainamide 500 mg qds, and 2 days later her trough concentrations of procainamide and acecainide were 4.5 and 4.9 μg/ml respectively. The following day she had visual hallucinations and was later found wandering the hospital asking about the babies under her bed. She had no previous history of psychiatric illness and she recovered completely 24 hours after withdrawal of procainamide.

There have been a few previous reports of similar adverse effects with procainamide in therapeutic dosages, and in most cases the plasma concentrations of procainamide and acecainide have been within the usual target ranges, as in this case.

Hematologic

Hematological abnormalities can occur in the absence of a lupus-like syndrome. Hemolytic anemia (21), a circulating anticoagulant (22), thrombocytopenia (23), granulocytopenia (24), and pancytopenia (25) have all been reported occasionally. Thrombocytopenia may be more common in patients taking modified-release formulations (23). Pure red cell aplasia has also been reported (26,27), but it was not clear whether or not there was an associated lupus-like syndrome.

The most common adverse hematological effect of procainamide is neutropenia, which has often been reported, particularly in patients taking modified-release formulations. In one case-control study 4.4% of 114 patients taking modified-release formulations had neutropenia, compared with none in a control group of 509 patients (28). However, a larger subsequent case-control study failed to confirm this association (29). Nevertheless, reports of neutropenia attributed to procainamide continue to appear (30).

There was a positive direct antiglobulin (Coombs') test in about 20% of elderly patients taking procainamide (31). Although a positive Coombs' test can occur in association with a lupus-like syndrome, there was no relation in these cases between positive tests and the presence of antinuclear antibodies. Three of the patients had an autoimmune hemolytic anemia.

Gastrointestinal

Nausea, vomiting, and diarrhea in response to procainamide are common with dosages of 4 g/day or more (32). Pseudo-obstruction has been attributed to the use of a modified-release formulation of procainamide, perhaps due to its anticholinergic effects (33).

Liver

Procainamide can cause intrahepatic cholestasis, perhaps as part of a hypersensitivity reaction (34).

Skin

Lichen planus has been attributed to procainamide as part of a lupus-like syndrome (35).

Procainamide has been reported to cause urticarial vasculitis, although it was not clear whether or not this was part of a lupus-like syndrome (36).

- A 70-year-old man developed a maculopapular skin rash on the trunk 10 days after starting to take procainamide 1.5 g/day (37). Resolution occurred soon after the withdrawal of procainamide and a similar skin rash occurred on rechallenge. In addition to the maculopapular rash, there was swelling and erythema around the eyes and a purpuric rash on the legs. At the time of rechallenge he also had an eosinophilia.

Musculoskeletal

Procainamide can cause an arthropathy as part of a lupus-like syndrome, and the histological findings are indistinguishable from those in idiopathic SLE (38).

Procainamide has occasionally been reported to cause muscle weakness (SEDA-14, 152) (SEDA-16, 183), and it can also cause or exacerbate myasthenia gravis (39).

Necrotizing myopathy of the diaphragm has been reported, perhaps as part of a lupus-like syndrome (40).

Immunologic

Lupus-like syndrome

DoTS classification (BMJ 2003;327:1222–5)
Dose-relation: collateral effect
Time-course: delayed
Susceptibility factors: genetic (slow acetylators)

Procainamide is one of the common causes of drug-induced lupus-like syndrome (41), which is contrasted with idiopathic lupus erythematosus in Table 1.

Frequency

About 29–35% of patients taking procainamide for at least a year are affected and the effect is dose-related. The average age of onset is 59–68 years and 35–58% of the subjects are women. The syndrome can come on within a few weeks, but has been reported as late as 9 years after starting treatment.

Table 1 The contrast between drug-induced lupus-like syndrome and idiopathic lupus erythematosus

Feature	Idiopathic lupus erythematosus	Drug-induced lupus-like syndrome
Age and sex	Typically young women	Any (depends on use)
Acetylator status	Any	More likely in slow acetylators
Organs involved	Any	Kidneys usually spared
Antinuclear antibody	Usually present	Usually present
Complement	Can be reduced	Usually normal
Anti-DNA antibodies	Usually present (native DNA)	Only to single-stranded DNA

Mechanism

The mechanisms whereby procainamide causes this lupus-like syndrome are not clear. Procainamide is associated with the production of many antibodies, including anti-histone, antiguanosine, anti-DNA, and antiphospholipid antibodies (42). The production of autoantibodies may be due to one of two major mechanisms: first, procainamide may act as a hapten, binding to DNA, nuclear protein, or some membrane constituent, the hapten-protein complex stimulating the production of antibodies; secondly, it may alter suppressor cell function (43). There is also evidence that procainamide can combine with ribonucleoprotein from damaged myocardium after myocardial infarction, thus precipitating the production of antibodies to ribonucleoprotein (44).

Thymus function in 10 patients with symptomatic procainamide-induced lupus has been compared with that in 13 asymptomatic patients who only developed drug-induced autoantibodies (45). Newly generated T cells were detected in all the subjects. Although there was no overall quantitative difference between the symptomatic and asymptomatic patients, there was a correlation between the level of T cell receptor rearrangement excision circles in peripheral lymphocytes and serum IgG antichromatin antibody activity in patients with drug-induced lupus. These results support the hypothesis that the thymus is important in the genesis of drug-induced lupus-like syndrome and that the production of autoreactive T cells starts in the thymus when procainamide hydroxylamine alters T cell tolerance.

In procainamide-induced lupus there is an increase in the number of B cells in both blood and pleural fluid to about 80% (normal 10–25%). Concentrations of IL-6 and soluble IL-2R are also increased (46).

IgG antibodies to the (H2A–H2B)-DNA complex are common in patients with immunological reactions to procainamide (SEDA-20, 178). In a prospective study of 62 patients who had taken procainamide for a mean duration of 23 months (range 1 month to 16 years), and excluding patients with pre-existing systemic lupus erythematosus or who were taking other drugs that have been associated with the lupus-like syndrome, nine developed evidence of lupus-like syndrome and were compared with the other 53 (47). The mean dosage in the patients with lupus-like syndrome was 3.7 g/day compared with 3 g/day in the others, and the durations of administration were 8.8 and 38 months respectively. All four patients who had polyarticular arthritis and/or pleural effusions were positive for the IgG antibodies and four of the other five, who had significantly lower IgG concentrations, presented with the more typical manifestations of vasculitic rashes, pericarditis, or agranulocytosis. In all cases the symptoms and signs either improved markedly or resolved within 3 weeks of withdrawal of procainamide. Seven asymptomatic patients had IgG concentrations comparable with those seen in the patients with lupus-like syndrome, and high concentrations of antibody, although not as high as the two highest in the latter group. Anti-double-stranded DNA antibodies were not detected in any patients. In 33 control subjects there were no detectable antibodies of any kind. The authors therefore suggested that the (H2A-H2B)-DNA IgG antibody is not a useful marker for the occurrence of lupus-like syndrome in patients taking procainamide, although they conceded that the presence of IgG antibody supported the diagnosis of lupus-like syndrome when the main clinical manifestations were arthritis or pleurisy. The significance of the presence of IgG antibodies in asymptomatic patients is not clear, but the authors suggested that it meant that those patients merited careful observation.

The lupus-like syndrome in patients taking procainamide is thought to be due to the procainamide itself, since it has rarely been reported when the main metabolite of procainamide, acecainide, has been administered itself (SEDA-18, 206). Alternatively, the syndrome may be due to a different metabolite of procainamide, and a hydroxylated derivative has been implicated (SEDA-15, 178) (48). CYP2D6 is the major isoform of cytochrome P450 that is involved in the hydroxylation of procainamide, and in the production of some other metabolites (49). It remains to be seen whether extensive CYP2D6 metabolizers are more likely to develop lupus-like syndrome than poor metabolizers.

Susceptibility factors

The lupus-like syndrome is more likely to occur in slow acetylators than in fast acetylators (50), and the rate of development of antinuclear antibody depends on acetylator status (51).

Presentation

The most common feature is arthralgia, in about 77% of cases, with pleural or lung involvement in about 75%. Other common features include myalgia, fever, hepatomegaly, pericarditis, arthritis, and splenomegaly. Skin rashes, adenopathy, and Raynaud's phenomenon occur in 5–10% of cases, and neuropsychiatric and renal involvement are rare. Thrombotic problems can occur because of the properties of anti-DNA and antiphospholipid antibodies (discussed in the next case report). The so-called lupus anticoagulant can be detected in people taking procainamide, even without clinical evidence of lupus

© 2006 Elsevier B.V. All rights reserved.

(52). Angioedema has been reported in a patient who had no history of hereditary angioedema (53).

A lupus-like syndrome with an antiphospholipid syndrome has been attributed to procainamide in a patient with pre-existing systemic sclerosis (54).

- A 51-year-old Korean man with systemic sclerosis was given procainamide 2–3 g/day for suppression of ventricular dysrhythmias. About 2 years later he noticed a new skin ulcer on one of his toes. His dorsalis pedis arteries were not palpable and there was tenderness over the proximal interphalangeal and metacarpophalangeal joints. He had a pancytopenia, prolonged coagulation (with prolongation of the activated partial thromboplastin time and prothrombin time and reduced concentrations of factors XI and XII), an increase in the plasma concentration of von Willebrand factor, a raised serum creatinine concentration, a raised serum C-reactive protein concentration, hypergammaglobulinemia, and hypocomplementemia. He had positive circulating immune complexes and mixed-type cryoglobulinemia, antinuclear antibodies, anti-DNA topoisomerase I antibodies, and a positive LE cell preparation. He had anti-DNA antibodies with a high titer of antibodies to single-stranded DNA and a slightly raised titer of antibodies to double-stranded DNA. Anti-U1 ribonuclear protein, anti-Sm, and anticentromere antibodies were negative. There were high titers of beta$_2$-glycoprotein-I-dependent IgG anticardiolipin antibodies and the lupus anticoagulant test was positive. There were antihistone antibodies. Procainamide was withdrawn and prednisolone and azathioprine given. The pancytopenia, coagulopathy, and renal dysfunction resolved, and his general condition improved; serum concentrations of several of the antibodies returned to normal.

The authors suggested that the pre-existence of systemic sclerosis in this case and the presence of allele HIA-DQBP1* 0303 had increased the patient's susceptibility to the lupus-like syndrome and antiphospholipid syndrome.

Diagnosis

The antinuclear antibody is positive in virtually all cases and the ESR is often raised. Antihistone antibodies are also present in most cases. The prevalence of serum autoantibodies to high-mobility group (HMG) proteins in the serum of patients with drug-induced lupus-like syndrome varies from protein to protein: 67% for HMG-14 and/or HMG-17 compared with 21% for HMG-1 and/or HMG-2. Procainamide-induced lupus is also associated with antibodies to the H2A–H2B dimer (55,56).

Antinuclear antibody is usually present (in 83% of cases), but antibodies to native DNA are not found, although there may be antibodies to single-stranded DNA. Patients taking procainamide can have antinuclear antibodies without developing a lupus-like syndrome.

Management

The syndrome usually regresses rapidly after withdrawal of procainamide, but in a few patients recovery may be delayed; if there are serious effects oral glucocorticoid therapy may be required.

Body temperature

Fever occasionally occurs in patients taking procainamide (SEDA-1, 155) and has been attributed to an allergic reaction (57).

Susceptibility Factors

Renal disease

Maintenance dosages should be reduced in the presence of renal or hepatic impairment, including hepatic congestion due to cardiac failure (58).

Hepatic disease

Maintenance dosages should also be reduced in the presence of renal or hepatic impairment, including hepatic congestion due to cardiac failure (58).

Other features of the patient

Care must be taken in patients with pre-existing connective tissue disease or heart failure. Loading dosages should be reduced in cardiac failure, because of a lowered apparent volume of distribution (58).

Drug Administration

Drug overdose

Procainamide overdose has been reported.

- A 14-year-old boy took about 21 g of procainamide and developed abdominal pain, weakness, blurred vision, dry mouth, pain on swallowing, and headache (59). His pupils were dilated, his skin dry and pale, and his mucous membranes dry. His blood pressure was 106/49 mmHg, his heart rate 91/minute. Following a tonic-clonic seizure his blood pressure was 125/57 mmHg and his heart rate 136/minute in sinus tachycardia. He became lethargic with slurred speech. He was given repeated doses of activated charcoal and made a full recovery. The serum procainamide and acecainide (*N*-acetylprocainamide) concentrations were 63 and 80 μg/ml respectively.
- A 79-year-old man took about 19 g of procainamide and developed lethargy, vomiting, a wide-complex tachycardia, hypotension, and coma (60). His serum procainamide concentration was 77 μg/ml at 3 hours. He was treated with vasopressors and peritoneal dialysis.
- A 67-year-old woman took about 7 g of procainamide and developed nausea, vomiting, lethargy, a junctional tachycardia, hypotension, and oliguria (61). She was treated with hemodialysis.

Drug–Drug Interactions

Amiodarone

The effects of procainamide on the QT interval may be potentiated by other drugs with this action, for example amiodarone (62).

© 2006 Elsevier B.V. All rights reserved.

The pharmacokinetics of procainamide are altered by amiodarone, with a reduction in clearance of about 25% due to changes in both renal and non-renal clearances (62).

Cimetidine

The renal clearance of procainamide is inhibited by cimetidine (63,64).

Class I antidysrhythmic drugs

The effects of procainamide on the QT interval can be potentiated by other drugs with this action, for example other class I antidysrhythmic drugs (62).

Glucose

Procainamide interacts with glucose in vitro to form glucosylamines (63). The reaction was pH-dependent, with a maximum rate of association at a pH of 3.0 and a maximum rate of dissociation at a pH of 1.5. The authors suggested that the loss of procainamide in an intravenous solution of glucose could be marked.

Ofloxacin

The renal clearance of procainamide is inhibited by ofloxacin (66).

Trimethoprim

The renal clearance of procainamide is inhibited by trimethoprim (67).

Monitoring Therapy

The use of serum procainamide concentration measurements in monitoring therapy has been reviewed (58,68). Serum concentrations of 4–10 μg/ml are associated with therapeutic benefit in over 90% of patients with ventricular tachydysrhythmias, and toxicity becomes highly likely over 12 μg/ml. However, the main metabolite of procainamide, acecainide, has antidysrhythmic activity of its own; thus, because metabolism varies widely between individuals, and because acecainide is eliminated by the kidneys, serum concentration measurement of procainamide alone has limited usefulness, particularly in renal insufficiency. There is currently little information on the interpretation of combined measurement of the two compounds.

Procaine

See also Local anesthetics

General Information

Procaine is an aminoester local anesthetic. It is most widely used as a component of procaine penicillin.

Organs and Systems

Nervous system

Rare cases of tonic seizures have been reliably attributed to the presence of procaine in procaine penicillin (1).

Skin

The incidence of pruritus has been evaluated in a retrospective study of patients receiving procaine, lidocaine, or bupivacaine in combination with fentanyl for spinal anesthesia for a variety of different surgical procedures (2). Procaine plus fentanyl and bupivacaine plus fentanyl produced a higher incidence of pruritus than lidocaine plus fentanyl. The severity of pruritus was also greater in those given procaine plus fentanyl. The incidence and severity of pruritus was not related to the dose of fentanyl. Although this may represent an interaction between fentanyl and ester local anesthetics that differs from the synergy occurring between fentanyl and amide local anesthetics, this was an observational study and was neither randomized nor blinded. Furthermore, the doses of local anesthetic or fentanyl were not standardized. Further prospective randomized studies are therefore required to confirm or refute these claims.

Drug–Drug Interactions

Acetylcholinesterase inhibitors

Acetylcholinesterase inhibitors inhibit the hydrolysis of procaine and concomitant use can cause procaine toxicity (3).

Suxamethonium

Procaine is hydrolysed by plasma cholinesterase and may therefore competitively enhance the action of suxamethonium (4).

Procarbazine

See also Cytostatic and immunosuppressant drugs

General Information

Procarbazine is an alkylating agent that is used in the treatment of Hodgkin's disease in regimens such as MOPP (chlormethine (mechlorethamine), vincristine (Oncovin), procarbazine, and prednisolone) and BEACOPP (bleomycin, etoposide, doxorubicin (Adriamycin), cyclophosphamide, vincristine, procarbazine, and prednisone) (1). It is also used to treat glioblastoma multiforme.

Organs and Systems

Respiratory

The permanent and acute reversible forms of lung disease attributed to procarbazine have been reviewed (2). Pneumonitis has rarely been reported (3).

Drug–Drug Interactions

Antiepileptic drugs

In a retrospective cohort study in 83 patients with primary brain tumors who were treated with procarbazine, 20 patients had procarbazine hypersensitivity reactions (4). There was a significant association between exposure to antiepileptic drugs and the development of procarbazine hypersensitivity reactions. The authors suggested that this association may have been due to a reactive intermediate generated by induction of CYP3A.

Prochlorperazine

See also Neuroleptic drugs

General Information

Prochlorperazine is a phenothiazine derivative.

Organs and Systems

Nervous system

In 192 consecutive patients attending an emergency department for nausea/vomiting or headache, akathisia occurred in 16% of those treated with prochlorperazine (5–10 mg intravenously or intramuscularly); 4% (all of them women) developed dystonias (1).

Slow infusion of prochlorperazine has been used to try to minimize the risk of akathisia in 160 patients randomly assigned to two groups; akathisia developed in 31 of 84 who were given a 2-minute infusion and in 18 of 76 patients who were given a 15-minute infusion (2).

Procyclidine

See also Anticholinergic drugs

General Information

Procyclidine is an anticholinergic drug (1). The usual oral dose, which lies between 20 and 30 mg/day, is likely to produce only mild anticholinergic adverse effects, but involuntary movements, with chewing and sucking, have been described in some patients (SEDA-1, 120). Even small doses have produced toxic confusional states when procyclidine was combined with phenothiazines for schizophrenia. Procyclidine is more likely to produce sedation than stimulation.

Progabide

General Information

Progabide is an antispasticity drug that is also used in the treatment of epilepsy (1). Together with its metabolites, it acts as an agonist at both $GABA_A$ and $GABA_B$ receptors.

A high proportion of patients suffer from transient minor adverse effects, such as drowsiness, nausea, weakness, or dizziness.

Organs and Systems

Liver

The most serious adverse effect of progabide is hepatotoxicity. In one study, seven of 30 patients given doses up to 45 mg/kg/day had significant disturbances of liver function tests (which returned to normal on withdrawing the drug) (2). In another study, abnormal liver function tests were reported in 8.4% of 1164 patients; clinical hepatotoxicity occurred in 0.5% and three patients died. Monitoring liver function is recommended and drug withdrawal is indicated if liver transaminases exceed twice normal (SED-13, 155).

Progestogens

See also Individual agents

General Information

Most aspects of progestogens are dealt with in the monograph on hormonal contraception. For a complete account of the adverse effects of progestogens, readers should consult the following monographs as well as this one:

- Hormonal contraceptives—intracervical and intravaginal
- Hormonal contraceptives—oral
- Hormonal contraceptives—progestogen implants
- Hormonal contraceptives—progestogen injections
- Hormone replacement therapy—estrogens + progestogens
- Medroxyprogesterone.

While the progestogens have certain characteristic effects of their own, notably on the female menstrual cycle, the spectrum of adverse effects of any particular progestogen (particularly when given in high doses) is likely to depend heavily on the extent to which it also has glucocorticoid, mineralocorticoid, estrogenic, or androgenic properties.

The natural endogenous progestogen is progesterone (rINN), but most progestogens are semisynthetic. Progestogens belong to two main families:

- hydroxyprogesterone derivatives, which include hydroxyprogesterone caproate, dydrogesterone, medroxyprogesterone, chlormadinone, and cyproterone acetate (all rINNs), and which tend to be antiandrogenic
- ethisterone derivatives, which include norethisterone, norgestrel, levonorgestrel, desogestrel, and gestodene (all rINNs), which have some androgenic activity, and norgestimate (rINN), which has some estrogenic activity.

Water retention occasionally occurs and may reflect a degree of deoxycortone acetate (DOCA)-like activity; virilization of a female fetus is more likely to occur with a product that has some androgenic activity, and breast tenderness with a product that has estrogenic activity.

Some individuals taking progestogens for breast cancer will therefore experience, for example, not only painful swelling of the breast and prolonged amenorrhea (which are progestogenic), but also weight gain and hypercalcemia (which are likely to be glucocorticoid effects). Patients who take progestogens during pregnancy are said to be susceptible to prolonged postpartum bleeding, but this probably reflects the pregnancy disorder for which these drugs were at one time given, for example habitual or threatened abortion. Virilization of the female fetus has been described after administration of various progestogens in early pregnancy and is presumably an androgenic effect.

Progestogens given alone for contraceptive purposes can cause a number of adverse effects, some of which may reflect their other hormonal properties while others are non-specific. Headache, nausea and vomiting, breast tenderness, and pain in the back or abdomen can occur.

Animal studies cannot be regarded as providing a reliable indicator of the spectrum of activity of individual compounds; suggestions that derivatives of hydroxyprogesterone (such as megestrol acetate, medroxyprogesterone acetate) are more "natural" (because of their progesterone-like structure) than derivatives of 19-nortestosterone (such as norgestrel, lynestrenol, ethynodiol acetate, norethisterone, and allylestrenol) are not reflected in any biological findings. Experience, too, can be misleading; there is some suggestion that hydroxyprogesterone caproate can have adverse effects on the fetus when used in pregnancy, while similar reports about allylestrenol (used for the same purpose) are lacking, but one must bear in mind the anecdotal nature of such evidence and especially the fact that hydroxyprogesterone caproate appears to have been more widely used than allylestrenol and is hence more likely to have given rise to reports of adverse reactions.

Progestogens belonging to the ethisterone family (norethisterone, levonorgestrel, desogestrel) have some androgenic activity; those in the hydroxyprogesterone family (hydroxyprogesterone caproate, chlormadinone, cyproterone acetate) tend to be antiandrogenic, while norgestimate seems to be somewhat estrogenic. Water retention occasionally occurs and may reflect a degree of DOCA-like activity; virilization of a female fetus is more likely to occur with a product that has some androgenic activity, and breast tenderness with a product that has estrogenic activity.

In a multicenter, prospective, double-blind, randomized, parallel group study undertaken by general practitioners to compare progesterone pessaries with placebo in the relief of symptoms of premenstrual syndrome, spontaneous reports of adverse events were recorded (1). The 41 patients were randomized to treatment or placebo groups. Patients taking active therapy reported more frequent vaginal pruritus, headache, and irregularities of menstruation. However, when cyclical treatment with progestogen alone was given to postmenopausal women, there was no greater degree of endometrial hyperplasia than in untreated women (2).

Semisynthetic progestogens

Desogestrel (rINN)

Desogestrel, one of the so-called third-generation progestogenic steroids intended for use in oral contraceptives, is metabolized to estrogen. It was developed and introduced because of its relatively favorable effect on blood lipids in experimental work; this led to the hope that it might, in the long run, have a relatively favorable effect on the risk of atherogenesis. However, it is not clear that this does in fact happen, and the third-generation progestogens have been associated with an increased risk of thromboembolism.

Gestodene (rINN)

Gestodene is a third-generation progestogen that has been implicated in an increased risk of thromboembolism.

Gestonorone caproate (rINN)

Gestonorone (17-hydroxy-19-norprogesterone) has been used in doses of 200 mg intramuscularly weekly for benign prostatic hyperplasia (3). Mild adverse effects included loss of appetite and mild fever, but more remarkable were significant reductions in erythrocyte count, hemoglobin, and hematocrit, which normalized after drug withdrawal (4).

Hydroxyprogesterone caproate (rINN)

High doses of hydroxyprogesterone and the related norderivative have been used to treat benign prostatic hyperplasia. Very striking is the high incidence of impotence recorded in these studies, which can affect two-thirds of patients and seems to persist in some patients after withdrawal (5).

Levonorgestrel (rINN)

Extensive clinical trials and premarketing studies were conducted before the Norplant (levonorgestrel) implant was registered and approved, in order to elucidate its mode of action, effectiveness, and adverse effects. However, none of these trials included either teenagers under 18 years of age or nulligravid women.

In an 18-month observational study of 136 adolescents (13–18 years) and 542 adults (19–46 years) who were given Norplant levonorgestrel contraceptive implants problems were reported by 110 patients, mostly irregular bleeding (53% of the adolescents and 38% of the adults) (6). Removal of the implant was requested by 11% of both

© 2006 Elsevier B.V. All rights reserved.

adolescents and adults, most commonly for intolerable menstrual cycle changes, and in 6% of all the adults for irregular bleeding; the time from insertion to removal was 3–15 months for the adolescents and 1–17 months for the adults. Other problems that led to removal (in 5% of adolescents and 7.5% of adults), apart from a desire to become pregnant, included headache, weight gain, and acne.

Lynestrenol (rINN)

Lynestrenol is one of the older progestogens used in oral contraceptives and has been very widely and successfully employed for nearly 40 years; as monotherapy it has been used to treat irregularity of the menstrual cycle.

In a Finnish study analysis of the association between the prolonged use of lynestrenol (to suppress menstruation in mentally retarded women) and arterial disease detected at autopsy, the conclusion was that such treatment, here given for a mean of more than 6 years, increases the risk of arterial disease and that such treatment must be very carefully considered (7).

Medroxyprogesterone acetate (rINNM)

Medroxyprogesterone acetate is the subject of a separate monograph.

Megestrol (rINN)

Megestrol acetate, like medroxyprogesterone acetate, is used for metastatic breast cancer in postmenopausal women. Its commonest adverse effects are typical of the progestogens as a group, but glucocorticoid-like effects are less prominent than with medroxyprogesterone acetate. Typical effects and incidence figures for effective doses in cancer patients (SED-12, 1036) (8,9) have been cited as including weight gain in some 81–88% of cases, mild edema in up to 34%, and hypertension in up to 25%. There are lower but appreciable occurrences of constipation, dyspnea or chest tightness, heartburn, hyperglycemia, and increased urinary frequency; a few cases of phlebitis or thrombosis have been described. Vaginal bleeding, nervousness, sweating, vertigo, gastrointestinal symptoms, skin rash, pruritus, and thrombocytopenia have also been incidentally recorded.

Megestrol acetate has also proved of value in patients with metastatic prostatic cancer, epithelial ovarian cancer, or malignant melanoma and is therefore used in both sexes. The adverse effects are very similar in men to those seen with oncological doses in women; loss of libido and potency is likely to occur in male patients. In one clinical study of 43 men with recurrent and metastatic cancer of the prostate given megestrol acetate 160 mg/day orally, five developed a symptomatic rise in liver enzymes but it resolved during further treatment. In three patients, increasing bone pain occurred, no doubt relating to changes in bony metastases and requiring analgesia. Another patient developed hypercalcemia and one patient developed convulsive epilepsy (10). These latter problems are characteristic of the primary condition as it responds, and not typical for megestrol acetate. The glucocorticoid-induced gain in body weight when it occurs is often linked to improved appetite (11), which can be a positive advantage in cachectic patients with advanced cancers.

When megestrol acetate was used alongside diethylstilbestrol or ethinylestradiol in men with previously untreated metastatic carcinoma of the prostate, there was a high incidence of feminizing adverse effects (70–74%), no doubt attributable to the estrogens; a higher than expected rate of cardiovascular complications (18%) and an unexplained need for cortisone replacement (13%) were also observed (12).

Organs and Systems

Cardiovascular

Progestogens with a degree of mineralocorticoid activity will tend to cause water and salt retention and to increase blood pressure in susceptible subjects. However, effects on blood pressure can be variable; for example, medroxyprogesterone has been variously reported to cause a fall in blood pressure in some initially hypertensive patients while rapidly increasing diastolic pressure in some other women, or to have no effect on blood pressure at all.

Since thromboembolic complications can occur with progestogens, there may be a danger in using them in patients in whom there are other risk factors for thromboembolism. A Spanish group had to deal with patients with AIDS in whom megestrol acetate seems to be helpful in countering AIDS-related anorexia or cachexia. However, advanced HIV infection is itself a risk factor for thromboembolism, as is tuberculosis, which readily occurs in this population. Of 199 patients with AIDS followed for 2 years, 25 took megestrol 320 mg/day. Deep vein thrombosis occurred in seven patients in the entire series, four of them being in the megestrol group and three having tuberculosis. The duration of hormonal therapy up to the moment of thrombosis averaged 98 days. Tuberculosis was an independent risk factor. Statistical analysis led to the conclusion that in this high-risk population the use of megestrol had increased the risk of thrombosis by a factor of 7.6 (13).

Thromboembolism and third-generation progestogens

In October 1995 the UK Committee on Safety of Medicines (CSM) issued a warning that oral contraceptives containing the third-generation progestogens gestodene or desogestrel carry a higher risk of venous thromboembolism, and that women using these should consider changing to another brand (14).

The warning was based on three unpublished studies that had not at the time been formally peer reviewed. All three showed about double the risk of venous thromboembolism with gestodene and desogestrel products compared with oral contraceptives containing other progestogens. The first, a large WHO collaborative case-control study of cardiovascular disease and oral contraceptives was undertaken in 17 countries. It was completed in July 1995, and involved 829 cases of venous thromboembolism and 2641 controls from nine countries in which third-generation oral contraceptives had been used (15). The second, from the Boston Collaborative Drug Surveillance Program, was an analysis of the occurrence of venous thromboembolism in a UK general practice cohort of 238 130 women who had received a

© 2006 Elsevier B.V. All rights reserved.

prescription for an oral contraceptive containing levonorgestrel, gestodene, or desogestrel (16). The third was a transnational case-control study conducted in five European countries, funded by Schering, the leading manufacturer of gestodene (17).

The WHO study was undertaken because the association between oral contraceptive use and venous thromboembolism had not been examined since the 1970s, when oral contraceptives contained higher doses of estrogen and progestogen than now, and because none of the earlier studies had been done in developing countries. The finding of a higher risk of venous thromboembolism with gestodene and desogestrel came as a surprise, and this, together with publicity in the media, prompted the CSM to commission the UK cohort study. The transnational study was set up at the request of the German regulatory authority to follow up German spontaneous reporting data that in 1990 had strongly suggested higher risks of thromboembolism with gestodene-containing oral contraceptives. This led to much controversy in the press and television. Schering had argued that highly publicized deaths had stimulated selective reporting, and that the claimed higher risk was an artefact.

The sudden announcement by the CSM in October 1995 caught prescribers and users of oral contraceptives completely unprepared. What some General Practitioners described as the "pill panic" in the media (18) drove thousands of women to consult their doctors (18–20), who had not been briefed. A heated debate ensued over whether the CSM's decision was justified, whether its announcement should have been delayed until the data were published, and over the dramatic and confusing way in which it was issued. Before long there was general agreement that the decision was necessary and correct, but that its communication had been handled badly, and the Health Minister said that the Government would review the incident to learn from it. Important suggestions for getting this kind of communication correct have subsequently been made (21–23). Official actions in other countries ranged from the imposition of stronger restrictions (in Germany) to decisions in the Netherlands and Canada to wait and consider the published studies, and in the USA not to advise switching to other products (24). The European Union's Committee on Proprietary Medicinal Products also decided to wait and see.

Although doubts about the relative safety of gestodene emerged in 1990, regulators did not publicly acknowledge them. Nor did they help independent scientists to examine all the relevant data (including prescribing figures, essential to provide denominators for the calculation of risk), perhaps because they were insufficient and might have been wrongly interpreted. In Germany, the regulatory authority privately asked Schering to undertake a case-control study; in the UK the Medicines Control Agency considered the available evidence inadequate and dismissed the doubts. Whether the CSM was consulted at that time or only later remains a minor official secret. The attitude changed early in July 1995, when the CSM saw the early results of the WHO Collaborative Study, and a highly critical UK television programme about gestodene-containing oral contraceptives was broadcast (Granada, "World in Action," 10 July). The CSM asked workers from the transnational case-control study to "expedite their results," and commissioned the cohort study using data routinely collected from General Practitioners. The analysis of venous thromboembolism in the transnational study was completed on 8 October, and was promptly discussed with members of the Medicines Control Agency and the CSM. The CSM quickly made its decision (17) and announced it on 18 October. The relevant data from the WHO study and the GP cohort study were published on 16 December; those from the transnational study were published on 13 January 1996 (25). A searching independent analysis of these three studies, and of a fourth (26) that the CSM had not considered, supported the decision (27).

In retrospect, what could the CSM and other authorities have done to alert the world to the potential problem during the 5 years of growing doubts about the relative safety of gestodene? To know about the doubts would have helped women and their doctors. They could then have begun to discuss among themselves whether to act on them or not, in order to weigh any real advantages of their gestodene oral contraceptive against the doubt and potential risk. A joint statement by regulators and manufacturers about their plans for further investigations would have made it clear that there was a problem to be resolved, instead of appearing to ignore or deny it. This would have allowed prescribers and independent experts to rethink their prescribing policies, for example deciding in what circumstances gestodene oral contraceptives should no longer be the first choice. That would not have pleased the manufacturers, since it would almost certainly have reduced the sales of their leading product in an uncontrollable way. The position of desogestrel creates additional complications, since its relative safety was not questioned until the data from the WHO study appeared in July 1995. If doubts had been officially expressed about the gestodene-containing products Femodene and Minulet, these oral contraceptives would meanwhile have lost some market share to Marvelon and Mercilon, the desogestrel-containing products. But greater openness from the start could have minimized the alarm and confusion.

Liver

The progestogens as a group have little effect on the liver. However, some progestogens can increase nonconjugated bilirubin (28); norethisterone acetate has been implicated in this effect (29).

Skin

Progestogens have very occasionally been reported to cause hypersensitivity reactions or skin disorders. Pemphigus has been reported (30).

- A 34-year-old woman with a 3-month history of dysphagia, odynophagia, and conjunctivitis with bulbar injection, who had been taking an oral contraceptive containing a progestogen for 7 months, developed typical bullous lesions on her trunk and nose, typical of pemphigus. Ceftriaxone and ampicillin, which can aggravate pemphigus, exacerbated the lesions. There was reason to believe that the patient had a genetic predisposition to the disorder.

© 2006 Elsevier B.V. All rights reserved.

The circumstances pointed strongly to a drug association, but the identity of the oral contraceptive was not stated; it is likely to have contained a synthetic progestogen and not progesterone itself.

However progesterone-induced dermatitis certainly does occur.

- A 68-year-old woman who took a formulation containing hydroxyprogesterone acetate + conjugated estrogens had for many years an autoimmune dermatitis (31).

Other complications (acne, alopecia, and pruritus) have been associated with Mirena, an intrauterine system containing levonorgestrel.

- Rosacea accompanied the use of Mirena in a 36-year-old woman for 2 years and disappeared within 6 months of removal (32).

However, one is bound to wonder whether this was a direct reaction to levonorgestrel or a stress reaction to the absence of menstrual periods. Like many other users of Mirena, this woman had amenorrhea associated with facial flushing and pustules; conditions such as urticaria, eczema, pompholyx, and erythema multiforme occur cyclically in some women in the second half of the menstrual cycle, irrespective of contraceptive use.

Long-Term Effects

Tumorigenicity

The effects of adding a progestogen on the carcinogenic effects of estrogens are discussed in the monograph on estrogens.

Second-Generation Effects

Teratogenicity

For a number of years from about 1950 onwards, progestogens were used in cases of threatened and habitual abortion. They were largely abandoned for this purpose because of the general conclusion that they were ineffective. There was no general conclusion as to any adverse effects that might have resulted, although some of the progestogens were suspected of having virilizing effects on the fetus. Subsequently, progestogens (usually natural progesterone) were used to provide "luteal support" for some 4 weeks after in vitro fertilization. In 283 women treated for this reason with injectable progesterone 300 mg/day, oral micronized progesterone 90 mg/day, or a sustained-release transvaginal gel, among the offspring there were incidental cases of facial teratoma associated with a cleft palate, a respiratory distress syndrome, and Pierre–Robin syndrome; there was no clear indication that in this respect one formulation was safer than another or that the effects observed were other than might have been anticipated in untreated controls with a similar history (33). Women who received the injectable progesterone tended to complain of drowsiness, reduced libido, dyspareunia, and vaginal irritability.

With regard to progestogens given alone to prevent threatened or habitual abortion, there is no good evidence that they are beneficial, and much evidence to the contrary; however, effects on the sexual development of the fetus cannot be excluded (34).

Tumors may possibly be induced in the second generation. Neuroblastoma in four infants has been attributed to pregnancy or to gonadotropins, clomiphene citrate, or progestational hormones (35), because these drugs result in increased exposure of the early pregnancy to estrogenic or progestogenic influences. Most of these neuroblastomas regress spontaneously, but when regression does not occur they may become malignant. Children born to women who have taken hormonal preparations in early pregnancy should therefore be screened for urinary vanillylmandelic acid concentrations at the age of 6 months.

Drug Administration

Drug formulations

As with estradiol, a case has been made for using natural progesterone, rather than synthetic analogues, largely because it is assumed that as a physiological substance it will be safer. Progesterone is unsuitable for oral use (unless given in a special micronized form), but it is used by other routes. These include systemic and intra-articular injection (36), an intranasal ointment (37), transdermal formulations (38), and intravaginal formulations (39). Apart from local irritation, the wanted and unwanted effects produced when using these modes of administration are the familiar manifestations of progestogen treatment and are proportional to the amount of the drug that actually enters the circulation.

Micronized oral formulations

The fact that progesterone when given by mouth has poor systemic availability can be largely overcome by micronization, and the first product based on this concept was marketed in France as long ago as 1980. Studies and reviews have appeared, particularly since 1997, suggesting that it is indeed less likely to cause adverse effects than the synthetic progestogens are (40). The most frequently reported adverse reactions are stated to be dizziness or drowsiness, which could be related to the pregnenolone metabolites and do not seem to reflect vasoactive changes. It has been argued theoretically that there might be altered sodium metabolism, but no hypertensive effects have been seen. Unusually high doses of micronized progesterone given in pregnancy (in the hope of avoiding premature labor) have been suspected of causing intrahepatic cholestasis, at least in women with a genetic predisposition, but these doses are much higher that those in normal use. No changes in lipid profile appear to occur.

With these very positive conclusions it is not clear why micronized progesterone has not been more widely used. Commercial factors may well have played a role in maintaining the overwhelming dominance of the patented synthetic progestogens. On the other hand, despite the fact that there are estimated to be 500 000 current users of micronized progesterone in France alone, the worldwide scope of experience is still limited compared with that of the synthetic analogues, and one must be prepared for surprises if this product should ever be used more widely. It

© 2006 Elsevier B.V. All rights reserved.

is a fact that in the 1970s, when studies in beagle dogs gave rise to much concern regarding progestogens and the induction of mammary tumors, the same effect was also observed with natural progesterone if sufficient doses were administered. Even a natural substance can have unpleasant effects when used in a manner not foreseen in nature.

Intrauterine release systems

The fiber-based ("frameless") FibroPlant delivery system for levonorgestrel has been tested in an open study in 32 women as a means of relieving menorrhagia or for contraceptive purposes (41). The period of exposure was 1–23 months. This system, which releases levonorgestrel 14 micrograms/day, appeared to be effective for both purposes, and there were no cases of infection, expulsion, or perforation.

An alternative intrauterine delivery system (LNG-IUS) consists of an adapted Nova-T device with a silastic reservoir attached to the vertical arm; the reservoir is impregnated with levonorgestrel and is covered with a rate-limiting silastic membrane. The release rate of levonorgestrel is about 20 micrograms/day for at least 5 years. In a 5-year study in which 1821 women used the combined device and 937 others used the plain Nova-T device, the Pearl index (the number of unwanted pregnancies occurring in 100 couples using a given method for a period of one year) was 0.09/100 woman-years for the LNG-IUS and the ectopic pregnancy rate was 0.02/100 woman-years (42). There were fewer withdrawals because of bleeding problems and pelvic inflammatory disease with LNG-IUS compared with Nova-T, but there were more withdrawals because of hormonal adverse effects and absence of bleeding. One of the advantages claimed for LNG-IUS is that there will be less menstrual blood loss. However, all women who used LNG-IUS had some change in their bleeding pattern after the device had been inserted, and some had many days of spotting. Of another 30 women who used the LNG-IUS system to relieve menorrhagia and who were followed for a year, 13 reported one or more pelvic adverse event; there were six complaints of irregular bleeding, four of abdominal pain, three of breast tenderness, and occasional cases of headache, mood changes, or acne (43).

A systematic review of Mirena, an intrauterine progestogen release system (44), has attracted correspondence (45,46). Like other devices, Mirena releases levonorgestrel, in this case 20 micrograms/day. Since it had no greater efficacy than the Copper T device and was very much more costly, the debate has turned on safety. Amenorrhea is common with this device, as with others like it, and correspondents have pointed out that this is regarded by many women as an unwelcome complication.

Transdermal administration

An older 19-norprogesterone (ST 1435, Merck Darmstadt) was used experimentally in a transdermal form as a possible hormonal contraceptive. A dose of 0.8–1 mg/day was needed to inhibit ovulation in all subjects. There was some irregularity of bleeding, and some subjects had breast tenderness (47).

Vaginal gel

To provide luteal support in ovarian stimulation protocols, especially when following the long procedure, progesterone can be administered by various routes. The oral route is relatively ineffective, since progesterone has a low oral systemic availability (below 10%), which may result in adverse effects such as somnolence. Intramuscular administration is painful and inconvenient. Some workers have therefore given progesterone in the form of an 8% vaginal gel, which is effective and better tolerated than alternative approaches. The gel adheres to the vaginal epithelium, and leakage is substantially less than when using capsules or suppositories; there are no local complications (48). No adverse reactions have been reported with the use of a modified-release vaginal gel containing polycarbophil-based progesterone (49).

Proglumetacin

See also Non-steroidal anti-inflammatory drugs

General Information

Proglumetacin, an indoleacetic acid derivative, is particularly associated with gastrointestinal adverse effects: in different trials 18–41% of patients had adverse effects, but not to the extent that they interfered with treatment. Comparisons of proglumetacin with indometacin and oxyphenbutazone showed that it is equally effective and usually better tolerated (SEDA-5, 103). In an uncontrolled, open, multicenter, short-term study in patients with cervical or low back pain treated with proglumetacin, the most frequent adverse effects were gastrointestinal, while adverse effects on the nervous system were rare (1).

Proguanil and chlorproguanil

General Information

Proguanil is one of the antimalarial drugs most widely used for prophylactic purposes, usually in combination with chloroquine or atovaquone in malaria prophylaxis, and with atovaquone in malaria treatment (SEDA-21, 297). A biguanide, it is rapidly absorbed in standard doses and mainly excreted by the kidneys. Its antimalarial effect is due to its metabolite cycloguanil. However, its metabolism varies individually, and this is reflected in a variable degree of efficacy (SEDA-17, 328).

A derivative, chlorproguanil, is similarly effective in chemoprophylaxis of malaria tropica (SEDA-20, 260).

No serious adverse effects of proguanil have been reported in otherwise healthy patients (SEDA-13, 811) (SEDA-17, 328). Skin rashes and hair loss can occur. Mouth ulcers have been mentioned, as have abdominal discomfort and vomiting. The incidence of mouth ulcers in a group of soldiers was 24% in those taking proguanil only and 37% in those taking proguanil 200 mg plus chloroquine either 300 or 150 mg weekly (SEDA-13, 811). With the use of large doses hematuria has been seen.

Organs and Systems

Hematologic

Since chlorproguanil + dapsone exerts lower resistance pressure on *Plasmodium falciparum* than does pyrimethamine + sulfadoxine, a randomized trial in outpatients with uncomplicated falciparum malaria was conducted in Africa in 910 children (1). Treatment failure was more common with pyrimethamine + sulfadoxine. Despite the rapid elimination of chlorproguanil + dapsone, children treated with this combination did not have more episodes of malaria than those who were treated with pyrimethamine + sulfadoxine. However, there was a higher incidence of anemia.

Liver

Hepatitis with mild jaundice has been attributed to proguanil (2).

Susceptibility Factors

Genetic factors

The major limitation of proguanil is that in most ethnic groups there are individuals who have limited ability to metabolize proguanil to the active metabolite cycloguanil. Consequently, poor proguanil metabolizers treated with combination drugs are effectively taking monotherapy. Poor metabolizers also have an increased incidence of adverse effects with proguanil, especially gastrointestinal effects (3).

Renal disease

The urinary excretion of proguanil may mean that caution is advisable when treating patients with renal disorders. Two patients with renal insufficiency became severely ill while taking standard doses of proguanil (SEDA-12, 694) (4). One developed anorexia, dizziness, vomiting, diarrhea, mouth ulcers, a low white cell count, and a low platelet count. The other developed extensive purpura, epistaxis, and vomiting. Bone marrow studies showed hypoplasia and gross megaloblastic changes. The relation of these findings to proguanil therapy is nevertheless questionable, and whether the drug was or was not causative is not known. While it is tempting to seek an explanation in the fact that these biguanides interfere with (plasmodial) folate synthesis, the serum folate and vitamin B_{12} concentrations were normal in both patients.

Drug–Drug Interactions

Cimetidine

Cimetidine co-administration increased the C_{max} of proguanil, and significantly reduced the C_{max} and AUC of cycloguanil, presumably by inhibiting the metabolism of proguanil; co-administration is probably inadvisable (5).

Coumarin

Proguanil potentiates the response to warfarin (6), perhaps by inhibiting CYP2C19 (7).

Levothyroxine

A rise in serum TSH has been described after antimalarial prophylaxis with chloroquine and proguanil in patients taking levothyroxine (SEDA-22, 469). In one case there was a marked increase in serum TSH in the same patient on two occasions after several weeks of antimalarial prophylaxis with chloroquine and proguanil, the likely mechanism being enzyme catabolism (8).

Prolintane

General Information

Prolintane, an amfetamine-related substance, is a central nervous system stimulant with similar structure and properties to dexamfetamine. Prolintane hydrochloride is available mainly in many formulations with multivitamin supplements in many European countries, Australia, and South Africa.

Organs and Systems

Nervous system

The adverse effects of prolintane include insomnia, nervousness, irritability, euphoria, headache, dizziness, and psychotic reactions (1).

Psychological, psychiatric

Prolintane can cause visual hallucinations (2).

Drug Administration

Drug overdose

Acute overdose can produce cardiorespiratory arrest and death (SEDA-22, 7).

Drug–Drug Interactions

Diphenhydramine

An interaction of prolintane with diphenhydramine has been reported (2).

- A young man developed visual hallucinations after taking prolintane and diphenhydramine. He had started to take prolintane 20 mg/day before 2 months, in order to enhance his intellectual performance and academic grades. Soon afterward he had sleep disturbance and resorted to a hypnotic containing diphenhydramine 25 mg. Despite this, insomnia preceded the acute psychotic episode. Prolintane and diphenhydramine were withdrawn, and he was given oral haloperidol and clorazepate. The symptoms gradually abated.

Pharmacological kindling resulting from increased dopaminergic activity could have explained this psychotic episode (3).

Promethazine

See also Antihistamines

General Information

Promethazine is a first-generation antihistamine (SEDA-15, 158) (SEDA-21, 176). In vitro studies suggest that CYP2D6 is a key enzyme for the metabolism for promethazine, which could lead to interaction problems (SEDA-21, 176).

Organs and Systems

Nervous system

Neuroleptic malignant syndrome has been associated with promethazine (1).

- A 42-year-old man took promethazine 50 mg every 4–6 hours for 2 days and developed hyperthermia (42.4°C). He died 3 days later despite intensive care and treatment with bromocriptine.

Promethazine intoxication from topical application has been observed in children (2) and adults (3). Symptoms include disorientation, hallucinations, hyperactivity, convulsions, and coma.

Propafenone

See also Antidysrhythmic drugs

General Information

Propafenone is both a class I antidysrhythmic drug and a beta-adrenoceptor antagonist. Its pharmacological effects, clinical pharmacology, therapeutic uses, adverse effects, and interactions have been reviewed (1–5).

The main adverse effects of propafenone are cardiovascular (27%), central nervous (21%), and gastrointestinal (20%) (6). Other adverse effects occur in under 6% of cases. The overall risk of non-cardiac effects is around 14%. These adverse effects are dose-related: the incidence is 11% at 300 mg/day, 22% at 450 mg/day, 33% at 600 mg/day, and 48% at 900 mg/day (6).

Observational studies

In 87 patients with atrial fibrillation who were given propafenone 2 mg/kg intravenously over 10 minutes, four had hypotension at 8–45 minutes after the start of infusion (7). In two cases this was accompanied by sinus bradycardia, nausea, and slight malaise. In all cases the hypotension resolved rapidly with saline infusion; the drug was withdrawn in only one case. In two cases atrial fibrillation was transformed to asymptomatic atrial flutter with 2:1 atrioventricular conduction.

Quinidine has been added to propafenone with the intention of inhibiting propafenone metabolism via CYP2D6 in the hope of improving outcome (8). Of 60 patients with paroxysmal atrial fibrillation given propafenone 300–450 mg/day for 8 weeks there were 19 refractory cases, who were then randomized double-blind to receive either a higher dose of propafenone (450–675 mg/day) or the standard dose of propafenone with extra low-dose quinidine (150 mg/day), each for 8 weeks, with subsequent crossover to the alternative. Patients who even then were not adequately controlled were given the standard dose of propafenone plus a standard dose of quinidine (600 mg/day) for a further 8 weeks. The plasma propafenone concentrations during the four phases were as follows:

1. standard-dose propafenone alone 128 ng/ml;
2. standard-dose propafenone plus low-dose quinidine 259 ng/ml;
3. high-dose propafenone alone 336 ng/ml;
4. standard-dose propafenone plus standard-dose quinidine 490 ng/ml.

The beneficial effects were related to these plasma concentrations, as were the time to the first bout of atrial fibrillation, the frequency of bouts of atrial fibrillation, and the time between episodes. However, when atrial fibrillation occurred there was no difference in the ventricular rate in the different groups. Adverse effects necessitated drug withdrawal in four patients; one had heart failure and two had gastrointestinal symptoms. These effects were not dose-related, although there were too few occurrences for a definitive conclusion. The authors suggested that this stepwise approach, with increasing doses of propafenone and increasing doses of quinidine could be beneficial in the treatment of paroxysmal atrial fibrillation.

Comparative studies

Amiodarone

Amiodarone 30 mg/kg orally for the first 24 hours plus, if necessary, 15 mg/kg over 24 hours has been compared with propafenone 600 mg in the first 24 hours plus, if necessary, 300 mg in the next 24 hours in 86 patients with recent onset atrial fibrillation (9). Conversion to sinus rhythm occurred faster with propafenone (2.4 hours) than amiodarone (6.9 hours). However, by 24 hours and 48 hours the same proportions of patients were in sinus rhythm; one patient given amiodarone had a supraventricular tachycardia and one a non-sustained ventricular tachycardia.

Of 136 patients with atrial fibrillation treated with either amiodarone ($n = 96$) or propafenone ($n = 40$), 15 developed subsequent persistent atrial flutter, nine of those taking amiodarone and six of those taking propafenone (10). In all cases radiofrequency ablation was effective. It is not clear to what extent these cases of atrial flutter were due to the drugs, although the frequencies of atrial flutter in previous studies with propafenone have been similar. Atrial enlargement was significantly related to the occurrence of persistent atrial flutter in these patients.

Procainamide

A comparison between procainamide and propafenone in 62 patients, who had undergone coronary artery bypass grafting or valvular surgery within 3 weeks and developed sustained atrial fibrillation, showed that both drugs converted the dysrhythmia to sinus rhythm in up to 76% of cases, but that propafenone did it more quickly (11). Symptomatic arterial hypotension occurred more frequently with procainamide (nine of 33 patients) than propafenone (two of 29 patients). Other adverse effects of procainamide were nausea ($n = 2$) and junctional escape rhythm ($n = 2$). Other adverse effects of propafenone were hot flushes ($n = 1$), nausea ($n = 3$), bronchospasm ($n = 1$), and junctional escape rhythm ($n = 2$).

Quinidine

A placebo-controlled study of the use of propafenone 450–600 mg orally, either alone or in combination with digoxin, has been carried out in 176 patients with atrial fibrillation; a further 70 patients were given digitalis plus quinidine (12). There were no significant differences across the groups in terms of percentage conversion to sinus rhythm,

© 2006 Elsevier B.V. All rights reserved.

although conversion occurred more quickly in those given digoxin plus propafenone; this catch-up of the other treatments was attributed to spontaneous conversion in those groups. There were no serious adverse effects in this study. The QT_c interval was slightly prolonged by digitalis plus quinidine and not by the other treatments. In six patients taking propafenone alone there were mild non-cardiac effects, including sickness in two, headache in one, gastrointestinal disturbances in two, and paresthesia in one. Four patients taking propafenone plus digitalis had either sickness or dizziness, and nine patients taking digitalis plus quinidine had gastrointestinal disturbances, sickness, dizziness, or headache. There were no major dysrhythmias; four of the patients who took digitalis plus propafenone had asymptomatic ventricular extra beats, as did one patient who took digitalis plus quinidine. In nine patients who took digitalis plus quinidine there were asymptomatic short-lasting episodes of atrial flutter with atrial ventricular conduction of at least 2:1 immediately before the restoration of sinus rhythm; this happened in 13 patients who took propafenone, 12 patients who took digitalis plus propafenone, and three patients who took placebo. There were two cases of complete left bundle branch block in patients who took digitalis plus quinidine, in three patients who took propafenone, and in two who took digitalis plus propafenone. In two patients who took digitalis plus quinidine and two who took propafenone there was reversible asymptomatic sinoatrial block of Wenckebach type II. Transient mild hypotension occurred in one patient taking digitalis plus quinidine, five taking propafenone, one taking digitalis plus propafenone, and one taking placebo, but the hypotension was transient and not severe. The authors concluded that the addition of digitalis to propafenone hastened cardioversion from atrial fibrillation, although they conceded that the balance of other evidence suggests that digitalis is not effective in restoring sinus rhythm and were unable to explain the efficacy of the combination of digitalis with propafenone.

Sotalol

In a randomized, double-blind, placebo-controlled comparison of propafenone (mean dose 13 mg/kg/day; $n = 102$) and sotalol (mean dose 3 mg/kg/day; $n = 106$) in maintaining sinus rhythm after conversion of recurrent symptomatic atrial fibrillation in 300 patients, efficacy was comparable (13). Tolerable adverse effects in those who took propafenone were gastrointestinal discomfort ($n = 15$), neurological disturbances ($n = 9$), a metallic taste ($n = 4$), and generalized weakness ($n = 1$); nine patients withdrew owing to adverse effects, four with gastrointestinal disorders, three with dizziness, and two with headache; there were no prodysrhythmias.

Propafenone 450 mg/day and sotalol 240 mg/day have been compared in a placebo-controlled study of 300 patients with atrial fibrillation (14). The two drugs had similar efficacy. There were adverse events in 38 of the patients who took propafenone, compared with 12 of those who took placebo. These included gastrointestinal discomfort, neurological disturbances, asymptomatic bradycardia, a metallic taste, and general weakness. In nine patients the adverse effects were sufficient to cause withdrawal of propafenone.

Placebo-controlled studies

In controlled trials in patients with recent-onset atrial fibrillation without heart failure, oral propafenone (450–600 mg as a single dose) had a relatively quick effect (within 3–4 hours) and a high rate of efficacy (72–78% within 8 hours) (15).

The adverse effects of propafenone in placebo-controlled trials in patients with atrial tachydysrhythmias have been reviewed (16). The following effects were reported after single intravenous oral doses to produce conversion of atrial fibrillation to sinus rhythm. Non-cardiac adverse effects included mild dizziness. Mild hypotension was also noted, but only required withdrawal of propafenone in one of 29 patients in one study. There have been prodysrhythmic effects in several studies, including atrial flutter with a broad QRS complex, which can occur in up to 5% of cases; in some cases atrial flutter can have a rapid ventricular response due to 1:1 atrioventricular conduction, which has been attributed to slowing of atrial conduction and reduced refractoriness of the atrioventricular node. Other prodysrhythmic effects in a few patients included sinus bradycardia with sinus pauses and effects on atrioventricular conduction.

In patients taking long-term propafenone for supraventricular dysrhythmias adverse effects were more common and have been reported in 14–60% of cases. Cardiac adverse effects were more common in patients with structural heart disease. The non-cardiac effects were either gastrointestinal (nausea, vomiting, taste disturbances) or neurological (dizziness). Adverse effects are dose-related. In one large study there was no difference between propafenone and placebo in the risk of death.

The use of propafenone in atrial fibrillation (SEDA-23, 202) has been studied in a randomized, double-blind, placebo-controlled trial in 55 patients (17). The dose of propafenone was chosen according to body weight: 450, 600, and 750 mg for those weighing 50–64, 65–80, and over 80 kg respectively. Propafenone converted atrial fibrillation to sinus rhythm significantly more quickly than placebo, and most patients given propafenone had converted by 6 hours. However, by 24 hours there was no significant difference between the two groups. Four patients had hypotension after propafenone, in three cases transiently. The patient with sustained hypotension had poor left ventricular systolic function, but it responded promptly to the administration of fluids and electrical cardioversion. In one patient with transient hypotension there was a brief episode of sinus bradycardia and in another an isolated sinus pause.

Organs and Systems

Cardiovascular

Cardiovascular adverse effects have been reported in 13–27% of patients taking propafenone and ventricular dysrhythmias in 8–19% in small studies. However, in large studies the risk has been reported to be about 5%.

Conduction disturbances are common with propafenone and can result in sinus bradycardia, sinoatrial block, sinus arrest, any degree of atrioventricular block, and right or left bundle-branch block (SEDA-10, 151) (SEDA-15, 179).

© 2006 Elsevier B.V. All rights reserved.

The adverse effects of a single oral dose of propafenone for cardioversion of recent-onset atrial fibrillation have been evaluated in a systematic review (18). The adverse effects were transient dysrhythmias (atrial flutter, bradycardia, pauses, and junctional rhythm), reversible widening of the QRS complex, transient hypotension, and mild non-cardiac effects (nausea, headache, gastrointestinal disturbances, dizziness, and paresthesia).

Dysrhythmias can occur; these include ventricular tachycardia, ventricular flutter, and atrial fibrillation (19–21). Hypotension and worsening of heart failure have occasionally been reported (SEDA-10, 151) (22).

- Wide-complex tachycardias occurred in two elderly patients (a 74-year-old man and an 80-year-old woman) who had taken propafenone for atrial fibrillation (23). In the first case the dysrhythmia was due to atrial flutter with 1:1 conduction.

Although drugs of class Ic, such as propafenone, can slow atrial and atrioventricular nodal conduction in patients with atrial fibrillation or atrial flutter, they do not alter the refractoriness of the atrioventricular node, and this allows 1:1 atrioventricular conduction as the atrial rate slows. This happens despite prolongation of the PR interval.

Class Ic drugs can also convert atrial fibrillation to atrial flutter, reportedly in 3.5–5% of patients. Of 187 patients with paroxysmal atrial fibrillation who were treated with flecainide or propafenone, 24 developed atrial flutter, which was typical in 20 cases (24). These patients underwent radiofrequency ablation, which failed in only one case. All the patients continued to take their pre-existing drugs, and during a mean follow-up period of 11 months, the incidence of atrial fibrillation was higher in patients who were taking combined therapy than in those taking monotherapy. The authors suggested that in patients with atrial fibrillation who developed typical atrial flutter due to class Ic antidysrhythmic drugs, combined catheter ablation and continued drug treatment is highly effective in reducing the occurrence and duration of atrial tachydysrhythmias. They did not report adverse effects.

In controlled trials of oral propafenone (450–600 mg as a single dose) in patients with recent-onset atrial fibrillation without heart failure, atrial flutter with 1:1 atrioventricular conduction occurred in only two of 709 patients (0.3%) who received propafenone (15).

Respiratory

Since propafenone is a beta-adrenoceptor antagonist it can cause shortness of breath or worsening of asthma (25).

Nervous system

Adverse effects on the nervous system are common with propafenone and include somnolence, weakness and disorientation, global amnesia (26), dizziness and vertigo, tremor, visual disturbances, and convulsions (SEDA-10, 151).

- Peripheral neuropathy has been reported in a 41-year-old man who took propafenone 450 mg/day for about a year (27).

Ataxia has been reported in patients taking propafenone (28).

- An 80-year-old man taking propafenone 150 mg tds for paroxysmal atrial fibrillation developed progressive generalized ataxia and weakness 4 days after starting treatment. He had a bilateral symmetrical ataxia, unclear speech, impairment of gait, altered hand coordination, and tremor. The ataxia resolved completely within 3 days of withdrawal.
- A 73-year-old woman taking propafenone 150 mg tds for paroxysmal atrial tachycardia underwent cardioversion during an attack, and the dose of propafenone was increased to 300 mg tds. After 5 days she developed severe ataxia and progressive weakness. The ataxia was symmetrical and there was severe impairment of gait, altered hand coordination, and tremor. The dose of propafenone was reduced to 600 mg/day and the ataxia resolved completely within 6 days. A year later, when the dose of propafenone was increased to 900 mg/day, progressive ataxia again developed after 2 days and became severe within 1 week. Propafenone was withdrawn and the ataxia resolved within a few days.
- An 85-year-old woman took propafenone 150 mg tds for paroxysmal atrial fibrillation and 2 months later developed a progressive ataxia and recurrent falls. The ataxia was symmetrical and there was altered hand coordination, impairment of gait, and tremor. The propafenone was withdrawn and the ataxia resolved completely within 4 days.

Endocrine

Propafenone can cause hyponatremia due to inappropriate secretion of ADH (29).

Hematologic

Propafenone can occasionally cause neutropenia, with a calculated incidence of about one in 10 000 prescriptions per year (30).

Gastrointestinal

Unwanted gastrointestinal effects are the most common adverse effects of propafenone, occurring in up to 30% of cases. They include anorexia, nausea and vomiting, dry mouth, a metallic or bitter taste in the mouth, abdominal discomfort, and constipation (SEDA-10, 151).

Liver

Propafenone can increase the serum activities of transaminases and other enzymes associated with liver function (31). There have also been reports of cholestatic jaundice (32).

Skin

Skin rashes have been reported occasionally (29); these include an acneiform rash and urticaria.

Sexual function

Impotence has occasionally been reported, in one case with a reduced sperm count (33,34).

© 2006 Elsevier B.V. All rights reserved.

Immunologic

Propafenone can cause a rise in antinuclear antibody titers (34) and has once been reported to have caused a lupus-like syndrome (35).

Body temperature

Drug fever without agranulocytosis has been attributed to propafenone (36).

Second-Generation Effects

Pregnancy

When a pregnant woman was given propafenone from the fifth month to term in a dosage of 300 mg tds her dysrhythmias responded satisfactorily and the neonate was healthy (37).

Susceptibility Factors

Genetic factors

Poor and extensive oxidation phenotypes for CYP2D6, which metabolizes propafenone, have been studied in 42 patients, aged 36–75 years, with paroxysmal atrial fibrillation (38). Efficacy was 100% in poor metabolizers, 61% in extensive metabolizers, and 0% in very extensive metabolizers. There was a significant correlation between oxidation phenotype and the ability to maintain sinus rhythm.

Age

The incidence of adverse effects of propafenone in children has varied from study to study, but has sometimes been as high as 25%, requiring withdrawal in 6% of cases (39). Elderly people are at increased risk of adverse effects.

The safety of oral propafenone in the treatment of dysrhythmias has been studied retrospectively in infants and children (40). There were significant electrophysiological adverse effects and prodysrhythmia in 15 of 772 patients (1.9%). These included sinus node dysfunction in four, complete atrioventricular block in two, aggravation of supraventricular tachycardia in two, acceleration of ventricular rate during atrial flutter in one, ventricular prodysrhythmia in five, and unexplained syncope in one. Cardiac arrest or sudden death occurred in five patients (0.6%); two had a supraventricular tachycardia due to Wolff–Parkinson–White syndrome; the other three had structural heart disease. Adverse cardiac events were more common in the presence of structural heart disease and there was no difference between patients with supraventricular and ventricular dysrhythmias.

Drug Administration

Drug dosage regimens

Three different regimens of oral propafenone have been compared in patients with paroxysmal atrial fibrillation (41). In 48 patients who took 600 mg followed 8 hours later by 150 mg there was a higher rate of early successful cardioversion with a lower incidence of adverse effects than in two other groups who took either 300 mg three times over 8 hours ($n = 82$) or four doses of 150 mg over 9 hours ($n = 58$). The rates of conversion were around 80%, similar to those found in other studies. There was QRS prolongation in all three groups, and four of those who took a total of 900 mg developed a broad complex tachycardia.

Drug overdose

About 60 cases of propafenone poisoning have been reported. Even low doses can lead to serious poisoning. Some symptoms, such as gastrointestinal or neurological symptoms, are misleading. Cardiovascular abnormalities include bradycardia, atrioventricular block, abnormal intraventricular conduction, shock, and electromechanical dissociation. The simultaneous presence of neurological symptoms (especially seizures) and abnormal cardiac conduction suggests serious poisoning.

The mortality from propafenone overdose is 23%, according to a retrospective series of 120 patients in Germany over 14 years (42). Severity was related to cardiac conduction disorders and cardiac hyperexcitability.

Seizures have been reported in cases of overdose.

- A 24-year-old woman who took an overdose of propafenone 2.7 g had a convulsion and complete heart block (43). The plasma propafenone concentration 4 hours after ingestion was 2930 ng/ml (target range 400–1600 ng/ml). She was given activated charcoal 50 g, mannitol 200 ml, and clonazepam 1 mg intravenously. By 19 hours after ingestion the electrocardiogram was normal and the plasma propafenone concentration was 858 ng/ml.
- A 22-year-old woman took an overdose of propafenone (amount unknown) and developed tetany and then generalized convulsions requiring intravenous clonazepam (44). She had a low blood pressure and first-degree atrioventricular block associated with prolonged intraventricular conduction. She was intubated and given intravenous fluids, equimolar sodium lactate, dopamine, and adrenaline. Her cardiac conduction returned to normal.

Treatment is symptomatic. Sodium lactate may be required for abnormal intraventricular conduction. Plasma exchange has been successfully used to treat propafenone overdose (45).

- An 18-year-old woman took 35 tablets of propafenone, 300 mg each. She had dilated, non-reactive pupils and greatly increased activity of neuron-specific enolase. She had atrioventricular and intraventricular conduction disorders, and repeated resuscitation was necessary. Propafenone was eliminated by plasma exchange, and the conduction disturbances disappeared rapidly during treatment.

Drug–Drug Interactions

Metoprolol

Propafenone reduces the apparent oral clearance of metoprolol, but it is not clear whether the mechanism is by reduction of true clearance or an increase

© 2006 Elsevier B.V. All rights reserved.

in systemic availability (46). In addition the beta-blocking action of metoprolol is increased by propafenone; this could be due either to reduced clearance of metoprolol or to a true pharmacodynamic interaction between the two drugs, since propafenone has beta-blocking activity.

Monitoring Therapy

Therapeutic benefit is most likely when the plasma propafenone concentration is in the range 0.5–2.0 mg/ml, although the correlation is poor (47), and there is a large overlap between therapeutic and toxic concentrations (32). The therapeutic effect of propafenone correlates better with prolongation of the PR and QRS intervals (48).

Propanidid

See also General anesthetics

General Information

Propanidid was used as an intravenous anesthetic for rapid induction and for maintenance of general anesthesia of short duration. However, it was withdrawn because of safety considerations regarding the solvent used, polyethoxylated castor oil (Cremophor EL) (SED-11, 211) (1).

Reference

Propantheline

See also Anticholinergic drugs

General Information

Propantheline is an anticholinergic drug. Oral doses are 7.5–30 mg, the latter being used at bedtime; injections of 15 mg have been used in radiology. The persisting doubt as to the incidence of adverse reactions probably reflects the poor and variable systemic availability of the oral form, which also seems to account for conflicting reports about its efficacy. All typical anticholinergic effects can occur if effective doses are given, but central nervous and ocular effects are relatively slight. Propantheline, like others of this type, is not contraindicated in glaucoma or prostatic hyperplasia, but it can influence the response of these conditions to other treatment and hence should be used with some caution.

Drug–Drug Interactions

Digoxin

The interactions of propantheline are similar to those of atropine; for example it increases the rate of absorption of digoxin (1).

Nitrofurantoin

Propantheline increases the rate of absorption of nitrofurantoin (2).

Paracetamol

Propantheline reduces the rate of absorption of paracetamol (3).

Propiverine

See also Adrenoceptor agonists

General Information

Propiverine is an anticholinergic drug, used mainly for its effects on the bladder. It is effective in detrusor hyperreflexia and in patients with symptoms of an overactive bladder. Adverse effects occur in about 13% of patients (1).

Organs and Systems

Nervous system

A report of parkinsonism due to propiverine combines a clinical observation with basic pharmacology (2).

- A 72-year-old man had taken propiverine 20 mg/day for nocturia. The exact symptoms are difficult to define, because of the rather curious terminology used in the report, but it appears that he rapidly developed parkinsonian symptoms soon after the start of treatment and was given levodopa 3 months later, with a limited response. After 1 month it was decided to withdraw propiverine and his symptoms disappeared within 2 weeks.

The authors then studied the effect of propiverine on the induction of catalepsy in mice, comparing it with oxybutynin, pentoxyverine, and etafenone, using haloperidol as a reference. They also examined dopamine receptor binding in the striatum. They concluded that any of these agents could cause catalepsy in mice, and that propiverine had greater potency than oxybutynin but less than the others. It was also noted that all the drugs had sub-micromolar affinity for striatal dopamine D_2 receptors. The authors suggested that any drug, such as these, that has a diethylaminomethyl moiety has the potential for extrapyramidal effects, because of interaction with dopamine receptors in the basal ganglia.

Sensory systems

The effect of propiverine on the eye has been investigated in normal and glaucomatous eyes. There was considerable reduction in accommodation in younger individuals in both groups. The drug should therefore be given to younger patients only on very strict indications (3).

General Information

Propofol is a short-acting intravenous induction agent, which is dissolved in a mixture of long-chain triglycerides and soya bean emulsion. It is now in general use in day-care anesthesia and is being increasingly used in infusions in intensive care units. Recovery from anesthetic doses compares favorably with that after enflurane and isoflurane (1).

It has been claimed that propofol produces good recovery after anesthesia. A review of the literature has shown that, for operations that last under 30 minutes, propofol seems to give the best recovery, but for longer operations isoflurane gave better quality recovery (2).

Comparative studies

Propofol versus midazolam

A combination of midazolam plus propofol has been compared with midazolam only for sedation in colonoscopy (3). Midazolam alone produced less profound amnesia, and patients took longer to recover. There

© 2006 Elsevier B.V. All rights reserved.

were no differences in cardiovascular or respiratory parameters. Oxygen saturation was poor in both groups, with saturations less than 85% in 22% of patients given midazolam and in 19% of patients given propofol, although the patients did not initially receive supplementary oxygen. In a similar comparison of midazolam and propofol as sedative agents for diagnostic endoscopy in 80 patients, endoscopy was judged successful in 98% of patients given propofol (mean total dose 354 mg) and 80% of patients given midazolam (mean total dose 8 mg) (4). Patients in the propofol group recovered consciousness more quickly and had complete amnesia. One patient in the propofol group suffered an apneic phase with impaired circulation, requiring manual ventilation and drug therapy.

In a Canadian multicenter, open, randomized trial in 156 patients to determine whether sedation with propofol would lead to shorter times to tracheal extubation and length of stay in ICU than sedation with midazolam, the patients who received propofol spent longer at the target sedation level than those who received midazolam (60 versus 44% respectively) (5). Propofol allowed clinically significantly earlier tracheal extubation than midazolam (6.7 versus 25 hours). However, this did not result in earlier discharge from the ICU.

Anesthetist-administered midazolam and patient-controlled propofol have been compared for sedation during vitreoretinal surgery (6). The patients received propofol 15–18 mg according to age, with a 1-minute lockout, or 0.25–0.5 mg of midazolam as judged necessary by the anesthetist. Few patients were amnesic for the procedure and both techniques produced satisfactory sedation and comfort. Non-anesthetists need to be extremely wary if using propofol for sedation, since propofol has a low therapeutic index and commonly causes unconsciousness, respiratory depression, and cardiovascular collapse, particularly when it is used in combination with either midazolam or alfentanil (7). Adequate staff, training, and facilities for resuscitation of patients must be available before considering propofol sedation. Propofol can cause deep sedation, and the episode reported in one of these studies is not surprising. Extreme caution must be exercised in recommending these techniques to non-anesthetists.

Organs and Systems

Cardiovascular

Propofol is a cardiodepressant and resets the baroreflex set-point, with a tendency to bradycardia (which occurs in some 5% of cases), hypotension (16%), or both (1.3%) (8). The hypotension may be brought about by peripheral vasodilatation, reduced myocardial contractility, and inhibition of sympathetic nervous system outflow (9). Four deaths due to cardiovascular collapse during induction have been reported in patients aged 78–92 years given propofol 1.1–1.8 mg/kg (10). The patients were of ASA classes 3 or 4.

Total intravenous anesthesia with propofol resulted in a reduced heart rate and a higher frequency of oculocardiac reflex bradycardia than thiopental/isoflurane anesthesia, with a higher sensitivity of children younger than 6 years in all groups (11).

Hemodynamic effects

The cardiovascular effects of propofol have been examined in a randomized trial in 40 healthy subjects using transthoracic echocardiography (12). Propofol was given to the same total dose (2.5 mg/kg) at two different rates, 2 mg/second or 10 mg/second. In both groups, global and segmental ventricular function was unchanged, but propofol caused a markedly reduced end-systolic quotient, presumably related to reduced afterload. With the higher infusion rate, there was a significant reduction in fractional shortening, thought to be related principally to reduced preload.

There has been a prospective, double-blind, controlled comparison of propofol, midazolam, and propofol + midazolam for postoperative sedation in 75 patients who received low-dose opioid-based anesthesia for coronary bypass grafting (13). Mean induction doses of propofol and midazolam used alone were 2.5 times higher than when both were used together. The single agents caused significant reductions in blood pressure, left atrial filling pressure, and heart rate after induction. These hemodynamic changes returned to normal after 15 minutes with midazolam and after 30 minutes with propofol, except for the bradycardia, which remained for the duration of the sedation. The combination of propofol + midazolam had no significant hemodynamic effects, but was also associated with bradycardia lasting the duration of the sedation. There was a greater than 68% reduction in maintenance doses with the combination. Propofol and propofol + midazolam were associated with comparable times to awakening and extubation, while with midazolam alone recovery was slower. This study clearly showed a reduction in adverse effects from exploiting the sedative synergism between propofol and midazolam.

In a placebo-controlled study of induction of anesthesia with a combination of propofol + fentanyl in 90 patients aged over 60 years, prophylactic intravenous ephedrine 0.1 or 0.2 mg/kg given 1 minute before induction of anesthesia significantly attenuated the fall in blood pressure and heart rate that is usually observed (14). Prophylactic use of ephedrine may be useful in preventing the occasional instances of cardiovascular collapse recorded after induction of anesthesia using these agents in elderly people.

The hemodynamic effects of combining ephedrine with propofol in an effort to prevent hypotension and bradycardia have been investigated in 40 elderly patients of ASA grades III and IV, who received ephedrine 15, 20, or 25 mg added to propofol 200 mg (15). The hypotensive response to propofol was effectively prevented, but marked tachycardia in the majority of patients meant that the technique may not be beneficial, given the high incidence of ischemic heart disease in this age group.

The effects of giving calcium chloride 10 mg/kg after induction of anesthesia with propofol, fentanyl, and pancuronium have been investigated in 58 patients undergoing elective coronary artery bypass grafting (16). Calcium chloride reduced the fall in arterial blood pressure and prevented the reductions in heart rate, stroke volume index, cardiac index, and cardiac output, compared with placebo. Propofol reduces the availability of calcium to the myocardial cells, and calcium chloride effectively minimizes the hemodynamic effects of

© 2006 Elsevier B.V. All rights reserved.

propofol. However, given that intravenous calcium can be locally toxic when given via peripheral veins, the technique may have limited applicability.

Cardiac dysrhythmias

Propofol causes bradydysrhythmias by reducing sympathetic nervous system activity.

- A four-year-old patient developed a nodal bradycardia while receiving propofol 6 mg/kg/hour + remifentanil 0.25 microgram/kg/minute (17). The bradycardia responded to atropine 0.3 mg.
- Complete atrioventricular heart block occurred in a 9-year-old boy with Ondine's curse who received a single bolus injection of propofol (18).

The authors questioned the safe use of propofol in congenital central hypoventilation syndrome, which is a generalized disorder of autonomic function.

- Propofol caused marked prolongation of the QT_c interval in a 71-year-old woman with an acute myocardial infarction who required ventilatory support (19). Substituting midazolam for propofol was associated with normalization of the QT_c interval. Rechallenge with propofol was associated with further prolongation. There were no malignant ventricular dysrhythmias.

Pain on injection

Propofol can cause severe pain on injection, especially when injected into a small vein (20); the incidence is 25–74% (21). Administration of the lipid solvent in which propofol dissolved has confirmed that the solvent is responsible for this adverse effect (22).

- Severe pain on injection of propofol occurred in a 36-year-old man with severe Raynaud's phenomenon, including a history of skin ulceration when he was given a 2% propofol + lidocaine mixture into a vein on the back of his hand (23).

The author suggested that selecting a larger antecubital vein might be a wiser choice in these patients.

The effectiveness of lidocaine in preventing pain on injection has been confirmed, and a concentration of 0.1% was optimal (24). The kallikrein inhibitor nafamostat mesilate was as effective as lidocaine.

A controlled study in 100 women showed that pretreatment with intravenous ketamine 10 mg reduced the incidence of injection pain from 84 to 26% of patients (25).

Warming propofol to 37°C had no effect on the incidence of pain (26,27).

The effects of different doses of ketorolac, with or without venous occlusion, on the incidence and severity of pain after propofol injection have been studied in a randomized, double-blind study in 180 patients (28). Pretreatment with intravenous ketorolac 15 mg and 30 mg reduced the pain after propofol injection. A lower dose of ketorolac 10 mg with venous occlusion for 120 seconds achieved the same effect.

Ondansetron, tramadol, and metoclopramide were less effective than lidocaine in preventing pain on injection (29–31). Ondansetron and tramadol have been compared in patients being given propofol in a randomized, double-blind study in 100 patients (32). Tramadol 50 mg intravenously was as effective as ondansetron 4 mg intravenously with 15 seconds of venous occlusion at preventing propofol injection pain. However, there was significantly less nausea and vomiting in those given ondansetron.

Respiratory

Respiratory depression due to propofol is well recognized; apnea can result, especially with rapid injection (33).

Pulmonary fat embolism after the use of propofol has been attributed to the milky emulsion in which the propofol was dissolved (34).

Two cases of propofol-induced bronchoconstriction have been reported (35). Both patients had allergic rhinitis and had taken antihistamines during the hay fever season, but were otherwise healthy.

Nervous system

Dystonias

Dystonic movements induced by propofol occurred in a patient undergoing elective cardioversion (36). Benzatropine 2 mg intravenously terminated the abnormal movements. The authors also reviewed all other reports of abnormal movements after propofol.

- Acute dystonia has been reported in a 14-year-old girl after the administration of propofol 150 mg + fentanyl 50 mg for dental anesthesia (37). The intraoperative course was uneventful, but she developed non-rhythmic and non-symmetrical shaking in her upper limbs, unresponsive to diazepam and paraldehyde. A CT scan of the brain was normal. Her symptoms were eventually relieved by procyclidine 2.5 mg.

This adverse effect has been reported many times with propofol in adults, but rarely in children.

Seizures

Myoclonus and opisthotonos, especially in children (38), and choreoathetosis (39) have been attributed to propofol. However, in experimental studies propofol has been shown to be effective against drug-induced seizures (40,41). It has been suggested that propofol inhibits efferent inhibitory neurons in the midbrain and reticular activating system, producing movements that originate subcortically and in the spinal cord (42).

- An otherwise healthy 63-year-old man was anesthetized with propofol 2 mg/kg + fentanyl 1 micrograms/kg followed by an infusion of propofol 6 mg/kg/hour (43). Three minutes after induction he developed myoclonus in his legs. This continued for 10 minutes and the anesthetic was abandoned. When he awoke 10 minutes later, the myoclonus stopped. A repeat anesthetic with propofol soon after caused the same response. When the procedure was performed 12 days later under regional block with propofol infusion for sedation, the myoclonus recurred, and lasted for 2 hours. The patient was alert after each anesthetic and did not appear to be post-ictal. An MRI scan of the spinal cord was normal.

Myoclonus after propofol does not appear to be associated with an adverse outcome.

© 2006 Elsevier B.V. All rights reserved.

Convulsions have been reported in two patients with no history of epilepsy after induction of anesthesia with propofol (44). However, in a crossover comparison in 20 epileptic patients undergoing cortical resection, in which the effects on the electrocorticogram of either propofol or thiopental during isoflurane + nitrous oxide anesthesia were studied, propofol caused no greater proconvulsive effect than thiopental, which is used to treat status epilepticus (45). In spite of occasional reports, a true epileptogenic effect of propofol remains to be proven.

A generalized tonic–clonic seizure has been attributed to propofol in a patient with tonic–clonic seizures after surgery for subarachnoid hemorrhage (46).

Psychological, psychiatric

The association of propofol with a range of excitatory events is well recognized. Behavioral disturbances with repeated propofol sedation have been reported in a 30-month-old child (47). Propofol was well tolerated initially, but the child then became increasing irritable, aggressive, and uncooperative during awakening from subsequent sedations, including screaming, kicking, hitting, and biting. The next two sedations were performed using methohexital and were not followed by any behavioral disturbances.

Prolonged delirium after emergence from propofol anesthesia has also been reported (48).

A psychotic reaction has been reported (49).

- A 37-year-old man who had abused metamfetamine, paint thinner, psychotomimetic drugs, and alcohol for 20 years was given chlorpromazine, haloperidol, and flunitrazepam just before surgery. After spinal anesthesia he was given propofol 5 mg/kg/hour intravenously. However, euphoria and excitement occurred 10 minutes after the start of the infusion and he had excitement, hallucinations, and delirium. His symptoms were suppressed by intravenous haloperidol 5 mg.

The authors speculated that propofol may produce psychotic symptoms when it is used in patients with a history of drug abuse.

Metabolism

Hyperlipidemia

Five cases of hyperlipidemia have been reported in 12 patients who received propofol infusions 3–8 mg/kg/hour for 10–187 hours for sedation in an intensive care unit (50). Propofol was their only source of lipids.

Propofol 2% has been compared with midazolam for sedation in 63 ventilated patients in intensive care (51). They were randomly assigned to either propofol 1.5–6.0 mg/kg/hour or midazolam 0.10–0.35 mg/kg/hour. Sedation was considered a failure if greater rates were required or if triglyceride concentrations were over 5.7 mmol/l (500 mg/dl) on one occasion or greater than 4.0 mmol/l (350 mg/dl) on two occasions. Hemodynamic, respiratory, and neurological variables were similar. Sedation failure occurred in 15 patients given propofol, three with increased triglyceride concentrations and 12 with poor sedation. In comparison, sedation failed in only one of the patients given midazolam. Average serum triglyceride concentrations were higher in the propofol group. In a separate retrospective comparison, triglyceride concentrations were lower than in similar patients treated with 1% propofol, and the sedation failure rate was lower using 2% propofol (9 versus 36%). The authors concluded that 2% propofol is safe but may be less efficient than midazolam. It should be noted that the dose ranges that they used may not have been comparable, leading to an artificially high rate of failure to provide adequate sedation in the propofol group.

Lactic acidosis

There have been several reports of lactic acidosis with and without rhabdomyolysis after propofol infusion, and two fatal cases have been reported (52).

- Two men, aged 7 and 17 years, presented with refractory status epilepticus. Both were treated with high-dose propofol infusions to achieve burst suppression on the electroencephalogram. During the second day of propofol infusion there was progressive severe lactic acidosis, hypoxia, pyrexia, and rhabdomyolysis, followed by hypotension, bradydysrhythmias, and renal dysfunction, leading to death. The total doses of propofol were 1275 mg/kg over 2.7 days and 482 mg/kg over 2 days.

Lactic acidosis and rhabdomyolysis have been reported in a child receiving an infusion of propofol for sedation in an intensive care unit (53).

- A previously healthy 10-month-old boy with an esophageal foreign body was given endotracheal intubation to protect his airway. Midazolam and morphine did not produce satisfactory sedation and he was given propofol by infusion, increased from 3.5 to 7 mg/kg/hour over 2 hours to a total dose of about 500 mg/kg over the next 2 days. Other drugs given included cefotaxime, flucloxacillin, and ranitidine. He developed green urine, triglyceridemia of 907 mg/dl (10 mmol/l), and lactic acidosis, with a peak lactate concentration of 18 mmol/l. He also developed hypotension, with first-degree atrioventricular block and right bundle branch block, unresponsive to atropine, external cardiac pacing, or isoprenaline. Continuous venovenous hemofiltration was instituted. He slowly improved over the next 2 days, but developed a raised creatine kinase activity (over 30 000 U/l) and myoglobinuria. A liver biopsy showed 10% necrosis of zone 3, with fatty infiltration characteristic of a toxic effect. A muscle biopsy showed large areas of muscle necrosis. Extensive investigations showed no underlying infectious or metabolic causes. He slowly recovered over 10 days and appeared to have completely recovered at 3 months.

Lactic acidosis without rhabdomyolysis has been reported in another case (54).

- A 61-year-old woman undergoing mitral valve surgery received fentanyl, midazolam, nitrous oxide, and propofol infusion 3 mg/kg/hour during a 5-hour anesthetic. She developed lactic acidosis soon after the completion of surgery and required reintubation and ventilation. The peak lactate concentration, which occurred 1 day later, was 14.3 mmol/l. There was also mild disturbance of liver function. She eventually recovered.

© 2006 Elsevier B.V. All rights reserved.

These cases are important because, unlike previous reports of metabolic acidosis after propofol infusion, the patients had no documented infections and, in at least one case, extensive investigation showed no other causes of the acidosis. The role of propofol in causing the metabolic problems appears to have been more likely in these than in previous reports. In the first three cases the doses of propofol used, both per hour and in all, were extremely high compared with normal therapeutic practice. The subject has also been reviewed, and it was pointed out that, although suggestive, the association of fatal metabolic acidosis with propofol infusion in sick patients is as yet unproven and to date hinges on 11 case reports of patients who had multiple problems (55).

Porphyria

An acute attack of porphyria has been reported in association with propofol (56).

- A 23-year-old man, with a past history of Fallot's tetralogy repaired at age 2, had catheter ablation of an aberrant conduction pathway causing right ventricular tachycardia, a procedure that took 16 hours. He was sedated with propofol at an average rate of 100 micrograms/kg/minute, and required intubation for respiratory insufficiency half way through the procedure. He also received caffeine and isoprenaline during the procedure to induce ventricular tachycardia. After the procedure he could not be roused or extubated for a further 10 hours and remained drowsy for a further day. He had weakness of an arm and a leg and had lancinating abdominal and shoulder pains. Urinary concentrations of porphyrins, aminolevulinic acid, porphobilinogen, and coproporphyrin III were markedly raised. He made a good recovery after administration of dextrose.

Propofol is regarded as being safe in patients with different types of porphyria. This is the first reported case in which propofol had a possible role in causing raised porphyrin concentrations perioperatively. However, severe illness can also precipitate porphyria, so the association with propofol may have been incidental.

Hematologic

In 10 patients, propofol, but not intralipos, its solvent, inhibited platelet aggregation both in vivo and in vitro (57). This defect was not associated with a change in bleeding time, and it was assumed that the effect is not clinically significant. The cause was probably suppression of calcium influx and release from platelets.

Fat emulsions affect coagulation and fibrinolysis (58). In a study of 36 patients undergoing aortocoronary bypass operations with midazolam + fentanyl or propofol + alfentanil anesthesia, factor XIIa concentrations and kallikrein-like activity were about 30% higher in the propofol group. The authors suggested that there had been stronger activation of the contact phase at the start of recirculation and stronger fibrinolysis in the propofol group. They also found more hypotension in the propofol group, which they assumed to be due to release of kallikrein, resulting in release of bradykinin. Propofol has not been shown to cause increased perioperative bleeding.

Gastrointestinal

Propofol in subhypnotic doses is a potent antiemetic. In a double-blind, randomized study, a small dose of propofol (0.5 mg/kg) was compared with droperidol (20 micrograms/kg) or metoclopramide (0.2 mg/kg) given at the completion of surgery performed in 90 patients under standard anesthesia with thiopental, fentanyl, and sevoflurane (59). Follow-up was to 24 hours. The incidence of emesis at 24 hours was significantly lower in those who received propofol (10 versus 33% and 40% for droperidol and metoclopramide respectively).

Liver

Hepatocellular injury has been reported after the sole use of propofol for outpatient anesthesia (60).

- A young woman with multiple allergies underwent femoral hernia repair and the next day developed acute hepatitis, with severe nausea and vomiting and diffuse abdominal tenderness. She had very high transaminase activities and the prothrombin time was slightly raised. No viral cause could be demonstrated. Antinuclear antibody and smooth muscle antibody titers were not raised and the ceruloplasmin concentration was normal. Abdominal ultrasound did not show gallstones or any other abnormality. The urine was normal and did not contain porphyrins or porphobilinogen. She recovered spontaneously and refused liver biopsy.

Pancreas

There have been several reports of postoperative pancreatitis in association with propofol-induced anesthesia (61–63). In view of the very widespread use of propofol for induction of anesthesia, the very rare reports, and the complexity of establishing the cause of acute pancreatitis, a causal relation between propofol and pancreatitis has not been clearly established.

- A healthy 35-year-old man developed acute pancreatitis a few hours after receiving a 15-minute propofol anesthetic for laser treatment of a urethral stricture (64). He spent 3 weeks in an intensive care unit, requiring both respiratory and renal support. There was no evidence of gallstones on abdominal imaging. There was no defect of lipid metabolism.
- A 51-year-old woman with a past medical history of a seizure disorder, schizophrenia, and asthma, who had been admitted with pneumonia, was sedated using a propofol infusion to assist mechanical ventilation (65). Over 7 days she received a total of 26.5 g of propofol at a maximum rate of 0.2 mg/kg/minute. When pancreatitis, which was associated with hypertriglyceridemia, was diagnosed, the propofol infusion was stopped. In addition to raised amylase activity, serum triglyceride concentrations peaked at 17 mmol/l and lipase activity at 564 U/l. She recovered over the next 7 days. On day 17 she underwent tracheostomy revision, during which

© 2006 Elsevier B.V. All rights reserved.

she received propofol 200 mg. The subsequent postoperative period was complicated by another episode of pancreatitis, this time without associated hypertriglyceridemia. She recovered over the next several days. An ultrasound examination ruled out gallstone pancreatitis, despite the presence of cholelithiasis.

- A healthy 21-year-old woman developed acute pancreatitis a day after an anesthetic that lasted 138 minutes, with propofol for induction (66). She recovered after supportive therapy for 6 days. There was no evidence of gallstones on abdominal imaging and there was no defect in lipid metabolism.

The association between propofol and pancreatitis has been listed as "probable" in 25 reports of pancreatitis associated with propofol to the FDA registry. However, the features of this case, which included resolution of pancreatitis on drug withdrawal and recurrence on rechallenge, suggested that the association should be upgraded to "definitely causal."

Skin

A fixed drug eruption has been attributed to propofol (67).

Musculoskeletal

In an in vitro experiment using uterine muscle strips from 10 consenting parturients undergoing cesarean section, therapeutic concentrations of propofol had no effect on isometric tension developed during contraction of the muscle (68). However, higher than therapeutic concentrations did reduce the peak muscle tension that developed. These results confirm that propofol is free of this adverse effect, which is a known cause of postpartum bleeding after the use of volatile anesthetic drugs.

Rhabdomyolysis

Rhabdomyolysis has been reported in two patients receiving propofol for sedation while being ventilated for severe asthma (69).

- A 47-year-old woman had an infusion of propofol 200 micrograms/kg/minute for 4 days. On day 2 she developed hematuria, and laboratory investigations showed renal insufficiency with hyperkalemic metabolic acidosis. She died as a result of rhabdomyolysis with cardiac involvement.
- A 41-year-old man, who received propofol at rates of up to 222 micrograms/kg/minute for 2 days, developed oliguria, and the propofol was withdrawn. He was also receiving fentanyl and low molecular weight heparin for prophylaxis of deep vein thrombosis. He subsequently developed a very high creatine kinase activity (over 170 000 IU/l). Echocardiography showed globally depressed myocardial dysfunction. He subsequently recovered. The rates of propofol infusion were high and this was thought to be a contributing factor.

A similar death, possibly relating to propofol, has been reported.

- An 18-year-old man suffered multiple trauma (70). He was sedated for 98 hours with propofol 530–700 mg/hour. On day 5 he developed a metabolic acidosis with hyperkalemia and his serum was lipemic. An echocardiogram showed global hypokinesia. He deteriorated and died shortly afterwards.

Although in none of these cases was a definitive link between propofol and the pathology established, the authors pointed out that several other cases have been reported, especially in children. Clinicians should be more aware that propofol may cause rhabdomyolysis, which appears to occur particularly at high doses.

Rhabdomyolysis and the propofol infusion syndrome

The propofol-infusion syndrome consists of a metabolic acidosis, rhabdomyolysis, and cardiovascular collapse. It occurs after prolonged infusion of propofol (over 48 hours) and has generally been reported in children, but also occasionally in adults.

Propofol infusion syndrome mimics the mitochondrial myopathies, in which there are specific defects in the mitochondrial respiratory chain. The clinical features of mitochondrial myopathy result from a disturbance in lipid metabolism in cardiac and skeletal muscle. These patients generally remain well until stressed by infection or starvation, although subclinical biochemical abnormalities of mitochondrial transport can be demonstrated. It has been suggested that early management of critically ill children may not include adequate calorific intake to balance the increase in metabolic demands, and that in susceptible children the diversion of metabolism to fat substrates may cause the propofol infusion syndrome. It is unclear if the dose or duration of propofol infusion alters this effect. As adults have larger carbohydrate stores and require lower doses of propofol for sedation, this may account for the relative rarity of the syndrome in adults. The authors suggested that adequate early carbohydrate intake may prevent the propofol infusion syndrome (71).

- Five adults with head injuries inexplicably had fatal cardiac arrests in a neurosurgical intensive care unit after the introduction of a sedation formulation containing an increased concentration of propofol (72). There were striking similarities with the previously reported syndrome of myocardial failure, metabolic acidosis, and rhabdomyolysis in children who received high-dose propofol infusions for more than 48 hours.

In a subsequent retrospective cohort analysis the odds ratio for the propofol infusion syndrome was 1.93 (95% CI = 1.12, 3.32) for every 1 mg/kg/hour increase in mean propofol dose above 5 mg/kg/hour. The authors suggested that propofol infusion at rates over 5 mg/kg/hour should be discouraged for long-term sedation.

- A 13-year-old girl with a head injury, who received a high-dose infusion of propofol for 4 days, developed the propofol infusion syndrome (73).

In an accompanying editorial, aspects of the propofol infusion syndrome were reviewed, and the author suggested that prolonged high-dose propofol infusions (over 4.8–6.0 mg/kg/hour for over 48–72 hours) should be avoided and that if high-dose metabolic suppression is required for more than 3 days in head injury, the alternative of a barbiturate should be considered (74). However, these long-acting agents have well-known potent myocardial depressant effects of their own, which are difficult to manage.

© 2006 Elsevier B.V. All rights reserved.

- A 2-year-old boy with a gunshot head injury developed the propofol infusion syndrome after receiving propofol in an average dosage of 5.2 mg/kg/hour for 72 hours (71). On the fourth day he became oliguric, with raised potassium, urea, and creatinine concentrations, and then developed a nodal bradycardia (28 minute). Propofol was withdrawn and an isoprenaline infusion was started, but only emergency transvenous pacing restored his heart rate. Hemofiltration was begun, on the basis of another case report, and the acidosis cleared and cardiovascular function was restored. In a blood sample taken before hemofiltration malonylcarnitine, C5-acylcarnitine, creatine kinase, troponin T, and myoglobinemia were raised. The child made a complete recovery and 9 months later all markers of fatty-acid oxidation were normal.

These findings are consistent with impaired fatty-acid oxidation: reduced mitochondrial entry of long-chain acylcarnitine esters due to inhibition of the transport protein (carnitine palmityl transferase 1) and failure of the respiratory chain at complex II. Another previously reported abnormality of the respiratory chain in propofol-infusion syndrome is a reduction in cytochrome C oxidase activity, with reduced complex IV activity and a reduced cytochrome oxidase ratio of 0.004. Propofol can also impair the mitochondrial electron transport system in isolated heart preparations.

Sexual function

Sexual illusions and disinhibition were a problem in two women (aged 20 and 47 years) after sedation with propofol (75).

Immunologic

True anaphylaxis to propofol has been observed (76).

Infection risk

Soon after the introduction of propofol in 1989, clusters of infections related to its use were reported, and there have since been several reports (77,78). The complications include hypotension, tachycardia, septic shock, convulsions, and death. Ethylenediaminetetra-acetic acid (EDTA) was added to the formulation to retard microbial growth. However, there have been concerns over the effects of this additive on trace element homeostasis, particularly when it is used in intensive care units for long-term sedation. Five randomized controlled trials have been reviewed, and minimal or no effects have been found on zinc, magnesium, or calcium homeostasis. However, there is no evidence to suggest that cluster infection has been or will be reduced with this formulation and there is still a need for care with sterility when using this product.

Long-Term Effects

Drug withdrawal

Excitation, including generalized tonic–clonic seizures, has been observed on withdrawal of a propofol infusion in intensive care (79).

Susceptibility Factors

Age

Propofol has previously been associated with death after prolonged infusion in seriously ill children. An in vitro study of the effects of propofol on GABA neurons in a cell culture showed evidence of toxicity after exposure for 8 hours (80). The authors proposed that this toxicity could be the cause of the problems observed in children.

In 21 critically ill children aged 1 week to 12 years, who were also receiving morphine by infusion, propofol kinetics were altered in very small babies and in children of all ages recovering from cardiac surgery (81). Increased volume of distribution and reduced metabolic clearance caused a prolonged half-life. The combination of morphine 20–40 micrograms/kg and 2% propofol 4–6 mg/kg/hour for up to 28 hours appears to be safe.

Drug Administration

Drug formulations

Propofol is formulated as a 1% solution in Intralipid 10% (82). This formulation has been associated with hyperlipidemia, especially raised triglycerides, when given by prolonged infusion to the critically ill, particularly children or patients with liver disease. A formulation of propofol 6% in lipofundin (medium-chain + long-chain triglycerides 10%) has been developed to reduce the risk of hyperlipidemia. In 24 patients who received an induction dose of propofol 2.5 mg/kg over 60 seconds of either the new formulation in 6% or 1% solution and of the original 1% formulation, the pharmacokinetics, induction time, dosage requirements, and safety profile of the three agents were similar. Pain on injection was reported by 17% of the patients, and did not vary between formulations. The 6% solution may be safer for long-term infusion, when reducing the fat load is important.

Propranolol

See also Beta-adrenoceptor antagonists

General Information

Propranolol is a lipophilic, non-selective, pure antagonist at beta-adrenoceptors, with membrane-stabilizing action.

Organs and Systems

Cardiovascular

An unusual dysrhythmia has been attributed to propranolol: alternating sinus rhythm with intermittent sinoatrial block. The authors suggested that this was

© 2006 Elsevier B.V. All rights reserved.

accounted for by the existence of sinoatrial conduction via two pathways, the first with 2:1 block and the second with a slightly longer conduction time and intermittent 2:1 block (1).

Immunologic

Propranolol has been implicated in hypersensitivity pneumonitis (2,3), although other beta-blockers have also been associated with this complication.

Propylhexedrine

General Information

In the form of the volatile base, propylhexedrine is used in nasal inhalers; it is also a component of some liquid decongestant mixtures. When inhaled, and especially if over-used, it can cause nasal irritation, rebound congestion, and chronic rhinitis.

Long-Term Effects

Drug abuse

There have been several reports of abuse of propylhexedrine by addicts, who extract the contents of the cotton wad (250 mg propylhexedrine with added aromatics) and take them either orally or intravenously (1). In a few reported cases, deaths have occurred in abusers because of myocardial infarction or pulmonary hypertension, and psychoses of the amphetamine type have been induced (SED-9, 216).

- A 25-year-old white man tried to inject his right internal jugular vein with "home-made crank" [propylhexedrine] (2). After injection, he developed right-sided neck pain, followed by fever, chills, inspiratory stridor, and respiratory distress. He had edema extending from his anterior chest to the right parotid. Neck radiography showed extensive paracervical swelling with displacement of the trachea. At surgery his neck contained extensive necrotic tissue that was debrided. In spite of treatment with antibiotics, he developed progressive renal insufficiency and hypotension unresponsive to fluid therapy, followed by cardiopulmonary arrest and death.

There have been cases of definite brainstem dysfunction and five of transient diplopia secondary to intravenous abuse of Benzedrex, a nasal decongestant that contains propylhexedrine (3). All seven had transient diplopia within seconds after injection. One had a right-internuclear ophthalmoplegia and another had a depressed right gag reflex and paralysis of the right half of the tongue. The deficits in these two patients persisted for many months.

Propyphenazone

General Information

Propyphenazone is a pyrazolone derivative that has been incorporated into many over-the-counter analgesic combinations in many countries. There is no evidence that it has a lower incidence of adverse effects than phenazone (antipyrine), as was originally supposed, since neither compound has been widely studied alone.

In a systematic review of comparisons of Saridon (propyphenazone 150 mg + paracetamol 250 mg + caffeine 50 mg), paracetamol 500 mg + aspirin 500 mg + ibuprofen 200 mg, and placebo in 500 healthy adults, of whom 329 (66%) had moderate and 171 (34%) severe acute dentoalveolar pain, more of the patients who received Saridon reported "pain gone/partly gone" and fewer reported "pain unchanged or worse" at 30 and 60 minutes (1). There were adverse events in 20 patients (4.0%), with no significant differences between the groups. The most common adverse events were gastrointestinal disorders, followed by nervous system, skin, subcutaneous tissue, respiratory, cardiac, and general disorders.

Organs and Systems

Immunologic

Severe type I hypersensitivity reactions have been reported (SEDA-16, 108). Serious generalized urticaria with angioedema has occurred (2). Rechallenge with oral propyphenazone caused a severe anaphylactic reaction in a patient with a negative skin test. Although the report stressed the importance of oral challenge, it also drew attention to its risks (SEDA-12, 83).

In 44 of 53 patients, all of whom developed symptoms suggestive of IgE-mediated anaphylaxis within 30 minutes of taking propyphenazone, skin tests showed typical

© 2006 Elsevier B.V. All rights reserved.

wheal and flare reactions and significant amounts of propyphenazone-specific serum IgE was detected in 31 (3). In seven of nine patients with negative skin tests, propyphenazone-specific IgE was detected.

Drug Administration

Drug overdose

In overdose, propyphenazone, like other pyrazolones, mainly affects the central nervous system, causing coma and convulsions, and the liver; dysrhythmias and cardiogenic shock can occur; hemoperfusion has been recommended for patients with severe pyrazolone intoxication (4).

Prostaglandins

See also Individual agents

General Information

Eicosanoids are the oxygenated metabolites of 20-carbon unsaturated fatty acids found in the phospholipids of cell membranes (Greek eikosi = 20). The eicosanoids include the prostaglandins, thromboxanes, and leukotrienes. Precursor fatty acids include arachidonic acid C20:4*n*–6 (for 2-series prostaglandins and thromboxane and 4-series leukotrienes), dihomogammalinolenic acid C20:3*n*–6 (for PGE_1), and eicosapentaenoic acid C20:5*n*–3 (for 3-series prostaglandins and 5-series leukotrienes). Naturally occurring eicosanoids are predominantly metabolites of arachidonic acid, reflecting the dominance of *n*–6 fatty acids in the terrestrial food chain.

The principal biologically active, naturally occurring prostaglandins are prostaglandin E_1 (PGE_1), prostaglandin E_2 (PGE_2), prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$), prostacyclin (PGI_2), and thromboxane (TXA_2). These agents have various, sometimes opposed, biological actions (1). Their half-lives are short, owing to their rapid breakdown (a few minutes for PGE_2 and $PGF_{2\alpha}$, a few seconds for PGI_2) (2). Prostaglandins thus have principally local biological actions. Analogues (mostly methyl derivatives) have been synthesized and are more slowly inactivated. The adverse reactions encountered when prostaglandins are used therapeutically will depend on the indications (see Table 1), since these will determine the dose and route of administration and hence the type of reaction likely to occur. Many of the problems experienced are attributable to their main pharmacological effects (Table 2).

Table 1 Indications for prostaglandin therapy

In obstetrics
First- and second-trimester abortion
Cervical reopening
Induction of labor
Augmentation of labor
Postpartum hemorrhage
Ectopic pregnancy
Lactation suppression
In gastrointestinal disease
Peptic ulceration
Liver transplantation
Chemotherapy-induced mucosal lesions
In cardiovascular disease
Congenital cardiac malformations
Raynaud's syndrome
Chronic obstructive pulmonary disease
Adult respiratory distress syndrome
Pulmonary hypertension
Arterial occlusive disease
Extracorporeal circulation
In urology
Erectile dysfunction
Cystitis after radiation or chemotherapy
In ophthalmology
Glaucoma

Nomenclature

The names of prostaglandins are generally abbreviated to a three-letter abbreviation with a subscripted number. The first two letters are always PG; the third is E, F, or I. The recommended International Non-proprietary Names (rINNs) of various prostaglandins are given in Table 3. The convention is that, for example, PGE_1 is the name given to the endogenous prostaglandin and alprostadil is the name given to the same compound available for exogenous administration.

Synthetic analogues of PGE_1, PGE_2, PGF_1, $PGF_{2\alpha}$, and PGI_2

Synthetic analogues of prostaglandins are listed in Table 4. Their use allows reduction of dosages and adverse effects. In general, they cause fewer adverse effects than their naturally occurring counterparts, although this depends on the method of administration. Newer analogues (3) and oral forms (4) are in development.

General adverse effects

The most prominent and frequent adverse effects of prostaglandins are those on the gastrointestinal tract. However, the most dangerous are likely to be the cardiovascular effects, which in predisposed patients can sometimes cause life-threatening collapse and heart failure. Hyperthermia and headache are frequent nervous

Table 2 Actions of prostaglandins

Prostaglandin E series
Increased hormone secretion
Growth hormone, corticotropin, thyrotropin, luteinizing hormone, thyroid hormone, insulin, glucocorticoids, progesterone, erythropoietin, renin
Increased body temperature
Sensitization of pain-mediating nerve fibers
Increased force of myocardial contraction
Increased blood flow in gastric mucosa, liver, kidney, and placenta
Increased renal secretion of sodium, potassium, and water
Antagonistic action against antidiuretic hormone
Increased intraocular pressure
Increased permeability of blood capillaries
Increased gastrointestinal motility
Reduced gastrointestinal secretions
Reduced blood pressure
Bronchodilatation
Inhibition of bronchial secretions
Sedation
Contraction of the non-pregnant uterus
Induction of abortion and labor
Prostaglandin F series
Bronchial constriction, especially in patients with asthma
Reduced pulmonary blood flow and increased pulmonary blood pressure
Increased erythropoietin secretion
Increased neurotransmission at sympathetic nerve endings
Increased gastrointestinal motility
Reduced blood pressure
Sedation (effects on the central nervous system)
Luteolytic effects in mammalian species (except man)
Induction of abortion and labor
Prostaglandin I series
Reduced platelet aggregation
Reduced mean arterial pressure
Reduced total peripheral and pulmonary resistances
Increased heart rate
Increased renal secretion of sodium (tubular effect)

system effects. Epileptiform convulsions occur rarely. When used for termination of pregnancy, uterine hyperstimulation and, less often, uterine rupture can occur (5). Hypersensitivity to prostaglandins can cause skin reactions, bronchospasm (also seen as a direct pharmacological effect), and occasionally anaphylaxis. Tumor-inducing effects have not been reported. There have been a few reports of infants with limb deformities with and without Möbius sequence after exposure to misoprostol (a PGE_1 analogue) in the first trimester.

Prostaglandins in cardiovascular disease

Maintenance of the ductus arteriosus

PGE_1 and PGE_2 are effective in maintaining the patency of the ductus arteriosus in the initial management of congenital cardiac malformations (6,7). The most frequent adverse effects during prolonged treatment are diarrhea, necrotizing enterocolitis, cortical hyperostosis (8–10), fever, respiratory depression and apnea, and seizure-like activity (11). The frequency of adverse effects is not necessarily reduced with low-dose intravenous or oral administration (12). Maternal/fetal hyperglycemia due to reduced insulin secretion is rare, except in the infants of diabetic mothers (13). Less common adverse effects include gastric outlet obstruction due to antral hyperplasia (14).

Raynaud's phenomenon and digital ischemia

Studies of PGE_1 infusion for treatment of Raynaud's syndrome have shown variable changes in frequency of attacks and of healing ischemic digital ulcers (15–18). Prostacyclin

infusion (using PGI_2 or its synthetic analogue iloprost) appears to have beneficial effects, both in reducing the severity and frequency of attacks and healing ischemic digital ulcers. Adverse effects are common and include headache, flushing, jaw pain, nausea, vomiting, diarrhea, and inflammation and pain at the injection site (19,20). Iloprost has also been used effectively in the treatment of local gangrene secondary to chemotherapy (21). Application of a PGE_2 analogue to the skin produced both subjective and objective improvement in patients with Raynaud's syndrome and produced only minor self-limiting adverse effects (headache, flushing, and diarrhea) (22).

Peripheral vascular disease

Synthetic PGI_2 has been used in arterial occlusive disease as an anti-aggregatory drug (23–28). Adverse effects are common (85%). Headache, fever, nausea, anorexia, diarrhea, pain at the infusion site, and arthralgia are the most prominent. A single study has suggested an increased risk of thromboembolism after the use of iloprost in peripheral vascular disease (29).

Beraprost, an epoprostenol (PGI_2) analogue, has been studied in intermittent claudication. Adverse events include gastrointestinal disorders, headaches, skin disorders, and fever (30).

Primary pulmonary hypertension

Initial studies of continuous intravenous prostacyclin infusion in patients with primary pulmonary hypertension have shown sustained improvement in pulmonary artery pressure, exercise capacity, and survival compared with historical controls (31,32). Minor complications (diarrhea, jaw pain, flushing, photosensitivity, and headache) were dose-related. Serious complications were related to problems with the drug delivery system, including catheter thrombosis, sepsis, and temporary interruption of the infusion, resulting in abrupt deterioration (31).

Regulation of pulmonary vascular perfusion in advanced respiratory disease

PGE_1 significantly reduces right ventricular pulmonary after-load in patients with pulmonary hypertension due to chronic obstructive airways disease (33). PGE_1 can also be useful in the treatment of adult respiratory distress syndrome (34). Preliminary studies using aerosolized prostacyclin showed a reduction in pulmonary artery pressure and improved arterial oxygenation with reduction in intrapulmonary shunt in ventilated patients with adult respiratory distress syndrome (35) and severe community-acquired pneumonia (36). However, ventilated patients with severe community-acquired pneumonia and pre-existing fibrosis required much higher doses, with a reduction in systemic vascular resistance and an increase in intrapulmonary shunting (36). A single report described improved oxygenation, mainly due to reduction of intrapulmonary shunting, in two neonates with pulmonary hypertension treated with aerosolized prostacyclin (37).

Other uses

PGI_2 has been used to reduce the re-stenosis rate during transluminal coronary angioplasty (38).

Prostacyclin infusion (using PGI_2 or its synthetic analogue, iloprost) has been used during extracorporeal circulation to prevent blood clotting in the dialyser coil (39). The risk of severe hypotension can be avoided by carefully controlling the infusion rate.

Prostaglandins in gastrointestinal disease

Peptic ulceration and NSAID-induced gastropathy

Prostaglandins of the E series (misoprostol, enprostil) have antiulcer activity in the upper gastrointestinal tract (40). They inhibit gastric acid secretion at modest doses and provide mucosal protection against noxious agents, including non-steroidal anti-inflammatory drugs, smoking, alcohol, and chemotherapy. They have been used to prevent NSAID-induced gastroduodenal lesions (41,42). They may also be effective in preventing NSAID-induced renal impairment (43).

The cure rate for gastric and duodenal ulcers is comparable to the results with H_2-receptor antagonists (44–46). Relapses appear to be fewer with prostaglandin therapy (44,45). Healing of duodenal ulcers refractory to H_2-receptor antagonists has been described.

Diarrhea (4–38%), abdominal pain or cramp, flatulence, and nausea or vomiting account for most of the adverse effects reported. No biochemical or hematological adverse effects have been noted.

These agents are contraindicated in women of childbearing age, unless they are using adequate contraceptive measures, because of uncertain abortifacient effects. They have been used as illegal abortifacients in some countries (47).

Prostaglandins in liver disease

Liver failure and transplant dysfunction

Prostaglandins of the E series (both intravenous and oral formulations) have been used to treat fulminant hepatic failure, primary non-function following orthotopic liver transplantation, and recurrent hepatitis B infection after orthotopic liver transplantation in open trials (48–50). Adverse effects are almost universal. They include gastrointestinal symptoms (abdominal pain and cramping, watery diarrhea), which affect 33–100% and are more common with oral formulations and possibly amongst those with raised blood glucose concentrations. Cardiovascular effects, which affect about 33%, include migraine, hypotension, peripheral edema, and myocardial infarction (in those with pre-existing risk factors). Painful clubbing and cortical hyperostosis (92–100%) developed 10–60 days after the start of intravenous or oral therapy. Arthritis/arthralgia developed in 8% of those receiving intravenous and 92% of those taking oral PGE_1 or PGE_2. All adverse reactions appear to be dose-related and resolve with reductions in dose. Two patients developed calcium oxalate stones after 1 year of oral therapy (51).

Prostaglandins in urology

Prostacyclin infusion in men with persistent pain associated with Peyronie's disease was of little value but produced marked adverse effects (bradycardia, hypotension, nausea, flushing) (52).

© 2006 Elsevier B.V. All rights reserved.

A single dose of PGE_1 into the corpus cavernosum is highly effective in inducing artificial penile erection in cases of erectile dysfunction. The reported adverse effects include pain and a burning sensation, prolonged penile erection, and local fibrosis. The incidence of pain was high (75%) in older studies (53), while later data improved to 13–44% (54–57). Pain is cited as a prominent factor in non-adherence to therapy and in the dropout rate of patients from self-injection programs, although the incidence may fall with time (57). An alprostadil sterile powder formulation had a lower incidence of pain after penile injection (6.6%), attributed to lower doses and the lack of alcohol in the formulation (58). Burning and pain can be reduced by using a lower initial dose, with incremental increases until a satisfactory erection is produced (59).

Although the incidence of priapism varies in different studies, depending on its definition (erection lasting anywhere from 2 to 11 hours), an analysis of 48 studies in 8090 patients showed an overall incidence of 1% (55).

Prolonged erections induced by PGE_1 usually require drainage and phenylephrine irrigation, although a small percentage can be managed with oral terbutaline or oral pseudoephedrine if treated within 3 hours of PGE_1 injection (56). Local fibrosis is infrequent, occurring in 2% at 6 months and in 8% at 18 months (60). A single case of Peyronie's-like plaque and penile curvature deformity has been reported after repeated PGE_1 use (61).

Complications of alprostadil injections include hematoma and ecchymoses (8%) and systemic effects (6%), which mostly occur in the urogenital system (testicular pain and swelling, scrotal pain and edema, changes in urinary frequency, hematuria, and pelvic pain) (62). In 1% there were symptoms related to hypotension.

Massive diffuse hemorrhage due to cyclophosphamide-induced or radiation cystitis has been treated successfully with intravesicular PGE_1, PGE_2, and carboprost. Febrile reactions and severe bladder spasm are dose-dependent (63–65).

Prostaglandins in ophthalmology

Topical PGE_2 and $PGF_{2\alpha}$ significantly reduce intraocular pressure for at least 24 hours and are used in the treatment of glaucoma. Derivatives of the isopropyl ester of $PGF_{2\alpha}$ appear to be the most effective. Transient ocular adverse effects include conjunctival hyperemia, local irritation, intermittent photophobia, and pain in the eye (66–68). Newer derivatives, such as latanoprost, travoprost, and bimatoprost, appear to be better tolerated, with less severe and less frequent adverse effects (69). They reduce intraocular pressure by increasing uveoscleral outflow. The ocular pressure-lowering effect of latanoprost appears to be additive with timolol, with mild transient hyperemia in 50% of those treated with latanoprost alone (70).

Latanoprost, travoprost, and bimatoprost cause increased pigmentation of the iris in some patients after prolonged treatment (3.0–4.5 months) (71). Most data have been obtained with latanoprost, and it appears that there is a predisposition to iris pigmentation in patients with eyes of hazel or heterochromic color. As latanoprost and travoprost are selective agonists at $PGF_{2\alpha}$ receptors, it is likely that the phenomenon is mediated by these receptors. Latanoprost stimulates melanogenesis in iris melanocytes, and transcription of the tyrosinase gene is upregulated. No evidence of harmful consequences of this adverse effect has been found, and the only disadvantage appears to be potential heterochromia between the eyes in unilaterally treated patients: the heterochromia is likely to be permanent, or very slowly reversible (72–74).

The adverse effects of travoprost include gradual darkening of the color of the iris and the eyelid skin, increased thickness, number, and darkness of the eyelashes, conjunctival hyperemia, and ocular pruritus (75).

Cystoid macular edema, iritis, *Herpes simplex* keratitis, periocular skin darkening, and headaches have been described in patients treated with prostaglandin analogues. These adverse effects occur rarely, and cystoid macular edema, iritis and *H. simplex* keratitis occur in eyes with risk factors. Repeated rechallenge with masked controls is required to establish a causal relation. However, even without firm establishment of a causal relation, caution is advised with the use of prostaglandin analogues in the eyes of patients with risk factors for macular edema, iritis, and *H. simplex* keratitis (76).

The ocular adverse effects of latanoprost include conjunctival hyperemia, iris pigmentation, periocular skin color changes, anterior uveitis, and cystoid macular edema in pseudophakic patients (77,78). *H. simplex* dendritic keratitis has been reported after treatment with latanoprost (79). In patients with uveitic glaucoma, latanoprost can cause increased intraocular pressure and recurrence of inflammation (80).

Exacerbation of angina pectoris has been described in association with latanoprost (81). $PGF_{2\alpha}$ is a vasoconstrictor, and systemic absorption of topical latanoprost can cause vasoconstriction in coronary arteries.

Three patients had new-onset migraine after using latanoprost, perhaps through activation of the trigeminal vascular system (82).

Prostaglandins in obstetrics

Prostaglandins of the E and F series are widely used in obstetrics for ripening the uterine cervix and stimulating uterine contraction at any stage of pregnancy. They are used in first- and second-trimester abortions, cervical priming, the induction and augmentation of labor, and postpartum hemorrhage (83–89). The route of administration can be vaginal, cervical, extra-amniotic, intra-amniotic, oral, intramuscular, or intravenous, and varies according to indication. Mifepristone (RU 486), a synthetic 19-norsteroid and progesterone antagonist, has been used in combination with synthetic prostaglandins in the induction of abortion.

A less well-established use involves intratubal injection of $PGF_{2\alpha}$ for ectopic pregnancy (90,91). Oral PGE_2 can be used to suppress lactation, for which it is as effective as bromocriptine, and causes less breast tenderness (92).

Organs and Systems

Cardiovascular

Both PGE_2 and $PGF_{2\alpha}$ commonly cause a fall in blood pressure and a degree of bradycardia (1,93). PGE_2 can cause vasodilatation of small vessels and $PGF_{2\alpha}$ can cause

© 2006 Elsevier B.V. All rights reserved.

vasoconstriction (94). These changes are common but often mild. However, angina pectoris and myocardial infarction have been reported with prostaglandins of all types, particularly after inadvertent intramyometrial injection (95–98). A single case of pulmonary edema after the infusion of PGE_1 has been reported (99). In patients with pre-existing cardiovascular disease, the risk of serious aggravation is very real, and both pre-existing hypertension and states of shock can be worsened. A severe rise in maternal blood pressure occurred in a few cases in which fetal death was associated with unresolved pre-eclampsia.

Respiratory

People with asthma are more sensitive than healthy subjects to bronchoconstriction induced by $PGF_{2\alpha}$ (100,101).

Nervous system

Increased body temperature, pyrexia (both intra- and postpartum), and chills are thought to result from central stimulation of temperature regulatory centers by prostaglandins (102,103). Headache and migraine are the most common adverse effects on the central nervous system (5,104).

Prostaglandin therapy can cause electroencephalographic abnormalities (105). Convulsions, which occur occasionally, are a particular risk in epileptic patients (5,104,105). The combination of prostaglandins and oxytocin can be complicated by tonic-clonic seizures (106).

Enhancement of the pain sensation may reflect a direct effect on nerve fibers. The presence of pain correlates well with the effect on the uterus.

Sensory systems

Increased intraocular pressure and miosis have been reported (5,104).

Mouth and teeth

Gingivitis has been associated with obstetric prostaglandins (5).

Gastrointestinal

Nausea, vomiting, diarrhea, and abdominal pain (107) occur in about 90% of all patients given prostaglandins systemically. The frequency and duration of these adverse effects depend on the mode of application, the dosage, and the molecule used, and are very variable (108).

Reproductive system

Uterine hypertonia and hyperstimulation are well-recognized adverse effects of induction of abortion and labor with prostaglandins. Cervical rupture and uterine rupture have been reported with every prostaglandin and analogue, even in previously unscarred uteri (5,109–116). The risks can be minimized by using lower doses (0.5 mg intracervically or 3 mg intravaginally), by allowing longer intervals between re-applications, and by avoiding combination with oxytocin, which has a potentiating effect. However, there is a single case report of uterine rupture in a multiparous woman with unscarred uterus following low-dose (1.5 mg) intravaginal PGE_2 (117). In the event of uterine hyperstimulation, $beta_2$-adrenoceptor agonists may reduce uterine contractility. Intensive monitoring of uterine activity and fetal condition is mandatory, since the rate of absorption of PGE_2 after intravaginal or cervical administration is unpredictable.

Second-Generation Effects

Teratogenicity

Seven Brazilian infants were born with limb deficiencies both with and without Möbius sequence after exposure to misoprostol in the first trimester during unsuccessful abortion attempts (118).

Fetotoxicity

Like oxytocin, prostaglandins have been responsible rarely for fetal distress and even fetal death (119,120). The risk of fetal death underlines the importance of cardiotocography during prostaglandin (pre)induction. Prostaglandins should be used with extreme caution if there is a risk of placental insufficiency (120).

The incidence of neonatal jaundice was not increased after induction of labor with prostaglandins (47).

Susceptibility Factors

When PGE_2 and $PGF_{2\alpha}$ are used for induction of labor and abortion, the following contraindications must be respected and (until proven otherwise) also apply to the methyl analogues of these two prostaglandins:

- previous cesarean section or hysterotomy (because of the risk of rupture) (110);
- previous major abdominal surgery;
- prior abnormal delivery;
- a history of severe abdominal inflammation and/or infection;
- a predisposition to uterine cramps or tetanus uteri.

However, uneventful vaginal deliveries have been reported in patients with two previous cesarean sections in whom labor was induced with vaginal PGE_2 (121). Women with a history of six or more deliveries and anomalies of the fetus (for example hydrocephalus causing cephalopelvic disproportion) must also be excluded.

Predispositions to glaucoma, epilepsy, pre-eclampsia, hypertension, asthma, and ischemic heart disease are relative contraindications.

Drug Administration

Drug administration route

Intrauterine infusion

Intrauterine infusion (intra-amniotic or extra-amniotic) has been reported to be associated with fewer gastrointestinal symptoms and less fever than parenteral or intravaginal administration (122). In intra-amniotic use, the puncture must be guided by ultrasonography, and before injection a control aspiration of some amniotic fluid is required in order to avoid intrauterine or intravascular

© 2006 Elsevier B.V. All rights reserved.

injection. Uterine rupture has been described with intra-amniotic treatment.

Intramuscular or intradermal injection

Inflammation and pain are common at the site of injection when prostaglandins are given intramuscularly or intradermally (123,124).

Intravenous injection

Prostaglandins have been used intravenously, both for induction of mid-trimester abortion and for induction of labor in cases of intrauterine death. The same adverse effects as described above occur, and are usually very pronounced. Routine premedication with an antiemetic and an antidiarrheal agent significantly reduces gastrointestinal adverse effects.

Inhalation

Intravenous epoprostenol increases exercise tolerance, improves pulmonary hemodynamics, and improves survival in patients with primary pulmonary hypertension. However, there are limitations to intravenous administration, and a significant proportion of patients develop catheter-related problems, such as thrombosis, pump failure, and catheter-related sepsis. In an attempt to improve delivery, several trials of aerosolized prostacyclin have been undertaken, primarily in patients with primary pulmonary hypertension.

There has been a sequential comparison of inhaled nitric oxide 40 ppm with aerosolized iloprost 14–17 micrograms in 35 adults with primary pulmonary hypertension (125). Five of the patients had minor headache and facial flushing during inhalation of iloprost, but these symptoms were short-lived and abated a few minutes after the inhalation ended. One patient had mild jaw pain after aerosolized iloprost, but again this was short-lived. There was an unexpected increase in pulmonary artery pressure in 10 patients and vascular resistance in six patients who received nitric oxide. The authors were uncertain of the cause of this increase, as nitric oxide generally behaves as a vasodilator, but they noted that nitric oxide is a vasoconstrictor in certain conditions, such as the presence of hemolysate (126).

There has been a trial of aerosolized iloprost in 24 patients with primary pulmonary hypertension and New York Heart Association class III or IV disability, who were refractory to conventional medical treatment (127). They were given aerosolized iloprost in a total daily dose of 100–150 micrograms (in 6–8 divided doses, given every 2–3 hours while awake) over 12 months. The treatment was generally well tolerated, except for coughing during inhalation, which was common initially but resolved spontaneously in all patients within the first 4 weeks. Five patients reported symptoms of flushing, headache, and jaw pain at the end of inhalation, but all rated the symptoms as mild and none discontinued treatment because of adverse effects. There was an asymptomatic but significant fall in systemic arterial pressure (from 98 to 90 mmHg) and vascular resistance at 3 and 12 months compared with baseline.

The effects of aerosolized iloprost have been reported in three patients with severe pulmonary hypertension (mean pulmonary artery pressure 50 mmHg or more) who were already being treated with intravenous epoprostenol (10–16 micrograms/kg/minute) (128). The aim of the study was to replace continuous intravenous epoprostenol with intermittent aerosolized iloprost (150–300 micrograms/day in 6–18 divided doses). All three patients had gradual weaning of intravenous epoprostenol (1 micrograms/kg/minute every 3–10 hours) under close supervision and hemodynamic monitoring in intensive care. All three had initial falls in pulmonary arterial pressure and improved right ventricular function with inhaled iloprost. The first could not be fully weaned from epoprostenol, because of right ventricular failure with dyspnea and hypoxemia, accompanied by a three-fold increase in serum bilirubin and lactate dehydrogenase and echocardiographically demonstrated right ventricular failure. The second and third patients both tolerated complete withdrawal of epoprostenol. However, one developed right ventricular failure within 2 hours of withdrawal. The third was successfully discharged from hospital taking aerosolized therapy, but presented 2 weeks later with severe right ventricular failure. Thus, caution should be taken in patients who have been previously maintained on intravenous prostacyclin when trying to convert to aerosolized therapy, as there appears to be a high chance of treatment failure, which can occur abruptly.

Platelet function after inhaled prostacyclin has been measured in a randomized, double-blind study in 28 patients undergoing elective cardiothoracic surgery (129). They were given aerosolized prostacyclin (5 or 10 micrograms) for 6 hours postoperatively. All the patients, regardless of dose, had a lower rate of platelet aggregation in response to adenosine diphosphate (ADP) than controls. There were no differences in clinically significant indices, such as chest tube drainage or bleeding time. This study has shown that prostacyclin, given as an aerosol, can cause measurable alterations in platelet function, with a possibly higher risk of bleeding.

Protamine

General Information

Protamine, derived from salmon sperm, combines with and neutralizes heparin through an acid-base interaction. It is most commonly used as the sulfate, but chloride and hydrochloride salts are also occasionally used.

The relative insolubility of protamine–insulin suspension in water slows the subcutaneous resorption of the hormone, and consequently prolongs its biological activity.

In a prospective study of patients undergoing cardiopulmonary bypass, 10.7% of patients receiving protamine sulfate had adverse reactions of varying types (1).

Protamine sulfate regularly induces hypotension, bradycardia, transient flushing, and a feeling of warmth when administered too rapidly. These non-allergic effects are not severe, provided the injection is given slowly (50 mg, the maximum recommended dose, over 10 minutes).

Comparative studies

In a double-blind, randomized trial, 167 patients undergoing aortocoronary bypass graft surgery received either heparinase I (maximum 35 μg/kg) or protamine (maximum 650 mg) for heparin reversal (2). Although the two treatments had similar efficacy, protamine had a better safety profile. Those given heparinase I had longer hospital stays, were more likely to have a serious adverse event, and were less likely to avoid transfusion. A composite morbidity score was not different, and there were similar rates of hemodynamic instability.

Organs and Systems

Cardiovascular

Severe acute pulmonary vasoconstriction with cardiovascular collapse was identified in 1983 and subsequent studies showed that the incidence of protamine-induced pulmonary artery vasoconstriction was about 1.5% after cardiac surgery (3). Protamine-induced pulmonary artery vasoconstriction is accompanied by generation of large quantities of thromboxane A_2, a potent vasoconstrictor (3).

The precise mechanisms that explain protamine-mediated systemic hypotension are unknown, but there is evidence that it may be mediated by the endothelium and dependent on nitric oxide/cyclic guanosine monophosphate; it has been suggested that methylthioninium chloride (methylene blue) may be of use in treating hemodynamic complications caused by the use of protamine after cardiopulmonary bypass (4).

Immunologic

Although protamine itself was for a long time not generally considered allergenic, allergic reactions can occur in susceptible individuals. Attributed to residual fish antigens that remained after purification, they are characterized by flushing, urticaria, wheezing, angioedema, and hypotension, and they can occur even after slow intravenous administration. True anaphylaxis with bronchospasm and/or anaphylactic shock is very rare (5).

It now seems to be widely believed that, exceptionally, protamine itself can act as an allergen. There were positive skin tests with protamine in patients who had anaphylaxis and who had all previously received protamine (5). Cases of anaphylactic shock after slow intravenous administration of protamine sulfate to patients with diabetes mellitus suggested cross-allergy to protamine present in protamine zinc insulin (6–8), especially in patients with serum antiprotamine IgE or IgG antibodies (9). Insulin-dependent patients with diabetes who use protamine insulin may be at greater risk of adverse effects when they receive protamine sulfate. A retrospective study in patients who received protamine sulfate to reverse the effects of heparin during catheterization procedures or cardiac surgery showed a relative risk of anaphylaxis four times higher in patients with diabetes who had used protamine insulin than in non-diabetic controls (10). In these patients, the risk of anaphylaxis on administration of protamine sulfate is about 1%.

Protease inhibitors

See also Individual agents

General Information

All the HIV protease inhibitors have in common a specific effect against the aspartic HIV protease that cleaves viral proteins to yield structural proteins. Competitive inhibition of this process by the protease inhibitors results in the production of immature, non-infectious virus particles. These drugs are also characterized by their high specificity, being more than a thousand-fold more active against viral than human aspartic proteases.

Combination therapy including a protease inhibitor resulted in the first breakthrough of antiviral treatment in the mid-1990s, since when several protease inhibitors have been developed. However, results from in vitro and clinical studies clearly showed that these drugs share a cross-resistance pattern, probably due to secondary conformational changes of the protease outside the active binding site of the protease inhibitor. Nevertheless, some patients may benefit from a second protease inhibitor if therapy is promptly switched before multiple mutations have accumulated.

Drug interactions with protease inhibitors

Drug interactions with protease inhibitors, which are potent inhibitors of CYP3A4 and CYP2D6, have been comprehensively reviewed (1), and an updated summary of interactions is presented on the World Wide Web by the University of Liverpool (http://www.hiv-druginteractions.org); the drugs that should not be co-administered with protease inhibitors are summarized in Table 1.

Interactions between protease inhibitors

Evidence suggests that some protease inhibitors can inhibit the metabolism of others. For example, ritonavir inhibits CYP3A4 and CYP2D6 and has been used to enhance the actions of other protease inhibitors, by inhibiting their clearance (2).

In an open, randomized study of amprenavir combined with indinavir, nelfinavir, and saquinavir (3), saquinavir lowered the amprenavir AUC by 32%; amprenavir did not alter the pharmacokinetics of saquinavir. The amprenavir AUC increased by 35% when it was combined with indinavir, and indinavir concentrations also fell, suggesting that this protease inhibitor combination should be avoided. There was no significant interaction of amprenavir with nelfinavir.

In attempts to lower the amprenavir capsule burden, low-dose ritonavir has been used as a pharmacokinetic booster. When ritonavir was added to amprenavir, the amprenavir AUC increased 3–4 times (4), which should allow the total daily capsule burden to be reduced. Adverse effects included diarrhea, nausea, paresthesia, rash, increased cholesterol, and increased triglycerides. The frequency of adverse events correlated with the dose of ritonavir.

In nine patients who received amprenavir 750 mg bd for at least 3 weeks plus one of two doses of lopinavir + ritonavir, the trough concentration of amprenavir was 0.35–2.54 with lopinavir + ritonavir 400/100 mg bd ($n = 5$) and 1.92–2.83 with lopinavir + ritonavir 532/133 mg bd ($n = 4$); the corresponding trough concentrations of lopinavir were 0.35–2.54 and 4.74–6.71 (5).

A pharmacokinetic model has been developed to describe the interaction of amprenavir with ritonavir (6). A two-compartment linear model with first-order absorption fitted the amprenavir data best, while a one-compartment model best described the ritonavir data. Inhibition of the elimination of amprenavir by ritonavir was modelled with an E_{max} inhibition model. Simulation of drug regimens based on the model suggested that in patients who fail to respond to a traditional amprenavir regimen, amprenavir 600 mg plus ritonavir 100 mg bd would produce similar C_{min}:IC_{50} ratios to amprenavir 1200 mg bd alone.

Using ritonavir as a booster allows indinavir to be given twice daily and with food. In a cohort survey of 100

patients the combination of indinavir plus ritonavir (400 mg/400 mg or 800 mg/100 mg bd) was a safe and effective option to reduce the tablet burden and improve adherence (7).

Observational studies

Combinations of NRTIs and protease inhibitors

A variable-dose plasma concentration-controlled approach to combination antiretroviral therapy (zidovudine, lamivudine, and indinavir) has been compared with conventional fixed-dose therapy in 40 patients in a randomized, 52-week, open trial (8). Significantly more concentration-controlled recipients achieved the desired concentrations for all three drugs: there was a good response in 15 of 16 concentration-controlled recipients compared with nine of 17 conventional regimen recipients. However, there was no difference in the occurrence of drug-related clinical events or laboratory abnormalities between the two regimens. Three patients withdrew because of gastrointestinal adverse effects, one because of a peripheral neuropathy, and one with headache and anemia. There was nephrolithiasis in four cases.

The combination of indinavir + ritonavir 400/400 mg bd plus two NRTIs has been studied in 93 patients in an open, uncontrolled, multicenter trial (9). Raised triglycerides ($n = 78$) and cholesterol ($n = 63$) were the commonest adverse effects, followed by nausea ($n = 22$) and circumoral paresthesia ($n = 9$). Withdrawal was required in four cases of nausea, four of lipodystrophy, one of diarrhea, and one of osteonecrosis.

Combinations of NRTIs, NNRTIs, and protease inhibitors

In an open, 48-week, single-arm, multicenter phase II study in 99 patients abacavir 300 mg bd, amprenavir 1200 mg bd, and efavirenz 600 mg/day were associated with rashes in 50 patients, possibly because of abacavir hypersensitivity; 17 permanently discontinued one or more drugs as a result (10). Other adverse effects included nausea ($n = 41$), diarrhea ($n = 27$), sleep disorders ($n = 27$), dizziness ($n = 25$), fatigue ($n = 23$),

Nausea/vomiting	29 (71)	32 (73)	18 (41)	15 (29)
Other	10 (24)	25 (27)	18 (41)	19 (37)
Liver	12 (29)	14 (32)	18 (41)	23 (44)
Skin	27 (66)	41 (93)*	32 (73)	17 (33)*
Body temperature (fever)	24 (59)	30 (68)*	20 (45)	10 (19)*

*Significantly different from the other groups

hypertriglyceridemia ($n = 18$), neutropenia ($n = 8$), hyperamylasemia ($n = 4$), leukopenia ($n = 3$), hypercholesterolemia ($n = 2$), raised alkaline phosphatase ($n = 1$), and raised aspartate transaminase ($n = 1$).

In infants and children assigned to different combinations of one or two NRTIs plus an NNRTI and/or a protease inhibitor, the numbers of patients with moderate or severe adverse events were as shown in Table 2 (11). In cases of rash, the rash was worse in those who were taking nevirapine-containing regimens.

Organs and Systems

Nervous system

In a randomized comparison of a protease inhibitor-containing regimen and an efavirenz-containing regimen, nervous system adverse effects were specifically sought (12). Patients were randomized to two NRTIs plus one or more protease inhibitors ($n = 49$) or two NRTIs plus efavirenz ($n = 51$). The patients who took the protease inhibitors reported the following at week 4: light-headedness (8%), dizziness (5%), difficulty in sleeping (4%), nervousness (4%), and headaches (3%). They reported the following at week 48: difficulty in sleeping (4%), nervousness (3%), headaches (3%), and light-headedness (2%). Three patients withdrew because of adverse events: diarrhea ($n = 2$) and nephrolithiasis ($n = 1$).

Sensory systems

- Lipemia retinalis and pancreatitis have been reported in a 39-year-old man with HIV infection associated with protease inhibitor therapy (13). He developed lipemia retinalis after switching to an antiretroviral regimen including ritonavir and saquinavir (together with zalcitabine and delavirdine). He had previously been taking zidovudine, lamivudine, and indinavir.

The ophthalmoscopic changes of lipemia retinalis include a milky-white discoloration of the retinal vessels, beginning at the periphery but progressing to involve the posterior pole as the triglyceride concentration rises. The fundus can appear salmon-colored, owing to the effect of triglycerides on the choroidal circulation. Experience from HIV-negative patients with hyperlipidemia has shown that plasma triglyceride concentrations must be at least 28 mmol/l (2500 mg/dl) for lipemia retinalis to occur (reference value below 1.52 mmol/l). This patient had a plasma triglyceride concentration of 53 mmol/l. On withdrawal of ritonavir and saquinavir the appearance of his retinal vessels returned to normal in parallel with a fall in his plasma triglycerides.

Endocrine

Two case reports have suggested that when a protease inhibitor is used with a glucocorticoid the tendency to adverse corticosteroid effects is potentiated (14,15). Two HIV-positive patients developed severely disfiguring skin striae within 3 months of starting indinavir therapy (16).

Metabolism

Metabolic changes that protease inhibitors can cause after prolonged therapy include raised serum lactate, hypogonadism, hypertension and accelerated cardiovascular disease, reduced bone density, and avascular necrosis of the hip. Two large prospective studies in 1207 patients (17) and 3191 patients (18) have clarified the spectrum and incidence of metabolic changes in HAART and have explored the relative importance of protease inhibitors. In addition, data on fat redistribution from a postmarketing review of HIV-infected individuals taking indinavir have been published (19).

Blood glucose concentration

Protease inhibitors can cause a rise in blood glucose concentration, although only a few cases have been reported. Patients with a family history of diabetes mellitus may be at a greater risk, and they demand especially close monitoring, for example with both baseline and quarterly glucose determinations, at least during the first 6–12 months of treatment (20,21).

Dyslipidemias

While abnormal concentrations of circulating lipids are common in patients with HIV infection (usually

© 2006 Elsevier B.V. All rights reserved.

hypercholesterolemia and moderate hypertriglyceridemia), there is no doubt that some members of this group of drugs can cause much more marked changes. The possible differences between the effects of various protease inhibitors on the lipid spectrum have been characterized in 93 HIV-infected adults taking ritonavir, indinavir, or nelfinavir, alone or in combination with saquinavir (22). There was a rise in plasma cholesterol concentration in all those who took a protease inhibitor, but it was more pronounced with ritonavir than with indinavir or nelfinavir. Plasma HDL cholesterol was unchanged. Ritonavir, but not indinavir or nelfinavir, was associated with a marked rise in plasma triglyceride concentrations. The combination of ritonavir or nelfinavir with saquinavir did not further alter plasma lipid concentrations. There was a 48% increase in plasma concentrations of lipoprotein(a) in those taking a protease inhibitor, with pretreatment values exceeding 200 μg/ml. There were similar changes in plasma lipid concentrations in six children taking ritonavir. The risk of pancreatitis and premature atherosclerosis as a consequence of such dyslipidemia remains to be established.

- A 35-year-old HIV-positive man developed a serum cholesterol concentration of 38 mmol/l and a fasting serum triglyceride concentration of 98 mmol/l after he started to take ritonavir, saquinavir, nevirapine, and didanosine (23). All other medications had been stable during this time; the condition resolved with antiretroviral drug withdrawal and lipid-lowering therapy. It was striking that the raised cholesterol and triglyceride concentrations did not recur when therapy was restarted in modified form with nelfinavir, saquinavir, nevirapine, and didanosine; the hyperlipidemia was therefore attributed to ritonavir.

In 19 consecutive HIV-positive men examined before and during treatment with a protease inhibitor (nelfinavir, ritonavir, or indinavir) and two nucleoside analogue reverse transcriptase inhibitors (NRTI), median treatment duration 22 (range 7–40) weeks, the predominant feature of dyslipidemia was an increase in triglyceride-containing lipoproteins (24). This observation is in accordance with the hypothesis of increased apoptosis of peripheral adipocytes, release of free fatty acids, and subsequent increased synthesis of VLDL cholesterol. The lipid profile, based on the ratio of total cholesterol to HDL cholesterol and the ratio HDL2 to HDL3, is significantly more atherogenic than normal.

Lipodystrophy

Soon after the introduction of highly active antiretroviral combination treatments (HAART), lipodystrophy was associated with the use of protease inhibitors, and several reports have confirmed that a syndrome of peripheral lipodystrophy, central adiposity, breast hypertrophy in women, hyperlipidemia, and insulin resistance with hyperglycemia is an adverse event associated with the use of potent combination antiretroviral therapy, particularly including HIV-1 protease inhibitors (25–30).

Peripheral lipodystrophy in patients is characterized by fat wasting of the face, limbs, buttocks, and upper trunk, while central adiposity can cause an increase in belly size ("Crix-belly" or "protease pouch") and an increase in the dorsocervical fat pad, creating the appearance of a "buffalo hump" (31–33). These effects may be related to a glucocorticoid-like action. The increase in belly size is often associated with symptoms of abdominal fullness, distension, and bloating. This is probably due to a change in body fat distribution, with selective accumulation of fat intra-abdominally (34).

Lipodystrophy is not limited to patients taking protease inhibitors (35,36). Nevertheless, protease inhibitors are strongly associated with metabolic alterations and with lipodystrophy, while NRTIs are associated with low-grade lactic acidosis and less markedly with lipodystrophy. Some reports have speculated a link between mitochondrial dysfunction and lipodystrophy. It is clear, however, that the syndrome is related to total duration of antiviral therapy and inversely related to viral load.

In a longitudinal study from an Aquitaine cohort of more than 1400 subjects, hypertriglyceridemia was significantly associated with age, low viral load, and protease inhibitors, but not NRTIs or NNRTIs. However, lipodystrophy also occurred in patients naive to protease inhibitors (37).

- "Buffalo neck" was described in a middle-aged man taking indinavir who developed a lipomatous formation in the retrocervical area; abdominal fat also increased in volume, while the subcutaneous fat on the lower limbs decreased (38).

Of 494 patients during median follow-up of 18 months, 17% developed lipodystrophy (39). Study limitations included the short time of follow-up and the lack of a standardized and accepted definition of lipodystrophy.

Hematologic

There is still no clear explanation for a series of seven patients in whom treatment with various protease inhibitors was associated with early thrombosis (40). Hematological or vascular effects conducive to thrombosis are not recognized as a complication with this group of compounds; the only previous similar cases were associated with prolonged therapy.

In contrast, a detailed report on a large series of patients has provided impressive evidence that the use of protease inhibitors in HIV-infected patients with hereditary bleeding disorders can lead to an increased bleeding tendency (41). This effect, which is most likely to occur when ritonavir is used, is also unexplained.

Liver

In a retrospective study of patients taking one protease inhibitor ($n = 39$) or two ($n = 27$) who discontinued protease inhibitor therapy as a result of hepatotoxicity, the proportions of patients with raised alanine transaminase activity to at least five times the upper limit of the reference range (26 versus 19%) and hyperbilirubinemia (38 versus 30%) were similar (42). Rates of withdrawal due to hepatotoxicity were also similar.

Pancreas

- Lipemia retinalis and pancreatitis have been reported in a 39-year-old man with HIV infection associated with protease inhibitor therapy (13). His plasma triglyceride concentration was 53 mmol/l.

© 2006 Elsevier B.V. All rights reserved.

Urinary tract

In a randomized comparison of a protease inhibitor-containing regimen and an efavirenz-containing regimen in 100 patients, six patients taking protease inhibitors developed nephrolithiasis; one withdrew as a result (12).

Musculoskeletal

The results of a questionnaire survey of 878 people with HIV infection treated with antiretroviral drugs also suggested that other protease inhibitors can cause arthralgia; indinavir and the combination of ritonavir + saquinavir were particularly implicated (43).

Immunologic

A man developed several erythematous plaques on his face due to borderline tuberculoid leprosy with a reversal reaction (44). He had severe CD4 T cell lymphocytopenia due to HIV infection and had been given highly active antiretroviral therapy (HAART). A fall in viral load and an increase in CD4 count preceded the development of the skin lesions, suggesting immune reconstitution as the underlying mechanism for the reversal reaction. Paradoxical reactions are often observed in patients with pulmonary and extra-pulmonary tuberculosis being treated with HAART. Clinicians need to distinguish these from other adverse reactions related to drug therapy. Reversal reactions in leprosy are increasingly likely as more patients with HIV infection are treated with HAART in developing countries.

Drug–Drug Interactions

See also General information and Table 1.

Ecstasy

A patient infected with HIV-1 who was taking ritonavir and saquinavir had a prolonged effect from a small dose of methylenedioxymetamfetamine (MDMA, ecstasy) and a near-fatal reaction from a small dose of gammahydroxybutyrate (45).

Gammahydroxybutyrate

A patient infected with HIV-1 who was taking ritonavir and saquinavir had a prolonged effect from a small dose of MDMA and a near-fatal reaction from a small dose of gammahydroxybutyrate (45).

Statins

There has been a study of the effects of ritonavir 400 mg bd plus saquinavir soft-gel capsules 400 mg bd on the pharmacokinetics of pravastatin, simvastatin, and atorvastatin (40 mg/day each), and of the effect of pravastatin on the pharmacokinetics of nelfinavir in a randomized, open study in 56 healthy HIV-negative adults (46). Ritonavir + saquinavir reduced the steady-state AUC of pravastatin, markedly increased the AUC of simvastatin, and slightly increased the AUC of total active atorvastatin. The AUCs of nelfinavir and its active M8 metabolite were not altered by pravastatin. The authors concluded that simvastatin (and by implication lovastatin, which in common with simvastatin inhibits CYP3A4) should be avoided and atorvastatin should be used with caution in people taking ritonavir and saquinavir, that dosage adjustment of pravastatin may be necessary with concomitant use of ritonavir + saquinavir, and that concomitant use of pravastatin with nelfinavir appears to be safe.

Protein hydrolysates

General Information

Protein hydrolysates are added to hair-care products, such as shampoos and conditioners, and are supposed to "repair" damaged hair. Hydrolysed proteins are also used in other body-care products, for example soaps, bath gels, and creams.

Organs and Systems

Immunologic

Occasionally single reports of contact urticaria and of allergic contact dermatitis due to hair conditioner and skin cleanser have been published (SEDA-21, 166) (1). Protein hydrolysates used in hair-care products have been tested in 11 hairdressers with hand dermatitis, in 2160 consecutive adults with suspected respiratory disease, and in 28 adults with chronic atopic dermatitis (2). The hairdressers underwent both scratch tests (1% aqueous) and patch tests (5% aqueous) with 22 protein hydrolysates (collagen, keratin, elastin, milk, wheat, almond, silk). Skin prick tests with one to three hydrolysates (1% aqueous) were conducted in the other patients. All 2199 patients were tested with hydroxypropyl trimonium hydrolysed collagen (Crotein Q). There were positive scratch/prick test reactions in 12 patients to three protein hydrolysates. Remarkably, all were women with atopic dermatitis. They reacted at least to hydroxypropyl trimonium-hydrolysed collagen (Crotein Q) and 11 had positive reactions to one or more allergens in a standard prick series. In three patients, clinical relevance could be confirmed by open tests with both undiluted and diluted hair conditioner containing Crotein Q (one hairdresser with contact urticaria on the hands, two cases of contact urticaria on the head, face, and upper body from a hair conditioner containing Crotein Q). Furthermore, in seven of eight sera studied, specific IgE to Crotein Q was detected, while 11 control sera were negative. These results show that protein hydrolysates in hair-care products may be underestimated causes of contact urticaria, particularly in patients with atopy.

Prothrombin complex concentrate

See also Coagulation proteins

General Information

Prothrombin complex products contain constant amounts of clotting factors II, VII, IX, and X, bypassing the need for factor VIII in the clotting cascade. They are used to reverse the effects of oral anticoagulants (for example during surgery or bleeding episodes) (1) and to treat bleeding episodes in hemophiliacs with inhibitors of factor VIII (2). Prothrombin complex achieves more rapid and effective reversal of acquired coagulation defects than fresh frozen plasma. However, a potential disadvantage is the risk of thromboembolism.

Organs and Systems

Cardiovascular

Thromboembolic events in relation to activated prothrombin complex products include deep venous thrombosis and pulmonary embolism (3–5). So far, the exact mechanism of how thromboembolic events are stimulated by prothrombin complex products is not known. It has been postulated that the presence of activated clotting factors VII, IX, and X, as well as procoagulatory phospholipids in prothrombin complex products, are responsible (6).

In 42 patients who required immediate reversal of oral anticoagulant therapy by prothrombin complex concentrate, no laboratory and clinical evidence for coagulation activation was found (7). The authors suggested that the concentration of protein C within the prothrombin complex concentrate is an important factor for preventing thrombosis. The activated form of protein C is an important natural anticoagulant.

Myocardial necrosis has been described after the administration of a prothrombin complex products, probably because of excessive kininogen in the product.

Hematologic

The administration of prothrombin complex concentrate to reverse anticoagulant treatment has been associated with thrombotic complications, such as disseminated intravascular coagulation (8). However, such complications have typically occurred in patients with liver failure or after repeated treatment, such as in patients with hemophilia B treated with prothrombin complex concentrate (9).

Hypofibrinogenemia has been observed immediately after infusion of one of the activated prothrombin complex products (such as Autoplex). It has been advised that antifibrinolytic substances should be avoided in conjunction with Autoplex.

Skin

An erythematous pruritic eruption has been described after infusion of Autoplex (3).

Immunologic

In about 5% of patients with hemophilia A with antibodies to factor VIII treated with an activated prothrombin

complex product (Autoplex), there was a significant increase in antibody titer (10).

Susceptibility Factors

Relative contraindications for prothrombin complex concentrate are liver disease, coronary heart disease, and factors that predispose to thrombosis (11). It is contraindicated in disseminated intravascular coagulopathy and hyperfibrinolysis.

Protirelin

General Information

Protirelin is a synthetic tripeptide that stimulates the hypophyseal secretion of thyrotrophin (thyroid-stimulating hormone, TSH). It is used mainly for diagnostic purposes in dynamic tests of pituitary and hypothalamic function, but its use in the assessment of hyperthyroidism has been superseded by sensitive assays of thyrotrophin (SED-13, 1311) (1). Protirelin has neurotransmitter properties and has been used to treat a variety of neurological disorders, including intractable epilepsy (2). Some experiments have also been performed to evaluate its effects in mental disorders.

Protirelin is generally given intravenously (as a bolus of 200 micrograms), as absorption after oral and intranasal administration is unpredictable.

Comparative studies

Protirelin has been given antenatally in combination with a glucocorticoid, to accelerate fetal lung maturation in an attempt to reduce the incidence of infant respiratory distress syndrome. However, there was no improvement in outcome and the mothers experienced more adverse effects (particularly flushing, headache, nausea, and vomiting) in the protirelin group in two large prospective studies (3,4). The infants were reported to have mild developmental delay at 12 months of age (5): this finding was initially criticized because of methodological problems and there was no consensus that protirelin induces harmful effects in these infants (6).

Subsequently, the addition of protirelin to glucocorticoid therapy was the subject of a meta-analysis (7). In 1134 premature infants the serum TSH concentration was increased for the first 6 hours after the last maternal dose of protirelin, then suppressed for 36 hours before returning to control values (8). The largest controlled trial (in 1368 infants) reported a small delay in development at 12 months (5). However, developmental assessment was by questionnaire, with incomplete ascertainment, and these findings have been questioned (6). In the mothers, there was a three-fold increase in nausea, vomiting, or flushing and a two-fold increase in hypertension compared with glucocorticoid therapy alone.

General adverse effects

The adverse effects of protirelin are usually mild. These include facial flushing, urinary urgency, vaginal sensations, nausea, chest pain, and altered taste sensation (9).

Organs and Systems

Cardiovascular

A transient rise in blood pressure occurs immediately after the administration of protirelin (10). In very rare cases, transient amaurosis and bronchospasm have been reported, thought to be due to either vasopressor syncope or cardiac arrhythmias (11–13).

Nervous system

The most serious adverse effect of protirelin is pituitary apoplexy (pituitary hemorrhage or infarction, characterized by severe headache, visual loss, and often by pituitary failure, hypotension, and coma). This complication has been described in 15 cases after pituitary function testing with protirelin. Pituitary macroadenoma was present in all cases. Although insulin and gonadorelin were also used in these patients, protirelin was considered to be

© 2006 Elsevier B.V. All rights reserved.

the most likely agent responsible, owing to its vasoactive properties (SED-13, 1311) (14).

- A woman developed severe bifrontal headache and visual blurring 5 minutes after the intravenous administration of protirelin 200 micrograms to investigate her pituitary macroadenoma (15). The symptoms resolved in less than 2 hours without sequelae.
- A patient developed a severe headache, nausea and vomiting, visual disturbance, and altered mental function 88 hours after a protirelin/gonadorelin stimulation test to investigate a pituitary macroadenoma (16). Bleeding into the tumor was seen on CT scan. The patient died 9 days later of pneumonia.

Loss of consciousness or convulsions occurred in a few patients who received high doses (400 micrograms) of protirelin intravenously.

Proton pump inhibitors

See also Individual agents

General Information

Proton pump inhibitors inhibit the H/K-ATPase (proton pump) in oxyntic cells of the stomach, the final common pathway in the secretion of gastric acid in response to a variety of stimuli, such as gastrin and histamine. Their use in acid-related disorders has been extensively reviewed (1–3).

Comparative studies

Comparisons between proton pump inhibitors

Lansoprazole 15 mg/day and omeprazole 10 mg/day for 4 weeks have been compared in the relief of heartburn and epigastric pain in a randomized, double-blind, parallel-group study in 609 patients with acid-related dyspepsia (4). Low-dose lansoprazole was more effective in controlling symptoms. There were no significant differences in adverse events between the two groups, although there was a trend toward a higher incidence of more severe adverse events with omeprazole. Most of the reported adverse events were difficult to relate to the treatments.

An unblinded questionnaire survey has been carried out to determine patients' perceptions of differences in the efficacy, adverse effects, and value of omeprazole versus lansoprazole for gastro-esophageal reflux disease maintenance therapy (5). The patients had been taking omeprazole for at least 2 months and then switched to lansoprazole for a minimum of 2 months. There was no significant difference between median symptom scores with the two drugs, but 64% of patients preferred omeprazole to lansoprazole. The most commonly reported adverse effects with both drugs were flatulence, headache, and diarrhea. Significantly more patients reported adverse effects with lansoprazole than with omeprazole.

Rabeprazole 20 mg/day has been compared with omeprazole 20 mg/day in a randomized, double-blind, multicenter study in 205 patients with active duodenal ulcers (6). Rabeprazole produced healing rates equivalent to omeprazole at 2 and 4 weeks of treatment (69 versus 61% and 98 versus 93% respectively) and greater improvement in day-time pain. Both drugs were well tolerated; adverse effects were similar, and included

© 2006 Elsevier B.V. All rights reserved.

headache, infections, diarrhea, gastritis, stomatitis, rash, and sweating. Serum gastrin concentrations increased over time in both groups. There was a statistically significant difference between the groups in the mean change in fasting serum gastrin from baseline to end-point; +40 pg/ml with rabeprazole and +19 pg/ml with omeprazole. However, mean values at the end of the study were in the reference range in both groups.

Rabeprazole 20 mg/day and omeprazole 20 mg/day have been compared in the treatment of erosive or ulcerative esophagitis in a double-blind, multicenter study in 202 patients (7). Overall healing rates for rabeprazole and omeprazole at 4 and 8 weeks of treatment were equivalent (81 versus 81% and 92 versus 94% respectively), as was symptom relief. Both drugs were well tolerated, and there was no significant difference in reported adverse events, except for flatulence, which was only reported by patients taking omeprazole (4%). Other adverse effects included headache, diarrhea, rash, flu-like syndrome, gastroenteritis, raised aspartate transaminase and gamma-glutamyltransferase, weakness, myalgia, somnolence, and hypertension. Serum gastrin concentrations increased over time in both groups; however, there was no significant difference between the treatment groups in the mean change in fasting serum gastrin concentrations from baseline to end-point.

The proton pump inhibitors produce a higher intragastric pH in the presence of *Helicobacter pylori* than after eradication. The mechanism of this effect is unclear, but possible explanations are reduced production of ammonia or other neutralizing substances after eradication of the infection or the development of gastritis during omeprazole therapy in the presence of *H. pylori*, leading to reduced acid secretion. In a double-blind, crossover study in 13 subjects with *H. pylori*, pumaprazole (BY841) 100 mg bd, a reversible proton pump inhibitor, which (unlike omeprazole) does not require activation in the acid compartment of the parietal cell, produced a similar rise in intragastric pH to that produced by omeprazole before and after eradication of *H. pylori* (8). Adverse events during the study were mild and assessed as probably not related to the drugs. They included headache, abdominal pain, and diarrhea. Serum gastrin concentrations rose during pumaprazole therapy and were higher than during omeprazole therapy, both before and after eradication of *H. pylori*.

The common adverse events during treatment with proton pump inhibitors used in general practice in England have been reviewed in a prescription event monitoring study in 16 205 patients taking omeprazole, 17 329 taking lansoprazole, and 11 541 taking pantoprazole (9). The commonest adverse events in all three groups were diarrhea, nausea/vomiting, abdominal pain, and headache. There was little difference in the adverse event rates between the three groups. However, diarrhea was more commonly associated with lansoprazole compared with omeprazole, particularly in elderly people.

To assess acid control, esomeprazole 20 or 40 mg/day has been compared with omeprazole 20 mg/day for 5 days in a double-blind, crossover study in 38 patients with symptoms of gastro-esophageal reflux disease (10). Pharmacokinetic variables and 24-hour intragastric pH were measured on day 5 of each dosing period. Esomeprazole provided more effective acid control than omeprazole. Both dosages of esomeprazole were well tolerated, and the profile and incidence of adverse events were similar to that observed with omeprazole. The most common were abdominal pain, nausea, diarrhea, respiratory infection, and headache.

Esomeprazole 20 or 40 mg/day and omeprazole 20 mg/day for 8 weeks have been compared in the treatment of gastro-esophageal reflux disease in a multicenter, randomized, double-blind trial in 1960 patients (11). Symptom control and healing rates were significantly better with either dose of esomeprazole than with omeprazole. There was no significant difference in reported adverse events between the treatment groups. The most commonly reported were headache, abdominal pain, and diarrhea.

The results of a therapeutic interchange program, in which 78 patients with acid peptic disease requiring proton pump inhibitor therapy (both newly diagnosed patients and those previously stabilized on omeprazole) were treated with lansoprazole, have been retrospectively analysed (12). Although the switch was associated with considerable pharmaceutical savings, there was an overall lansoprazole-associated failure rate of 28%. Reported lack of efficacy required withdrawal of lansoprazole in 15%, while adverse effects required withdrawal of lansoprazole in 13% of patients (versus none with omeprazole). The main adverse effect was diarrhea.

The clinical and fiscal impact of replacing omeprazole with lansoprazole as the only proton pump inhibitor has been assessed by reviewing the medical records of 3833 patients requiring long-term proton pump inhibitor therapy (2224 were started on lansoprazole and 1479 were converted from omeprazole to lansoprazole) (13). There were considerable pharmaceutical savings. The true lansoprazole failure rate (requiring conversion to omeprazole) was 5.3%. Withdrawal of lansoprazole was due to poor symptom control (in 69%) and/or adverse effects (in 22%). The most common adverse effects were diarrhea (10%), abdominal pain (5%), and urticaria (1%).

Omeprazole 40 mg/day for 6 weeks and lansoprazole 30 mg bd have been compared for symptom control in a randomized study in 96 patients with gastro-esophageal reflux disease who had earlier failed to respond to lansoprazole 30 mg/day (14). The two drugs were equally effective in symptom control. There were no significant differences in adverse events between the two groups. The most frequent adverse events reported were diarrhea, abdominal pain/discomfort, bloating/gas, vomiting, and headache.

Omeprazole multiple unit pellet system (MUPS) 20 mg/day and pantoprazole 40 mg/day for 8 weeks were more effective than lansoprazole 30 mg/day in relieving heartburn in a randomized, double-blind trial in 461 patients with symptomatic reflux esophagitis (15). Patient satisfaction and adverse effects were similar in the three groups. The most common adverse effects were diarrhea, headache, and nausea.

In a multicenter, double-blind, crossover study in primary care in 240 patients with acid-related disorders, omeprazole 20 mg/day and rabeprazole 40 mg/day for 4 weeks provided similar symptom control (16). The adverse effect profiles were also similar in the two groups. However, more patients preferred rabeprazole to omeprazole.

© 2006 Elsevier B.V. All rights reserved.

Omeprazole 40 mg/day and rabeprazole 20 mg/day for 4 weeks have been compared in a randomized, double-blind trial in 251 patients with erosive esophagitis (17). The two treatments had similar efficacy in relieving symptoms on day 4 and healing esophageal lesions, but rabeprazole had a faster onset of action in patients with severe heartburn. Both drugs were well tolerated and gave rise to similar frequencies of adverse effects, commonly involving the gastrointestinal tract (10%) and nervous system (4.4%).

Rabeprazole 10 or 20 mg bd and omeprazole 20 mg/day have been compared in the healing of erosive gastro-esophageal reflux disease in a double-blind, multicenter study in 310 patients (18). Overall healing rates for rabeprazole (both dosage regimens) and omeprazole at 4 and 8 weeks of treatment were equivalent. The drugs were equally well tolerated, and there was no significant difference in reported adverse events. The more frequent were abdominal pain, pharyngitis, bronchitis, headache, and diarrhea.

Esomeprazole 40 mg/day and omeprazole 20 mg/day for 8 weeks have been compared in the treatment of erosive esophagitis in a multicenter, randomized, double-blind trial in 2425 patients (19). Significantly more patients were healed with esomeprazole. There was no significant difference in reported adverse events between the treatment groups. The most commonly reported were headache, diarrhea, and nausea.

The effects of omeprazole 40 mg/day and esomeprazole 40 mg/day for 5 days on intragastric acidity have been compared in an open, crossover study in 130 patients with symptoms of gastro-esophageal reflux (20). Esomeprazole provided more effective acid control than twice the standard dose of omeprazole. Adverse effects were similar with the two drugs, and the most commonly reported were headache, nausea, and abdominal pain.

Pantoprazole 20 mg/day and omeprazole 20 mg/day for 8 weeks have been compared in the treatment of grade I reflux esophagitis in a multicenter, randomized, open trial in 328 patients (21). Symptom relief and healing rates were similar and both treatments were well tolerated. There was no significant difference in reported adverse events between the groups. The most commonly reported were nausea, diarrhea, and headache.

Lansoprazole 30 mg/day and omeprazole 20 mg/day for 8 weeks have been compared in the relief of heartburn in a multicenter, randomized, double-blind trial in 3510 patients with erosive esophagitis (22). Symptom control was significantly more effective and faster with lansoprazole than omeprazole. Both drugs were well tolerated. The most common adverse effect was diarrhea.

Rabeprazole 10 mg bd or 20 mg/day, omeprazole 20 mg/day, and placebo for 7 days in reducing esophageal acid exposure have been compared in a multicenter, randomized, double-blind trial in 82 patients with symptomatic gastro-esophageal reflux disease (23). Esophageal pH was monitored for 24 hours before treatment and on day 7. Esophageal acid exposure was significantly reduced in all the treatment groups compared with placebo, with no significant difference in efficacy. Both rabeprazole and omeprazole were well tolerated. The most commonly reported adverse effects were diarrhea, abdominal pain, nausea, and headache.

Comparisons between proton pump inhibitors and H_2 receptor antagonists

The effects of famotidine 20 mg bd and omeprazole 20 mg/day for 8 weeks have been compared in the treatment of reflux esophagitis in a randomized trial in 56 patients (24). Omeprazole was more effective in healing esophagitis and providing symptom relief. Adverse events, which were rare, were similar in the two groups, and consisted of nausea, palpitation, abdominal pain, and mild abnormalities of liver function tests.

Lansoprazole 30 mg/day, lansoprazole 15 mg/day, and ranitidine 150 mg/day have been compared in a randomized, double-blind, multicenter trial in the prevention of relapse of duodenal ulcer and symptom control over 12 months in 359 patients (25). Both doses of lansoprazole were superior to ranitidine. There was no significant difference between the two lansoprazole groups, although there was a trend in favor of lansoprazole 30 mg/day. There were no differences in adverse effects profiles in the three groups. The adverse effects included diarrhea, abdominal pain, viral infections, headache, and vomiting.

Lansoprazole 30 mg/day, lansoprazole 15 mg/day, and ranitidine 150 mg bd for 8 weeks have been compared in a randomized, double-blind, multicenter trial in the healing of NSAID-associated gastric ulceration in 353 patients (26). Both doses of lansoprazole were superior to ranitidine in healing gastric ulcers. Healing rates were similar between *H. pylori* infected and non-infected patients, again with significantly better healing rates with lansoprazole than ranitidine. There were no differences in adverse effects profiles in the three groups. The most commonly reported adverse effect was diarrhea.

Lansoprazole 15 or 30 mg/day and ranitidine 150 mg bd for 8 weeks have been compared in the treatment of non-erosive gastro-esophageal reflux disease in two double-blind, multicenter trials in 901 patients (27). Overall symptom control was significantly better with either dose of lansoprazole than with ranitidine or placebo. There was no significant difference in reported adverse events between the treatment groups. The more commonly reported were abdominal pain and diarrhea.

Pantoprazole 20 mg/day (low dose) and ranitidine 300 mg/day (standard dose) have been compared in the treatment of mild gastro-esophageal reflux disease in a double-blind, multicenter trial in 201 patients (28). Overall symptom control and healing rates were significantly better with pantoprazole. There was no significant difference in reported adverse events between the treatment groups. The more commonly reported were diarrhea, headache, and abdominal pain.

General adverse effects

The adverse effects profile of the proton pump inhibitors during short-term administration (under 12 weeks) is similar to that reported with short-term use of histamine receptor antagonists. The type and frequency of adverse effects reported with lansoprazole, omeprazole, pantoprazole, and rabeprazole are comparable. The most common adverse effects include headache, diarrhea, nausea, abdominal pain, constipation, dizziness, and skin rashes.

Proton pump inhibitors can interact with other drugs by increasing gastric pH, inhibiting hepatic cytochrome

© 2006 Elsevier B.V. All rights reserved.

P450, or inducing specific isoforms of this enzyme system. However, drug interactions involving these isoenzymes and omeprazole or lansoprazole are uncommon and generally appear to be clinically unimportant. Pantoprazole seems to have a lower drug interaction potential than either omeprazole or lansoprazole.

Organs and Systems

Cardiovascular

Reversible peripheral edema has been reported in five women taking the proton pump inhibitors omeprazole, lansoprazole, or pantoprazole for 7–15 days for peptic disorders in recommended standard doses (29). Edema disappeared within 2–3 days of withdrawal and reappeared in all five patients after re-exposure. High-dose intravenous infusions of omeprazole and pantoprazole (8 mg/hour) caused peripheral edema in three of six young female volunteers and two of six female volunteers respectively. The edema disappeared within 24 hours of stopping the infusion. Similar high doses of omeprazole did not produce edema in male volunteers. Subsequent studies performed on 10 female volunteers to elucidate the cause of the edema did not show any changes in concentrations of serum hormones or C1 esterase inhibitor.

Long-Term Effects

Tumorigenicity

There has been concern about the potential for proton pump inhibitors to cause enterochromaffin-like cell hyperplasia, gastric carcinoid tumors and gastric cancers, colorectal polyps and adenocarcinoma, atrophic gastritis, and intestinal metaplasia in patients with *H. pylori* infection, and bacterial overgrowth.

Carcinoid nodules were detected in the stomach of rats given large doses of omeprazole over prolonged periods. A variety of evidence, however, suggests that these findings were neither specific to omeprazole nor likely to indicate material risks to man (30), and that other arguments for a tumor-inducing effect of proton pump inhibitors are equally unconvincing. Firstly, similar carcinoid change has been detected with secretory antagonists and the fibrates, which are anti-secretory in rats. Secondly carcinoidogenesis can be inhibited by antrectomy, presumably by removing an antral gastrin drive, and it can be enhanced by partial fundectomy, when relative anacidity increases antral gastrin release. Thirdly, although omeprazole treatment can raise serum gastrin levels quite markedly in man, they do so by a level of magnitude less than in pernicious anemia, in which carcinoid tumors are recorded, albeit rarely. Fourthly, despite close searching, carcinoids have not been detected complicating ordinary ulcer treatment in man. Others have claimed on the basis of tissue work in vitro that omeprazole may itself be a mitogen or mutagen; it has been counter-claimed that the technique used in the studies concerned is inherently unreliable and that other standard techniques have failed to reveal mutagenic potential (SED-12, 943). Finally, selective and important actions on a cytochrome which would activate carcinogens have been claimed, but seem unlikely experimentally. This is one of the situations in which there is inherent difficulty in disproving a postulated relationship. Currently it seems very unlikely that an appreciable risk exists, but most experts would now recommend that any patient requiring long-term treatment with a proton pump inhibitor should take treatment to eradicate *H. pylori* infection (SEDA-20, 318).

Therapeutic doses of proton pump inhibitors usually produce somewhat higher serum gastrin concentrations than histamine receptor antagonists. However, except for small intestinal bacterial overgrowth, there is no convincing evidence yet to implicate proton pump inhibitors in the development of malignant or premalignant lesions in the human gastrointestinal tract. Nevertheless, although omeprazole has been used for more than 14 years and lansoprazole for more than 10 years, longer-term data are required to completely rule out the possibility of increased risk of gastric tumor formation.

An increasing number of gastric polyps is being reported in patients taking proton pump inhibitors. Although these may be coincidental and may only account for a minority of sporadic cases (31), it is too early to disregard the possibility that they are treatment induced (32). Long-term prospective controlled trials including investigation of the effects of stopping and restarting proton pump inhibitors on the evolution of gastric polyps will have to be done before a firm causal relation can be established.

An uncontrolled retrospective study of patients who had taken proton pump inhibitors for an average of 33 months found gastric polyps in 17 of 231 patients who underwent two or more endoscopies for complicated gastro-esophageal reflux disease (33). The polyps were generally small (under 1 cm), sessile, and multiple, and were present in the proximal or mid gastric body. Of the 15 polyps removed endoscopically, nine were fundic gland type, four were hyperplastic, and two were inflammatory. None had any dysplasia or carcinoma.

A gastric carcinoid tumor, detected during long-term anti-ulcer therapy with a histamine receptor antagonist and proton pump inhibitors, has been reported (34).

- A 31 year old Japanese man with recurrent duodenal ulcer was treated with famotidine, omeprazole, and lansoprazole at different times over 3 years. Gastroscopy showed a small carcinoid tumor in the upper cardia after 35 months. The lesion became larger while the patient was taking lansoprazole.

Proxymetacaine

See also Local anesthetics

General Information

Proxymetacaine is an ester of meta-aminobenzoic acid. It is often used in ophthalmology.

Organs and Systems

Skin

Proparacaine has been reported to cause contact dermatitis.

- A 49-year-old ophthalmologist developed fissuring and bleeding of his finger-tips (1). Skin patch tests using a series of standard and preservative allergens showed only mild reactions to some. Various treatments were attempted, with minimal success, and skin patch testing was repeated using 32 specific formulations that he had contact with in his practice; he had a severe reaction to proxymetacaine hydrochloride 0.5%. Subsequent removal of proparacaine from his practice resulted in resolution over 6 months.
- An ophthalmologist developed chronic finger pad dermatitis with fissuring and scaling, which mainly affected his thumbs for 3 years (2). Patch testing confirmed that "ophthetic solution" (proxymetacaine hydrochloride 0.5%, glycerine, and benzalkonium chloride 0.01%) was the sensitizing agent. He was instructed to change to tetracaine, to which he had had a negative patch test. However, 2 years later his symptoms recurred and a repeat patch testing was carried out. This was now positive to both tetracaine 1% and proxymetacaine 0.5%.

Cross-sensitization between proxymetacaine and tetracaine is thought to be rare. Moreover, the chemical structure of proxymetacaine is sufficiently different from tetracaine to make cross-reactivity unlikely. This case suggests, however, that some degree of cross-sensitization can occur.

Proxyphylline

General Information

Proxyphylline is a theophylline derivative used as a bronchodilator. It is readily absorbed from the gastrointestinal tract and is not converted to theophylline.

In 12 patients with chronic obstructive pulmonary disease, intravenous proxyphylline 16 mg/kg lowered airway resistance by 30% in 9 patients and by 40% in 7 (1). There were no serious adverse effects and, in particular, no adverse cardiovascular effects or muscle tremor.

In a short-term, double-blind, crossover study in 10 adult asthmatics, a modified-release formulation of proxyphylline (2400 mg/day) was compared with theophylline (800 mg/day) and placebo (2). There were no significant differences between the treatments with regard to relief of asthma symptoms, the need for additional medication, or the incidence and intensity of adverse effects. The adverse reactions included loss of appetite, palpitation, headache, nausea, stomach ache, muscle tremor, and sleep disturbances.

Pyrantel

General Information

Pyrantel is an antihelminthic drug that is effective against intestinal nematodes, including roundworms (*Ascaris lumbricoides*), threadworms (*Enterobius vermicularis*), *Trichostrongylus* species, and the tissue nematode *Trichinella spiralis*. Although it is effective against hookworms, it is less effective against *Necator americanus* than against *Ancylostoma duodenale*.

Pyrantel is usually given as the embonate or pamoate in a single dose of 10 mg/kg, and adverse reactions rarely

© 2006 Elsevier B.V. All rights reserved.

impede treatment. They include gastrointestinal disturbance (nausea, anorexia, abdominal pain, diarrhea), headache, and vomiting, which are usually mild but can occur in up to 20% of patients.

Organs and Systems

Nervous system

Myasthenia gravis has reportedly been aggravated by pyrantel pamoate (1).

Liver

In children aged 5–10 years pyrantel caused mild transient changes in liver function tests (2).

Drug–Drug Interactions

Theophylline

An interaction of pyrantel with theophylline has been reported (3).

- An 8-year-old boy with status asthmaticus was given intravenous aminophylline and then switched to modified-release oral theophylline on day 3, when his serum theophylline concentration was 15 μg/ml. On day 4 he was given a single dose of pyrantel 160 mg (for *A. lumbricoides* infection) at the same time as his second oral dose of theophylline. About 2.5 hours later his serum theophylline concentration was 24 μg/ml, and a further 1.5 hours later it had risen to 30 μg/ml. No further theophylline was given and no theophylline toxicity occurred.

Pyrazinamide

See also Antituberculosis drugs

General Information

Pyrazinamide is a pyrazine analogue of nicotinamide. It is bactericidal for *Mycobacterium tuberculosis* in an acid environment and within macrophages (1). Regimens that include pyrazinamide produce significantly more rapid rates of sputum conversion than any other combination. Pyrazinamide is therefore especially appropriate in the initial phase of treatment. In the 6-month regimen of the American Thoracic Society, pyrazinamide was used together with isoniazid and rifampicin for the first 2 months (2).

Pyrazinamide is distributed throughout the body. Peak plasma concentrations are reached 2 hours after oral administration. Excretion is primarily by glomerular filtration. Serum concentrations are generally 30–50 μg/ml with daily doses of 20–25 mg/kg. The maximum daily dose should not exceed 3 g, regardless of weight. At a pH of 5.5, the minimal inhibitory concentration of pyrazinamide for *Mycobacterium tuberculosis* is 20 μg/ml (1).

Observational studies

The combination of pyrazinamide plus levofloxacin is first-line treatment for multidrug-resistant latent tuberculosis. In 17 Canadian patients there were important adverse reactions affecting the musculoskeletal and central nervous systems; hyperuricemia, gastrointestinal effects, and dermatological effects were also common (3). This combination may be used with careful monitoring for adverse effects.

General adverse effects

Most of the adverse effects of pyrazinamide are toxic effects. Reactions involving the liver, hyperuricemia with and without gout, and symptoms of pellagra have particularly been recognized. Fever and urticaria are described. Sideroblastic anemia, thrombocytopenia, anorexia, nausea and vomiting, dysuria, malaise, and aggravation of peptic ulcer can occur (SEDA-13, 261). Allergic reactions and tumor-inducing effects have not been reported.

Organs and Systems

Cardiovascular

Acute symptomatic hypertension consistently followed the administration of pyrazinamide to a 65-year-old woman with pulmonary tuberculosis (4).

Metabolism

Pyrazinamide interferes with the renal excretion of urate, resulting in hyperuricemia. Acute episodes of gout or arthralgia have occurred. Arthralgia responds better to NSAIDs than to uricosuric drugs (5).

Pyrazinamide can aggravate porphyria (1).

Liver

Liver damage is the most common adverse effect of pyrazinamide (6). It varies from asymptomatic alteration of liver function detectable only by laboratory tests, through a mild syndrome characterized by fever, anorexia, malaise, liver tenderness, hepatomegaly, and splenomegaly, to more serious reactions with clinical jaundice, and finally the rare form with progressive acute yellow atrophy and death. As most patients take a combined regimen of pyrazinamide with isoniazid and rifampicin, it is difficult to determine which of the three drugs causes the hepatotoxicity; it could be due to a combined effect (7). As with isoniazid and rifampicin, hepatic function should initially be monitored every few weeks.

© 2006 Elsevier B.V. All rights reserved.

Skin

Pyrazinamide can cause pellagra. However, prophylactic nicotinamide is not generally recommended. In cases of pellagra, a dosage of 300 mg/day should be given (8).

In one case, erythema multiforme and urticaria occurred together after administration of pyrazinamide, and there were circulating immune complexes (9).

Photosensitization has been rarely described in patients taking pyrazinamide (10).

Susceptibility Factors

Age

00Although pyrazinamide is a part of conventional combination therapy for children with tuberculosis, as in adults (11), there is little published information on its safety. In those with raised transaminases before the start of therapy there was no increase during therapy, and the activities normalized in all patients after its conclusion.

Hepatic disease

Pyrazinamide should be avoided in patients with liver disease and porphyria (1). Liver function tests should be repeated at frequent intervals during the entire period of treatment.

Other features of the patient

Pyrazinamide should be used with extreme caution in patients with a history of gout, especially in elderly people, in whom urinary urate stones can cause renal insufficiency.

In patients with hemoptysis, the possibility that pyrazinamide may have an adverse effect on blood clotting time or vascular integrity should be borne in mind (12,13).

Pyridoxine

See also Vitamins

General Information

Pyridoxine (vitamin B_6) requirements vary with protein intake: the daily Average Requirement is 13 micrograms/g protein intake and the Population Reference Intake is 15 micrograms/g protein intake. In adults this translates into a daily Average Requirement of 1.3 mg/day for men and 1.0 mg/day for women, and a Population Reference Intake of 1.5 mg/day for men and 1.1 mg/day for women.

Uses

Pyridoxine is used to prevent the adverse nervous system effects of isoniazid (1). Adherence to therapy is improved by prescribing combined tablets containing 20 mg of pyridoxine per 100 mg of isoniazid.

Megadoses of pyridoxine are commonly used to treat homocystinuria, cystathioninuria, and primary oxalosis type I (2,3). In some diseases pyridoxine is used empirically, including rheumatic diseases, degenerative joint diseases, carpal tunnel syndrome, Chinese restaurant syndrome, and premenstrual syndrome. A rare form of neonatal seizures, reported as early as 1954, seems to respond only to large doses of pyridoxine (4,5). Occasionally, the condition can appear up to 2 years after birth. Affected patients can have abrupt seizure cessation and dramatic improvement in the electroencephalogram after receiving an intravenous dose of pyridoxine 50–100 mg. The mechanism of this rare condition is unclear. It has been suggested that in these infants there is a shift in the balance of glutamate and GABA in the central nervous system; giving pyridoxine increases the co-enzyme pool, offsetting the adverse kinetics that result from altered glutamate decarboxylase binding. One adverse consequence

© 2006 Elsevier B.V. All rights reserved.

of the large dose of pyridoxine required is a diffuse inhibitory state, with effects ranging from excessive drowsiness to coma and electrocerebral silence. Resuscitation equipment should be on hand if this treatment is used.

Extremely high doses of pyridoxine, even up to 6000 mg/day, have also sometimes been used therapeutically. While few problems arise from controlled application of high doses of pyridoxine under medical supervision, self-medication in doses exceeding 300–500 mg/day can lead to adverse effects, especially when continued over a long period of time. Many patients have self-medicated with more than 2000 mg/day for long periods of time (SEDA-10, 334) (6,7).

In many countries, pyridoxine is a component of "vitamin B complex" products, administered orally or parenterally as "tonics," commonly because of their supposedly beneficial effects on the nervous system.

General adverse effects

Under the headline "Still time for rational debate about vitamin B_6" the controversial debate on the safety of pyridoxine has been revived (8). Pyridoxine is marketed for stress in general, for depression associated with premenstrual syndrome and oral contraceptives, and for carpal tunnel syndrome, although it is doubtful that it has more than a placebo effect. It is legitimately prescribed in general deficiency states in doses starting at 150 mg/day. Adverse events include sensory neuropathy at oral doses about 2–3 g/day or more.

The editorial refers to the attempts of the UK Government's Committee on Toxicity to find the safe level of daily consumption of pyridoxine. In July 1997 the committee recommended that the sale of pyridoxine in, for instance, health-food shops would be restricted to doses of 10 mg/day. Doses between 10 and 50 mg would be restricted to sale at pharmacies; and doses of 50 mg and above would be available only on prescription. Contrary to these UK recommendations the Committee of the US National Academy of Science concluded that there were no convincing reports of adverse events at doses of up to 200 mg/day. Paying attention to the fact that recommendations tend to be more cautious than might seem necessary from the available evidence, the US experts halved the 200 mg/day dose to define their limit as 100 mg/day.

The author of the editorial found fault with the fact that the US experts have based their recommendations on the slimmest of evidence. The main human study was a self-recall series of 172 patients presenting to a private practice in London (9). In a letter to the editor, Beckett (10) pointed out that daily doses of 200 mg or less have been taken by millions of people worldwide for several decades without evident toxicity and that testimonials from clinicians expert in the use of pyridoxine have attested to its safety in these doses (11). Referring to the editorial, the author of the study in question stated that their study referred to 172 women with raised blood concentrations of pyridoxine that reverted to normal within 4 days of stopping pyridoxine, and was not a "self-recall series." In a recent follow-up of these women who had raised blood concentrations, compared with controls from the same practice who had had a blood test in 1985–86 and whose record showed that they were not taking pyridoxine or multivitamins at that time or since, 16 of 50 respondents had subsequently had autoimmune disease, compared with one of the 38 controls. The autoimmune diseases included thyroid disease ($n = 5$), rheumatoid arthritis ($n = 3$), diabetes ($n = 2$), Sjögren's syndrome ($n = 2$), primary biliary cirrhosis ($n = 1$), polymyalgia rheumatica ($n = 1$), and polyarteritis nodosum ($n = 1$). In the controls there was one case of diabetes.

In another letter to the editor (12) it was mentioned that the suspicion of partiality about the Committee on Toxicity becomes more plausible when one considers the issue of homocysteine. This intermediate metabolite may well turn out to be of greater importance as a risk factor for cardiovascular disease than cholesterol and blood pressure. Raised homocysteine concentrations appear to be accessible to treatment with pyridoxine (100 mg/day) together with vitamin B_{12} and folic acid (13). Furthermore, the statement that there is no good evidence for the efficacy of pyridoxine in any disease, apart from depression, was criticized, because this ignores important studies in autism, pregnancy outcome, asthma, and sickle-cell anemia (12).

In a systematic review on the efficacy of pyridoxine in the treatment of premenstrual syndrome, adverse effects were reported in 63 patients (6.7%) (see Table 1) (14). In another study of 940 women one had a neuropathy associated with pyridoxine toxicity (15).

Table 1 Adverse effects of pyridoxine in the treatment of premenstrual syndrome

Number taking		Dosage and duration	Adverse effects	Number with adverse effects	
Pyridoxine	Placebo			Pyridoxine	Placebo
204	230	10–200 mg/day	Tingling in the fingers	11	8
49	70	200 mg/day*, four cycles		5	1
46	59	100 mg/day*, four cycles		5	2

Organs and Systems

Nervous system

Pyridoxine has both dopamine-enhancing and dopamine-blocking properties: on the one hand pyridoxine (like dopamine) depresses the release of prolactin from the pituitary gland; on the other hand, in oral doses of 10–20 mg it rapidly reverses the therapeutic effect of dopamine (16). This should be borne in mind if pyridoxine is prescribed for nursing mothers or for patients treated with levodopa for Parkinson's disease or syndrome, although the problem does not seem to arise when using the combination of levodopa with decarboxylase inhibitors.

Reviews of sensory neuropathies and pyridoxine toxicity have been published (17–19). Sensory neuropathy has been described in certain individuals taking high daily doses of pyridoxine on a long-term basis. Although it is generally reversible, a chronic painful neuropathy can occur. Besides individual patient susceptibility, the risk of neurotoxic effects of pyridoxine is related to both the daily dose and the duration of administration. Peripheral neuropathy did not develop in individuals taking 500 mg/day for up to 2 years, whereas it did develop almost universally in patients who took more than 1000 mg/day for variable periods (17). In an adult, a daily dose of 500 mg/day is about 7.1 mg/kg/day. Therefore a child with pyridoxine-dependency taking 5 mg/kg/day may not be at risk of neuropathy. Only one patient with pyridoxine-dependent seizures in whom a sensory neuropathy developed has been described (20). It is recommended that patients with this disorder who will require life-long pharmacological doses of pyridoxine should be assessed for signs of a sensory peripheral neuropathy.

Sensory neuropathy was reported as an adverse effect in eight patients with homocystinuria who took 600–1200 mg/day of pyridoxine for 4–22 years. Nerve conduction studies of the sural nerve in five affected patients showed abnormalities in four (21). Neuropathies have been observed in women taking doses as low as 50–500 mg/day for one to several months (22,23).

Neurotoxicity can be associated with pyridoxine megavitamin therapy (24), the main symptom being a peripheral sensory neuropathy (see Table 2) (25,26).

Table 2 Peripheral sensory neuropathy during pyridoxine megatherapy

Hematologic

Reduced serum folate concentrations have been demonstrated in patients with homocystinuria taking pyridoxine. The mechanism of this effect may involve removal of substrate inhibition of the enzyme, *N*5-methyltetrahydrofolate homocysteine methyltransferase, due to pyridoxine-induced reduction of the substrate, homocysteine (27).

Skin

Pyridoxine-induced photosensitivity has been reported in a patient with hypophosphatasia (28).

- A 30-year-old woman, a heterozygote for hypophosphatasia, who had been taking two tablets of a multivitamin formulation (pyridoxine hydrochloride 100 mg, riboflavin butyrate 30 mg, nicotinamide 40 mg, biotin 0.05 mg, ascorbic acid 100 mg) once daily for 6 years, had severe skin eruptions and pruritus on exposure to the sun. The minimum erythema doses for UVB (20 mJ/cm^2) and UVA (4 J/cm^2) were lower than normal only for UVB (reference ranges 60–100 mJ/cm^2 for UVB and below 10 J/cm^2 for UVA). Patch and photopatch tests with the constituents of the tablets produced reactions to pyridoxine and pyridoxal phosphate only.

The authors suggested that photosensitivity in this patient may have been caused by abnormal metabolism of pyridoxine because of hypophosphatasia. Pyridoxine (given alone or in combination with vitamin B_{12}) can aggravate acne vulgaris or eruption of an acneiform exanthema (29). Excessive doses of pyridoxine appear to cause a metabolic defect that impairs the structural integrity of the skin, especially during the summer months (30). There are some case reports of photosensitive dermatitis caused by pyridoxine hydrochloride (31–33). Vesicular skin lesions on the hands and feet have also been reported, possibly as a symptom secondary to the neurological disturbances (34).

Contact hypersensitivity to pyridoxine is rare. Only three cases of allergy to pyridoxine have been reported: in hair lotion (35), a glucocorticoid cream (36), and a skin cream (Iruxol) (37). There have also been a few reports of photosensitivity due to pyridoxine hydrochloride (30,31,33).

Occupational systemic contact dermatitis with photosensitivity has been attributed to pyridoxine (38).

- A 45-year-old man developed eczema over the back of his hands, the back and sides of his fingers (sparing the little fingers), the forearms, and the face. This lasted for 6 years, with recurrences and remissions. He was tested with allergens, supplemented with a drop each of various injectable medicaments (streptomycin, benzylpenicillin, ampicillin–cloxacillin, oxytetracycline, vitamins B_1, B_2, and B_{12}, gentamicin, amikacin, and analgesics). Patch tests were positive to nitrofurazane and three different B vitamins. Reactivation of lesions on the hands, face, and neck was noted during patch-testing, and subsided within 1 week. After a further 6 weeks he was tested on the forearms with B_1, B_6, and B_{12}, each in 10% propylene glycol, resulting in a ++ reaction for B_6. Prick testing with B_1, B_2, and B_6 gave negative results. Another 2 months later oral provocation with two tablets each containing B_6 100 mg was performed. Before taking the

© 2006 Elsevier B.V. All rights reserved.

second tablet he started to itch, and 18 hours later he developed itching and severe erythema over the face, neck, back of the hands, forearms, and the distal half of the upper arms (sun-exposed areas). Reactivation of previous positive patch test sites (on the back and forearms) and a negative prick test site were also observed.

Rosacea fulminans is a rare variant of rosacea conglobata and is seen almost exclusively in postadolescent women. It is characterized by the sudden appearance of abscess-forming nodules and draining sinuses. The lesions are usually limited to the center of the face and are precipitated by marked seborrhea. The cause is unknown. Rosacea fulminans temporally associated with the ingestion of high-dose vitamin B supplements has been reported (39).

- A 17-year-old woman with a 5-week history of a facial rash took minocycline (100 mg/day for 14 days) without effect. She had been taking vitamin B supplements (pyridoxine 80 mg, which is over 40 times the recommended daily allowance) and vitamin B_{12} (20 micrograms, which is 20 times the recommended daily allowance) for 2 weeks before the onset of the eruption. She had had low-grade acne vulgaris since puberty and a tendency to facial flushing after drinking alcohol and eating spicy food. There were numerous confluent nodules and pustules on a livid erythematous background on the cheeks and chin, and a few pustules on the neck. There was seborrhea on the affected skin areas. There was an indolent lymphadenopathy in the submandibular region. Histology showed a superficial and deep inflammatory infiltrate with perifollicular distribution, from the upper dermis down to the septa of the subcutaneous fat. Routine laboratory tests showed no abnormalities. There were no pathogenic organisms in bacteriological or mycological cultures from the pustules on the face. She stopped taking the nutritional supplement and was given warm compresses and clobetasol propionate cream twice daily for 2 weeks, methylprednisolone 60 mg/day for 2 weeks, followed by isotretinoin 60 mg/day. Her skin changes resolved within 4 months, with no residual scarring.

Second-Generation Effects

Teratogenicity

- A malformed infant was born to a mother who had taken daily doses of pyridoxine during pregnancy (50 mg for the first 7 months) and unknown doses of lecithin and vitamin B_{12}. The girl was born with near-total amelia of her left leg at the knee (40).

Although this case may have been coincidental, as a precaution, megadoses of pyridoxine should be avoided during pregnancy.

Pyrimethamine

General Information

Pyrimethamine

Pyrimethamine is the most active antimalarial of the 2–4-diaminopyrimidines, its effect being due to inhibition of the conversion of folic acid to its active form, folinic acid. It is also effective in toxoplasmosis. Its antiprotozoal and antimalarial activity is enhanced by the addition of sulfonamides.

Pyrimethamine is well absorbed in healthy subjects; the half-life is 80–95 hours (SEDA-13, 811). Absorption after intramuscular injection is slower; this may be of importance in patients with reduced muscle blood flow (SEDA-17, 328). Pyrimethamine penetrates the cerebrospinal fluid.

With the usual antimalarial prophylactic dosage of 25 mg/week, adverse reactions are generally slight or absent. With intensive treatment in high cumulative doses, as used in the treatment of toxoplasmosis, gastrointestinal intolerance, neurological symptoms, and depression of hemopoiesis can occur. Allergic reactions have not been reported. Tumor-inducing effects have also not been reported.

Pyrimethamine + azithromycin

Azithromycin is efficacious in animal models of toxoplasmic encephalitis. In a Phase I/II dose-escalation study of pyrimethamine (50 mg/day) plus azithromycin (900, 1200, or 1500 mg/day) for induction and maintenance treatment in 30 patients with AIDS and definite or suspected *Toxoplasma* encephalitis, the overall response rate was 67% after 6 weeks of induction therapy (1). However, maintenance therapy for 24 weeks with this combination was associated with a high relapse rate (47%); only six patients successfully completed induction and maintenance therapy. Adverse events were common (particularly in those taking azithromycin 1500 mg) and included hepatotoxicity, bone marrow suppression, ototoxicity, and gastrointestinal disturbances, which led 20% of patients to withdraw. All adverse events resolved on withdrawal.

In a prospective, randomized, open, multicenter trial of pyrimethamine + azithromycin versus pyrimethamine + sulfadiazine for the treatment of ocular toxoplasmosis in 46 patients with sight-threatening ocular toxoplasmosis, the two regimens had similar efficacy; however, the adverse effects were significantly less common and severe with pyrimethamine + azithromycin (2).

Pyrimethamine + clarithromycin

Clarithromycin, a macrolide, and other macrolide and lincosamine antibiotics (azithromycin, clindamycin, spiramycin, and roxithromycin) have been used in combination with pyrimethamine in the treatment of *Toxoplasma gondii* infections, especially cases of *Toxoplasma* encephalitis.

Clarithromycin 2 g plus pyrimethamine 75 mg/day has been given for 6 weeks to a few AIDS patients with encephalitis (SEDA-13, 814). The adverse effects were many and severe: severe thrombocytopenia, anemia, neutropenia, liver toxicity of varying degree, nausea, vomiting, skin rashes, and hearing loss were found in two of three patients tested in a group of 13. The dose of clarithromycin in this study was the maximum dosage used in an earlier investigation of the treatment of mycobacterial infections in HIV-infected patients.

Pyrimethamine + clindamycin

Pyrimethamine 50 mg/day has been used in combination with clindamycin for the treatment of *Toxoplasma* encephalitis in AIDS. Adverse effects were common (rash, diarrhea, nausea), but the incidence of hematological reactions was lower than with the combination of sulfadiazine and pyrimethamine (SEDA-16, 309).

© 2006 Elsevier B.V. All rights reserved.

Pyrimethamine + dapsone

Pyrimethamine and dapsone are available in two fixed combinations:

1. 12.5 mg of pyrimethamine + 100 mg of dapsone = Maloprim.
2. 25 mg of pyrimethamine + 100 mg of dapsone = Deltaprim.

A "dapsone syndrome" was reported in a 30-year-old woman after 4 weeks of treatment with Maloprim and chloroquine base 300 mg/weekly. The symptoms comprised fever, joint and muscle pains, dry cough, and a diffuse red urticarial rash, followed by generalized lymphadenopathy, a painful exudative tonsillitis, and a prominent atypical lymphocytosis.

In Britain, the retrospective reported rate for serious reactions with Maloprim was one in 9100, the incidence of blood dyscrasias being one in 20 000. These figures are lower than those reported with Fansidar (pyrimethamine + sulfadoxine) (SEDA-16, 309).

Pyrimethamine + sulfadoxine

Pyrimethamine 25 mg plus sulfadoxine 500 mg is available in the combination formulation known as Fansidar. This combination, while effective in the prevention and treatment of *Plasmodium falciparum* malaria, carries a high frequency of adverse effects; hematological and serious skin reactions occur, but there are also reports of polyneuritis, vasculitis, and hepatotoxicity. Most of the severe skin reactions and the cases of vasculitis developed within under a month (SEDA-13, 812). The use of Fansidar for malaria prophylaxis has therefore been virtually abandoned (SEDA-21, 297). However, Fansidar is being increasingly used for the treatment of *P. falciparum* malaria in Africa. With the higher dosage used for that purpose, an increase in adverse effects, particularly hematological, can be expected. In Britain the retrospective reported rate for all serious reactions to Fansidar was one in 2100 prescriptions and for skin reactions one in 4900 prescriptions, the death rate being one in 11 100 (SEDA-16, 309).

Observational studies

In a single-arm, open, prospective study between 1990 and 1995 (before HAART) the prophylactic efficacy of Fansidar was evaluated in 95 HIV-infected patients with successfully treated *Pneumocystis jiroveci* pneumonia and no history of *Toxoplasma* encephalitis (3). Patients took Fansidar with folinic acid (15 mg) twice weekly and were followed for a median of 19 (range 1–72) months. Five patients had a *Pneumocystis* relapse, but three had not taken their therapy. Of the 69 patients positive for anti-*Toxoplasma* IgG antibodies, only one developed toxoplasma encephalitis after 50 months. A rash developed in 16 patients after a median of 3 weeks, and required withdrawal in six. Two developed Stevens–Johnson syndrome after three or four doses. There was no significantly increased risk of adverse reactions to Fansidar in patients with previous hypersensitivity reactions to co-trimoxazole. The results of this study are of particular relevance to areas in which HAART is unavailable and where the antimalarial activity of Fansidar may confer additional benefit.

Placebo-controlled studies

In a placebo-controlled study of chemoprophylaxis for malaria, 701 Tanzanian infants were assigned to intermittent pyrimethamine + sulfadoxine (under 5 kg, a quarter of a tablet; 5–10 kg, half a tablet; over 10 kg, one tablet; each tablet contained pyrimethamine 25 mg plus sulfadoxine 500 mg) alongside routine childhood immunizations and iron supplementation at 2, 3, and 9 months of age (4). The combination was well tolerated, with no reported adverse events. Episodes of clinical malaria fell by 59% (95% CI = 41, 72) and the incidence of severe anemia by 50% (95% CI = 8, 73%) in the first year of life. Contrary to previous studies involving continuous prophylaxis in infants, there was no increase in the frequency of rebound episodes of malaria up to 18 months of age, suggesting that the development of malaria-specific immunity was unimpaired. Responses to vaccines were unaffected.

Pyrimethamine + sulfadoxine + mefloquine

Pyrimethamine (25 mg), sulfadoxine (500 mg), and mefloquine (250 mg) are available in the combination formulation known as Fansimef. The adverse effects characteristic of all three components can be expected.

Pyrimethamine + trimethoprim

With the combination of pyrimethamine plus trimethoprim the risk of megaloblastic anemia is higher than with pyrimethamine alone, which on theoretical grounds might be expected. Concomitant administration of folic acid has been recommended (SEDA-11, 590), but the effect of folic acid on efficacy is not known.

Organs and Systems

Respiratory

Pyrimethamine

Non-cardiogenic pulmonary edema has been reported with pyrimethamine alone (SEDA-13, 811).

Pyrimethamine + sulfadoxine

Dyspnea and pleurisy have been described. Of 52 travellers with adverse reactions to Fansidar in Sweden, six had pulmonary infiltrates accompanied by fever (SEDA-13, 241). Such infiltrates have also been described in the past, and in one case a diagnosis of eosinophilic infiltration was made (SEDA-11, 590). A case of non-cardiogenic pulmonary edema was reported in 1989 (SEDA-13, 813).

Nervous system

High doses of pyrimethamine can cause rapid development of neurological symptoms such as ataxia, tremor, and convulsions, probably by a direct toxic effect (SEDA-11, 588).

Hematologic

Pyrimethamine

Leukopenia, agranulocytosis, and thrombocytopenia have been reported and, as might be expected in view of folate antagonism, megaloblastic anemia. The latter is more

© 2006 Elsevier B.V. All rights reserved.

common when high doses are used or when pyrimethamine is given in combination with a drug such as trimethoprim. The bone marrow depression can be reversed using folic acid (SEDA-18, 287).

Pancytopenia has been reported after the use of pyrimethamine alone, but is more often the result of its use in combination with dapsone or sulfonamides (SEDA-11, 589) (SEDA-14, 241) (SEDA-17, 328).

Although the hematological complications of pyrimethamine are generally a consequence of therapeutic use, long-term prophylactic treatment with pyrimethamine and dapsone in malaria could well involve an increased risk of megaloblastic anemia in patients whose nutritional state is not optimal (SEDA-13, 812).

Pyrimethamine + dapsone

The combination of pyrimethamine plus dapsone causes a higher incidence of blood dyscrasias than pyrimethamine alone; in particular, the occurrence of agranulocytosis increases and even deaths have been reported (SEDA-13, 812) (SEDA-18, 287).

Dapsone (alone or in combination with pyrimethamine) can cause methemoglobinemia and hemolytic anemia. These complications tend to be dose-related and are more often encountered in G6PD-deficient subjects (SEDA-18, 287).

When the pyrimethamine + dapsone combination was used in the prophylaxis of *Pneumocystis jiroveci* pneumonia in 173 patients with AIDS, there was anemia in about 20, and in all 117 cases for which data were available, serum haptoglobin concentrations had fallen (SEDA-18, 287).

Pyrimethamine + sulfadoxine

The hematological adverse effects of the combination of pyrimethamine plus sulfadoxine are largely those known from pyrimethamine, that is leukopenia, agranulocytosis, thrombocytopenia, and pancytopenia, but the literature gives the impression that when using this combination these effects are more marked, with lower cell counts (5).

Intermittent iron supplementation with pyrimethamine + sulfadoxine has been investigated in 328 anemic but symptom-free Kenyan children, who were randomly given either iron (ferrous fumarate suspension 6.25 g/l twice a week) or placebo and pyrimethamine + sulfadoxine (25 mg and 1.25 mg/kg once every 4 weeks) or placebo (82 in each group) (6). After 12 weeks, those who took iron and pyrimethamine + sulfadoxine, iron alone, or pyrimethamine + sulfadoxine alone had higher hemoglobin concentrations than those who took the double placebo. No adverse effects were reported.

Severe megaloblastic anemia has also been described (7).

- Hemolytic–uremic syndrome was reported in a 24-year-old man with glucose-6-phosphate dehydrogenase (G6PD) deficiency (SEDA-18, 288).

Gastrointestinal

Gastric disturbances due to pyrimethamine are dose-related; the high doses used in the treatment of toxoplasmosis caused abdominal pains, vomiting, and dizziness (8). Gastrointestinal bleeding related to thrombocytopenia has also been reported (SEDA-11, 589).

Liver

Pyrimethamine + sulfadoxine

Liver function abnormalities with Fansidar (pyrimethamine + sulfadoxine) vary from raised serum transaminase activities to more marked disturbances, with jaundice and granulomatous hepatitis. An occasional case of fatal hepatic failure has been reported; this was the case in a young white American woman who had taken three doses of Fansidar with chloroquine (SEDA-12, 242). Hepatic symptoms may be part of a vasculitis syndrome or can be seen in association with skin reactions (SEDA-13, 241).

Skin

Pyrimethamine

Photosensitivity has been attributed to pyrimethamine (9).

Hyperpigmentation is a very rare adverse effect of pyrimethamine.

- A 29-year-old woman (HIV-negative) developed hyperpigmentation after taking pyrimethamine 25 mg bd for 40 days (10). The hyperpigmentation regressed 15 days after withdrawal of pyrimethamine.

Pyrimethamine + dapsone

Skin rashes are uncommon with the combination of pyrimethamine + dapsone. A lichen planus type of skin reaction has been described (11).

Pyrimethamine + sulfadoxine

Severe skin reactions have been reported with the combination of pyrimethamine + sulfadoxine (Fansidar) from various countries. These include erythema exudativum multiforme, Stevens–Johnson syndrome, toxic epidermal necrolysis, cutaneous vasculitis, lichen planus, a single case of ectodermosis pluriorificialis, and some cases of photosensitivity.

The incidence of skin reactions seems to vary regionally: there is a low incidence in Switzerland (12), but a high incidence has been reported by the US Centers for Disease Control. The latter reported skin reactions in 1:5000 to 1:8000 cases, with fatal reactions in 1:10 000 to 1:25 000 users (SEDA-12, 242). In Britain the retrospective reporting rate for all serious reactions was 1:2100 and for cutaneous reactions one in 4900 prescriptions, with a fatality rate of one in 11100 (SEDA-16, 309).

In a spontaneous reporting system of individuals who had been exposed to Fansidar in 27 countries, an estimated 117 million users, there were 126 reports: 87 cases of erythema multiforme or Stevens–Johnson syndrome and 39 cases of toxic epidermal necrolysis; 86% of the cases were reported in Europe or North America (13). The fatality rates were 36% for toxic epidermal necrolysis (95% CI = 21, 53) and 9% for erythema multiforme/Stevens–Johnson syndrome (4, 18). The overall SCAR risk was 1.1 (0.9, 1.3) per million. For developing countries with mainly single-dose use, the risk was estimated at 0.1 (0.0, 0.1) per million. For Europe and North America, with mainly prophylactic use, the risks were 10 (8, 12) and 36 (23, 48) per million respectively.

The prevalence of oral lichenoid reactions was 4.8% in 186 Malay army personnel who used Fansidar for 9 weeks, 0.5% in 186 army personnel who had stopped using Fansidar

© 2006 Elsevier B.V. All rights reserved.

for 2 months, and 0% in 143 army personnel (control group) who had not used Fansidar for at least 4 months (14).

- Exudative erythema multiforme with chronic proliferation of the conjunctiva causing blindness was described in a 24-year-old man who had taken one tablet of Fansidar at 6-day intervals on three occasions (SEDA-16, 309).

Immunologic

Pyrimethamine + dapsone

Maloprim given for antimalarial prophylaxis was associated with immunosuppression: in military personnel in Singapore (15). The incidence of upper respiratory tract infections was 64% higher than in the non-treated group.

Three patients developed a hypersensitivity syndrome after taking pyrimethamine 12.5 mg + dapsone 100 mg weekly as malaria prophylaxis (16). The diagnosis was based on the presence of fever, lymphadenopathy, a maculopapular rash, and hepatitis. A mild Coombs'-positive hemolytic anemia was also observed in one of the patients. All the clinical, hematological, and biochemical abnormalities normalized within 3 months of tapering regimens of moderate-dose prednisolone.

Pyrimethamine + sulfadoxine

Generalized vasculitis was reported in two cases in Sweden; one developed fever, jaundice, orchitis, and gastrointestinal bleeding after 2 weeks, the other cutaneous vasculitis and rapid progressive nephritis after 3 weeks (SEDA-13, 241).

An illness resembling Sézary syndrome was seen after combined treatment with chloroquine 150 mg every third day (total seven tablets) plus Fansidar one tablet weekly (total six tablets); the symptoms comprised fever, diarrhea, erythroderma, jaundice, lymphadenopathy, and hepatosplenomegaly (SEDA-12, 696).

The safety and efficacy of a fixed combination of pyrimethamine 25 mg + sulfadoxine 500 mg, supplemented with folinic acid 15 mg, both twice a week, as primary prophylaxis of *Pneumocystis* pneumonia and *Toxoplasma* encephalitis has been evaluated in 106 patients infected with HIV in a single-arm, open, prospective study (17). There were allergic reactions in 18 patients and permanent withdrawal was required in seven. One patient who took continued prophylaxis despite progressive hypersensitivity reactions developed a serious adverse reaction (Stevens–Johnson syndrome).

Long-Term Effects

Drug tolerance

Resistance to pyrimethamine has been reported from the Amazon region and Southeast Asia (SEDA-21, 297).

Second-Generation Effects

Pregnancy

Pyrimethamine + dapsone

A stillborn male child with a severe defect of the abdominal and thoracic wall and a missing left arm was delivered at 26 weeks to a woman who had used Maloprim on days 10, 20, and 30 after conception (SEDA-11, 589). The case was anecdotal and the relation to medication uncertain.

Teratogenicity

Pyrimethamine

Pyrimethamine is an inhibitor of dihydrofolate reductase and causes tetrahydrofolate deficiency. It is teratogenic in animals: in rats it produces limb defects, cleft palate, and brachygnathia, and in chick embryos micromelia. Fetal death has been seen in rats and hamsters. However, in toxoplasmosis, pyrimethamine, with or without a sulfonamide, has been given to pregnant women without evidence of subsequent abnormalities. Supplementation with folic acid has been advocated to prevent or reduce adverse effects (SEDA-13, 812), but it is not known if this could impair efficacy.

Pyrimethamine + sulfadoxine

Malaria during pregnancy is associated with an increased risk of severe anemia and babies of low birth weight. Effective intermittent therapy with pyrimethamine + sulfadoxine reduces parasitemia and severe anemia and improves birth weight in areas in which *P. falciparum* is sensitive to this combination. In an open, prospective trial in 287 pregnant women in the Gambia who were exposed to a single dose of a combination of artesunate and pyrimethamine + sulfadoxine there was no evidence of a teratogenic or otherwise harmful effect (18).

Susceptibility Factors

Pyrimethamine

Pyrimethamine should not be given to patients with depleted folic acid reserves (19).

Pyrimethamine + sulfadoxine

Sulfonamide and/or pyrimethamine sensitivity, pregnancy, and G6PD deficiency are contraindications. Use in young infants is considered inadvisable; the history of an 8-month-old infant with *P. falciparum* malaria who developed high fever, tachycardia, hypotension, chills, jaundice, and splenomegaly 48 hours after a single parenteral dose of Fansidar (pyrimethamine + sulfadoxine) (SEDA-16, 309) seems to confirm the wisdom of this advice. It has been advocated that Fansidar should not be used prophylactically if exposure to malaria will last less then 3 weeks, in view of the incidence of severe skin reactions during the first month.

Drug–Drug Interactions

Chloroquine

Pyrimethamine + sulfadoxine

The combined use of Fansidar (sulfadoxine + pyrimethamine) with chloroquine has been reported to result in more severe adverse reactions (20). However, an increased risk has not been reported in recent studies (21).

© 2006 Elsevier B.V. All rights reserved.

Liver metabolized drugs

Pyrimethamine + sulfadoxine
Both pyrimethamine and sulfonamides are liver enzyme inhibitors, and can cause interactions with drugs that are normally metabolized in the liver.

Pyritinol

General Information

Pyritinol is a sulfhydryl-containing compound, a dimer of 5-thiopyridoxine. It was used from 1961 onwards as a psychostimulant of doubtful efficacy, but apparently without adverse effects, and then largely abandoned. When it was re-introduced in some countries for rheumatoid arthritis, adverse effects were registered in 25% of patients.

Cross-allergy with D-penicillamine has been hypothesized to explain the apparently higher frequency of adverse effects of pyritinol in patients with rheumatoid arthritis (1).

In usual doses, 600–800 mg/day, pyritinol has a profile of adverse reactions reminiscent of that of penicillamine (2,3). Some 40% of users have adverse reactions, leading to withdrawal in about 23% of the total. The most common are non-specific rashes and stomatitis; in addition, pemphigus, lichen planus, and photosensitivity have occurred. Gastrointestinal symptoms (diarrhea, gastralgia, nausea, loss of taste) can occur, but are less frequent than with penicillamine. Thrombocytopenia, reversible extramembranous glomerulonephritis with nephrotic syndrome (4), a myasthenia-like picture, and acute polymyositis with positive rechallenge have also been described (5).

In a collaborative study of the French Pharmacovigilance Centers there were 23 reports of suspected reactions to pyritinol, including four cases of pemphigus, three of agranulocytosis (but other drugs taken were oxyphenbutazone or clomipramine), two of nephrosis, and two of a lupus-like syndrome (6).

© 2006 Elsevier B.V. All rights reserved.

Comparative studies

In a multicenter, double-blind study, patients with rheumatoid arthritis took pyritinol 600 mg/day or auranofin 6 mg/day for 1 year (7). Of 139 patients randomized to pyritinol, 61 (44%) dropped out because of adverse events or response failure compared with 44 (31%) of the 142 patients randomized to auranofin. Among the rest, adverse events occurred in 64% of patients taking pyritinol and in 58% of patients taking auranofin: the main events were mucocutaneous symptoms (pyritinol 36%, auranofin 23%) and gastrointestinal complaints (pyritinol 30%, auranofin 37%). There were single cases of proteinuria, hepatic abnormalities, and hematological abnormalities in both groups.

Organs and Systems

Metabolism

Autoimmune hypoglycemia with detectable anti-insulin antibodies, probably caused by pyritinol, has been described in one patient (8). This syndrome has previously been reported in connection with other thiol compounds, (penicillamine, methimazole, and tiopronin).

Liver

Pyritinol-induced acute hepatitis has been described (9).

Pancreas

Pancreatitis has been attributed to pyritinol.

- A 23-year-old student had three episodes of acute pancreatitis after the occasional ingestion of pyritinol for better performance in examinations. Immunological investigations pointed to a probable T cell-mediated hypersensitivity reaction (10).

Immunologic

A high titer of antinuclear antibodies and anti-double-stranded native DNA antibodies occurred during treatment with pyritinol 400 mg/day in a woman with rheumatoid arthritis (11). A clear temporal relation and a reduction in antinuclear antibody titers and disappearance of anti-DNA antibodies after drug withdrawal strongly suggested a causal relation.

Pyrrolizidine alkaloids

General Information

Pyrrolizidine alkaloids occur in a large number of plants, notably the genera *Crotalaria* (Fabaceae), *Cynoglossum* (Boraginaceae), *Eupatorium* (Asteraceae), *Heliotropium* (Boraginaceae), *Petasites* (Asteraceae), *Senecio* (Asteraceae), and *Symphytum* (Boraginaceae) (Table 1). Certain representatives of this class and the plants in which they occur are hepatotoxic as well as mutagenic and hepatocarcinogenic. They can produce veno-occlusive disease of the liver with clinical features like abdominal pain with ascites, hepatomegaly and splenomegaly, anorexia with nausea, vomiting, and diarrhea. Sometimes there is also damage to the pulmonary region.

The German Federal Health Office has restricted the availability of botanical medicines containing unsaturated pyrrolizidine alkaloids (1,2). Herbal medicines that provide over 1 mg/day internally or over 100 mg/day externally are not permitted; herbal medicines that provide 0.1–1 mg/day internally or 10–100 mg/day externally may be applied for only a maximum of 6 weeks per year, and they should not be used during pregnancy or lactation.

Table 1 Pyrrolizidine alkaloids in various genera

Genus	Pyrrolizidine alkaloids
Crotalaria albida	Croalbidine
Crotalaria anagyroides	Anacrotine, methylpyrrolizidine
Crotalaria aridicola	Various dehydropyrrolizidines
Crotalaria axillaris	Axillaridine, axillarine
Crotalaria barbata	Crobarbatine
Crotalaria burha	Croburhine, crotalarine
Crotalaria candicans	Crocandine, cropodine
Crotalaria crassipes	Retusamine
Crotalaria crispata	Crispatine, fulvine
Crotalaria dura	Crotaline
Crotalaria fulva	Fulvine
Crotalaria globifer	Crotaline, globiferine
Crotalaria goreensis	Hydroxymethylenepyrrolizidine
Crotalaria grahamiana	Grahamine
Crotalaria grantiana	Grantianine
Crotalaria incana	Anacrotine
Crotalaria intermedia	Integerrimine, usaramine
Crotalaria laburnifolia	Crotalaburnine, hydroxysenkirkine
Crotalaria madurensis	Crotafoline, madurensine
Crotalaria mitchelii	Retusamine
Crotalaria mucronata	Mucronitine, mucronitinine
Crotalaria nana	Crotaburnine, crotananine
Crotalaria novae-hollandiae	Retusamine
Crotalaria retusa	Retusamine
Crotalaria semperflorus	Crosemperine
Crotalaria spectabilis	Retronecanol
Crotalaria stricta	Crotastrictine
Crotalaria trifoliastrum	Various alkylpyrrolizidines
Crotalaria usaramoensis	Usaramine, usaramoensine
Crotalaria virgulata	Grantaline, grantianine
Crotalaria walkeri	Acetylcrotaverrine, crotaverrine
Cynoglossum amabile	Amabiline, echinatine
Cynoglossum glochidiatum	Amabiline
Cynoglossum lanceolatum	Cynaustine, cynaustraline
Cynoglossum latifolium	Latifoline
Cynoglossum officinale	Heliosupine
Cynoglossum pictum	Echinatine, heliosupine
Cynoglossum viridiflorum	Heliosupine, viridiflorine
Eupatorium cannabinum	Echinatine, supinine
Eupatorium maculatum	Echinatine, trachelantimidine
Heliotropium acutiflorum	Heliotrine
Heliotropium arguzoides	Trichodesmine
Heliotropium curassavicum	Angelylheliotridine
Heliotropium dasycarpum	Heliotrine
Heliotropium eichwaldii	Angelylheliotrine
Heliotropium europeum	Acetyl-lasiocarpine, helioitrine
Heliotropium indicum	Acetylindicine, indicine, indicinine
Heliotropium lasiocarpum	Heliotrine, lasiocarpine
Heliotropium olgae	Heliotrine, incanine, lasiocarpine
Heliotropium ovalifolium	Heliofoline
Heliotropium ramosissimum	Heliotrine
Heliotropium strigosum	Strigosine
Heliotropium supinum	Heliosupine, supinine
Heliotropium transoxanum	Heliotrine
Petasites japonicus	Fukinotoxin, petasinine, petasinoside
Senecio adnatus	Platyphylline
Senecio alpinus	Seneciphylline
Senecio amphibolus	Macrophylline
Senecio angulatus	Angulatine
Senecio aquaticus	Aquaticine
Senecio argentino	Retrorsine, senecionine
Senecio aureus	Floridanine, florosenine, otosenine
Senecio auricula	Neosenkirkine
Senecio borysthenicus	Seneciphylline
Senecio brasiliensis	Brasilinecine
Senecio campestris	Campestrine
Senecio cannabifolius	Senecicannabine
Senecio carthamoides	Carthamoidine
Senecio cineraria	Jacobine, seneciphylline
Senecio cissampelinum	Senampelines
Senecio crucifolia	Jacobine
Senecio doronicum	Doronine
Senecio erraticus	Erucifoline, floridanine
Senecio filaginoides	Retrorsine, ionine
Senecio franchetti	Franchetine, sarracine
Senecio fuchsii	Fuchsisenecionine
Senecio gillesiano	Retrorsine, senecionine
Senecio glabellum	Integerrimine, senecionine
Senecio glandulosus	Retrorsine, senecionine
Senecio glastifolius	Graminifoline
Senecio hygrophylus	Hygrophylline, platyphylline
Senecio ilicifolius	Pterophine, senecionine
Senecio illinitus	Acetylsenkirkine, senecionine
Senecio incanus	Seneciphylline
Senecio integerrimus	Integerrimine, senecionine
Senecio isatideus	Isatidine, retrorsine
Senecio jacobaea	Jacobine, jacoline, jaconine, jacozine, otosenine, renardine
Senecio kirkii	Acetylsenkirkine, senkirkine
Senecio kubensis	Seneciphylline
Senecio latifolius	Senecifolidine, senecifoline
Senecio leucostachys	Retrorsine, senecionine
Senecio longibolus	Integerrimine, longiboline, retronecanol, retrorsine, riddelline, senecionine, seneciphylline
Senecio macrophyllus	Macrophylline
Senecio mikanoides	Mikanoidine
Senecio nemorensis	Nemorensine, oxynemorensine
Senecio othonnae	Floridnine, onetine, otosenine
Senecio othonniformis	Bisline, isoline
Senecio palmatus	Seneciphylline
Senecio paucicalyculatus	Paucicaline
Senecio petasis	Bisline
Senecio phillipicus	Retrorsine, seneciphylline
Senecio platyphylloides	Neoplatyphylline, platyphylline, sarracine, seneciphylline
Senecio platyphyllus	Platyphylline, seneciphylline
Senecio pojarkovae	Sarracine, seneciphylline
Senecio procerus	Procerine
Senecio propinquus	Seneciphylline
Senecio pseudoarnica	Senecionine
Senecio pterophorus	Pterophine
Senecio ragonesi	Retrorsine, senecionine, uspallatine
Senecio renardi	Renardine, seneciphylline
Senecio retrorsus	Senkirkine
Senecio rhombifolius	Isatidine, retrorsine, neoplatyphylline, platyphylline sarracine, seneciphylline
Senecio Riddellii	Riddelline
Senecio rivularis	Angeloyloxyheliotrine
Senecio rosmarinifolius	Rosmarinine

© 2006 Elsevier B.V. All rights reserved.

Genus	Pyrrolizidine alkaloids
Senecio ruwenzoriensis	Ruwenine, ruzorine
Senecio sarracenicus	Sarracine
Senecio scleratus	Isatidine, scleratine
Senecio seratophiloides	Senecivernine
Senecio spartioides	Seneciphylline, spartoidine
Senecio squalidus	Senecionine, squalidine
Senecio stenocephalus	Seneciphylline
Senecio subalpinus	Seneciphylline
Senecio subulatus	Retrorsine, senecionine
Senecio swaziensis	Swazine
Senecio triangularis	Triangularine
Senecio uspallatensis	Senecionine, uspallatine
Senecio vernalis	Senecivernine
Senecio vira-vira	Anacrotine, neoplatyphylline
Senecio viscosus	Senecionine
Senecio vulgaris	Senecionine
Symphytum asperum	Asperumine, echinatine
Symphytum caucasicum	Heliosupine, echinatine
Symphytum officinalis	Lasiocarpine, symphytine, viridiflorine
Symphytum orientale	Echinatine, heliosupine
Symphytum tuberosum	Lasiocarpine, symphytine
Symphytum uplandicum	Viridflorine, anadoline, heneicisane, tricosane, acetylintermedine, acetyllycopsamine, uplandicine

Organs and Systems

Liver

In a South African study 20 children were identified as suffering from hepatic veno-occlusive disease thought to be caused by the administration of traditional remedies (3). The predominant clinical presentation was ascites and hepatomegaly. Nine children died. The surviving patients progressed to cirrhosis and portal hypertension. In four cases early urine specimens were available, and in all of these the presence of pyrrolizidine alkaloids was confirmed.

Second-Generation Effects

Fetotoxicity

It is prudent to avoid exposing unborn or suckling children to herbal remedies containing pyrrolizidine alkaloids. Animal studies have shown that transplacental passage and transfer to breast milk are possible, and there is a human case on record of fatal neonatal liver injury, in which the mother had used a herbal cough tea containing pyrrolizidine alkaloids throughout her pregnancy.

Pyrvinium embonate

General Information

Pyrvinium is a deep-red insoluble dye used as an antihelminthic drug. It is well tolerated in doses up to 5 mg/kg. Nausea, vomiting, diarrhea, and cramping abdominal pain are more frequent at higher doses. Feces and vomit are stained red. Isolated cases of severe allergy (1), transient photosensitivity, and Stevens–Johnson syndrome (2) have been reported.

Quazepam

See also Benzodiazepines

General Information

Quazepam is a long-acting benzodiazepine with effects similar to those of diazepam.

Food–Drug Interactions

The disposition of quazepam 20 mg, in the fasting state and 30 minutes after the consumption of meals containing different amounts of dietary fat, has been studied in a three-arm, randomized, crossover study in nine healthy men (1). Plasma concentrations of quazepam and its metabolite, 2-oxoquazepam, were measured for up to 48 hours after dosing. The peak concentrations of quazepam 30 minutes after low-fat and high-fat meals were 243% and 272%, respectively, of those in the fasted state. The AUCs of quazepam from 0 to 8 hours and from 0 to 48 hours were increased by both the low-fat and high-fat meals by 1.4–2 times. Quazepam was well tolerated, with no significant difference in the Stanford Sleepiness Scale between fasted and fed conditions. Thus, food significantly increased the absorption of quazepam but did not prolong the half-life. Quazepam is lipophilic; it would therefore be more highly dissolved in a fatty meal and more available for absorption.

Quetiapine

See also Neuroleptic drugs

General Information

The pharmacology, efficacy, and safety of quetiapine, an atypical neuroleptic drug, have been extensively reviewed (1). Quetiapine interacts with a broad range of neurotransmitter receptors and has a higher affinity for serotonin ($5\text{-}HT_{2A}$) receptors than dopamine (D_2) receptors in the brain. In a meta-analysis, quetiapine was as effective as haloperidol with fewer extrapyramidal adverse effects (2).

Data from short-term clinical trials (6 weeks) suggest that quetiapine may be useful for the management of psychotic disorders in patients who do not tolerate the adverse effects of the typical antipsychotic drugs or clozapine (3). The most common adverse effects of quetiapine were dizziness, hypotension, somnolence, and weight gain. Raised hepatic enzymes have also been reported. In addition, two patients with idiopathic Parkinson's disease and psychosis were treated with quetiapine for 52 weeks (4). Psychotic symptoms were successfully controlled without worsening of motor disability.

Organs and Systems

Nervous system

Although quetiapine seems to cause a lower incidence of extrapyramidal symptoms, a case of neuroleptic malignant syndrome has been described (5).

- A 40-year-old man with chronic schizophrenia and borderline intelligence presented with acute psychotic decompensation. He had previously taken several different neuroleptic drugs and had had significant extrapyramidal symptoms but never neuroleptic malignant syndrome. He was given quetiapine 25 mg bd, increasing to 250 mg bd by day 13. He then had increasing symptoms of restlessness, agitation, and episodic sweating. Loxapine 25 mg and lorazepam 2 mg were added. On day 14 he developed confusion, lead-pipe muscle rigidity, a temperature of 38.2°C, a labile blood pressure, tachypnea, and tachycardia; creatine kinase activity was 18 354 IU/l and he had myoglobinuria. Quetiapine was withdrawn and supportive treatment was instituted. He recovered 5 days after withdrawal.

Endocrine

The effects of haloperidol and quetiapine on serum prolactin concentrations have been compared in 35 patients with schizophrenia during a drug-free period of at least 2 weeks in a randomized study (6). There was no significant difference in prolactin concentration between the groups at the start of the study, and control prolactin concentrations were significantly lower with quetiapine than haloperidol. No patients taking quetiapine had galactorrhea.

Dose-dependent decreases in total T3 and T4 and free T4, without an increase in TSH, have been reported (7,8). Such changes have not been observed with other neuroleptic drugs.

Quinagolide

General Information

Quinagolide is a non-ergot benzoquinoline dopamine D_2 receptor agonist. Reported adverse effects include gastrointestinal upsets, anorexia, weight loss, and episodes of fainting (1).

Reference

1. Khalfallah Y, Claustrat B, Grochowicki M, Flocard F, Horlait S, Serusclat P, Sassolas G. Effects of a new prolactin inhibitor, CV 205-502, in the treatment of human macroprolactinomas. J Clin Endocrinol Metab 1990;71(2):354–9.

Quinapril

See also Angiotensin converting enzyme inhibitors

General Information

The pharmacology, therapeutic uses, and safety of the ACE inhibitor quinapril have been reviewed (1).

Organs and Systems

Psychological, psychiatric

Depression has been attributed to quinapril (2).

- A 90-year-old man with a history of peripheral arterial disease and mild heart failure presented with reduced appetite, insomnia, anhedonia, reduced energy, and suicidal ideation. His symptoms had started a month before, when he had begun to take quinapril 10 mg/day. He was also taking furosemide 20 mg/day and digoxin. He was alert, coherent, and cognitively intact, but depressed with a flat affect. He had no psychotic symptoms. Quinapril was withdrawn. He improved within 48 hours and recovered fully in 5 days.

The authors cited several reports of depression, mania, and psychosis with various ACE inhibitors.
Acute psychosis has been attributed to quinapril (3).

- A 93-year-old woman with heart failure was given quinapril 2.5 mg bd. Two hours after the first dose she became confused, disoriented, and anxious. During the night, she made many frantic telephone calls to her daughter and other family members complaining that she was being assaulted. Her anxiety, disorientation, and visual hallucinations continued for 5 days. She had had an episode of hallucinations 2 years before, while taking a beta-blocker. Quinapril was withdrawn. She recovered over the next day.

The authors commented on three previous cases of visual hallucination with other ACE inhibitors.

Pancreas

A possible association between quinapril and pancreatitis has been reported in an 85-year-old woman, very similar to other previously reported cases with other ACE inhibitors (4).

Quinethazone

See also Diuretics

General Information

Quinethazone is chemically related to the thiazides; early work suggested that it was in all essential respects identical (SED-8, 488), and there is no newer evidence that it has any special characteristics.

Quinfamide

General Information

Quinfamide acts on the trophozoites of *Entamoeba histolytica*, making the trophozoite incapable of propagation. It is not active against amebic cysts. In doses of 100–1200 mg adverse effects have been frequent but

© 2006 Elsevier B.V. All rights reserved.

mild, mainly comprising headaches and nausea (SEDA-12, 705) (1).

Reference

1. Robinson CP. Quinfamide. Drugs Today 1984;20:479.

Quinidine

See also Antidysrhythmic drugs

General Information

Quinidine is a class I antidysrhythmic drug. Its actions, clinical use, interactions, and adverse effects have been reviewed (1).

In 652 consecutive inpatients 91 adverse reactions to quinidine occurred in as many patients (14%); of these, 51 were gastrointestinal, 16 dysrhythmic, 11 febrile, six dermatological, and one hematological; there were six cases of cinchonism (2). Although there were four cases of potentially fatal dysrhythmias, there were no deaths.

In a study of 245 patients, the most common adverse effects were diarrhea (35%), upper gastrointestinal distress (22%), and light-headedness (15%). Other common adverse effects included fatigue (7%), palpitation (7%), headache (7%), angina-like pain (6%), weakness (5%), and rash (5%) (3).

Comparative studies

Quinidine and sotalol have been compared in a prospective multicenter trial of 121 patients after conversion of atrial fibrillation (4). Patients with low left ventricular ejection fractions (below 0.4) or high left atrial diameters (over 5.2 cm) were excluded. After 6 months the percentages of patients remaining in sinus rhythm were similar in the two groups (around 70%), but when the dysrhythmia recurred it occurred later with sotalol than with quinidine (69 versus 10 days). There was also a difference between patients who had been converted from recent-onset atrial fibrillation, in whom sotalol was more effective than quinidine, and in patients who had had chronic atrial fibrillation for more than 3 days, in whom quinidine was more effective. There were significant adverse effects requiring withdrawal of therapy in 17 patients, of whom nine were taking quinidine; three patients had gastrointestinal symptoms, two had central nervous symptoms, two had allergic reactions, one had undefined palpitation, and one had QT interval prolongation. One patient taking quinidine, a 65-year-old man, had frequent episodes of non-sustained ventricular tachycardia.

General adverse reactions

Gastrointestinal symptoms, including anorexia, nausea, and vomiting, are common. Quinidine has a negative inotropic effect on the heart and can cause heart failure and hypotension. It prolongs the QRS complex and QT interval and can cause cardiac dysrhythmias, which can result in syncope (so-called "quinidine syncope"). "Cinchonism" is the term used to describe a cluster of adverse effects that occur at high dosages, including nausea, vomiting, diarrhea, tinnitus, dizziness, and blurred vision; in severe cases there may be deafness and toxic amblyopia in addition to cardiac abnormalities. Other adverse effects that have been described include dementia, psychosis, esophagitis, sometimes resulting in stricture, and exacerbation of myasthenia.

Various hypersusceptibility reactions have been attributed to quinidine, including fever, skin rashes, various types of hematological abnormalities (particularly thrombocytopenia), hepatitis, asthma, and anaphylactic shock. Quinidine has rarely been reported to cause a lupus-like syndrome. Tumor inducing effects have not been reported.

Organs and Systems

Cardiovascular

Quinidine prolongs the QRS complex and QT interval, the effect being related to plasma quinidine concentrations (5) and being greater in women (6). As a result, torsade de pointes or other ventricular tachydysrhythmias can occur and may lead to syncope ("quinidine syncope"). The minimum risk of torsade de pointes has been estimated at 1.5% per year (7).

The relation between serum quinidine concentrations and QT interval dispersion has been studied in 11 patients with atrial dysrhythmias and subtherapeutic or therapeutic serum quinidine concentrations (1.48 and 3.78 μg/ml respectively) (8). The baseline QT_c interval was 430 ms. At subtherapeutic and therapeutic serum quinidine concentrations, mean QT_c intervals were 451 and 472 ms respectively. Mean QT dispersion was 47 ms at baseline, 98 ms at subtherapeutic concentrations, and 71 ms at therapeutic concentrations. Despite QT interval lengthening with increasing serum quinidine concentrations, QT dispersion was greatest at subtherapeutic concentrations.

Quinidine has also been incriminated in cases of sinoatrial block and sinus arrest, but it was not clearly established that quinidine was responsible (9,10). The anticholinergic effects of quinidine can increase the risk of dysrhythmias (11).

Treatment of tachydysrhythmias secondary to quinidine is problematic. Other class I antidysrhythmic drugs are theoretically contraindicated. Some success has been reported with bretylium and with a combination of a beta-adrenoceptor antagonist and phenytoin (12,13). Overdrive pacing has also been reported to be of value (14).

Quinidine has a negative inotropic effect on the heart and causes peripheral vasodilatation. Hypotension can occur secondary to these effects (15).

Nervous system

Quinidine rarely causes effects on the nervous system when used in therapeutic dosages, although there have been occasional reports of dementia (16–18). However, in toxicity it can cause vertigo and tinnitus (19).

© 2006 Elsevier B.V. All rights reserved.

Sensory systems

Quinidine rarely affects vision, but can cause scotomata, impaired color vision, and toxic amblyopia (20), altered vision (21), sicca syndrome (22), keratopathy (23), and granulomatous uveitis (24).

Hematologic

Hypersusceptibility reactions to quinidine include thrombocytopenia, hemolytic anemia, and neutropenia.

The overall annual incidence of acute thrombocytopenia has been estimated at 18 cases per million (25), and two possible mechanisms have been invoked:

1. direct combination of quinidine with platelets, causing the production of antibodies, which then cause platelet lysis;
2. formation of quinidine-antibody complexes, which are then deposited on the platelet (the so-called "innocent bystander" mechanism).

There is evidence in favor of both of these mechanisms (26).

Other hematological effects are much less common, and include hemolytic anemia (26,27), neutropenia (28,29), and eosinophilia (30).

Withdrawal of quinidine and the administration of corticosteroids is the usual treatment for thrombocytopenia (31), although intravenous immune globulin has also been used (32).

In a review of all English-language reports on drug-induced thrombocytopenia, excluding heparin, 561 case articles reporting on 774 patients were analysed (33). A definite or probable causal role for the drug used was attributed in 247 case reports, and of the 98 that were implicated quinidine was mentioned in 38 cases. The next most common drugs involved were gold salts (11 cases) and co-trimoxazole (10 cases).

Mouth and teeth

A blue–black pigmentation of the oral mucosa has been reported with quinidine (34).

Gastrointestinal

Anorexia, nausea, vomiting, and diarrhea are common adverse effects of quinidine and occur in up to 30% of patients (2,35). These effects can be minimized by the use of modified-release formulations (36).

In one series diarrhea was reported commonly (37), and it can occur late in treatment (38).

Quinidine sometimes causes esophagitis (39,40), especially when there is some abnormality of the esophagus or cardiomegaly. This sometimes results in esophageal stricture (41).

The quinidine derivative hydroquinidine had some beneficial effects in 10 patients with myotonic dystrophy with slow saccadic eye movements, apathy, and hypersomnia (42,43). However, two patients had nausea and epigastric pain and withdrew while taking the active treatment. Although there were no cases of cardiac abnormalities, the authors raised the concern that in patients with myotonic dystrophy, who have a high frequency of cardiac disturbances, the risk of cardiac dysrhythmias with quinidine derivatives may be too high to take.

Liver

Hypersusceptibility reactions to quinidine include granulomatous hepatitis. In one retrospective series of 487 patients, 32 had evidence of hypersusceptibility, 10 of whom had hepatotoxicity (44). In another series of 1500 patients, quinidine-induced hepatitis was identified in 33 (2.2%) (45); these represented one-third of all cases of drug-induced hepatitis in those patients. In all cases the liver damage resolved on withdrawal.

Urinary tract

Glomerulonephritis has been reported in association with Henoch–Schönlein purpura (46) and nephrotic syndrome, possibly as part of a lupus-like syndrome (47).

Skin

Skin rashes are uncommon (48), but can occur as part of a hypersusceptibility reaction. In a review of drug-induced skin disorders, from a list of 26 drugs or groups of drugs, only quinidine was mentioned of all antidysrhythmic drugs (49). The reaction rate was quoted as 12 per 1000 recipients. Several different kinds of rash have been reported, including photosensitivity (50), which can result in a variety of types of rash, contact dermatitis (51), pigmentation (52), urticaria (53), exfoliative dermatitis (54,55), granuloma annulare (56), and exacerbation of psoriasis.

Musculoskeletal

Quinidine is a neuromuscular blocking drug and can exacerbate myasthenia gravis (57). It can also cause an increase in the serum activity of the muscle-specific isozyme of creatine phosphokinase (58–60).

- A 56-year-old man who took quinidine 324 mg five times daily for prevention of paroxysmal atrial fibrillation developed a syndrome similar to polymyalgia rheumatica which settled on drug withdrawal (60).

Quinidine can cause polyarthropathy (61), both in association with and independent of a lupus-like syndrome.

Immunologic

A variety of immune syndromes have occasionally been reported with quinidine, including a lupus-like syndrome, polymyalgia rheumatica, and vasculitis (SEDA-20, 179) (SEDA-23, 202).

Life-threatening vasculitis has been attributed to quinidine in a healthy volunteer taking part in a clinical trial (62).

- A 58-year-old man took quinidine 200 mg tds for 7 days as part of an interaction study with a new alpha-blocker. He developed widespread maculopapular purpuric lesions on the limbs, trunk, and ears. His temperature rose to 38.4°C and some of the lesions on his fingers, toes, ears, and nose became necrotic. He had peripheral edema with a bluish purpuric discoloration of the hands and feet. There was mucous membrane involvement

© 2006 Elsevier B.V. All rights reserved.

with purpuric, partially necrotic lesions on the tongue and palate. A skin biopsy showed necrotizing vasculitis with focal leukocytoclasia. Direct immunofluorescence showed microgranular deposits of IgA, IgM, and C3 around the superficial skin vessels. Quinidine was withdrawn and he was given intravenous methyl prednisolone followed by oral prednisone for one month. He recovered completely within 3 weeks.

There has been a report of a dermatomyositis-like illness in a man taking quinidine (63).

- A previously healthy 63-year-old man, who had taken quinidine gluconate 972 mg/day for 9 months, developed diffuse edematous erythema on the extensive surfaces of the hands, arms, and face, with marked accentuation over the joints. His nail-fold capillaries were dilated and the shoulder abductors were slightly weak. His erythrocyte sedimentation rate was slightly raised (29 mm/hour) and there was a positive ANA titer (1:640) with a speckled pattern. There were no antibodies to Sm, ribonucleoprotein, SSA or SSB antigens, or histones. There was no evidence of inflammatory myopathy on electromyography, and a skin biopsy showed a mild, superficial, perivascular, lymphocytic inflammation with positive direct immunofluorescence for IgG and IgM at the dermoepidermal junction. There was no evidence of malignancy. All these abnormalities resolved rapidly after quinidine withdrawal.

Lupus-like syndrome

A lupus-like syndrome has occasionally been reported in patients taking quinidine (60,61,64). It usually presents with polyarthralgia, a raised erythrocyte sedimentation rate, and a raised antinuclear antibody titer. It can occasionally be associated with antihistone antibodies and a circulating coagulant. In two cases (65) the syndrome was associated with quinidine and not with procainamide. Lupus anticoagulant has been reported with the use of quinine and quinidine, and an associated antiphospholipid syndrome has been described (66).

Susceptibility Factors

Age

Maintenance dosages should be reduced in elderly people (67).

Sex

The effect of quinidine on the QT interval is greater in women than in men at equivalent serum concentrations (6). In 12 men and 12 women who received a single intravenous dose of quinidine (4 mg/kg) in a randomized, single-blind, placebo-controlled, crossover study, total and unbound serum concentrations of quinidine and 3-hydroxyquinidine were measured and QT intervals were corrected for differences in heart rate using Bazett's method. The QT interval at baseline was longer in women than in men (407 versus 395 ms). The slope of the relation between the serum concentration of quinidine and the change in the QT_c interval from baseline was 44% greater in the women than in the men. However, there were no significant differences between the men and the women in the disposition of quinidine, apart from a small reduction in the unbound fraction of 3-hydroxyquinidine in the men (0.47 versus 0.53). The authors proposed that estrogens and androgens differentially affect the expression and activity of potassium channels in the heart, and that a lower density of potassium channels could contribute to a larger effect of quinidine in the women. They suggested that women are at greater risk of quinidine-induced cardiac dysrhythmias and that altering dosages according to weight would not correct for this difference. They also pointed to the fact that in the SWORD study the risk of excess mortality in those taking D-sotalol was greater in the women than in the men.

Hepatic disease

Maintenance dosages should be reduced if hepatic metabolism is reduced, for example in congestive cardiac failure and hepatic disease and in elderly people (67).

Other features of the patient

Care must be taken in patients with pre-existing conduction tissue disease or heart failure. Loading doses should be reduced in cardiac failure, because of a lowered apparent volume of distribution (67).

Drug Administration

Drug overdose

In acute overdosage the chief effect of quinidine is profound hypotension, due to the combination of peripheral vasodilatation, and a negative inotropic effect on the heart (68,69). Charcoal hemoperfusion has been successfully used in the treatment of quinidine overdose (70).

Drug–Drug Interactions

Amiloride

Quinidine has a pharmacodynamic interaction with amiloride, further prolonging the duration of the QRS complex, but not the QT interval (71).

Amiodarone

Quinidine prolongs the QT interval and will therefore potentiate the effects of other antidysrhythmic drugs that have the same effect (for example amiodarone) (72).

Antacids

The interactions of quinidine with antacids have been reviewed (73). Although the data are inconclusive, it has been suggested that at least 2 hours should elapse between quinidine and antacid doses.

Class I antidysrhythmimc drugs

Quinidine prolongs the QT interval and will therefore potentiate the effects of other antidysrhythmic drugs that have the same effect (for example Class I antidysrhythmic drugs). Specific interactions of this kind have

© 2006 Elsevier B.V. All rights reserved.

been reported with tocainide (74) and mexiletine (75); in these cases the interactions were reported to be beneficial in terms of antidysrhythmic effects.

Diclofenac

In human liver microsomes, diclofenac inhibited testosterone 6-beta-hydroxylation with characteristics that suggested that it inactivated CYP3A4 (76). Quinidine, which stimulates CYP3A4-mediated diclofenac 5-hydroxylation, did not affect the inactivation of CYP3A4 assessed by testosterone 6-beta-hydroxylation activity but accelerated the inactivation assessed by diazepam 3-hydroxylation activity.

In 30 healthy young men the pharmacokinetics of a single oral dose of quinidine 200 mg were studied before and during the daily administration of diclofenac 100 mg (a substrate of CYP2C9) (63). The clearance of quinidine by *N*-oxidation was reduced by diclofenac, but only by 27%. This small effect of diclofenac suggests a minor role for CYP2C9 in the metabolism of quinidine.

Digoxin

Quinidine reduces the renal and non-renal clearance of digoxin and reduces its apparent volume of distribution. The combination should be avoided. This interaction is discussed fully in the monograph on cardiac glycosides.

Enzyme-inducing drugs

The metabolism of quinidine is enhanced by drugs that induce hepatic microsomal drug-metabolizing enzymes (67), such as rifampicin (77) and phenytoin and phenobarbital (78). This leads to an increase in the first-pass metabolism of quinidine, and thus increased requirements of oral quinidine but little change in intravenous dosages.

Inhibitors of CYP3A4

There is in vitro evidence that the oxidation of quinidine to 3-hydroxyquinidine is catalysed by CYP3A4. However, the extent to which other cytochrome P450 isoforms, such as CYP2C9 and CYP2E1, are involved in the oxidation of quinidine is not clear. In 30 healthy young men the pharmacokinetics of a single oral dose of quinidine 200 mg were studied before and during the daily administration of diclofenac 100 mg (a substrate of CYP2C9), disulfiram 200 mg (an inhibitor of CYP2E1), three inhibitors of CYP3A4 (grapefruit juice, itraconazole, and erythromycin), and probes of other enzyme activities, namely caffeine (CYPA2), sparteine (CYP2D6), mephenytoin (CYP2C19), and tolbutamide (CTP2C9) (63). The clearance of quinidine by *N*-oxidation was reduced by 27% by diclofenac. Itraconazole, grapefruit juice, and erythromycin all reduced the clearance of quinidine, including its partial clearance by 3-hydroxylation and *N*-oxidation, by up to 84%, confirming the involvement of CYP3A4 in the in vivo oxidation of quinidine. Specifically, itraconazole reduced quinidine total clearance, partial clearance by 3-hydroxylation, and partial clearance by *N*-oxidation by 61, 84, and 73% respectively. Thus, it is likely that inhibitors of CYP3A4 will cause significant drug interactions with quinidine.

Metoprolol

Quinidine inhibits drug hydroxylation and can thus convert extensive hydroxylators to poor hydroxylators, as in the case of metoprolol (79). Inhibition of hydroxylation does not occur in poor hydroxylators.

Neuromuscular blocking drugs

Quinidine is a non-depolarizing muscle blocker and potentiates the effects of neuromuscular blocking drugs (80).

Timolol

The combination of quinidine with timolol causes an increased risk of bradycardia (81).

Warfarin

Quinidine potentiates the effects of warfarin by a pharmacodynamic effect (82).

However, it has also been reported that quinidine increased the 4′-hydroxylation of *S*-warfarin and the 10-hydroxylation of *R*-warfarin in human liver microsomes and intact hepatocytes by stimulation of CYP3A4 (83). The increases were concentration-dependent and respectively maximized at about three and five times control values. In contrast, warfarin did not affect the 3-hydroxylation of quinidine. These results are consistent with previous findings suggesting that there is more than one binding site on CYP3A4 through which interactions can occur.

Quinine

General Information

Quinine was originally extracted from the bark of the *Cinchona* tree (Peruvian bark or Jesuits' bark) and was used to treat ague, that is fever, usually due to malaria. It fell out of fashion with the advent of other antimalarial drugs, but has once again become the drug of first choice for malaria originating in areas with multiresistant *Plasmodium falciparum*. To be effective, quinine plasma concentrations greater than the minimal inhibitory concentration must be achieved and maintained.

Pharmacokinetics

Quinine given orally is well absorbed; the half-life is 11 hours. Clearance is predominantly by hepatic metabolism; urinary clearance accounts for only 20%. Information on pharmacokinetics in healthy volunteers can be misleading, since plasma quinine concentrations are higher in the presence of malaria infection than in healthy subjects given the same dose (SEDA-13, 814). The dosage regimen therefore needs to be adapted to the severity of the illness and amended as improvement occurs.

A population pharmacokinetic study of intramuscular quinine (loading dose 20 mg/kg salt diluted 1:1 in water) in 120 Ghanaian children with severe malaria showed predictable profiles, which were within the target range for quinine (15–20 μg/ml) and independent of clinical and laboratory variables (1). Adverse events included skin induration or abscesses at the injection site (12%), all of which resolved without surgical intervention, and hypoglycemia (10%), a special risk in children who were hypoglycemic at presentation.

Adverse effects of quinine are common at plasma concentrations over 10 μg/ml. The dose often recommended, 10 mg/kg intravenously over 10–20 minutes, may be too high in patients with cerebral malaria (SEDA-14, 240). In the USA, intravenous quinine has been discontinued in favor of quinidine (SEDA-17, 329). In some areas, a high rate of recrudescence is seen after short-term treatment with quinine. The addition of specific antibiotics may improve the cure rate.

Placebo-controlled studies

A double-blind, placebo-controlled trial of a 3-day combination regimen of quinine (8 mg/kg tds) and clindamycin (5 mg/kg tds) ($n = 53$) versus 7-day quinine (8 mg/kg tds intravenously for 3 days, then orally; $n = 55$) to treat uncomplicated imported falciparum malaria showed no significant differences in the parasite and fever clearance

© 2006 Elsevier B.V. All rights reserved.

times or the 28-day cure rate (100 versus 96%) (2). The frequencies of mild adverse events (tinnitus and nausea) were similar in the two groups. There were two serious adverse events that necessitated treatment withdrawal: one patient taking quinine alone had a hemolytic episode and another a "severe toxic rash."

General adverse effects

Quinine is not pleasant to take, and adverse effects, including nausea, tinnitus, dizziness, and hypoglycemia, are well recognized and common compared with other antimalarial drugs (3) in the doses used to treat malaria, although not in the smaller doses used to prevent leg cramps, when classical allergic reactions can still occur (4). Most serious adverse effects are due to the prodysrhythmic properties of quinine, and its effects as a hypoglycemic agent, especially in pregnant women with severe malaria. The prolonged use of normal or low doses of quinine can lead to "cinchonism" in sensitive individuals; this in mild form consists of tinnitus, headache, nausea, and visual disturbances (SEDA-13, 814). Overdosage can cause marked gastrointestinal intolerance, central nervous system disturbances (especially vertigo), visual disorders (very occasionally involving sudden blindness), and cardiovascular problems related to impaired intracardiac conduction. A major risk with quinine is that of direct intravenous injection given too fast. Allergic reactions are not uncommon. They are usually limited to fever and rashes, but angioedema and asthma have been seen. Thrombocytopenic purpura and thrombocytopenia are, at least in some cases, caused by an allergic reaction, and the amounts of quinine present in some "tonics" are sufficient to trigger thrombocytopenia in such patients. Anaphylactic shock has been reported in rare cases (SEDA-13, 814).

Organs and Systems

Cardiovascular

Quinine can cause atrioventricular conduction disturbances. In sensitive patients, such changes can occur with normal dosages given over a prolonged period; however, in most cases cardiac effects are due to overdosage.

Electrocardiographic changes, such as prolongation of the QT interval, widening of the QRS complex, and T wave flattening, can be seen with plasma concentrations above 15 μg/ml (SEDA-11, 590) (SEDA-14, 239).

Quinine, and more profoundly quinidine, its diastereomer, can cause ventricular tachycardia, torsade de pointes, and ventricular fibrillation by prolonging the QT interval (SEDA-20, 261).

- An 8-year-old child given an incorrect dose of quinine had ventricular tachycardia and status epilepticus after 48 hours; the plasma quinine concentration was 20 μg/ml (SEDA-18, 288), compared with the target range of 1.9–4.9 μg/ml.

Respiratory

Quinine can cause allergic asthmatic reactions.

- A 45-year-old woman with long-standing rheumatoid arthritis developed wheeze, severe anxiety, breathlessness, cough, orthopnea, mild fever, chills, and pleuritic chest discomfort after taking a single dose of quinine for nocturnal leg cramps (5). A chest X-ray showed diffuse, bilateral pulmonary infiltrates suggestive of pulmonary edema. No cause other than acute quinine ingestion was identified despite thorough cardiac and infectious disease evaluation.

Quinine poisoning can cause respiratory depression.

Nervous system

Tinnitus and vertigo are not uncommon with quinine, especially at higher dosages (6,7).

Headache and tinnitus occur in chronic toxicity (cinchonism) (8).

Acute intoxication can be followed by convulsions and coma (9).

- A general organic brain syndrome was observed in a 24-year-old woman with tropical malaria after the third day of treatment with quinine sulfate 500 mg tds; her symptoms were headache, blurred vision, vertigo, tinnitus, impaired hearing, increasing apathy, disorientation, speech changes, incoherent thinking, and disorientation with respect to time and place; recovery followed withdrawal (SEDA-16, 305).

A quinidine-induced myopathy has been reported (10).

Sensory systems

Eyes

Amaurosis connected with damage to the retina is most common with high plasma concentrations, and thus follows high dosages and especially overdosage. The outdated, but still practiced, use of quinine to induce abortion is probably the most common cause. Quinine initially affects the photoreceptor and ganglion cell layers; retinal vascular changes are secondary. The first sign may be widely dilated pupils that still respond to light; later, visual field contraction and loss of vision can occur. In milder cases, vision can return, but possibly with a residual disturbance of dark adaptation and/or restricted visual fields. However, loss of vision can be permanent. In cases of permanent damage, the classic late appearance of the fundus after quinine intoxication, with marked pallor and vascular narrowing, appears after some months (SEDA-13, 815). Loss of vision occurs mainly at serum concentrations over 10 μg/ml. Such concentrations are thought not to be toxic in patients with malaria, who have high circulating concentrations of alpha$_1$-acid glycoprotein, resulting in a lower fraction of unbound drug in the plasma (SEDA-17, 329).

Ocular toxicity with vasospasm has been described after poisoning with 4.5 g of quinine 24–36 hours before (11). Therapy for vasospasm using nimodipine, hemodilution, and hypervolemia was instituted, with subsequent resolution of the symptoms.

Blindness has been attributed to quinine (12).

- A 43-year-old Ghanaian man with a mild attack of malaria due to *P. falciparum* received quinine 750 mg intravenously over 5 hours and another identical

© 2006 Elsevier B.V. All rights reserved.

infusion 3.5 hours after the end of the first infusion. Half an hour after the start of the second infusion he wakened and reported complete blindness. The infusion was immediately stopped, and ocular examination showed fixed, dilated pupils, complete blindness, and normal fundi. A CT scan of the brain, electroencephalography, and retinal fluorescein angiography were all normal. Serum quinine concentrations continued to rise after the end of the infusion, but this effect was mitigated by an increase in the serum concentration of alpha$_1$-acid glycoprotein, to which quinine binds. Six hours after the end of the infusion of quinine his sight began to improve.

In a case of quinine poisoning, stellate ganglion block was performed immediately on the basis of the clinical history of visual disturbance without waiting for physical signs to develop. There was no residual field defect despite the presence of toxic concentrations of the drug. The authors suggested that stellate ganglion block may prevent development of visual field defects due to quinine toxicity (13). However, in other cases it was ineffective (14,15). The effectiveness of this treatment may be a function of the speed with which it is instituted.

Ears

Tinnitus is a fairly frequent complaint and is not only seen after quinine overdosage. Permanent impairment of hearing has long been thought to be a possible consequence of long-term use of quinine, but this belief has recently been challenged, and the original description of it is questionable (SEDA-13, 816); the complication is certainly rare (16).

Serial audiometry in 10 patients receiving quinine for acute falciparum malaria showed a reduction in high-tone auditory acuity in all patients, resulting in flattening of the audiogram. The onset of the effect was rapid and it resolved completely after the end of treatment; only seven of these patients reported tinnitus. Hearing impairment was investigated in six volunteers after single doses of quinine at 5, 10, and 15 mg/kg. A clear effect on hearing was found, but with high variability (SEDA-17, 306).

Metabolism

Clinical signs and symptoms of hypoglycemia are reported occasionally; most cases are subclinical, but severe cases have been described (SEDA-13, 815). A study of the effect of quinidine on glucose homeostasis in Thai patients with malaria showed a near doubling of plasma insulin concentrations and a corresponding fall in serum glucose concentrations. An additional factor may have been impaired nutritional status and the effects of parenteral quinine in severely ill patients not taking food (SEDA-13, 815) (SEDA-14, 240) (SEDA-18, 288).

Hematologic

Thrombocytopenia is often reported with quinine. It is probably due to hypersusceptibility rather than a toxic effect, since even the ingestion of minimal amounts of quinine, such as those present in commercial tonic waters, can cause it. A drug–antibody complex has been demonstrated (SEDA-11, 591). In some cases of quinine-induced thrombocytopenia, there was autoantibody-binding to glycoprotein Ib-IX, IIb, and IIIa complexes. In three published cases, quinine-dependent autoantibodies to glycoproteins Ib-IX and IIb/IIIa were associated with both thrombocytopenia and a hemolytic–uremic syndrome (SEDA-16, 305) (SEDA-17, 329). Two other patients had recurrent febrile illnesses characterized by hypotension, pancytopenia, coagulopathy, and renal insufficiency, and both had high titers of quinine-dependent antibodies, which showed cross-sensitivity with quinidine. In one case there was a link with tonic water, while the other had taken quinine sulfate for leg cramps before each episode (17). A list of nine earlier published cases with antibody findings was added to these two case histories.

Isolated thrombocytopenia after the use of quinine for malaria or leg cramps has been described in isolated cases. The FDA's Center for Drug Evaluation and Research received 141 reports of isolated thrombocytopenia in association with quinine from 1974 to December 2000 (18). After elimination of cases that were confounded by acute or chronic disease or concomitant drug therapy, 64 reports of quinine-associated thrombocytopenia were analysed. Thrombocytopenia occurred soon after the start of therapy (median 7 days) and was often severe (hospitalization reported in 55 of the 64 cases).

Since 1972, the Australian Adverse Drug Reactions Advisory Committee has received 198 reports of thrombocytopenia associated with quinine, four of which had a fatal outcome (19). In 17 of the 20 reports received since the beginning of 2000, patients had platelet counts of 0–14 $\times$ 10^9/l; most of them required hospitalization and treatment with platelet transfusions, glucocorticoids, or immunoglobulin. In most cases the platelet count normalized within 1 week of quinine withdrawal. As quinine-induced thrombocytopenia has an immune-based mechanism, the Committee suggested that patients who develop this reaction should subsequently avoid all products that contain quinine, including drinks such as tonic water. They also reminded prescribers that quinine is no longer recommended for the treatment of nocturnal cramps; the FDA withdrew nocturnal cramps as an indication for all quinine products in 1995 because of lack of evidence of efficacy, and the Australian Medicines Handbook advises against its use for this indication.

Glycoprotein epitopes involved in quinine-induced thrombocytopenia have been characterized (20).

Acute intravascular hemolysis with renal involvement and even renal insufficiency can occur with quinine and can follow relatively small doses. Quinine-induced hemolysis has probably played a role in the clinical syndrome of blackwater fever in the past.

- The combination of renal insufficiency with cortical necrosis, thrombocytopenia, intravascular coagulation, and deposition of fibrin was seen in a 63-year-old woman who had drunk tonic water. She had had two previous episodes of acute renal insufficiency also associated with quinine-containing drinks; this most certainly reflected a hypersensitivity reaction (SEDA-13, 815).

© 2006 Elsevier B.V. All rights reserved.

- A 65-year-old man, who had taken a single dose of quinine 300 mg for leg cramps, developed both acral necrosis and hemolytic–uremic syndrome, which resolved promptly after treatment with glucocorticoids (21).

Lupus anticoagulant has been reported with the use of quinine and quinidine, and an associated antiphospholipid syndrome has been described (22).

Disseminated intravascular coagulation has been attributed to quinine (23).

- A 79-year-old woman developed disseminated intravascular coagulation. She had taken a dose of quinine for leg cramps 3 months before and on the day before admission. Her only other medication was bendroflumethiazide. Investigations showed a platelet-associated immunoglobulin with positive immunofluorescence on exposure to quinine sulfate.
- Quinine-induced disseminated intravascular coagulation and hemolytic–uremic syndrome occurred in a 78-year-old woman who took quinine 150 mg for leg cramps; this is the first report of the two diseases occurring simultaneously after quinine (24).

In a retrospective survey of thrombotic thrombocytopenic purpura with hemolytic–uremic syndrome reported to the Oklahoma TTP/HUS Registry, 17 of 225 cases were associated with quinine (doses not stated) taken long-term for leg cramps (25). Patients typically presented with an acute onset of fever, chills, nausea, vomiting, diarrhea, and abdominal pain within hours of quinine ingestion. Laboratory findings included thrombocytopenia, microangiopathic hemolytic anemia, and liver and renal dysfunction. This is an immune-mediated reaction associated with quinine-dependent antiplatelet antibodies and a high mortality (three of the 17 patients). It can be triggered by small amounts of quinine, such as those present in tonic water.

Gastrointestinal

Nausea and abdominal pain can occur with quinine (26). With high doses, diarrhea has been seen (26).

Liver

Granulomatous hepatitis has been reported in a patient taking quinine sulfate for night cramps (27). Cholestatic jaundice was reported in another patient who had taken quinine for night cramps (SEDA-13, 815). Except for the occasional anecdotal case, there is no evidence that true hepatotoxicity occurs with quinine.

Urinary tract

Renal damage accompanies acute hemolysis due to quinine. Renal insufficiency in cases of quinine poisoning is probably due to circulatory collapse. Allergic reactions underlie at least some cases. The picture can be complex, with the renal insufficiency coming in association with cortical necrosis, thrombocytopenia, intravascular coagulation, and deposition of fibrin.

Skin

Rashes are common in allergic reactions. Photosensitivity induced by quinine has been reported; some of the cases occurred in elderly persons taking quinine for night cramps (28). Another form of hypersensitivity to quinine is cutaneous neutrophilic vasculitis, which is a form of photosensitivity (SEDA-16, 305). Local pigmentation has been described after intramuscular injection (SEDA-13, 815).

Immunologic

Quinine can cause a variety of immune-mediated syndromes, most commonly isolated thrombocytopenia, but rarely microangiopathic hemolytic anemia with thrombocytopenia and acute renal insufficiency (hemolytic–uremic syndrome). Two reports of immune-mediated syndromes following the use of quinine for leg cramps have helped to provide an immunopathological explanation for the diversity of such presentations (29,30).

- One patient presented with thrombocytopenic purpura, presumed to be idiopathic (which responded to glucocorticoids and intravenous immunoglobulin) and subsequently presented again with hemolytic–uremic syndrome, and required intensive renal replacement and immunosuppressive therapy. Analysis of serum samples from the isolated thrombocytopenic stage of the presentation showed the presence of quinine-dependent antibodies specific for platelet surface glycoprotein GPIb/IX. Quinine-dependent antibody targets widened to include glycoprotein IIb/IIIa during the hemolytic–uremic phase of the illness, with additional binding to neutrophils and lymphocytes.
- In another case of acute systemic allergy to quinine, which mimicked septic shock, with little hemolysis or renal involvement, the patient presented twice with a virtually identical clinical picture: sudden fever, rigors, and back pain, followed by hypotension, metabolic acidosis, granulocytopenia, and disseminated intravascular coagulation. On each occasion clinical and laboratory indices recovered spontaneously within 36 hours. A retrospective analysis of the patient's serum showed the presence of neutrophil-specific, quinine-dependent antibodies.

A quinine-induced lupus-like syndrome, including pericarditis and polyarthralgia, and positive antinuclear and anti-cardiolipin antibodies, and a polymyalgia rheumatica-like syndrome have been described with quinine or quinidine (SEDA-20, 261) (SEDA-21, 298).

Second-Generation Effects

Teratogenicity

Quinine crosses the placenta and can be found in relatively high concentrations in cord blood; it is also excreted in the breast milk. Data about possible teratogenicity related to the therapeutic use of malaria are scanty (SEDA-14, 239). Hypoplasia of the optic nerve and deafness have been reliably described in children born after failure to induce abortion with the drug.

© 2006 Elsevier B.V. All rights reserved.

Susceptibility Factors

Age

Children under 2 years are more vulnerable to quinine toxicity as measured by prolongation of the QRS interval at 2–4 hours after intravenous quinine (SEDA-20, 261).

Renal disease

A pharmacokinetic study in adults with renal insufficiency showed that concentrations of the main metabolite, hydroxyquinine, rose to 45% of the concentrations of the parent compound, and may contribute up to 25% of the cardiac effects of quinine (31).

Other features of the patient

The use of quinine to treat cerebral malaria, and to a lesser extent severe malaria, has always been considered more risky than treatment of common cases of malaria. The changes in the pharmacokinetics of quinine caused by the malaria provide an explanation: the standard dose of 10 mg/kg is usually well tolerated in patients with uncomplicated malaria but causes markedly higher plasma serum concentrations in patients with cerebral malaria. Total quinine clearance and total apparent volume of distribution are significantly lower in severe malaria, and after recovery, the pharmacokinetics return to normal. Probably the first loading dose should be as generally advised, but with a reduction in subsequent doses until the general condition has improved. Monitoring of plasma or red cell concentrations of quinine would of course be ideal, but this luxury is rarely available (SEDA-13, 816).

Drug Administration

Drug overdose

Early symptoms of intoxication with quinine are unremarkable, except for mild visual and auditory complaints (32,33). The principal sign is the sudden onset of bilateral pupil dilatation. Other symptoms are tinnitus, mild deafness, vertigo, mild drowsiness, vague disturbances of consciousness, headache, nausea, vomiting, and abdominal pain. The electrocardiogram may show prolongation of the QT interval and ST abnormalities. Deafness can occur within hours or days of the acute symptoms. Visual disturbances do not necessarily occur early on. Acute intoxication can be seen after ingestion of doses of 4–12 g, but a dose of 8 g can prove lethal. Death is commonly caused by respiratory arrest, but is sometimes due to renal insufficiency. In five children with quinine overdosage, there were serious neurological and cardiac effects, such as seizures, ventricular tachycardia, and cardiac arrest (SEDA-20, 261).

Repeated oral administration of activated charcoal reduces plasma quinine concentrations and mitigates toxicity (34).

Drug–Drug Interactions

Anticoagulants

Quinine can increase the action of anticoagulants, possibly by inhibition of prothrombin synthesis (35).

Carbamazepine

Quinine inhibits the metabolism of carbamazepine (36).

Chloroquine

Chloroquine antagonizes the action of quinine against *P. falciparum* in vivo (37). However, no such evidence of antagonism was found in a study in which Malawian children with cerebral malaria were treated with quinine. There was no difference in survival and rate of recovery in patients who had also been given chloroquine compared with those who had not (SEDA-13, 816).

Clindamycin

The combination of quinine with clindamycin improved the cure rate after a short course of quinine (38). This combination enhances parasite clearance and recovery from fever and is of value in combating bacteremia (39).

Codeine

Quinidine inhibits the metabolism of codeine by CYP2D6 in extensive but not in poor metabolizers (40).

Digoxin

Quinine reduces the clearance of digoxin by inhibiting its biliary excretion (41). There may also be a small effect on renal digoxin clearance (42).

Enzyme inhibitors and inducers

Enzyme inhibitors, such as cimetidine and ketoconazole, increase the toxicity of quinine or quinidine (43), while enzyme inducers, such as rifampicin, reduce the toxic effects (44).

Erythromycin

Erythromycin is a competitive in-vitro inhibitor of quinine 3-hydroxylation and may therefore interact with quinine (45).

Flecainide

Flecainide is metabolized by CYP2D6, and is subject to polymorphic metabolism. In extensive metabolizers its clearance is reduced by quinine (46).

Halofantrine

Quinine should not be combined with halofantrine, since both drugs impair atrioventricular conduction and since quinine can enhance the cardiotoxic effects of halofantrine by inhibiting its metabolism (47).

Phenobarbital

Quinine inhibits the metabolism of phenobarbital (36).

© 2006 Elsevier B.V. All rights reserved.

Tetracycline

The antimalarial effect of tetracycline is well known. The combination of quinine with doxycycline improved the cure rate (38,39). However, none of the patients taking quinine in combination with either clindamycin or tetracycline had high-grade resistant *P. falciparum* infections. The drawback of combining quinine with tetracycline is the longer time required for adequate treatment, which in most cases demands supervision. Furthermore, tetracycline should not be given to young children or pregnant women. The combination can be used in multiresistant and mefloquine-resistant *P. falciparum* malaria. When quinine is combined with doxycycline, the effects of the antibiotic itself may be enhanced.

Theophylline

Quinine raised serum theophylline concentrations in an elderly patient (48).

Rabeprazole

See also Proton pump inhibitors

General Information

The benefits and risk profile of rabeprazole, a proton pump inhibitor, have been reviewed (1,2). It has been well tolerated in both short-term and long-term studies. The overall rate of drug withdrawal because of adverse effects was 3%. Common adverse effects included diarrhea, headache, and rash.

Observational studies

Rabeprazole 10 and 20 mg/day in the morning were effective in erosive or ulcerative gastro-esophageal reflux disease, gastric and duodenal ulcers, and long-term maintenance of gastro-esophageal reflux disease healing (1). Healing rates were equivalent to those with omeprazole and superior (gastro-esophageal reflux disease healing and duodenal ulcer healing) or equal (gastric ulcer healing) to ranitidine.

In an open study in 189 patients rabeprazole 20 mg/day for 4 weeks was effective in functional dyspepsia (3). The incidence of adverse events was 8%, and included dysgeusia, diarrhea, constipation, and headache.

In a crossover study in 24 healthy volunteers, rabeprazole 10, 20, and 40 mg produced significant dose-related reductions in intragastric acidity associated with a significant rise in serum gastrin concentration (4). There were no serious adverse effects. After taking into account increases in serum gastrin concentrations and interindividual variation in the antisecretory response, 20 mg appears to be the preferred dose for routine clinical use. Similar potent dose-related gastric acid inhibition and rises in serum gastrin were found with rabeprazole 5–40 mg/day in the morning for 7 days in 38 subjects infected with *Helicobacter pylori* (5). There was less than 50% recovery of acid by 48 hours after the seventh dose. In this study the optimal acid inhibitory dose appeared to be 20 mg/day, and there were no serious adverse effects.

The safety and efficacy of rabeprazole have been evaluated in 124 patients aged 65 years and over being treated for a variety of acid-related disorders (6). Rabeprazole controlled symptoms and healed mucosal lesions. The incidence of adverse effects was 4.9%, and adverse effects were more common in the presence of hepatic dysfunction and with increasing duration of treatment.

The efficacy and tolerability of rabeprazole 10 mg/day for 8 weeks in the treatment of reflux esophagitis has been assessed in an open, postmarketing surveillance investigation in 61 patients (7). Rabeprazole was well tolerated and was effective in relieving symptoms and healing esophagitis. Two patients developed slight rises in liver enzymes, which resolved after treatment.

In an open, multicenter trial in 2579 patients with erosive gastro-esophageal reflux disease, rabeprazole 20 mg/day for 8 weeks relieved symptoms in most patients (in over 60% by day 1 and over 80% by day 7) (8). Rabeprazole was well tolerated, and the most common adverse effects were headache, diarrhea, abdominal pain, and nausea, each reported by under 2% of the patients.

In another open, multicenter study in 92 patients with erosive esophagitis, rabeprazole 20 mg/day was effective in healing esophageal lesions and relieving heartburn (9). Adverse effects (diarrhea, headache, and nausea) were attributed to the medication in four cases.

Placebo-controlled studies

In a double-blind, placebo-controlled study in 288 patients with previously treated erosive or ulcerative gastro-esophageal reflux disease rabeprazole 10 or 20 mg/day was significantly more effective than placebo in preventing relapse of erosive or ulcerative gastro-esophageal reflux disease and was well tolerated (10). Commonly reported adverse events were abdominal pain, nausea, diarrhea, rhinitis, pharyngitis, a flu-like syndrome, and back pain. Rabeprazole had no clinically significant effects on laboratory values, thyroid function tests, the electrocardiogram, vital signs, or body weight.

General adverse effects

Rabeprazole was generally well tolerated in both short-term and long-term studies of up to 2 years. Headache was the most important reported adverse effect. Other commonly reported adverse effects were diarrhea, rhinitis, nausea, pharyngitis, abdominal pain, and flatulence. The changes in serum gastrin concentrations were consistent with proton pump inhibitor pharmacology, and no study has reported mean values at end-point that were outside the reference range. In controlled trials, the frequency of abnormalities of hepatic aminotransferases was similar to that of placebo. Scoring of enterochromaffin-like cells in gastric biopsies taken prospectively from patients in studies of up to 2 years have shown some hyperplastic changes, but no evidence of adenomatous, dysplastic, or neoplastic changes.

Organs and Systems

Liver

- Acute fulminant hepatitis occurred in a previously healthy 46-year-old man who took rabeprazole and terbinafine (11). His condition improved gradually after withdrawal of both drugs.

Rabies vaccine

See also Vaccines

General Information

Rabies vaccine was for a long time prepared from infected brain tissue, and neurological complications were likely to occur in as many as one in 300 cases. A second-generation vaccine prepared from duck embryo tissue has been found to be better tolerated in this respect, and third-generation vaccines prepared in non-neural tissue cultures or in human diploid cell (HDC) vaccines with a progressive improvement in safety have now become the vaccines of choice where they are available.

Any rabies vaccine can apparently cause mild local discomfort and swelling, and either of the animal preparations can result in hypersensitivity reactions, for example pyrexia, serum sickness, or urticaria; sensitization can occur.

Third-generation rabies vaccines include a purified vero-cell rabies vaccine (PVRV) and HDC vaccine purified by zonal centrifugation. In clinical trials (SEDA-12, 284) (SEDA-15, 357) the improved vaccines were well tolerated. In 1988, Rabies Vaccine Adsorbed (RVA), a new cell culture-derived rabies vaccine (Kissling strain of rabies virus adapted to a diploid cell line of the fetal rhesus lung cells in medium-free of human albumin and adsorbed on aluminium phosphate) for human use was licensed in the USA. Reactions after primary immunization are similar to those observed with HDC. Systemic allergic reactions have been reported at a rate <1% (HDC 6%) (1).

Organs and Systems

Nervous system

Brain tissue rabies vaccine

There are many countries that still use first-generation brain tissue rabies vaccine because of limited financial resources and where neurological complications after immunization still occur. The neurological effects produced by this type of vaccine are very variable. Sometimes a peripheral neuropathy occurs, while other vaccinees develop encephalomyelitis, dorsolumbar myelitis, ascending myelitis, hemiplegia, or general subjective neurological symptoms, such as stiffness of the neck or physical weakness.

It has been argued that there may be a risk of transmitting scrapie (spongiform encephalopathy of sheep, similar to bovine spongiform encephalopathy of cattle) through blood donation from individuals who have been immunized against rabies with sheep brain rabies vaccine still used in developing countries (2).

Duck embryo rabies vaccine (DEV)

Nervous system complications after administration of DEV occurred, but in much lower frequency than after brain tissue rabies vaccines. Reports of transverse myelitis and other neurological complications have been published (SEDA-8, 300). There have been some efforts to develop a more purified version of DEV, but improvements in third-generation vaccines have made these the vaccines of choice when they can be afforded, much reducing the motivation to develop duck embryo vaccines further.

Human diploid cell (HDC) vaccines

The major advantage of third-generation rabies vaccines prepared in non-neural tissue cultures or in human diploid cells is the greatly reduced risk of neurological complications. Millions of doses of these vaccines have been administered worldwide since 1974, and only a few neurological complications have been reported. The overall risk of neurological complications is estimated to be less than 1 per 150 000 (SEDA-15, 356), and complications after the administration of third-generation rabies vaccines cultured in non-neural tissues have been very rarely reported. However, those that have been published are of various types.

Isolated case reports of Guillain–Barré syndrome after HDC vaccine have been published (SED-11, 684) (SEDA-15, 356) (3). Polyneuropathy and oculomotor nerve impairment have been reported after Russian cell-culture vaccine (SEDA-12, 284).

- Two weeks after the second injection of HDC vaccine a 45-year-old farmer developed meningoradiculitis. The symptoms regressed spontaneously (4).
- A 25-year-old veterinary practitioner developed an inflammatory demyelinating process affecting the

© 2006 Elsevier B.V. All rights reserved.

central nervous system 8 days after the second HDC vaccine immunization (5).
- Acute disseminated encephalomyelitis developed in a 15-year-old boy after HDC vaccine immunization (SEDA-21, 337).
- A 14-year-old boy had a seizure after the administration of human diploid rabies cell vaccine simultaneously with rabies immune globulin. The symptoms developed within minutes after injection. After treatment and about 2 hours later, his mental status returned to normal (6).

Immunologic

In recipients given primary courses of third-generation rabies vaccines, only mild local and systemic reactions were reported by about 20%. Systemic allergic reactions have occurred in 11 per 10 000 vaccinees (7). However, 2–21 days after the administration of HDC vaccine, about 5% of patients receiving booster injections for pre-exposure prophylaxis and a few receiving postexposure primary immunization develop an immune complex (serum sickness-like) reaction, including urticaria, fever, malaise, arthralgias, arthritis, nausea, and vomiting. This syndrome may prove to be less common with RVA, but direct comparisons are lacking.

Anaphylaxis has been reported rarely after HDC vaccine prophylaxis (3).

Racecadotril

General Information

Racecadotril is an orally active potent inhibitor of enkephalinase, which has an antihypersecretory effect without increasing intestinal transit time.

Racecadotril 100 mg tds has been compared with loperamide 2 mg tds in a single-blind study in 945 outpatients with acute diarrhea in 21 centers in 14 countries (1). Racecadotril resolved acute diarrhea as rapidly and as effectively as loperamide and produced more rapid resolution of abdominal symptoms and less constipation. The incidence of adverse effects attributable to medication was less in the racecadotril group (9 versus 18%). Common adverse effects were constipation, abdominal distension, anorexia, headache, and abdominal pain.

Radioactive iodine

General Information

Three radioactive isotopes of ^{127}I are currently used in clinical medicine:

1. ^{131}I (radioactive half-life of 8 days and a high-energy emitter), used mainly in the therapy of hyperthyroidism and thyroid cancer.
2. ^{123}I (radioactive half-life 13 hours) has replaced ^{131}I for diagnostic purposes; however, for in vivo imaging meta-stable technetium-99 (^{99m}Tc) is often preferred, because of its lower radiation dose, availability, and cost.
3. ^{125}I (radioactive half-life of 60 days and a low energy emitter), previously used in the treatment of hyperthyroidism, but now replaced by ^{131}I because of disappointing therapeutic results (1,2).

Radioactive isotopes of iodine are handled by the thyroid in the same way as stable iodine and are therefore actively concentrated, incorporated into thyroglobulin, stored, metabolized, and secreted as thyroid hormones. Small amounts of radioactive iodine are therefore ideal probes to analyse the uptake of iodine, the distribution of iodine in the gland, and possibly even its turnover and incorporation into thyroid hormones. Larger amounts of radioactive iodine selectively radiate the thyroid gland and therefore selectively impair the function of the follicular thyroid cells and eventually destroy them.

Doses

Three dosage ranges for radioactive forms of iodine are used:

1. For diagnostic purposes usually much less than 1 mCi (37 MBq) is given with thyroid radiation doses of a few rads of ^{123}I up to 50–200 rads (0.5–2.0 Gray) (^{131}I).
2. In the treatment of hyperthyroidism the dose of ^{131}I is usually a few millicuries and is either roughly estimated or calculated according to the size of the thyroid gland, the uptake of a tracer dose of iodine, and the type of thyroid disorder (diffuse or nodular), with doses ranging from 80 to 150 microCi (3.0–5.5 MBq) per gram of thyroid tissue (3,4).

© 2006 Elsevier B.V. All rights reserved.

3. In thyroid cancer, ^{131}I can be used to eliminate tumor tissue that cannot be removed surgically but still captures iodine; in such circumstances, amounts of 100 mCi (4000 MBq) of ^{131}I or more are not unusual; with such high amounts, other tissues besides the thyroid gland can also receive substantial amounts of radiation.

The administration of ^{131}I requires safety measurements to reduce to a minimum the irradiation of medical personnel and to avoid contamination of rooms and relatives of patients. Capsules containing ^{131}I are therefore to be preferred to liquid iodine. At doses above 25 mCi (555 MBq), usually intended only for treatment of patients with thyroid cancer, isolation in a specially constructed room of a service for nuclear medicine is necessary. Waste disposal should also be carefully managed so as to avoid overall contamination (5,6).

General adverse effects

Radiation thyroiditis is an infrequent complication resulting in swelling and localized pain over the thyroid gland which subsides spontaneously or with anti-inflammatory or corticosteroid therapy (SEDA-1, 314).

Acute exacerbation of hyperthyroidism, resulting particularly in cardiac complications (arrhythmias or decompensation) or even "thyroid storm," has been reported several times (SEDA-1, 314) and should be avoided by treating very severely hyperthyroid patients with antithyroid drugs prior to the administration of ^{131}I. A temporary increase in serum triiodothyronine and l-thyroxine without clinical symptoms of exacerbation of hyperthyroidism, however, occurs much more frequently (SEDA-1, 314). In 71 patients given ^{131}I for differentiated thyroid carcinoma, short-term adverse effects included gastrointestinal complaints, salivary gland swelling with pain, change in taste and headache (7).

Organs and Systems

Cardiovascular

In a series of thyrocardiac patients, of those dying primarily from thyrotoxicosis more than 21% did so within 3 weeks of ^{131}I treatment (8), presumably reflecting too sudden a change in metabolic activity for patients with existing cardiac complications.

Respiratory

Acute respiratory embarrassment due to thyroid swelling or subsequently due to cicatrization occurs only rarely.

Nervous system

Although aseptic meningitis has been associated with the use of radioactive iodine, the products used were albumin complexes (^{131}I-RISA); this complication is almost certainly attributable to the protein content or to pyrogens rather than to the radioactive iodine itself (8).

Sensory systems

Several papers have reported that radioiodine therapy can lead to worsening of ophthalmopathy, possibly because of the release of thyroid antigens during the inflammatory reaction after ^{131}I therapy. The worsening can be prevented by glucocorticoid therapy (9).

Endocrine

The calcitonin-producing cells of the thyroid are usually destroyed by ^{131}I (SEDA-14, 369).

Both hyperfunction (10) and hypofunction of the parathyroid glands have been described after the use of ^{131}I (11).

Hypothyroidism

There is an increased incidence of late hypothyroidism in patients with autoimmune hyperthyroidism, but the risk increases markedly after extensive thyroid surgery and especially after ^{131}I treatment. Analysis of the cumulative incidence of hypothyroidism shows two phases: an early phase of radiation death of thyroid cells, depending on the ^{131}I dosage and occurring during the first 1–2 years after treatment; a second period of a lower (0.5–3.5% per year) but life-long risk of developing hypothyroidism for a variety of reasons (natural history of the disease, autoimmune processes) (see Table 1) (12–14).

The total incidence of hypothyroidism can therefore be reduced by lowering the therapeutic dose, but at the expense of a higher incidence of more prolonged or recurrent hyperthyroidism. Calculation of the therapeutic dose according to thyroid gland size, iodine uptake, or biological half-life and type of thyroid disorder can help to reduce the total incidence of hypothyroidism, although this is less well documented than many believe (15,16). Moreover, the occurrence of hypothyroidism after the use of ^{131}I should not be dramatized, since treatment is much

Table 1 The risk of hypothyroidism after ^{131}I

N	^{131}I dose (mCi)	Total follow-up period (years)	Incidence of hypothyroidism (%)				Total annual cumulative incidence (% per year)	Reference
			One-year follow-up		End of follow-up			
			Diffuse goiter	Nodular goiter	Diffuse goiter	Nodular goiter		
4473	8–20	26	8	3	77	64	3	(12)
1369	9	17	6	3	26	14	3.5	(13)
248	6–10	10	38	11	70	18	0.5	(14)

simpler than abandoning the patient first to the prolonged risk of recurrent hyperthyroidism and thereafter to lifelong follow-up for hypothyroidism. Hypothyroidism after ^{131}I can also be transient, and replacement therapy should not be started too early (17).

Hematologic

Leukemia does not occur more often in patients treated with ^{131}I for hyperthyroidism than in similar patients treated by surgery. After use of the high doses used in the treatment of thyroid cancer there was a definite increase in the incidence of leukemia (18).

Salivary glands

In 71 patients given ^{131}I for differentiated thyroid carcinoma, salivary gland swelling with pain occurred in 50% (7); women had a significantly higher incidence than men.

Gastrointestinal

Of 71 patients given ^{131}I for differentiated thyroid carcinoma, 65% had gastrointestinal complaints: appetite loss, nausea, and vomiting occurred in 61, 40, and 7.6% respectively and increased significantly in the patients who received doses above 55.5 MBq/kg and with rises in TSH (7).

Reproductive system

Large amounts of ^{131}I, as used in thyroid cancer therapy, can cause testicular damage as documented from hormonal and sperm analysis (19), but long-term results are nevertheless reassuringly normal (20).

Long-Term Effects

Mutagenicity

Mutagenic effects on the sexual organs are difficult to determine in practice. However, while the radiation dose to the ovary and testes is rather small after ^{131}I treatment for hyperthyroidism (maximum 5 roentgens) it can be substantial after the higher amounts of ^{131}I that are used for thyroid cancer. In any case, children born to mothers previously treated with ^{131}I did not have an increased incidence of congenital malformations. The number of such observations is too small, however, to allow definite conclusions about its safety (21). In patients treated for thyroid carcinoma there was no differences in fertility rate, birth weight, prematurity, or congenital malformations compared with healthy subjects, providing reassurance about the use of radioiodine to treat hyperthyroidism in women of child-bearing age (SEDA-20, 394).

Tumorigenicity

The total number of case reports of thyroid cancer after ^{131}I is very small (under 30 cases) (22) in relation to the estimated number of patients treated with ^{131}I since 1941 (over 1 000 000 patients). Moreover, systematic follow-up or retrospective studies did not show an increased risk of thyroid carcinoma in patients treated with ^{131}I for hyperthyroidism. The results of two such studies are shown in more detail in Table 2 (23) and Table 3 (24).

Table 2 ^{131}I treatment and thyroid cancer: a comparison with thyroidectomy and antithyroid drugs

Incidence of thyroid cancer	Thyroidectomy (n = 11 732)	^{131}I (n = 21 714)	Antithyroid drugs (n = 1238)
Within 1 year of treatment	50	9	0
After 1 year of treatment	4	19	4
Total	54 (4.6%)	28 (11.3%)	4 (3.2%)
Number of deaths from thyroid cancer	4	6	0

Table 3 ^{131}I treatment and thyroid cancer

Number of patients treated with ^{131}I	3000
Mean age	57 years
Mean dose of ^{131}I	13.3 mCi
Mean observation period	13 years
Thyroid cancer	
Observed incidence	4%
Expected incidence	3.2%
Thyroid cancer more than 5 years after ^{131}I	
Observed incidence	2.1%
Expected incidence	3%

In another follow-up study of 1005 women treated with ^{131}I there was no increase in total morbidity or in the incidence of thyroid cancer (20).

In 10 552 Swedish patients (mean age 57 years) who received ^{131}I for hyperthyroidism (mean follow-up 15 years) there were increases in overall cancer mortality and deaths due to carcinoma of the stomach, lung, and kidney. While the findings for stomach cancer may be of significance, for tumors at other sites, because of an association with time after ^{131}I treatment (58 cases at 10 years or more of follow-up against the expected 44 cases), the lack of a relation between cancer mortality and either the time from radioiodine treatment or the dose administered argues against a carcinogenic effect of radioiodine (SEDA-17, 475) (25).

The use of very high amounts of ^{131}I for thyroid cancer imposes special care and risks: the frequency of radiation thyroiditis is much higher (more than 20%) and similar symptoms of pain and swelling can also be observed in the salivary glands. Nausea and vomiting may also occur. The incidence of leukemia is increased: 15 cases being reported in 5000 patients treated with ^{131}I for thyroid cancer (18); it therefore seems wise to limit the total dose of ^{131}I in a single patient to 500 mCi unless the thyroid disease activity permits higher long-term risks. It is also important to keep such patients well hydrated to allow rapid elimination of ^{131}I not retained by thyroid tissue. The radiation dose to the ovaries is not negligible, being approximately 200 roentgens after 500 mCi of ^{131}I, a dose sufficient to increase slightly the subsequent risk of miscarriage or congenital abnormalities. However, no apparent increase in the rate of abnormalities has been observed in the outcome of pregnancies among women previously treated for thyroid cancer.

The use of ^{131}I in children is different from its use in adults. Experience worldwide is much more limited as regards both the number of children treated and the total number of years of observation (SEDA-20, 394). The risk of eventual tumor-inducing effects in the thyroid or other tissues is real. The young thyroid is very sensitive to external radiation or to nuclear fall-out: 66% of young adults developed thyroid lesions 25 years after such exposure (26). One report on a high prevalence of hypothyroidism after ^{131}I showed no cases of thyroid or other malignancies after a mean follow-up period of almost 15 years (27). However, others found an increased frequency of thyroid nodules: among case reports on thyroid cancer after ^{131}I in the world literature the younger age group is largely over-represented, owing to the frequency of ^{131}I use in this age group (22). In view of the small number of long-term results in a young population with probably higher susceptibility for thyroid tumors it seems unwise to use ^{131}I as preferred treatment for adolescents or young adults with hyperthyroidism. Much longer follow-up periods will be necessary, preferably with central registration to allow a definite conclusion about treatment (21,18). However, many experts consider the current follow-up period sufficiently long to extend the use of ^{131}I to all patients with Graves' disease above the age of 25 (SEDA-14, 368) (28). There are, however, large discrepancies in treatment strategies globally.

Second-Generation Effects

Pregnancy

Radioactive iodine passes the placenta and accumulates in the fetal thyroid where the concentration probably exceeds that in the maternal thyroid. Detailed studies show that the fetal dose of iodine is virtually nil before the 90th day of gestation but sharply increases thereafter (29). This alone is sufficient reason to avoid the use of ^{131}I in pregnancy, but there is also some controversial evidence that various congenital deformities have been produced by the isotope (30).

Teratogenicity

Concern about possible second-generation effects of ^{131}I is difficult to allay but has not been substantiated, since there is an absence of obvious birth defects or genetic changes in the offspring of patients treated with ^{131}I (20,22,24,31,32). Moreover, the radiation dose to the ovaries in ^{131}I therapy for hyperthyroidism is usually below three roentgens and thus comparable to the radiation due to common radiographic abdominal examinations. If ^{131}I is given during pregnancy, fetal hypothyroidism and chromosomal aberrations can occur (33).

Lactation

^{131}I is transferred in the milk and should not be given during lactation. Even the diagnostic use of radioisotopes of iodine should be avoided (34).

Interference with Diagnostic Tests

Detection of pulmonary embolism

Injections of ^{131}I given to detect pulmonary embolism can result in false-negative results in the ^{125}I-labeled fibrinogen test for venous thrombosis.

Radiopharmaceuticals

General Information

Radioactive substances may be used in medicine as tracers, the quantities used in this case being merely sufficient to enable them to be detected, or as therapeutic agents, in which case the quantities employed and the amount of radiation emitted may be considerable. Risks resulting from the radiation itself fall outside the scope of this volume.

Radio-iodine is covered in a separate monograph.

General adverse effects

Radiopharmaceuticals have a good safety record. The prevalence of adverse reactions is approximately 1000-fold than less than that occurring with iodinated contrast media and drugs. The Society of Nuclear Medicine has maintained a register of adverse reactions to radiopharmaceuticals occurring in USA since 1976. The frequency of reactions appears to be falling because of improved quality control of radiopharmaceuticals. Many of the earlier adverse reactions were attributed to iron-containing formulations, gelatin-stabilized formulations, materials such as albumin contaminated with pyrogens, and other products no longer in use. The overall incidence of reactions for the year 1978 was estimated to be 1–6 per 100 000 examinations (1).

In order to determine the prevalence of adverse reactions to radiopharmaceuticals, a 5-year prospective study (1989–94) was performed in 18 institutions in the USA (2). The reported incidence rate was 0.0023%. No adverse reaction required hospitalization or had significant sequelae. The adverse reactions and types of radiopharmaceuticals are shown in Table 1.

Another study was undertaken to determine the prevalence of adverse reactions to positron-emitting radiopharmaceuticals through a prospective 4-year study in 22 institutions. PET radiopharmaceuticals have an excellent safety record because no adverse reactions were reported in over 80 000 administered doses in this study (3).

In a review of UK reports of adverse reactions to radiopharmaceuticals from 1977 to 1983, there was a changing distribution pattern with time (Table 2) (4). This was partly due to elimination of some of the earlier, more toxic formulations and partly due to changing usage, more particularly the increased use of phosphonate formulations. The authors estimated that only 10% of reactions were reported and that the probable

Table 1 Adverse reactions to 783 525 radiopharmaceutical doses in 1989–94 in the USA

Radiopharmaceutical	Adverse reaction	Number
^{67}Gallium citrate	Rash	1
[^{131}I] Iobenguane (MIBG)	Chest discomfort, light-headedness	1
^{99m}Tc-macroaggregated albumin	Rash	1
^{99m}Tc-medronate (MDP)	Rash/nausea/mild anaphylaxis	2/1/1
^{99m}Tc-oxidronate (HDP)	Rash/sweating	4/1
^{99m}Tc-pentetate (DTPA)	Rash	1
^{99m}Tc-sestamibi	Rash	1
^{99m}Tc-sulfur colloid	Nausea, vomiting, rash, headache	1
Stannous pyrophosphate (non-radioactive)*	Mild anaphylaxis/ light-headedness	2/1
Total		18

*Given intravenously to allow in vivo radiolabeling of erythrocytes and considered part of the final radiopharmaceutical.

Table 2 Major groupings of adverse reactions to radiopharmaceuticals reported in the UK from January 1977 to December 1983

Period	Colloids	Phosphonates	Albumin particulates	Others
1977 to mid-1980	12 (48%)	2 (8%)	5* (16%)	8* (28%)
Mid-1980 to 1983	8† (21%)	15† (45%)	3 (10%)	8* (24%)
Total	20† (33%)	17† (28%)	8* (13%)	16* (26%)

*1 case or †2 cases considered to be "unlikely to be due to the radiopharmaceutical".

incidence rate was between one in 1000 and one in 10 000. There was one death associated with a hypotensive reaction to colloid in a severely ill patient. One elderly patient had a cardiac arrest after injection of macroaggregated albumin but was resuscitated. In a European prospective survey during 1996, there was a prevalence of 11 events per 105 administrations of radiopharmaceuticals. No serious or life-threatening events were reported (5).

^{99m}Technetium

The widespread use of ^{99m}Tc-DTPA (diethylaminetriaminepenta-acetate), mostly used for renal imaging, has brought with it a number of reported DTPA adverse reactions. Typical symptoms include low pressure, loss of consciousness, feeling faint and occasionally skin rash and bronchospasm. In Europe, a patient with a history of asthma developed severe bronchospasm and died within a matter of minutes (6). A series of very serious problem developed following intrathecal injection of ^{99m}Tc-DTPA in what turned out to be, strictly speaking, a misformulation incident. Almost all currently used DTPA formulations contain the mixed calcium/sodium salt of DTPA. However, one particular manufacturer used the trisodium salt. This form is capable of chelation of cerebrospinal fluid calcium and magnesium and causing gradual onset of severe neurological signs and severe paresthesia (7).

^{99m}Tc-labeled serum albumin microspheres have in one case caused collapse, apparently because the patient in question had earlier been sensitized by blood transfusions (SEDA-2, 376).

A case of anaphylaxis occurred after the injection of a leukocyte suspension labeled with ^{99m}Tc-hexamethyl propylene amine oxime (8).

Inhalation of Technigas (an ultrafine suspension of ^{99m}Tc-labeled carbon particles) for ventilation scintigraphy, in a series of patients led to a temporary reduction in oxygenation in 87% of cases, often in sufficient degree to cause some discomfort (SEDA-17, 539) (9). Injection of ^{99m}Tc-MAA for perfusion scintigraphy similarly tended to cause a decrease in oxygenation, but insufficient to cause symptoms.

Others

Aseptic meningitis has been reported after isotope cisternography with indium diethylenetriaminopentaacetic acid (SEDA-2, 376).

Dipyridamole-^{201}thallium imaging has been used to assess cases of suspected coronary disease (SEDA-15, 506) (SEDA-16, 537) (SEDA-17, 539). It is difficult to distinguish the adverse effects of dipyridamole from those of the pharmaceutical agent (dipyridamole-^{201}thallium), since dipyridamole can cause bronchospasm. In one series of 400 examinations, there was severe chest pain due to myocardial ischemia in 9% of cases, milder chest pain (probably not associated with cardiac events) in 21%, and severe hypotension in 2.5% (10). Others have reported instances of cardiovascular collapse (SEDA-15, 506).

Second-Generation Effects

Lactation

Many radiopharmaceuticals are excreted in breast milk, and two reviews have discussed the implications of nuclear medicine examinations in the nursing mother (11,12).

Iodides are excreted in high concentrations in breast milk. The use of the short half-life ^{123}I in preference to ^{131}I partly overcomes this problem, but iodide or perchlorate, which is used to block thyroid uptake in the mother can be excreted in the milk. Likewise, furosemide or cholecystokinin, which can be used to alter the distribution of radiopharmaceuticals, can be excreted in breast milk.

Technetium compounds are the most widely used radiopharmaceuticals; the highest excretion in breast milk occurs with sodium pertechnetate and the lowest with technetium diethylenetriaminepenta-acetic acid, which is rapidly excreted by the kidneys. Depending on the type of examination and the dose of radiopharmaceutical, the mother should be advised to withhold breastfeeding for 12–24 hours. Advice may also be required concerning external radiation when the mother holds the child.

Before deciding to perform nuclear medicine tests in young women, it is important to consider the possibility of future lactation. Only essential investigations should be performed: the most appropriate radiopharmaceutical should be selected, and the dose reduced to the minimum compatible with obtaining a diagnostic result. According to the radiopharmaceutical in question, interruption of breastfeeding may be necessary. Breastfeeding is contraindicated for ^{201}thallium chloride, ^{67}gallium citrate, ^{131}iodide, ^{75}selenomethionine, and ^{125}I fibrinogen (13).

Drug–Drug Interactions

Heparin

The use of heparinized catheters for in vivo erythrocyte labelling with ^{99m}Tc-pyrophosphate occasionally produces adverse reports, such as diminution of cardiac activity and increase of renal activity due to the formation of a technetium-heparin complex which localizes avidly in the kidneys. A few cases reported the possibility of reaction of radiopharmaceuticals with the components of a syringe or needle.

Drugs that interfere with the radiolabeling of blood cells

There is evidence that some drugs can adversely affect the radiolabeling of leukocytes. In a survey for the years 1981–97 of instances of unusually low labelling efficiencies of leukocytes labelled with ^{111}In-tropolone and ^{99m}Tc-HMPAO, respondents were asked to ascertain which drugs were being taken on the day of the test (14). Fifty adverse reports were received during that period. Many patients were taking drugs that are known to affect leukocyte function, including azathioprine, cephalosporins, cyclophosphamide, heparin, iron salts, nifedipine, prednisolone, and sulfasalazine. The author used Bradford–Hill's criteria (15) to assess whether the association between two variables was also one of causation, and thought that there was a high probability that these drugs had caused the low labeling efficiency.

Raloxifene

General Information

Raloxifene is a non-steroidal so-called "selective estrogen receptor modulator" (SERM), that is it binds to estrogen receptors, but this binding produces agonist effects at some sites and antagonist effects at others (1). It has estrogen agonist effects on bone and lipid metabolism but estrogen antagonist effects on the breast and endometrium; it is also claimed by its protagonists to have cardioprotective effects, perhaps through an effect on endothelial cells and a reduction in homocysteine concentrations (2).

Reports of adverse reactions to raloxifene should be considered alongside those reported for tamoxifen and other anti-estrogens. However, earlier reports have pointed to a considerable increase in thromboembolism, as has some recent large-scale work (3), and it would be premature to draw final conclusions about the conditions in which it can safely be used.

Raloxifene has been studied for its ability to reduce bone loss in postmenopausal women (4). Some specialized SERMs could reduce the risk of osteoporosis after the menopause without having other troublesome hormonal effects (5), but much more work is needed to determine whether they will fulfill this hope.

In a critical review of raloxifene, published in France, it was concluded that the compound has no advantages compared with a traditional estrogen, and that in view of certain findings in animal studies there is a possibility that it might increase the risk of ovarian cancer; there is also a need to determine whether it is sufficiently safe in women with a history of (or predisposition to) breast cancer (6).

One also finds a critical view expressed in the USA, where a survey of the literature up to the end of 1999 concluded that while raloxifene might carry a lesser risk of breast cancer than estrogen replacement therapy, it was also less effective in maintaining bone density, and that as regards cardiovascular risk the estrogenic treatment produced a more favorable outcome (7).

The use and adverse effects of raloxifene have been reviewed (8–10). Many centers continue to examine this and other SERMs, for example in countering menopausal bone loss (11), in the hope that they can take the place of tamoxifen and provide a means of avoiding the risks of such complications as endometrial cancer, cataract, and stroke (12–14).

Organs and Systems

Cardiovascular

In one published study there was a two- to three-fold rise in the incidence of thromboembolism, similar to that seen

© 2006 Elsevier B.V. All rights reserved.

with estrogen treatment. There were also some cases of leg cramps and hot flushes (15).

There have been conflicting reports on the incidence and severity of symptoms such as hot flushes (also known as hot flashes) during long-term treatment with raloxifene for the prevention of osteoporosis. In fact the difference between raloxifene and placebo does not seem to be very great. In a review of three identical randomized trials in which raloxifene 60 mg was given for long periods to healthy postmenopausal women of various ages it was concluded that after 30 months the cumulative incidence of hot flushes was 21% for placebo and 28% for raloxifene, but the difference in frequency was confined to the first 6 months of therapy (16). There was no difference between placebo and raloxifene in the maximum severity of symptoms or the rate of early discontinuation, while the period during which hot flushes continued was only a little shorter in the raloxifene group. In a US study in more than 1100 postmenopausal women who took raloxifene 30–150 mg/day the only significant adverse effect of therapy was hot flushes (25% with 60 mg/day and 18% in the placebo group) (17).

Metabolism

LDL cholesterol and total cholesterol concentrations fell significantly in women taking raloxifene compared with placebo, but there was no change in HDL cholesterol or triglyceride concentrations, nor was endometrial thickness affected; the incidence of vaginal bleeding was not increased (18).

Reproductive system

Several sources have suggested that raloxifene can on occasion either cause uterine endometrial polyps or cause pre-existent polyps to enlarge considerably (19).

Drug–Drug Interactions

Warfarin

To assess the potential for an interaction between raloxifene and warfarin, 15 healthy postmenopausal women each received single doses of warfarin 20 mg before and during 2 weeks of dosing with raloxifene 120 mg/day (20). Raloxifene reduced the oral clearance of *R*- and *S*-warfarin respectively by 7.1 and 14% and the oral volume of distribution by 7.4 and 9.8%. Raloxifene reduced the maximum prothrombin time by 10% and the area under the prothrombin versus time curve from 0–120 hours by an average of 8%. The authors concluded that raloxifene may produce a small increase in systemic warfarin exposure but a reduced pharmacodynamic effect. Since the effects are slight this interaction is unlikely to have clinical consequences.

Raltitrexed

See also Cytostatic and immunosuppressant drugs

General Information

Raltitrexed is a specific inhibitor of thymidylate synthase. It is used to treat colorectal cancers.

In about 1000 patients with advanced colorectal cancer, the dose-limiting toxic effects in phase 1 studies were gastrointestinal toxicity, myelosuppression, and weakness; adverse events during phase 2 and 3 studies were similar to those seen during phase 1 (1). In all comparative studies, mucositis and leukopenia were markedly less common and less severe in patients treated with raltitrexed than with bolus fluorouracil + leucovorin. Thrombocytopenia was more common with raltitrexed but it was not associated with an increase in clinically significant hemorrhage. In contrast, raltitrexed-related myelosuppression was more severe than with fluorouracil + leucovorin when the antimetabolite was given by continuous infusion. Raised transaminases were common with raltitrexed but were usually reversible with continued dosing and were not associated with clinical sequelae.

Organs and Systems

Hematologic

In 21 patients with advanced colorectal cancer, intravenous raltitrexed 3 mg/m^2 plus mitomycin 6 mg/m^2 was associated with WHO grade 3/4 anemia in 2, and neutropenia and thrombocytopenia in one each (2).

Liver

Raltitrexed-induced hepatotoxicity is usually characterized by a transient and self-limiting increase in transaminases. However, it can occasionally be fatal.

- A woman aged 76 years and a man aged 56 years were given raltitrexed as adjuvant treatment of colorectal carcinoma and as palliative therapy for advanced biliary carcinoma respectively (3). Both developed fulminant liver failure with rapid deterioration after the second and sixth cycles of chemotherapy respectively, and both died within 24 hours. Autopsy showed signs of acute necrosis involving roughly 50% of the liver without signs of subacute liver damage.

In 130 patients treated with raltitrexed 3 mg/m^2 ($n = 52$) or raltitrexed plus oxaliplatin ($n = 78$), of whom 78 had liver metastases and 25 had raised transaminases, hepatotoxicity caused delays of a week or more in 60 of 584 chemotherapy cycles and was the reason for withdrawal of chemotherapy in eight patients (4). Raised baseline transaminases, the number of chemotherapy cycles, the cumulative dose of raltitrexed, short intervals between courses, and the addition of oxaliplatin predicted hepatotoxicity, while sex, age, creatinine clearance, previous chemotherapy, and the presence of liver metastases did not. Whether glutathione and ademethionine are hepatoprotective is unclear.

Skin

Two patients, aged 75 and 65 years, were given raltitrexed for colorectal cancers. After 5 and 7 days they developed erythematous, edematous, and purpuric skin reactions associated with weakness, diarrhea, and moderate fever (5). The lesions were painful and pseudocellulitic. They were generalized in the first case and localized to the legs in the second. They subsided 15 days after drug withdrawal.

Immunologic

Of 52 patients with colorectal cancer treated with a median of six 3-weekly cycles of raltitrexed 1.5–3.0 mg/m^2 combined with oral carmofur 300–400 mg/m^2 on cycle days 2–14, 39 had a fever on days 2–9 after receiving raltitrexed, 49 had fatigue, and 49 had a raised serum C-reactive protein concentration without a documented infection (6). Median concentrations of C-reactive protein, interleukin-6, interleukin-8, and tumor necrosis factor-alfa were higher 7 days after raltitrexed or raltitrexed + carmofur than at baseline. The authors suggested that patients with colorectal cancer treated with raltitrexed may develop drug-related systemic inflammation, which may be difficult to distinguish from infection.

Susceptibility Factors

Age

Of 90 patients treated with raltitrexed 3 mg/m^2 every 3 weeks, of whom 50 were aged over 70 years, 437 cycles of chemotherapy were administered and grade 3–4 toxicity was reported in under 10% (7). There were no significant differences between younger and older patients, apart from grade 3–4 weakness, which was reported by three of the older patients and none of the younger. This was despite a significantly lower calculated mean creatinine clearance in the older patients.

Renal disease

The pharmacokinetics of raltitrexed, and hence its toxic effects, particularly on the bone marrow and gut, are directly related to creatinine clearance (8). It is recommended that the dose be reduced and dosage interval increased in patients with mild to moderate renal impairment, based on the fact that raltitrexed is mainly excreted unchanged in the urine.

Ramipril

See also Angiotensin converting enzyme inhibitors

General Information

Ramipril is an ACE inhibitor, a prodrug that is rapidly hydrolysed after absorption to its active metabolite ramiprilat. It has been used in patients with hypertension, heart failure, and myocardial infraction.

Organs and Systems

Metabolism

Hypoglycemia has been attributed to several drugs in a complicated sequence of effects (1).

- A 64-year-old man with type II diabetes, hypertension, and bilateral renal artery stenosis presented with confusion and dysarthria related to profound hypoglycemia (2.2 mmol/l). He was taking naproxen 500 mg bd, ramipril 2.5 mg/day, glibenclamide 2.5 mg bd, metformin 850 mg bd, a thiazide diuretic, terazosin, ranitidine, paracetamol, and codeine. His plasma creatinine concentration, previously 185 μmol/l, was 362 μmol/l and it fell to 210 μmol/l after the withdrawal of ramipril and naproxen.

The authors discussed the possible role of renal insufficiency, resulting from co-prescription of naproxen and ramipril in the presence of volume depletion, which may have increased the risk of hypoglycemia related to glibenclamide plus metformin.

Gastrointestinal

Two cases of severe vomiting, dyspepsia, and headache, with falls in body weight and plasma albumin, have been reported in patients on chronic peritoneal dialysis (2). Both occurred a few days after they started to take ramipril (dose not reported) and totally resolved after withdrawal. Both patients subsequently took losartan, which was well tolerated. This led the authors to suggest that the mechanism was mediated by bradykinin and/or prostaglandins, through an interaction with gastrointestinal motility, which may also be affected by peritoneal dialysis.

Diarrhea is a recognized infrequent adverse effect of ACE inhibitors. A convincing case of diarrhea associated with ramipril has been reported (3).

Ranitidine

See also Histamine H_2-receptor antagonists

General Information

Ranitidine is a histamine H_2 receptor antagonist. Compared with cimetidine, it inhibits hepatic metabolism of other substances only to a very slight extent and is not anti-androgenic. In most other respects it is similar to cimetidine.

Comparative studies

Effervescent ranitidine 150 mg bd has been compared with as-needed calcium carbonate antacids 750 mg in a randomized study in 115 subjects who frequently self-treated heartburn (1). Effervescent ranitidine was significantly more effective than antacids in reducing heartburn, healing erosive esophagitis, alleviating pain, and improving quality of life. The overall incidences of adverse events were not significantly different in the two groups; 12% in the antacid group and 3% in the ranitidine group had adverse events related to the gastrointestinal system: nausea, vomiting, diarrhea, constipation, gas, fecal incontinence; and 1% in the antacid group and 4% in the ranitidine group had adverse events related to the central nervous system: headache, dizziness, insomnia, malaise, fatigue, weakness, nervousness.

Placebo-controlled studies

The efficacy of low-dose ranitidine for the relief of heartburn has been studied in a double-blind, placebo-controlled trial (2). Subjects with heartburn were

© 2006 Elsevier B.V. All rights reserved.

randomized to ranitidine 75 mg ($n = 491$), ranitidine 25 mg ($n = 504$), or placebo ($n = 494$), to be taken as needed up to four times a day for 2 weeks. Ranitidine 75 mg was significantly more effective than placebo and provided prompt relief of heartburn lasting up to 12 hours. The most common adverse effects were nausea, diarrhea, and headache, which occurred in under 2% of patients in each group.

In a randomized, placebo-controlled, four-way, crossover study of the effects of low-dose ranitidine and an antacid on meal-induced heartburn and acidity in 26 subjects, ranitidine 75 mg significantly reduced gastric but not esophageal acidity, calcium carbonate 420 mg significantly reduced esophageal but not gastric acidity, and ranitidine plus calcium carbonate reduced both esophageal and gastric acidity (3). Both drugs given alone reduced heartburn severity compared with placebo.

Organs and Systems

Cardiovascular

Atrioventricular block has been attributed to ranitidine (4).

- A 20-year-old man taking ranitidine 300 mg/day had a brief episode of syncope. The only abnormal finding was first-degree atrioventricular block, which disappeared after withdrawal of ranitidine. Rechallenges on two separate occasions produced recurrence of asymptomatic first-degree atrioventricular block, but cimetidine 400–800 mg/day and famotidine 40–80 mg/day caused no electrocardiographic abnormalities.

The authors hypothesized that this patient may have been abnormally susceptible to the cholinergic or cholinergic-like effect of ranitidine, unrelated to its histamine H_2 blocking action. However, the ability of ranitidine to release histamine may also have contributed.

Bradycardia occurred in a 4-day-old full-term male neonate 2 hours after the intravenous injection of ranitidine and resolved over 24 hours (5).

Respiratory

H_2 receptor antagonists can increase the risk of respiratory infections, and the possible significance of this effect has been studied best with ranitidine; there seems to be no reason for concern in most patients, but the risk can be considerable in some older patients with pre-existing health problems rendering them unduly susceptible to infection (SEDA-18, 372).

Nervous system

Chorea has been reported occasionally with ranitidine (6). Headache and lethargy have been described in a neonate (SEDA-18, 372).

Psychological, psychiatric

Depression has been estimated to occur in 1–5% of patients taking ranitidine (SEDA-17, 418) (7).

Occasional confusion and behavioral disturbances have been attributed to ranitidine (8–10).

Hematologic

Pancytopenia and agranulocytosis have been documented with ranitidine (11).

Liver

There seem to be individuals with a metabolic idiosyncrasy who develop serious but probably fully reversible liver damage when exposed to ranitidine. The Netherlands Centre for Monitoring of Adverse Reactions has published data on six cases, in most of which other causal factors could be excluded (12), and a fatal case of liver injury has been reported from France (SEDA-16, 422).

Cholestatic liver damage due to ranitidine has been reported (13).

- A 29-year-old man developed cholestasis (confirmed histologically) having taken ranitidine 150 mg bd for about 2 weeks. The drug was withdrawn and he was treated with glucocorticoids and ursodeoxycholic acid. Three months later he had recovered completely. Rechallenge was not attempted.
- Cholestatic jaundice has been reported in a 73-year-old woman who had taken ranitidine 150 mg bd (14). She developed pruritus 4 days after starting to take the drug and jaundice after 3 weeks. Her liver function tests returned to normal 50 days after ranitidine was withdrawn.

Hepatitis associated with ranitidine is rare.

- Drug hypersensitivity hepatitis with progression to fulminant hepatic failure and death has been reported in a previously healthy 66-year-old woman who had taken ranitidine for 14 days before the onset of jaundice and for 5 days after hepatitis was diagnosed (15).
- A 45-year-old woman with multiple sclerosis developed severe liver injury after taking ranitidine 300 mg/day (16).

Pancreas

In one case where pancreatitis occurred without identifiable cause other than ranitidine, it was confirmed by rechallenge on two occasions (SEDA-16, 422).

Urinary tract

As with cimetidine, acute interstitial nephritis has been documented in a few cases (17).

- Acute interstitial nephritis in a cadaveric renal allograft occurred in a 44-year-old man who had taken ranitidine 150 mg bd for 2 days (18). Allograft function improved rapidly and returned to normal after ranitidine was withdrawn.

Skin

- Stevens–Johnson syndrome has been reported in two patients, a 62-year-old woman and a 58-year-old man, with severe liver disease and jaundice, who had taken ranitidine 150 mg bd; both recovered on withdrawal (19).

© 2006 Elsevier B.V. All rights reserved.

Persistent UVB photosensitivity due to ranitidine (300 mg/day) has been reported (20).

Sexual function

Several cases of impotence have been described in patients taking ranitidine, strongly suggesting that this is an effect that all H_2 receptor antagonists can have on occasion (21).

Long-Term Effects

Tumorigenicity

- A gastric carcinoid tumor was found in a man of 62 taking ranitidine (22). The dosage had been unusually high and there was pre-existing chronic renal insufficiency as well as diabetes, but the tumor was similar in type to that seen in animals; it was successfully removed by partial gastrectomy and did not recur.

Susceptibility Factors

Age

The pharmacokinetics and pharmacodynamics of a single dose of ranitidine 75 mg have been evaluated in a randomized, double-blind, placebo-controlled trial in 29 children aged 4–11 years with gastro-esophageal reflux disease (23). Ranitidine significantly increased the intragastric pH in children, and the pharmacokinetics and pharmacodynamics were similar to those in adults. The drug was effective in the control of intragastric acidity for 5–6 hours. Adverse effects were reported only in children taking ranitidine, and included nausea, vomiting, abdominal pain, dizziness, intermittent headache, and lightheadedness.

Renal disease

In renal impairment, the risk of adverse reactions with intravenous ranitidine is doubled (SEDA-18, 371).

Drug Administration

Drug dosage regimens

Different doses of ranitidine (150 mg bd and 300 mg bd for 8 weeks) have been compared in resolving heartburn in 271 patients with gastro-esophageal reflux disease who had been symptomatic after 6 weeks of therapy with ranitidine 150 mg bd (24). Less than 20% of the patients in either group had complete resolution of heartburn at 4 and 8 weeks; there was no significant difference in the efficacy between the two treatment groups. At least one adverse event was reported by 38% of the patients in each group. They included sinusitis, nausea, abdominal pain, dyspepsia, constipation, and increased liver enzymes.

Ranunculaceae

See also Herbal medicines

General Information

The genera in the family of Ranunculaceae (Table 1) include anemone, buttercup, columbine, hellebore, larkspur, marsh marigold, and pasque flower.

Aconitum species

Species of aconite contain a variety of diterpene alkaloids; *Aconitum napellus* (monkshood) contains isonapelline, luciculine, and napelline.

Adverse effects

Aconite roots can produce serious heart failure. Among the other symptoms of aconite poisoning are numbing of mouth and tongue, gastrointestinal disturbances, muscular weakness, incoordination, and vertigo (1). A review from Hong Kong reported 17 cases of aconite poisoning after the administration of Chinese herbal mixtures. The toxicity of raw aconite can be reduced substantially by decoction, as this process leads to a change in alkaloid composition (2).

Table 1 The genera of Ranunculaceae

Aconitum (monkshood)
Actaea (baneberry)
Adonis (pheasant's eye)
Anemone (anemone)
Aquilegia (columbine)
Caltha (marsh marigold)
Ceratocephala (curveseed butterwort)
Cimicifuga (bugbane)
Clematis (leather flower)
Consolida (knight's-spur)
Coptis (gold thread)
Delphinium (larkspur)
Enemion (false rue anemone)
Eranthis (eranthis)
Helleborus (hellebore)
Hepatica (hepatica)
Hydrastis (hydrastis)
Kumlienia (false buttercup)
Myosurus (mousetail)
Nigella (nigella)
Pulsatilla (pasque flower)
Ranunculus (buttercup)
Thalictrum (meadow rue)
Trautvetteria (bugbane)
Trollius (globe flower)
Xanthorhiza (yellow root)

Cimicifuga racemosa

Cimicifuga racemosa (black bugbane, black cohosh, black snakeroot, rattleroot, rattletop, rattleweed) contains a variety of cycloartane triterpene glycosides, some of which have cytotoxic effects (3).

Cimicifuga racemosa has been used to relieve symptoms of menopause, although with little evidence of efficacy (4).

Adverse effects

Liver damage has been attributed to black cohosh, which contains diterpenoids that cause liver damage in animals, either via reactive metabolites or by an autoimmune mechanism. However, causality was not demonstrated beyond reasonable doubt.

- A 47-year-old woman took an extract of *C. racemosa* for 1 week to treat menopausal symptoms; she developed jaundice and raised liver enzymes (5). No other causes of liver damage were found. She required liver transplantation.

Delphinium species

Delphinium species contain complex diterpenoid alkaloids that cause acute intoxication and death in cattle (6). The alkaloids and their concentrations vary with the species and plant part involved, which causes variability in toxicity. In *Delphinium consolida* (larkspur) there are toxic alkaloids in the non-medicinal plant parts (root, seed, herb), but they are purportedly absent in the medicinal part (the flower).

Hydrastis canadensis

The root of *Hydrastis canadensis* (golden seal) contains isoquinoline alkaloids, including the quaternary base berberine and the tertiary base hydrastine. As the latter can stimulate uterine contractions, it is prudent to avoid golden seal root during pregnancy, even though the actual risk of premature labor still has to be verified.

Adverse effects

In man berberine has positive inotropic, negative chronotropic, antidysrhythmic, and vasodilator properties (7).

Cardiovascular

There is experimental evidence that berberine can cause arterial hypotension (8,9).

Nervous system

Berberine displaces bilirubin from albumin and there is therefore a risk of kernicterus in jaundiced neonates (10).

© 2006 Elsevier B.V. All rights reserved.

Gastrointestinal
In a study of the effect of berberine in acute watery diarrhea, oral doses of 400 mg were well tolerated, except for complaints about its bitter taste and a few instances of transient nausea and abdominal discomfort. However, patients with cholera given tetracycline plus berberine were more ill, suffered longer from diarrhea, and required larger volumes of intravenous fluid than those given tetracycline alone (11).

Skin

- A 32-year-old woman had a phototoxic reaction after taking a dietary supplement containing ginseng, golden seal, bee pollen, and other ingredients (12). She had a pruritic, erythematous rash, localized to the sun-exposed surfaces of her neck and limbs. She had no significant past medical history and was not taking any other medications. The skin rash slowly resolved after withdrawal of the supplement and treatment with subcutaneous and topical glucocorticoids.

Although the individual ingredients in this dietary supplement have not been associated with cases of photosensitivity, it is possible that the combination of ingredients may have interacted to cause this effect.

Drug interactions
Golden seal root inhibits various isoforms of cytochrome P450, including CYP3A4 (13). However, in a crossover study, goldenseal root (1140 mg bd for 14 days) had no effect on the pharmacokinetics of a single oral dose of indinavir 800 mg (14).

Pulsatilla species

Pulsatilla (pasque flower) species are widely used in homeopathic medicine. Some of them contain podophyllotoxins. High doses of *Pulsatilla vulgaris* (meadow windflower) can irritate the kidneys and urinary tract. Pregnancy is a contraindication.

Ranunculus damascenus

Ranunculus damascenus (buttercup) is used topically for abscess drainage, hemorrhoids, and burns.

Adverse effects
Ranunculus damascenus has been reported to cause skin damage (15).

- A 45-year-old Turkish woman developed open wounds on the abdomen, right knee, and neck. She had used buttercup topically and orally for pain relief. She was treated with antibiotics and adequate wound care. Complete healing was achieved within 10 days.

The authors argued that protoanemonin, a constituent of *R. damascenus*, which inhibits mitosis in plants, had caused this severe reaction.

Rapacuronium

See also Neuromuscular blocking drugs

General Information

Rapacuronium, an aminosteroid non-depolarizing neuromuscular blocking agent with a rapid onset and a comparatively short duration of action (1,2), was withdrawn from the US market in March 2001 and subsequently worldwide. The manufacturers informed the FDA in an open letter about postmarketing reports of severe bronchospasm and some deaths of unknown origin associated with rapacuronium. The severity of the incidents recently reported to the manufacturers was impressive enough to cause fears about patient safety. This event highlights the need for continued surveillance, not only during clinical trials but also during the routine use of approved drugs.

© 2006 Elsevier B.V. All rights reserved.

Organs and Systems

Cardiovascular

A major adverse effect of rapacuronium is an increase in heart rate (3). Plasma histamine concentrations may increase after rapacuronium injection, but this was not correlated with changes in blood pressure or heart rate (4).

Respiratory

In a study of the effects of rapacuronium on respiratory function, performed while rapacuronium was still on the market in the USA, the authors observed statistically significant reductions in peak inspiratory flow rate, peak expiratory flow rate, and dynamic compliance, and increases in peak inflating pressure when rapacuronium 1.5 mg/kg was given under steady-state conditions to patients who were already anesthetized, intubated, and ventilated (5). In five of the 10 patients these changes amounted to more than 25% from baseline and were considered clinically relevant. As rapacuronium is no longer available this has no direct clinical impact. However, while discussing the mechanisms of rapacuronium-induced bronchospasm the authors speculated that differential effects of the drug on several subtypes of muscarinic acetylcholine receptors might be responsible. As raised histamine concentrations were not found in seven patients with rapacuronium-induced bronchospasm in another study (4), they reckoned that histamine release was an unlikely explanation. Referring to the observation that pipecuronium, another non-steroidal muscle relaxant, blocked pilocarpine-stimulated prejunctional M_2 receptors in vitro (6), they suggested that a similar effect might result in rapacuronium-induced bronchospasm. Prejunctional M_2 receptors are thought to have a role in negative feedback and inhibition of further acetylcholine release, thereby reducing smooth muscle relaxation. These aspects will need to be taken into account when new substances are considered for clinical use.

Second-Generation Effects

Pregnancy

Some controversy has been raised by the use of rapacuronium for rapid sequence induction in elective cesarean section (7). The authors reported that intubating conditions 60 seconds after rapacuronium 2.5 mg/kg were comparable with those after suxamethonium 1.5 mg. The percentage of the drug that crossed the placenta to the fetus was low (umbilical/maternal vein concentration ratio 0.088) compared with other non-depolarizing agents, and there were no adverse effects on the fetus. Others, however, would not use rapacuronium or other non-depolarizing agents for cesarean section, referring to the longer duration of action, which might be a problem in cases of failed intubation (8). Rapid sequence induction with thiopental plus suxamethonium is still standard for cesarean section. Rapacuronium should be considered for cesarean section only in patients in whom suxamethonium is contraindicated. In such cases, induction with propofol plus alfentanil without a neuromuscular blocking agent may be an alternative, which still awaits evaluation with regard to maternal and fetal safety.

Susceptibility Factors

Renal disease

Rapacuronium plasma clearance was reduced in patients with renal insufficiency, but this did not result in an increased duration of action (9).

Hepatic disease

Although not completely understood, hepatic uptake is assumed to be the reason for the short duration of action of rapacuronium. However, neither recovery time nor drug half-life after a single bolus of rapacuronium was prolonged in patients with liver cirrhosis compared with healthy controls (10).

Ravuconazole

See also Antifungal azoles

General Information

Ravuconazole is similar in structure to fluconazole. It has a long half-life suitable for once-daily dosing.

The safety and efficacy of ravuconazole have been studied in a randomized, double-blind comparison with fluconazole in 71 patients with esophageal candidiasis; ravuconazole was as effective as fluconazole and there were no apparent differences in adverse effects (1,2).

Reboxetine

See also Antidepressants, second-generation

General Information

Reboxetine is a selective noradrenaline re-uptake inhibitor with low affinity for α-adrenoceptors and muscarinic receptors. In controlled trials the following adverse events occurred significantly more often with reboxetine than with placebo: dry mouth (27%), constipation (17%), increased sweating (14%), insomnia (14%), urinary hesitancy (5%), impotence (5%), tachycardia (5%), and vertigo (2%) (SEDA-21, 13).

Organs and Systems

Electrolyte balance

Hyponatremia has been reported with reboxetine (1,2).

- A 72-year-old man with diabetes mellitus and cardiovascular disease developed major depression. He was taking aspirin (100 mg/day), enalapril (20 mg/day), and glibenclamide (5 mg/day). His serum sodium was 133 mmol/l (reference range 134–146 mmol/l). He started to take reboxetine (4 mg/day) and after 8 days experienced malaise and nausea, at which time his serum sodium had fallen to 118 mmol/l. The reboxetine was withdrawn, and both his symptoms and the low serum sodium remitted over the next 6 days. Rechallenge with reboxetine produced a recurrence of both the low sodium and the accompanying symptoms.

It appears that, like SSRIs, reboxetine can cause sodium depletion in elderly people. However, in this case the contributions of concomitant general medical illness and its treatment were uncertain.

Urinary tract

One of the adverse effects of reboxetine is difficulty in passing urine (SEDA-21, 13). Eight patients taking reboxetine (4–8 mg/day) had troublesome urinary hesitancy (3). They were successfully treated with tamsulosin (0.4 mg/day), and in two patients tamsulosin was withdrawn after 2 weeks without recurrence of the urinary symptoms. Reboxetine is a selective noradrenaline re-uptake inhibitor and may therefore produce urinary symptoms by activating α_1-adrenoceptors in the bladder, which tamsulosin would be expected to reverse. However, tamsulosin is also effective for urinary symptoms caused by other mechanisms, for example benign prostatic hyperplasia. Whether its apparent effectiveness in reboxetine-induced dysuria represents specific pharmacological antagonism is therefore uncertain.

Drug–Drug Interactions

Fluoxetine

In the pharmacological management of patients with treatment-resistant depression, it is a common strategy to combine a drug that selectively inhibits noradrenaline re-uptake (for example reboxetine) with one that selectively inhibits the re-uptake of serotonin (for example an SSRI). As well as the hoped-for pharmacodynamic interaction, a kinetic interaction can also occur, because of the effect of SSRIs on CYP450 enzymes. The effect of combined treatment with reboxetine (8 mg/day) and fluoxetine (20 mg/day) has been compared with each treatment given alone for 8 days in 30 healthy volunteers in a parallel design (4). There was no potentiation of adverse effects by the combination. Fluoxetine increased the plasma AUC of reboxetine by 20%, but this was not statistically significant. The authors suggested that the combination of fluoxetine and reboxetine should have minimal adverse impact in depressed patients. However, the major metabolite of fluoxetine, norfluoxetine, is also an inhibitor of CYP3A4 and would not have reached steady-state concentrations during the time of the study. This suggests that caution might still be needed during longer-term use of this combination in depressed patients.

Ketoconazole

Reboxetine is metabolized by CYP3A4. In 11 healthy volunteers ketoconazole, an inhibitor of CYP3A4, increased the plasma AUC of reboxetine by about 50% and prolonged the half-life (5). The adverse effects profile of reboxetine was not altered by ketoconazole, but the finding suggests that reboxetine should be used with caution in combination with drugs that inhibit CYP3A4, for example nefazodone and fluvoxamine.

Remacemide

See also Antiepileptic drugs

General Information

Remacemide hydrochloride is a low-affinity, non-competitive *N*-methyl-D-aspartate (NMDA) channel blocker that has been used in epilepsy, Parkinson's disease, Huntington's chorea, and neuroprotection after stroke. Its pharmacology, clinical pharmacology, uses, and adverse effects and interactions have been reviewed (1,2).

The adverse effects of remacemide have been studied in 40 patients with refractory epilepsy randomized to placebo or ascending weekly doses of remacemide in a twice or four times a day regimen for up to 1 month (3). There were adverse events in 38 patients; the most common were dizziness, abdominal pain, headache, diplopia, fatigue, dyspepsia, and abnormal vision.

Observational studies

The efficacy of adjunctive therapy with remacemide has been evaluated in 11 children (4). Remacemide was well tolerated in doses up to 13.5 mg/kg/day. The most common adverse events were dizziness, ataxia, and gastrointestinal events. One patient died after a suspected seizure, which was unlikely to have been related to remacemide.

Placebo-controlled studies

The efficacy, safety, and pharmacokinetics of adjunctive remacemide have been investigated in a randomized, double-blind, placebo-controlled, crossover study in 28 adult patients with refractory epilepsy (5). The mean plasma carbamazepine concentration increased by about 15%. Three patients withdrew owing to adverse events (two remacemide, one placebo). Adverse events that occurred more often with remacemide than placebo included dyspepsia, dizziness, abnormal gait, diplopia, abnormal vision, somnolence, chest pain, and fatigue.

In a randomized, double-blind, placebo-controlled study of remacemide in 200 patients with early Parkinson's disease who were not yet taking levodopa or dopamine agonists, remacemide did not produce improvement in signs or symptoms (6). Significantly fewer patients taking remacemide 600 mg/day were able to tolerate 5 weeks of their assigned treatment on a twice-daily schedule compared with patients taking placebo (64 versus 94%). However, most patients who had intolerable adverse effects with the twice-daily schedule could tolerate the same daily dosage given in four parts during the day. The most common adverse events were dizziness and nausea. There were no serious adverse events or clinically significant treatment-related changes in vital signs, laboratory values, or electrocardiograms.

In a double-blind, randomized study of remacemide in 262 patients with partial seizures there was a trend for efficacy, but not significantly different from placebo (7). The most frequent adverse events were headache, fatigue, dizziness, diplopia, and somnolence. There were no significant changes in vital signs, electrocardiograms, or biochemistry. In another double-blind, placebo-controlled study in patients with refractory epilepsy undergoing in-patient video-electroencephalographic monitoring, the pattern of adverse events was similar (8).

Drug–Drug Interactions

Levodopa

Remacemide delays the absorption of levodopa and increases the concentrations of drugs that are metabolized by CYP3A4 (2).

Remifentanil

General Information

Remifentanil is a pure OP_3 (μ) opioid receptor agonist with a very short duration of action. It therefore has to be given by continuous intravenous infusion and is used as a supplement to general anesthesia during induction and as an analgesic during maintenance of anesthesia. It has the familiar adverse effects of opioids: respiratory depression, sedation, nausea and vomiting, muscle rigidity, bradycardia, and pruritus. These are short-lived and are antagonized by naloxone. The onset of muscle rigidity and apnea can be alarmingly rapid. Bradycardia occurred more often with remifentanil than alfentanil in patients undergoing abdominal surgery and in children undergoing strabismus surgery; the oculocardiac response was more marked with remifentanil than alfentanil (1).

Drug studies

Pain relief

Three studies have focused on the analgesic use of remifentanil (2–4). In a double-blind, crossover, randomized study 20 healthy volunteers received an infusion of either remifentanil or saline (2). Thermal sensory testing of the heat pain threshold was performed every 5 minutes and the dose of remifentanil was increased by 0.01 micrograms/kg/minute every 5 minutes. Remifentanil produced a dose-dependent increase in the heat pain threshold, and a dose of 0.05 micrograms/kg/minute was suggested as an effective and safe increment in healthy volunteers. The rate of adverse effects (nausea, vomiting, and pruritus) was comparable with previous reports; there were no cardiovascular adverse effects.

General surgery

Mixtures of remifentanil and sevoflurane have been used in two prospective, open, randomized studies (5,6), which showed that adding remifentanil results in a reduced requirement for sevoflurane for maintenance of anesthesia, leading to faster and easier recovery.

In a double-blind, randomized study a continuous infusion of remifentanil (1 microgram/kg followed by 0.5 micrograms/kg/minute) was compared with alfentanil (25 micrograms/kg followed by 1 microgram/kg/minute) during anesthesia in patients undergoing major abdominal surgery (7). Both systolic pressure and heart rate were significantly lower with remifentanil, with a higher incidence of hypotension (53 versus 39%) and bradycardia (10 versus 3%).

Bronchoscopy

In a randomized study, remifentanil 0.5 micrograms/kg/minute was compared with fentanyl 2 micrograms/kg in 22 patients undergoing rigid bronchoscopy (8). The results suggested that remifentanil attenuated the hemodynamic response to bronchoscopy without significantly increasing the incidences of hypotension or bradycardia. Four patients given remifentanil developed ST segment depression compared with eight patients given fentanyl.

Colonoscopy

Remifentanil by infusion ($n = 49$) has been compared with titrated boluses of pethidine ($n = 51$) in a randomized, double-blind study in 100 patients undergoing outpatient colonoscopy (9). The incidences of tachycardia, hypotension, and nausea were significantly less with remifentanil than with pethidine, but there were higher anxiety and pain scores with remifentanil. However, the study was a comparison of two opioids with different pharmacokinetic profiles, which makes it very difficult to achieve equipotent doses for the purpose of comparison.

Lithotripsy

In two randomized, double-blind, controlled comparisons of anesthetic techniques for extracorporeal shock wave lithotripsy remifentanil infusion had no advantage over the combination of fentanyl bolus plus propofol infusion, but caused more adverse effects (nausea and vomiting) (10). In another study remifentanil infusion provided comparable analgesia and caused less respiratory depression and fewer gastrointestinal symptoms than intravenous boluses of sufentanil (11).

Cardiac surgery

In a prospective multicenter, double-blind, randomized study in 297 patients undergoing elective coronary artery bypass surgery, remifentanil infusion 1 microgram/kg/minute was compared with a loading dose of fentanyl 15 micrograms/kg (12). The most common adverse effects were nausea and vomiting, which occurred equally often in the two groups. Hypertension and shivering were significantly more common with remifentanil (12).

Obstetrics and gynecology

The role of remifentanil-based anesthesia in gynecological and obstetric procedures has been reviewed (13).

In a double-blind, randomized comparison of remifentanil (0.25/0.5 micrograms/kg/minute) and alfentanil (50 micrograms and 0.5 micrograms/kg/minute) in 35 patients undergoing total abdominal hysterectomy, remifentanil provided more stable analgesia during anesthesia but caused significantly more hypotension (14).

Orthopedic surgery

Intravenous remifentanil 0.3 micrograms/kg with propofol 2 micrograms/ml has been compared with propofol 2 micrograms/ml alone in a double-blind, randomized study in 86 day-case adults undergoing elective orthopedic surgery (15). The study was designed to assess whether remifentanil improves conditions for laryngeal mask airway insertion. Those given remifentanil had a better quality of airway patency, with minimal cardiorespiratory changes.

Orthopedic and urological surgery

The respiratory depressant and gastrointestinal adverse effects of remifentanil have been observed in a randomized, single-blind study of 125 patients undergoing elective orthopedic and urological surgery under spinal or brachial plexus anesthesia (16). They were randomized to either remifentanil (a bolus of 0.5 micrograms/kg plus an infusion of 0.1 micrograms/kg/minute) or propofol

© 2006 Elsevier B.V. All rights reserved.

(a bolus of 500 micrograms/kg plus an infusion of 50 micrograms/kg/minute). Owing to a significantly higher rate of respiratory depression with remifentanil (46%) than with propofol (19%), the mean remifentanil infusion rate was reduced to 0.078 ± 0.028 micrograms/kg/minute. The incidence of intraoperative nausea and vomiting with remifentanil was 27% compared with 2% with propofol. Postoperatively there was no significant difference in the incidence of gastrointestinal symptoms. Remifentanil may be considered as an alternative if propofol is contraindicated (for example because of amnesic episodes).

Vascular surgery

In a double-blind, randomized, placebo-controlled study in 28 adults undergoing carotid endarterectomy, remifentanil provided adequate analgesia, and supplementary local anesthetics were not needed (17). The remifentanil infusion rate was as low as 0.04 micrograms/kg/minute and there were no episodes of respiratory depression or hemodynamic instability.

In 60 patients receiving cervical plexus block during carotid endarterectomy who were given either remifentanil 3 micrograms/kg/hour or propofol 1 mg/kg/hour there was a higher incidence of adverse respiratory effects with remifentanil and a similar sedative effect (18). The authors suggested that when using remifentanil for sedation in patients undergoing carotid endarterectomy, the initial dose of remifentanil should be reduced to 1.5–2 micrograms/kg/hour to minimize cardiovascular and respiratory adverse effects.

Ophthalmological surgery

The analgesic effects of remifentanil and alfentanil have been compared during ophthalmological nerve block in a randomized, double-blind, parallel-group study in 79 patients (19). Remifentanil (as a single dose of 1 microgram/kg or as a loading dose of 1 microgram/kg followed by an infusion of 0.2 micrograms/kg/minute) was more effective than alfentanil (as a single dose of 7 micrograms/kg). Of the patients given remifentanil, three had mild nausea and three had transient muscle rigidity that resolved spontaneously within 1 minute. There were no adverse effects of alfentanil. The authors suggested that remifentanil 1 microgram/kg given over 30 seconds is a useful alternative to alfentanil 7 micrograms/kg as an analgesic before ophthalmological nerve block.

Anesthesia in ischemic heart disease

In a prospective randomized comparison of combined sevoflurane plus remifentanil with combined fentanyl plus etomidate for induction of anesthesia in 10 patients with ischemic heart disease, 3 of the 20 patients given sevoflurane plus remifentanil developed severe bradycardia (heart rate less than 40) and one developed asystole, but the difference between the two groups did not reach statistical significance (20). Therefore, in patients with ischemic heart disease remifentanil should be used with caution, and concurrent administration of glycopyrrolate 0.2 mg is advisable to reduce the incidence of bradycardia, hypotension, or both, without increasing the heart rate.

Organs and Systems

Cardiovascular

Three groups of 20 women due to undergo elective surgery were recruited into a randomized, double-blind study (21). Group 1 received a bolus dose of remifentanil 1 microgram/kg and an infusion of remifentanil (0.5 micrograms/kg/minute); groups 2 and 3 received remifentanil 0.5 micrograms/kg and an infusion of 0.25 micrograms/kg/minute. Groups 1 and 2 received pretreatment with glycopyrrolate 200 micrograms whilst group 3 did not. Cardiovascular responses to laryngoscopy and orotracheal intubation were measured. There were no significant differences in the three groups, except that there was a significantly lower heart rate in group 3 after induction of anesthesia and after intubation.

The hemodynamic effects of bolus intravenous remifentanil 0.2, 0.33, and 1 microgram/kg/minute have been studied in patients scheduled for coronary artery bypass grafting (22). The study was terminated after only eight patients had been recruited, because of severe hypotension, bradycardia, and/or evidence of myocardial ischemia. The authors concluded that remifentanil should not be given as a bolus dose of 1 microgram/kg but as an infusion at a low rate. An editorial response to this article suggested that the hemodynamic instability reported may have resulted from other contributing factors, such as hypovolemia, impairment of venous return, or excessive anesthesia due to remifentanil toxicity (23).

In a prospective study in 12 men undergoing elective coronary artery bypass grafting, remifentanil 0.5 and 2.0 micrograms/kg/minute combined with propofol preserved hemodynamic stability and reduced myocardial blood flow and metabolism to a similar extent (24).

Asystole has been attributed to remifentanil (25).

- A 78-year-old man with laryngeal cancer developed asystole 1 minute after an intravenous bolus of remifentanil 0.5 micrograms/kg followed by a continuous infusion of 0.5 micrograms/kg/hour. The asystole was unresponsive to intravenous atropine 1 mg. The remifentanil infusion was stopped and cardiac sinus rhythm resumed after two precordial thumps.

The authors postulated that rapid-sequence induction of anesthesia with sevoflurane had blunted sympathetic tone and allowed uncompensated parasympathetic activation by remifentanil.

Remifentanil-induced bradycardia and asystole may be useful as a protective effect in patients with atrial fibrillation (26).

- A 90-year-old woman with atrial fibrillation was given digoxin for 3 days before surgery for a pelvic mass. Following anesthesia, induced with thiopental and atracurium, her heart rate rose to 105/minute and her electrocardiogram showed fast atrial fibrillation and ST segment depression. She was given remifentanil 0.25 micrograms/kg/minute and her heart rate fell to 95/minute.

Nervous system

Seizures have been attributed to remifentanil (27).

© 2006 Elsevier B.V. All rights reserved.

- A 42-year-old woman asked for an intravenous opioid as analgesia during paracervical block and was given an intravenous infusion of remifentanil 1.0 microgram/kg/minute. After 3 minutes she became unresponsive, with upward deviation of gaze and tonic-clonic contractions of the arms. The infusion was discontinued and after another 3 minutes of generalized seizure activity she was given intravenous propofol 80 mg and intravenous suxamethonium 60 mg; she recovered completely 15 minutes later.

Psychological, psychiatric

In 201 patients scheduled for day-case surgery, those who received remifentanil had significantly fewer responses to surgical stimulation and had better psychomotor and psychometric function during the recovery period, although there was no significant difference in time to recovery room or hospital discharge (28).

Second-Generation Effects

Pregnancy

Six patients admitted at 36 weeks pregnancy with pre-eclampsia received patient-controlled intravenous analgesia with remifentanil for labor (3). Remifentanil was delivered as continuous background infusion of 0.05 micrograms/kg/minute and boluses of 25 micrograms with a 5-minute lockout period. The procedure did not cause adverse maternal or neonatal adverse effects and this small uncontrolled study suggests that patient-controlled intravenous analgesia with remifentanil might be an effective alternative when epidural analgesia is contraindicated.

In a dose-finding study in 17 healthy pregnant women in the first stage of labor, the PCA bolus of remifentanil was increased from 0.2 micrograms/kg in 0.2 micrograms/kg increments during 60 minutes until analgesia was considered adequate (29). The median effective dose of remifentanil was 0.4 (range 0.2–0.8) micrograms/kg and consumption was 0.066 (range 0.027–0.207) micrograms/kg/minute. All the women reported slight sedation; five had slight to moderate nausea throughout the study. Supplementary oxygen 2 l/minute via nasal cannula was given to three women who had repeated episodes of oxygen desaturation. Two women reported difficulties in reading and visual focusing and one woman had difficulty in swallowing toward the end of remifentanil administration. In five cases there were changes in fetal heart rate indices within 30 minutes of the first dose. The neonates had Apgar scores of 8–10. The authors concluded that remifentanil is a potentially effective obstetric analgesic but that adverse effects will limit its use.

A similar observation was made in an open pilot study in 36 women randomized during the early stages of labor to either intramuscular pethidine 100 mg or remifentanil given as patient-controlled analgesia (20-microgram bolus over 20 seconds) (30). Remifentanil provided better pain relief but a higher risk of lower oxygen saturation compared with pethidine. Remifentanil was given only a cautious welcome by the authors, owing to its respiratory depressant effects.

Susceptibility Factors

Age

In maintenance of anesthesia in 62 children vomiting occurred in 31% (31). However, the dose of remifentanil was twice the ED_{50} in adults and may have been much larger than required.

The effects of remifentanil on vomiting and the quality of emergence from anesthesia have been studied in children undergoing dental restoration and extraction (32). The children received desflurane with or without remifentanil 0.2 micrograms/kg/minute. The two groups did not differ in adverse effects profile or quality of recovery.

Seven randomized controlled trials and one descriptive trial using infused remifentanil as part of an anesthetic technique in children between 1997 and 2000 have been reviewed (33). The general consensus is that a bolus dose of remifentanil 0.5–1 microgram/kg appears to be well tolerated when it is given over at least 60 seconds. However, a loading dose is not required if the infusion can be started at least 10 minutes before the skin incision is made. Infusion rates of 0.25–0.5 micrograms/kg/minute provide hemodynamic stability when propofol or a volatile agent is also given. The authors advised that infants who receive remifentanil should be paralysed and mechanically ventilated, because of the possible risk of respiratory depression due to chest wall rigidity in non-paralysed patients.

Remifentanil is liable to cause respiratory depression in children (33,34), as well as muscle rigidity, hypotension, and bradycardia, without increasing the incidence of gastrointestinal symptoms (35).

The adverse effects profiles of remifentanil in neonates and infants undergoing pyloromyotomy have been investigated (36,37).

The hemodynamic responses, recovery profiles, and perioperative and postoperative respiratory patterns in 38 children given remifentanil plus nitrous oxide and 22 given halothane plus nitrous oxide have been studied in a multicenter, open, randomized comparison (36). There were no cases of bradycardia or dysrhythmias. There were hypertensive responses at the time of incision in 24% of those given remifentanil and 18% of those given halothane and vomiting in 34 and 45% respectively. None of those who were given remifentanil developed new-onset postoperative apnea compared with three of those who were given halothane. All other adverse effects had similar incidences in the two groups.

Remifentanil 0.1 micrograms/kg/minute by infusion was safe and efficacious in 55 patients (aged 2 months to 12 years) undergoing cardiac catheterization (38).

Drug Administration

Drug dosage regimens

In a double-blind, randomized study of 178 patients scheduled for major thoracic, intra-abdominal, and orthopedic surgery, a high dose of remifentanil (bolus dose of 1 microgram/kg followed by 1 microgram/kg/minute) was compared with a low dose (bolus dose 1 microgram/kg followed by 0.5 micrograms/kg/minute) (39). In this study, intraoperative hypotension (30% and 27% respectively)

© 2006 Elsevier B.V. All rights reserved.

and bradycardia (9% and 7% respectively) were equally frequent in the two groups. The authors proposed that infusion rates of remifentanil over 0.4 micrograms/kg/minute provide satisfactory analgesia throughout surgery but can cause significant hypotension. Prolonged infusion of remifentanil for several hours of surgery does not delay recovery or cause respiratory depression.

The postoperative analgesic efficacy and safety of two continuous constant-dose intravenous remifentanil infusions have been investigated in a double-blind, randomized study in 30 patients scheduled to undergo elective abdominal or thoracic surgery (4). The patients were randomly assigned to intravenous remifentanil 0.05 micrograms/kg/minute or 0.1 micrograms/kg/minute. There were no cases of respiratory depression, and nausea and vomiting occurred in one patient in each group. There was adequate analgesia in 75% and 78% of the patients in the low-dose and high-dose groups respectively and pethidine rescue analgesia was required in 26% and 6% respectively. Remifentanil 0.1 micrograms/kg/minute was therefore effective and safe for postoperative pain.

Drug overdose

A nurse was found dead at home with a syringe and empty vials of remifentanil (2 mg) and midazolam (1 mg/ml); toxicological studies showed that she had not been a chronic user of remifentanil (40).

Drug–Drug Interactions

Propofol

In eight subjects the concentration of remifentanil was significantly increased when therapeutic concentrations of propofol were present in the body (41). The combination of propofol and remifentanil can cause cardiovascular depression. As with other opioids, remifentanil competes with propofol for hydrophobic binding in the lungs and heart.

Repirinast

General Information

Repirinast is an antiallergic prodrug whose active metabolite has a stabilizing action on mast cells that resembles that of sodium cromoglicate (1).

When repirinast was given to 56 asthmatic patients for 6 months, it was effective in 47% and moderately effective in 81%. Two patients complained of sleepiness, but repirinast was continued with or without dosage reduction (SEDA-17, 205).

Organs and Systems

Skin

Solar urticaria has been attributed to repirinast in a 72-year-old woman who had taken it for 20 months (2). She developed urticaria immediately after irradiation with 1.5 J/cm^2 of UVA, and a provocation test confirmed that repirinast was responsible for the urticarial reaction, with a spectrum of 320–350 nm.

Reserpine

General Information

The Rauwolfia alkaloids, including reserpine, are now little used. They act by depleting neurotransmitter stores of catecholamines and reducing sympathetic nervous activity, but their effects are non-specific, and nervous system adverse effects (depression, drowsiness, tiredness, confusion) are prominent. There is also a troublesome incidence of diarrhea, hyperprolactinemia, gynecomastia, and a possible withdrawal syndrome.

Organs and Systems

Psychological, psychiatric

Depression is a very common adverse effect of reserpine (SED-9, 328) (1).

- A 66-year-old woman was admitted to hospital suffering from an agitated depressive psychosis. This settled with standard antipsychotic therapy. It was subsequently found that she had been taking reserpine in an over-the-counter formulation and had

© 2006 Elsevier B.V. All rights reserved.

stopped this a week before her admission (2). Her doctor felt that the syndrome had occurred as a result of nervous system hypersensitivity after reserpine withdrawal.

Endocrine

In women reserpine causes a small increase in circulating concentrations of prolactin (3), which could be related to the small increase in the risk of breast cancer. In 27 hypertensive men reserpine 0.25 mg/day for 3 months had no effect on testosterone, dihydrotestosterone, estradiol, luteinizing hormone, or prolactin (4).

Long-Term Effects

Drug withdrawal

Acute psychosis has been reported after the withdrawal of reserpine (2,5). During long-term therapy in animals reserpine causes denervation sensitivity to dopamine in the basal ganglia and chemotactic trigger zone in man and to catecholaminergic agents in the basal ganglia and mesolimbic system; withdrawal could lead to rebound supersensitivity of these systems to endogenous catecholamines, causing the reported symptoms.

Tumorigenicity

Early retrospective studies suggested that reserpine was associated with breast cancer, but prospective studies and meta-analyses of case-control studies have shown only a weak association (6). In vitro studies have shown that rauwolfia alkaloids are not genotoxic or mutagenic (7).

Resorcinol

General Information

Resorcinol, which was formerly used to treat leg ulcers, is nowadays mainly used in the treatment of acne vulgaris as a peeling agent. In the older literature (1), several cases of systemic toxicity from percutaneous absorption were reported and there were deaths (2). The use of resorcinol in the treatment of acne is considered safe (SEDA-9, 142).

Signs and symptoms of resorcinol intoxication (1,2) include:

- pallor, dizziness, cold sweat, collapse, cyanosis;
- tremor;
- hypothyroidism;

Organs and Systems

Immunologic

Systemic allergic reactions have been reported in eight patients after topical application of a wart formulation containing resorcinol (3). All developed a marked eczematous, sometimes bullous reaction, localized to the site of application; in four cases there were generalized urticaria and angioedema, in one pompholyx eczema, and in three generalized eczema with pompholyx. In all cases there were positive patch tests with resorcinol.

Rhamnaceae

See also Herbal medicines

General Information

The genera in the family of Rhamnaceae (Table 1) include buckthorn and jujube.

Rhamnus purshianus

The bark of *Rhamnus purshiana* (cascara sagrada) contains laxative anthranoid derivatives, which occur primarily in various laxative herbs (such as aloe, cascara sagrada,

Table 1 The genera of Rhamnaceae

Adolphia (prickbush)

Smythea
Ziziphus (jujube)

medicinal rhubarb, and senna) in the form of free anthraquinones, anthrones, dianthrones, and/or *O*- and *C*-glycosides derived from these substances.

Adverse effects

The anthranoids produce harmless discoloration of the urine. Depending on intrinsic activity and dose, they can also produce abdominal discomfort and cramps, nausea, violent purgation, and dehydration. They can be distributed into breast milk, but not always in sufficient amounts to affect the suckling infant. Long-term use can result in electrolyte disturbances and in atony and dilatation of the colon.

Respiratory

Cascara sagrada can cause IgE-mediated occupational asthma and rhinitis (1).

Liver

Cascara sagrada has been reported to cause liver damage (2).

- A 48-year-old man developed cholestatic hepatitis and hypertension shortly after he started to use the herbal laxative cascara sagrada. He took one capsule (425 mg of aged cascara sagrada bark) tds for 3 days and subsequently developed right upper quadrant pain, nausea, abdominal bloating, anorexia, and jaundice. The cascara was withdrawn, but his symptoms persisted and his liver function tests were abnormal. One week later, he developed ascites and jaundice and underwent liver biopsy, which showed moderately severe portal inflammation, intracanalicular bile stasis, portal bridging fibrosis, and mild steatosis. He gradually improved without specific treatment and 3 months later his ascites and jaundice had resolved.

Tumorigenicity

Several anthranoid derivatives (notably the aglycones aloe-emodin, chrysophanol, emodin, and physicon) are genotoxic in bacterial and/or mammalian test systems (SEDA-12, 409), and two anthranoid compounds (the synthetic laxative dantron and the naturally occurring 1-hydroxyanthraquinone) have carcinogenic activity in rodents. In an epidemiological study, chronic abusers of anthranoid laxatives (identified by the presence of pseudomelanosis coli) had an increased relative risk of 3.04 (95% CI = 1.18, 4.90) for colorectal cancer (3). The German health authorities therefore restricted the indication of herbal anthranoid laxatives to constipation which has not responded to bulk-forming therapy (which rules out their inclusion in slimming aids). In addition, they imposed restrictions on the laxative use of anthranoid-containing herbs (for example not to be used for more than 1–2 weeks without medical advice, not to be used in children under 12 years of age, and not to be used during pregnancy and lactation) (3,4).

Zizyphus jujuba

The fruit of *Ziziphus jujuba* (dazao) is often consumed in Eastern Asia as food or as a tonic and sedative.

Adverse effects

Angioedema has been described after the oral ingestion of dazao (5).

Ribavirin

General Information

The synthetic triazole nucleoside, ribavirin (1-beta-D-ribofuranosyl-1,2,4-triazole-3-carboxamide, tribavirin, virazole), has a broad spectrum of antiviral activity, including DNA as well as RNA viruses (1). Ribavirin closely resembles guanosine and is converted intracellularly to mono-, di-, and triphosphate derivatives, which inhibit the virally induced enzymes involved in viral nucleic acid synthesis by different mechanisms that are not fully understood (2). Of the DNA viruses, ribavirin is active against *Herpes simplex* virus and hepatitis B virus; among the RNA viruses, good activity has been observed against hepatitis C virus, orthomyxoviruses,

© 2006 Elsevier B.V. All rights reserved.

paramyxoviruses, arenaviruses, and bunyaviruses. Although active against HIV in vitro and in vivo (3), ribavirin is not widely used in the treatment of HIV infection. So far, drug resistance has not been described.

Oral ribavirin has been successfully used in the treatment of Lassa fever (4), Crimean Congo hemorrhagic fever (5), and in combination therapy with interferon alfa for hepatitis C infection (6,7). Several publications have suggested enhanced efficacy of the combination of interferon alfa with ribavirin when compared with monotherapy with interferon alfa. There is also evidence that re-treatment with the combination may succeed in controlling or eliminating viremia when monotherapy has failed. Although the combination may lead to some increase in the adverse effects normally associated with interferon alfa (dyspnea, pharyngitis, pruritus, nausea, insomnia, and anorexia) (SEDA-23, 315), there is no doubt that oral ribavirin adds to the overall toxicity of the combination by causing hemolytic anemia, which is usually mild.

Ribavirin is well absorbed orally, but it can be given in aerosol form for the treatment of respiratory syncytial virus (RSV) infections in immunocompromised patients, and in those with cardiopulmonary abnormalities, or in infants receiving mechanical ventilation (8,9).

The adverse effects and other safety aspects of interferon and ribavirin in the treatment of hepatitis C infection have been reviewed (10).

Comparative studies

Two, large, randomized, placebo-controlled comparisons of interferon alfa-2b alone with the combination of interferon alfa-2b plus ribavirin have been published. In the initial treatment of chronic hepatitis C, 912 patients were randomly assigned to receive standard-dose interferon alfa-2b alone or in combination with ribavirin (1000 or 1200 mg/day orally, depending on body weight) for 24 or 48 weeks (7). As expected, dosage reduction for anemia was necessary in 8% of patients taking the combination therapy and in none of those treated with interferon alone. Dyspnea, pharyngitis, pruritus, rash, nausea, insomnia, and anorexia were adverse effects that were reported more often during combination therapy with ribavirin (7). In patients whose chronic hepatitis had relapsed after therapy with interferon alfa-2b alone, 345 patients were randomized to receive standard-dose interferon alfa-2b alone or in combination with ribavirin (1000 or 1200 mg/day orally, depending on body weight) for 6 months (6). Dosage reduction for anemia was required in 12/173 patients assigned to combination therapy and in none assigned to interferon alone. As was the case in the initial therapy study, dyspnea, nausea, and rash were significantly more common in patients treated with the combination of interferon and ribavirin (6).

Ribavirin 15 mg/kg/day plus interferon alfa in 12 teenagers has been compared with interferon alone in 10 (11). There was no difference in dropout rate, but viral clearance was achieved in 50% of the patients who took the combination treatment versus 30% of those who took monotherapy. Adverse events were similar in the two groups. There was mild hemolytic anemia at the end of the first month in most of the children who took ribavirin, but four had moderate to severe hemolysis and two had to stop taking ribavirin. Severe hemolysis in a patient with thalassemia warranted withdrawal of ribavirin within 3 months.

Organs and Systems

Hematologic

Ribavirin accumulates in erythrocytes, resulting in hemolysis by an unknown mechanism, perhaps related to oxidative damage to the erythrocyte membrane. Time-dependent and dose-dependent hemolytic anemia (eventually associated with hyperbilirubinemia and a high reticulocyte count) is the only major toxic effect associated with oral or intravenous ribavirin and is reversible on withdrawal. There was a fall in hemoglobin concentrations below 10.0 g/dl in 9% of patients with hepatitis C treated with ribavirin and interferon alfa (6,7).

In 140 patients with Nipah virus infection there was no difference in the incidence of adverse effects between those who elected to have ribavirin treatment and those who refused (12). Dosing was based on recommendations used to achieve the same approximate concentrations as those seen with 100–1200 mg/day in the treatment of hepatitis C. Anemia occurred in 37% of the ribavirin-treated patients and in the same number of controls, suggesting that ribavirin was equally well tolerated in the two groups.

In patients taking ribavirin plus interferon alfa-2b the average fall in hemoglobin is 2–3 g/dl. Of 57 patients taking ribavirin 800 mg/day 28 were randomized to a high dose of peginterferon alfa-2b once a week (3 micrograms/kg for 1 week, 1.5 micrograms/kg for 3 weeks, and 1.0 microgram/kg for 44 weeks) and 27 patients were randomized to receive a low dose (0.5 micrograms/kg) for 48 weeks; three patients required reduced doses of ribavirin because of anemia (13).

In a randomized controlled trial of high-dose interferon alfa-2b plus oral ribavirin for 6 or 12 months in 50 patients with chronic hepatitis C, the sequential effects of treatment on hemoglobin, leukocytes, and platelets were recorded (14). There was a fall in hemoglobin, and the lowest concentrations were recorded after 6 months of treatment in both groups. All hematological measurements returned to normal after the end of treatment.

Detailed studies of the effects of ribavirin on erythrocyte ATP content and on the hexose monophosphate shunt have been conducted in vitro. ATP concentrations were significantly reduced and the hexose monophosphate shunt increased, suggesting erythrocyte susceptibility to oxidation. In vivo, ribavirin, alone or in combination with interferon, was associated with significant reductions in hemoglobin concentrations and a marked increase in absolute reticulocyte counts. Erythrocyte Na/K pump activity was significantly reduced, whereas K/Cl co-transport and its dithiothreitol-sensitive fraction and malondialdehyde and methemoglobin concentrations increased significantly. Ribavirin-treated patients showed an increase in aggregated band 3, which was associated with significantly increased binding of autologous antibodies and complement C3 fragments,

© 2006 Elsevier B.V. All rights reserved.

suggesting erythrophagocytic removal by the reticuloendothelial system (15).

A low pretreatment platelet count, the dose of interferon alfa, and the haptoglobin phenotype are risk factors for ribavirin-induced anemia, and the fall in hemoglobin is independent of dose in the therapeutic range (16). In five patients with chronic hepatitis C on hemodialysis who received subcutaneous interferon alfa-2b and oral ribavirin for 40 weeks, the dose of ribavirin was titrated based on hemoglobin, with bone marrow support by erythropoietin (17). There was significant bone marrow toxicity in all five. A dose of 200 mg/day produced a steady-state AUC comparable to that obtained with 1000–1200 mg/day in historical controls with normal renal function. More severe anemia was possibly due to chronic renal insufficiency in addition to the prolonged effects of ribavirin.

Treatment of ribavirin-induced hemolytic anemia with recombinant human erythropoietin has been described in 13 patients (18). The hemoglobin concentration increased from a nadir of 10.2 g/dl to a median of 11.5 g/dl and ribavirin treatment did not have to be withdrawn.

Liver

As part of a multicenter, randomized, double-blind, placebo-controlled trial of ribavirin in 59 patients with hepatitis C virus infection, liver biopsies were studied for iron deposition (19). Increased total iron deposition, preferentially in hepatocytes, occurred during a 9-month course of ribavirin. The deposition had no apparent effect on the biochemical or histological response to ribavirin therapy.

Skin

Photosensitivity after administration of ribavirin has been described (20). A well-documented photoallergic reaction in a woman who was taking both ribavirin and interferon alfa provided evidence that ribavirin is a potential photosensitizer for UVB, a problem that may become increasingly relevant in patients with chronic hepatitis C taking combination therapy for 6–12 months with interferon alfa and ribavirin (20).

Transient acantholytic dermatosis (Grover's disease) was first described by Grover in 1970 as a pruritic, self-limiting, popular, or papulovesicular eruption, mainly distributed on the trunk of white middle-aged men. The histopathological hallmark is suprabasal acantholysis at different levels of the epidermis. Its origin is uncertain; most cases are related to sunlight, heat, or sweating. Grover's disease has been attributed to ribavirin (21).

- A 55-year-old man with chronic hepatitis C presented with a pruritic papular eruption on the trunk lasting 2 weeks. He had multiple, erythematous, excoriated papules on the neck, trunk, upper arms, and thighs. The lesions appeared 2 weeks after combination therapy with oral ribavirin and subcutaneous interferon alfa-2b. He had previously been treated with interferon alfa alone (in the same dosage). On withdrawal of ribavirin the lesions gradually faded, but they returned 1 week after reintroduction.

Second-Generation Effects

Teratogenicity

Ribavirin is teratogenic and embryotoxic in laboratory animals and should not be given to pregnant women. Concern has been expressed about the safety of people in the same room as patients being treated with ribavirin by aerosol, particularly women of child-bearing age. However, no ribavirin was detected in the urine, plasma, or erythrocytes of 19 nurses exposed to ribavirin administered via ventilator, oxygen tent, or oxygen hood over 3 days (22).

Drug–Drug Interactions

Didanosine

Multisystem organ dysfunction and lactic acidemia occurred in two of 15 patients with HIV and hepatitis C infections who received interferon alfa, didanosine, and ribavirin (23). Co-administration of didanosine with ribavirin can lead to increased toxicity secondary to raised intracellular concentrations of phosphorylated didanosine (ddA-TP) (24,25). Thus, the evidence suggests that the combination of didanosine plus ribavirin increases the risk of lactic acidosis.

Warfarin

An interaction of warfarin with ribavirin has been reported (26).

- In a 61-year-old white man with chronic hepatitis C, who took interferon plus ribavirin, the dosage of warfarin had to be increased by about 40% (from 45 to 63 mg/week) in order to maintain the desired degree of anticoagulation. This effect was reproduced on rechallenge with ribavirin.

The mechanism of this supposed interaction is not known. For example, ribavirin is cleared by intracellular phosphorylation and its metabolites by the kidneys, warfarin by cytochrome P450 isozymes in the liver; warfarin is highly protein bound, ribavirin is not. However, an effect on warfarin absorption or its action on clotting factor synthesis is possible.

Riboflavin

See also Vitamins

General Information

The Average Requirement of riboflavin is 1.3 mg/day for men and 1.1 mg/day for women, the Population Reference Intake 1.6 and 1.3 mg/day respectively, and the Lowest Threshold Intake 0.6 mg/day for both.

Riboflavin is poorly absorbed and adverse reactions are almost unknown.

Because it can be detected fluorimetrically in the urine it has been used as a tracer to mark adherence to therapy (1,2).

Organs and Systems

Immunologic

Anaphylaxis has been reported in a boy who took a multivitamin tablet containing riboflavin (3).

- A 15-year-old boy developed flushing and a generalized papular rash after taking one multivitamin tablet, followed by dizziness, dyspnea, nausea, and severe angioedema of the face 40 minutes later. He became drowsy and developed hypotension (67/48 mmHg) and tachycardia (131/minute). He was given subcutaneous adrenaline, intravenous isotonic saline, and diphenhydramine and hydrocortisone, and after 30 minutes his vital signs became stable; he recovered consciousness shortly after. He had no history of atopic diseases or adverse drug reactions, but reported that he had had dizziness many times after drinking one particular yellow-colored brand of soft drink and that he had lost consciousness twice after drinking it about 5 years before. Intradermal skin tests with the vitamins

© 2006 Elsevier B.V. All rights reserved.

and determination of in vitro histamine release showed a strong positive response to riboflavin. He was advised to exclude riboflavin-containing products from his diet and to carry adrenaline for self-administration. During the next 13 months he had no further adverse reactions.

The multivitamin tablet that this boy took contained 100 mg of vitamins B_1, B_2, and B_6, cyanocobalamin concentrate 500 micrograms, and vitamin C 500 mg. The soft drink contained vitamin B_1 (0.6 ppm), vitamin B_2 (8.9 ppm), and vitamin C 200 micrograms/ml.

Ribonucleic acid

General Information

Ribonucleic acid has been used to enhance immune function in patients with cancer. Of 83 patients who received subcutaneous injections of ribonucleic acid (10 mg every other day) for various skin diseases, three developed an erythematous edematous reaction around the injection sites after the 7th to 15th injections (1). Although patch tests were negative in all three patients, lesions were reproduced after intradermal injection in one patient.

Rifamycins

See also Antituberculosis drugs

General Information

The rifamycins are a group of macrocyclic antibiotics that were originally derived from a culture of *Streptomyces mediterranei*, the products of which were named after the French film "Rififi chez les hommes" (director Jules Dassin).

Rifampicin

Rifampicin (rINN) is a semisynthetic derivative of rifamycin B. By suppressing the initiation of chain formation in RNA synthesis, it inhibits the DNA-dependent RNA polymerase of mycobacteria and other microorganisms (1). It inhibits the growth of most Gram-positive and many Gram-negative bacteria: *Escherichia coli*, some strains of *Pseudomonas*, *Proteus*, *Klebsiella*, *Staphylococcus aureus*, *Neisseria meningitidis*, *Hemophilus influenzae*, and *Legionella* species. *Mycobacterium tuberculosis*, *Mycobacterium kansasii*, *Mycobacterium scrofulaceum*, and *Mycobacterium intracellulare* are suppressed with increasing concentrations between 0.005 and 4 μg/ml. Rifampicin is bactericidal for *Mycobacterium leprae* in a concentration of less than 1 μg/ml. *Mycobacterium fortuitum* is not susceptible. Primary resistance is very rare, but secondary resistance among mycobacteria and meningococci develops very rapidly when rifampicin is used as a single drug (1).

In a prospective, randomized trial in 12 high-risk adult patients, the use of polyurethane, triple-lumen, central venous catheters impregnated with minocycline and rifampicin (on both the luminal and external surfaces) is associated with a lower rate of infection than the use of catheters impregnated with chlorhexidine and silver sulfadiazine (on the external surface only) (2). There were low rates of catheter-related bloodstream infection (0.3%) and catheter colonization (7.9%) with the use of catheters impregnated with minocycline and rifampicin. This favorable result may be explained either by differences in the coating of the catheters (internal and external surfaces versus external surface only), by microbiological advantages of minocycline and rifampicin over chlorhexidine and silver sulfadiazine, or even by an effect unrelated to the antibacterial activity. The additional costs of preventing an infection and a death would be about $3125 and $12 500 respectively (3).

Pharmacokinetics

Rifampicin is distributed to nearly all organs and body fluids in adequate antibacterial concentrations. The rifamycins are concentrated several-fold in alveolar macrophages (4). This explains their efficacy against intracellular bacteria. Peak concentrations of up to 7 μg/ml are reached within 2–4 hours after a dose of 600 mg before a meal. After gastrointestinal absorption, rifampicin is quickly eliminated in the bile, following enterohepatic circulation. It is also excreted in various fluids, and causes orange–red discoloration of the urine, feces, saliva, tears, sputum, and sweat (SED-10, 576) (5). Rifampicin is progressively deacetylated. Its half-life varies between 2.5 and 5 hours and is prolonged to various degrees by isoniazid and hepatic disorders (1). There is a progressive shortening of the half-life of rifampicin by about 40% during the first 14 days of treatment, owing to self-induction of the hepatic microsomal enzymes that metabolize it (6).

Because rifampicin is a potent inducer of hepatic microsomal drug-metabolizing enzymes, it has been implicated in reducing the effectiveness of many drugs that are metabolized in the liver (SEDA-21, 313). Interactions continue to be recognized, reflecting the

© 2006 Elsevier B.V. All rights reserved.

extension of the use of rifampicin from an antituberculosis agent to an antistaphylococcal drug, particularly useful in the treatment of methicillin-resistant *Staphylococcus aureus* (MRSA) and when prostheses are infected.

General adverse effects

Rifampicin given in usual doses (for example 10 mg/kg/day) is well tolerated and causes adverse effects in only about 4% of patients. Adverse reactions are predominantly hepatic and allergic. Gastrointestinal symptoms are generally transient. Risk factors are age, alcoholism, and hepatic disorders (1). As a potent microsomal enzyme inducer, rifampicin shortens the half-lives of many other drugs (1). This effect occurs after about 7 days and persists for a few days after withdrawal. Allergic reactions can cause rashes (in 0.8%), fever, a flu-like illness (malaise, headache), eosinophilia, and much less often hemolytic anemia, hemoglobinuria, and kidney damage with acute renal insufficiency. These reactions occur especially during intermittent treatment (less than twice weekly) or after re-introduction of rifampicin. Anaphylactoid reactions to rifampicin have been described in HIV-positive patients (7). Light-chain proteinuria and concomitant kidney damage are attributed to an immunological process (SEDA-10, 273). Rifampicin antibodies have been found using an antiglobulin test (8). Hemolysis as an adverse effect seems to be mainly of the immune-complex type, exceptionally of the IgG-antibody type (9). The drug-induced lupus-like syndrome has been linked to rifampicin in a few cases. Tumor-inducing effects and chromosome aberrations have not been noted with rifampicin or during the combined use of isoniazid and rifampicin (SEDA-9, 276).

A flu-like illness, with fever, headache, malaise, and bone pain, can occur shortly after the administration of rifampicin, and was observed in a man who had taken rifampicin 600 mg monthly for multibacillary leprosy (10). However, the reaction usually occurs with higher doses given weekly or twice weekly. The usual procedure is to reduce the dose or increase the frequency of treatment. Antipyretic drugs can be used to provide symptomatic relief.

Intermittent rifampicin therapy introduces risks of hematological and renal adverse reactions, probably through immunological mechanisms. Restarting rifampicin after a drug-free interval has to be carefully guided using small initial dosages of about 75 mg/day and increasing to a final dosage of about 500–600 mg/day. It is essential to monitor blood counts, coagulation factors, and kidney function. The authors of a comprehensive review of the adverse effects of rifampicin (11) have made the point that these are likely to increase, because reactions such as hemolysis, thrombocytopenia, and flu-like syndromes are more likely in patients who take rifampicin intermittently, a pattern of treatment that is becoming recognized as the best way to manage tuberculosis in developing countries and in patients everywhere whose compliance cannot be relied upon, since it is impractical to administer directly observed therapy (DOTS) more often than two or three times a week.

Some drug interactions with rifampicin have been reviewed (SEDA-21, 313) (SEDA-24, 354).

Rifabutin

Rifabutin (rINN), a spiropiperidyl derivative of rifamycin, is more effective in vitro against *M. tuberculosis* than rifampicin. It has a longer half-life, better tissue penetration, and causes less enzyme induction than rifampicin. Rifabutin is well absorbed from the gastrointestinal tract and reaches a peak serum concentration of about 0.5 μg/ml 4 hours after a single dose of 300 mg.

A 300 mg dose of rifabutin is usually well tolerated. Adverse effects include neutropenia, thrombocytopenia, rash, and gastrointestinal disturbances (nausea, flatulence). Myositis (12) and uveitis (13) are rarely observed. The drug-induced lupus-like syndrome has been linked in a few cases with rifampicin and rifabutin.

In a multicenter study from the National Institute of Allergy and Infectious Diseases in the USA, azithromycin (600 mg/day) plus rifabutin (300 mg/day) was poorly tolerated by 31 patients with or without HIV infection (14). Gastrointestinal symptoms and neutropenia were the major adverse effects. There was no significant pharmacokinetic interaction between the two drugs.

Rifamycin SV

Rifamycin SV (rINN), a semisynthetic macrocyclic antibiotic derived from natural rifamycin B, has been used in the therapy of tuberculosis and in some European countries as a topical antibiotic. Anaphylaxis has been reported after systemic administration, and rarely after topical application.

Organs and Systems

Cardiovascular

Shock and a flu-like illness (fever, chills, and myalgia) have been observed most often in patients taking intermittent rifampicin, dosages over 1000 mg/day, or on restarting treatment (1,15). Shock and cerebral infarction have been reported in an HIV-positive patient after re-exposure to rifampicin (16).

Local thrombophlebitis can occur during prolonged intravenous administration (17).

Respiratory

Respiratory symptoms from rifampicin are very rare. They can be part of a flu-like illness with bronchial obstruction (18,19).

Rifampicin-induced pneumonitis is rare.

- An 81-year-old man with smear- and culture-positive pulmonary tuberculosis developed clinical and radiological features of localized interstitial pneumonitis 1 week after starting to take rifampicin, isoniazid, and ethambutol (20). The bronchoalveolar lavage fluid contained 83% lymphocytes with a CD4/CD8 ratio of 10.5. Antituberculosis treatment was withheld and he was treated with methylprednisolone for 3 days because of progressive respiratory failure. A drug lymphocyte stimulation test showed a high stimulation index with rifampicin (370%). He was subsequently treated with streptomycin instead of rifampicin. Rechallenge with rifampicin was not undertaken.

© 2006 Elsevier B.V. All rights reserved.

Sudden clinical and radiological worsening during treatment for pulmonary tuberculosis may be due to bronchogenic spread of infection, immune reconstitution producing a paradoxical reaction, drug-induced hypersensitivity pneumonitis, or other unrelated causes, such as pulmonary embolism. Allergic pneumonitis with rifampicin is most unusual, as is the high CD4/CD8 ratio observed in the bronchoalveolar lavage fluid.

Nervous system

Rifampicin is widely used in tuberculous and meningococcal meningitis, since it passes into the cerebrospinal fluid (21). Rifampicin-induced neurological effects include drowsiness, headache, dizziness, ataxia, generalized numbness, pain in the extremities, muscular weakness, confusion, inability to concentrate, delusions, disorientation, hallucinations, and agitation (1,22).

Sensory systems

Drug-induced uveitis is rare. Antibiotics that have been implicated include rifabutin and sulfonamides. Furthermore, nearly all antibiotics injected intracamerally have been reported to produce uveitis (23).

In one study, the most important adverse effect of rifabutin was uveitis, which occurred in 24 of 63 patients taking rifabutin 600 mg/day and three of 53 patients taking 300 mg/day (24). No patients taking quadruple therapy developed uveitis (25). Initially, uveitis was thought to occur only with dosages of rifabutin over 1200 mg/day. However, a review of 54 cases has shown that it can occur at dosages of 300–600 mg/day and is more likely to occur in patients with a low body mass (26). The patients presented with uveitis 2 weeks to 7 months after starting therapy. In all cases they were also taking fluconazole and clarithromycin, drugs that inhibit cytochrome P450 drug metabolism, leading to increased blood concentrations of rifabutin. Rifabutin is less likely to cause uveitis when it is used in combination with azithromycin 500 mg/day than with clarithromycin. If rifabutin is combined with clarithromycin 1 g/day the dose of rifabutin should be limited to 300 mg/day—advice which has been endorsed by the UK Medicines Control Agency (27).

Topical administration of a glucocorticoid and a cycloplegic drug (such as atropine) is suitable as initial treatment. Withdrawal of causative drugs is not always necessary (28).

Endocrine

In patients taking glucocorticoids for Addison's disease, rifampicin may necessitate an increase in glucocorticoid dosage. Thus, incipient adrenal insufficiency can be unmasked by rifampicin (SEDA-13, 261). The phenomenon is due to liver enzyme induction (29).

A significantly raised concentration of TSH during therapy with rifampicin has been reported in a man taking levothyroxine; TSH concentrations returned to baseline 9 days after withdrawal of rifampicin (30).

Metabolism

The combination of rifampicin and isoniazid reduces serum concentrations of 25-hydroxycholecalciferol. Rifampicin acts by induction of an enzyme that promotes conversion of 25-hydroxycholecalciferol to an inactive metabolite, and isoniazid acts by inhibiting 25-hydroxylation and 1-hydroxylation (SEDA-14, 258). Children or pregnant women with tuberculosis have increased calcium requirements independent of rifampicin administration (31). In 132 children of Afro-Asian origin there was a significant increase in serum alkaline phosphatase activity. This was more pronounced in patients taking both isoniazid and rifampicin than with isoniazid alone (32). The rise in alkaline phosphatase could reflect an effect on either liver or bone. The possibility of a link between this effect and osteomalacia is unclear.

Rifampicin-induced porphyria cutanea tarda has been described in one case, combined with altered liver function (33).

Hematologic

Hemolysis (34,35), agranulocytosis (36), leukopenia (37), and thrombocytopenia (38) have been reported in patients taking rifampicin (SED-10, 578) and constitute contraindications to continuation of therapy.

Hemorrhagic states have been induced by rifampicin in pregnant women and their offspring because of drug-induced hepatic breakdown of vitamin K (39).

Disseminated intravascular coagulation has been attributed to rifampicin (40).

- A 46-year-old woman died of severe disseminated intravascular coagulation after her third monthly dose of rifampicin, given with daily dapsone for the treatment of leprosy (41).

Erythrocytes

Isolated cases of massive hemolysis, with or without renal insufficiency, have been observed in patients taking rifampicin (42–44). Whereas rifampicin given repeatedly and in the usual dose is quite safe, it can cause intravascular hemolysis when given intermittently (45).

Antibodies to rifampicin have been found in several studies, with a positive Coombs' test in the presence of the drug (SEDA-5, 291), more often of the immunocomplex type (46,47) than with IgG or IgM antibodies (43,44).

- In one case, hemolysis started after the second dose of rifampicin, and the patient's blood contained rifampicin-dependent IgG and IgM antibodies, which caused erythrocyte lysis through an interaction with the I antigen on the erythrocyte surface (35). This antigen is also expressed on renal tubular epithelium and the hemolysis was accompanied by acute renal insufficiency.

Intermittent or interrupted treatment appears to predispose to this complication.

Leukocytes

There were four cases of agranulocytosis due to antituberculosis drugs (rifampicin, isoniazid, ethambutol, streptomycin, or pyrazinamide) among about 6400 patients who underwent chemotherapy from 1981 to 2002; the incidence rate of agranulocytosis was estimated at 0.06% (36).

In 140 patients who took Rimapen (Orion, Finland) there were 11 cases of leukopenia, while in 132 patients

© 2006 Elsevier B.V. All rights reserved.

who took Rimactan (Ciba-Geigy, Switzerland) there was only one case, a statistically significant difference (37).

Platelets

Reports of drug-induced thrombocytopenia have been systematically reviewed (48). Among the 98 different drugs described in 561 articles, the following antibiotics were found with level I (definite) evidence: co-trimoxazole, rifampicin, vancomycin, sulfisoxazole, cefalothin, piperacillin, methicillin, novobiocin. Drugs with level II (probable) evidence were oxytetracycline and ampicillin. There is an increased frequency of thrombocytopenia with intermittent therapy (40).

Immune thrombocytopenia during rifampicin therapy has been attributed to drug-dependent binding of an IgG antibody to platelets; the binding epitope of the antibody was found in the glycoprotein Ib/IX complex (38).

Gastrointestinal

Nausea, vomiting, epigastric pain, diarrhea, loss of appetite, abdominal cramps, and meteorism are often restricted to the beginning of rifampicin therapy. However, gastric burning can oblige some patients to take the drug after meals. Hemorrhage from gastric erosions is a rare complication (49).

- Tablet-associated esophagitis has been reported in a 70-year-old white man on the fourth day of antibiotic therapy with vancomycin, gentamicin, and oral rifampicin for *Staphylococcus epidermidis* prosthetic valve endocarditis (50).

The authors noted that age, bedridden state, gastroesophageal reflux disease, simultaneous administration of several medications, and nasopharyngeal obstruction may have increased the risk of esophagitis. They found a second case of tablet-associated esophagitis caused by rifampicin in their review of the published literature.

Histologically confirmed pseudomembranous colitis has been reported in patients taking rifampicin. Bacteriology showed mainly *Clostridium difficile* resistant to rifampicin and several other antibiotics. Withdrawal of rifampicin and the use of vancomycin has been helpful (SEDA-6, 275) (SEDA-7, 310) (51).

Liver

Rifampicin is rarely used as monotherapy. The risk of hepatotoxicity appears to be very low in patients with normal liver function, especially if rifampicin is given continuously. When given with isoniazid, rifampicin can cause a fulminant liver reaction. This may be attributable to enhancement of isoniazid hepatotoxicity as a result of enzyme induction by rifampicin. In some cases, jaundice occurred within 6–10 days after beginning isoniazid plus rifampicin (52). High serum transaminase activities, disturbances of consciousness, and centrilobular necrosis were found. All the patients recovered.

Hepatotoxicity of combined therapy for leprosy has been reported in 39 patients treated with dapsone, protionamide, and rifampicin. There were similar findings in 50 patients treated with dapsone, clofazimine, rifampicin, and protionamide. Deaths probably related to the drugs occurred in both groups after 3–4 months of treatment (53). The drug responsible for liver injury may have been protionamide, although rifampicin administered simultaneously could also have contributed (53).

Among 50 000 patients treated prophylactically with rifampicin, there were 16 deaths associated with jaundice (0.03%) (SED-10, 578) (54,55).

Raised transaminases in children commonly cause withdrawal of therapy (56).

Transaminase activities and other liver function tests should be measured weekly in cases with liver dysfunction and every 4 weeks in patients with no known liver disease.

Severe itching is often a distressing symptom in patients with primary biliary cirrhosis and in cholestatic jaundice due to other causes. Rifampicin has been recommended for controlling this symptom, even though it is known to be hepatotoxic. Rifampicin-induced hepatitis has been reported in three of 41 patients with primary biliary cirrhosis (7.3%; 95% CI = 2.5, 19) (57). This risk is greater than the risk of hepatitis during rifampicin monotherapy for latent tuberculosis. Pre-existing liver disease is a recognized risk factor for drug-induced hepatitis, and these patients need to be monitored carefully during rifampicin therapy.

Biliary tract

Total serum bile acid concentrations were raised in 72% of 61 patients treated with rifampicin and isoniazid; in some patients, the concentrations were as much as 40 times above normal, but in only four was the serum bilirubin raised (58).

Skin

Pruritus, rashes, and urticaria have been reported. Rifampicin-induced rashes often resolve spontaneously, even without drug withdrawal, although in others they can be severe and can be accompanied by systemic symptoms, in some cases amounting to anaphylaxis (11).

Acne occurs more often in patients taking rifampicin and isoniazid combinations than those without rifampicin (SEDA-9, 270).

- A patient developed pemphigus foliaceus induced by rifampicin and improved after withdrawal (72).
- Another patient developed an exacerbation of pemphigus vulgaris during rifampicin therapy, which improved after withdrawal (73).

Severe bullous reactions have been associated with subepidermal detachment typical of toxic epidermal necrolysis (74).

After intravenous rifampicin, a severe cutaneous hypersensitivity reaction has been described, similar to the pattern known as the red man syndrome seen after rapid infusion of vancomycin. The reaction responded to a histamine H_1 receptor antagonist (75).

Rifampicin can cause a fixed drug eruption (76).

Musculoskeletal

Of 26 patients who received rifabutin 600 mg/day in combination with ethambutol, streptomycin, and either clarithromycin (500 mg bd; $n = 15$) or azithromycin (600 mg/day; $n = 11$), there were rifabutin-related

© 2006 Elsevier B.V. All rights reserved.

adverse events in 20; these included a diffuse polyarthralgia syndrome in 5 (77).

Immunologic

There is no evidence that rifampicin causes clinically significant deleterious effects on the immune system in humans (78), whereas it can cause immunosuppression in animals (79). Rifampicin partially suppresses cutaneous hypersensitivity to tuberculin and T cell function (80). In 33 patients with leprosy treated with a rifampicin drug combination, a flu-like illness or antibodies to rifampicin-conjugated proteins were not observed (81).

A possible explanation of the association of allergic reactions with intermittent therapy is that during daily regimens the antigen–antibody complexes are continuously cleared from the plasma without reaching a critical concentration, whereas in intermittent regimens, antibody titers can increase markedly during the drug-free days. This is supported by the observation that anti-rifampicin antibodies, measured by the indirect Coombs' test, developed more commonly during intermittent than during daily therapy and that antibodies may disappear from the serum when patients change from intermittent to daily regimens.

Severe anaphylaxis has been reported in two patients with infected wounds that had been treated with topical rifamycin for several months (82). There was urticaria, angioedema, and hypotension in one case, and urticaria, wheezing, dyspnea, and hypotensive shock in the other. In both cases, prick tests with 10% rifamycin solution were positive, while there were no positive reactions in 20 controls.

- A 36-year-old woman developed generalized urticaria during a second course of treatment with rifamycin eyedrops within a month and a 49-year-old man had systemic urticaria, bronchospasm, and hypotension shortly after his surgical wound had been washed with a solution of rifamycin (83). Both patients had positive skin prick tests to rifamycin (1 mg/ml) when tested several weeks after the acute episode, while 10 healthy volunteers had negative tests. The woman also had a positive skin prick test to rifampicin 2 mg/ml, although she had never taken it before.

An HIV-infected patient who developed an anaphylactic reaction to rifampicin tolerated treatment with rifabutin without any adverse event.

The lupus-like syndrome has been reported in seven patients, six of them women who were taking rifampicin ($n = 4$) or rifabutin ($n = 3$) in standard dosages for mycobacterial infections (84). None was HIV-1 positive, none was also taking isoniazid, and although they were taking other antimycobacterial drugs, their symptoms disappeared after withdrawal of the rifamycin alone. All had two or more episodes of fever, malaise, myalgia, and arthralgia, and all had positive antinuclear antibodies. All were also taking either ciprofloxacin or clarithromycin, and the authors speculated that these drugs, which are cytochrome P_{450} enzyme inhibitors, could have increased the serum concentrations of the rifamycins.

Desensitization protocols can be helpful in patients who have had anaphylactic reactions, and the detection of IgE antibodies to rifampicin may be helpful in clarifying pathogenesis. A switch to a daily regimen, when administration was previously intermittent, may allow resumption of rifampicin without further problems. In 35 HIV-positive patients with previous allergic reactions to rifampicin, oral desensitization was safe and allowed the reintroduction of rifampicin in 60% of cases (85). However, the flu-like syndrome, hemolytic and thrombocytopenic crises, and acute renal insufficiency are not IgE-mediated, and when rifampicin is thought to be indispensable, a course of treatment may be completed under glucocorticoid cover. Four patients with reactions to rifampicin, one with rash, fever, and lymphadenopathy and one with hepatitis, completed courses of antituberculosis therapy for nervous system infections under glucocorticoid cover (86).

Second-Generation Effects

Pregnancy

Rifampicin is currently recommended by the WHO for the treatment of tuberculosis during pregnancy. On the other hand, drug companies advise against the use of rifampicin during the first 3 months of pregnancy, even though deleterious effects on the fetus have not been confirmed in man.

Induction of hepatic microsomal enzymes by rifampicin is believed to be the cause of vitamin K deficiency in pregnancy, leading to hemorrhagic disturbances in pregnant women and their neonates. Prophylactic vitamin K should therefore be given to all mothers and their offspring when the mother has taken rifampicin during late pregnancy. Blood coagulation tests should be done on both (SEDA-8, 288).

Teratogenicity

Rifampicin crosses the placenta, and although teratogenicity is uncertain, it may not be as innocuous during pregnancy as isoniazid or ethambutol (SEDA-6, 277) (87).

Lactation

Lactation is not a contraindication to rifampicin; only small amounts pass into the milk with no relevant effects on the newborn (88).

Susceptibility Factors

Renal disease

Impaired renal function has to be taken into consideration when calculating the dosage of rifampicin (89).

Hepatic disease

Pre-existing liver damage has to be taken into consideration when calculating the dosage of rifampicin (90).

Other features of the patient

Chronic alcoholism is an important risk factor for adverse effects of the rifamycins. In 79 consecutive patients taking rifampicin in combination with isoniazid and another drug, there was a high incidence of acute clinical liver

© 2006 Elsevier B.V. All rights reserved.

disease; about half of the patients were advanced alcoholics and almost all the cases of hepatitis came from this group (91). Most of those with pretreatment abnormalities of liver function had abnormalities in liver biopsies, not attributable to alcohol. In one patient, active chronic hepatitis was attributed to rifampicin.

However, in 531 eligible patients enrolled in a US Public Health Service Cooperative Trial of Short-Course Chemotherapy of Pulmonary Tuberculosis, of whom 58% were classified as alcoholic, although the alcoholics had more abnormal concentrations of aspartate transaminase before and during therapy, there was no significant difference between the alcoholics and non-alcoholics in the incidence of adverse reactions, including hepatotoxic reactions (92). The authors concluded that in the absence of clinically significant and persistent pretreatment abnormalities of hepatic function tests, rifampicin and isoniazid are not contraindicated in patients categorized as alcoholic.

In patients with suspected disorders of vitamin D and calcium metabolism, caution has to be taken (SEDA-9, 269).

Drug Administration

Drug overdose

Severe overdosage has been observed in inadvertent administration of an excessive dose of rifampicin in children (93) and also in suicide attempts (94,95). It can also occur when there is impaired hepatic function or severe renal insufficiency. Symptoms are nausea, vomiting, headache, abdominal pain, diarrhea, and pruritus.

Drug–Drug Interactions

Amiodarone

Rifampicin has been reported to reduce the effects of amiodarone (96).

- A 33-year-old woman was given rifampicin to suppress an MRSA infection of a pacing system that could not be removed. She was already taking amiodarone which, with the pacing system, was intended to manage her complex dysrhythmias. The introduction of antibiotic therapy was followed by an increase in bouts of palpitation and in shocks from her defibrillator. Her amiodarone concentrations had fallen and returned to the target range, with disappearance of her symptoms, when the rifampicin was withdrawn.

The authors discussed the possible reasons for this interaction, including a reduction in systemic availability of amiodarone or induction of metabolism by rifampicin.

Antacids

Antacids, particularly aluminium hydroxide gel, magnesium trisilicate, and sodium bicarbonate, reduce the systemic availability of rifampicin (97).

Antiretroviral drugs

The recommendations of the Center for Disease Control and Prevention in Atlanta regarding the use of antituberculosis drugs in combination with antiretroviral drugs have been published (98). In general, the use of rifampicin in patients taking protease inhibitors is contraindicated, except in the following circumstances:

- patients taking the NNRTI efavirenz and two NRTIs;
- patients taking the protease inhibitor ritonavir and one or more NRTIs;
- patients taking a combination of the two protease inhibitors ritonavir and saquinavir.

However, Roche Pharma have recommended that rifampicin should not be used in patients who are taking ritonavir + saquinavir, because of the results of a study in which 11 of 28 patients who took rifampicin 300 mg/day with ritonavir 100 mg bd + saquiniavir 1000 mg bd developed severe hepatotoxicity [http://www.fda.gov/medwatch/safety/2005/Saquinavir-Rifampin_deardoc_Feb05].

The use of rifampicin with the protease inhibitors indinavir, nelfinavir, and amprenavir is contraindicated. However, these agents can be used with rifabutin after appropriate dosage reduction. Failure to reduce the dosage of rifabutin can result in toxic manifestations, such arthralgia and uveitis.

Rifamycins can be used with the NNRTIs nevirapine or efavirenz, but not with delavirdine.

Data on drug pharmacokinetics and drug interactions in patients taking treatment for HIV infection and tuberculosis are scanty, and the current recommendations are almost certain to be modified in the near future. Furthermore, it may be prudent to monitor rifampicin concentrations in the event of intolerance or adverse drug reactions.

Barbiturates

Barbiturates, which induce liver drug-metabolizing enzymes, increase the rate of metabolism of rifampicin (99).

Cardiac glycosides

In eight healthy volunteers rifampicin reduced digoxin plasma concentrations (100), mirroring clinical experience. The authors hypothesized that this effect may be brought about by induction of P-glycoprotein, which increases excretion of digoxin into the gut lumen; however, renal digoxin clearance, which is also mediated by P-glycoprotein, was not affected. In these healthy volunteers, rifampicin reduced digoxin concentrations by about 50%, so the interaction is likely to be clinically important.

Digitoxin plasma concentrations can be reduced by rifampicin, and the dosage should be adjusted according to the serum concentration (SEDA-10, 272).

Ciclosporin

Increased dosages of ciclosporin are recommended when patients take rifampicin (SEDA-21, 314). In one study it was necessary to increase the dosage of ciclosporin from 225 to 800 mg/day during treatment with rifampicin and for 7 days afterwards in order to maintain therapeutic concentrations (101). Low ciclosporin blood

© 2006 Elsevier B.V. All rights reserved.

concentrations and acute graft rejection have been observed in a renal transplant recipient during prophylactic rifampicin therapy (102).

Clarithromycin

Severe interactions have been observed when rifabutin and clarithromycin were given simultaneously (103). The mean concentrations of rifabutin and 25-*O*-desacetyl-rifabutin in healthy subjects who took clarithromycin and rifabutin concomitantly were respectively more than 4 times and 37 times greater than the concentrations recorded when rifabutin was administered alone. Neutropenia was detected in 14 of 18 subjects taking rifabutin. Myalgia and high fever were also common. In another study, clarithromycin increased the AUC of rifabutin by 76% (104). Physicians should be aware that recommended prophylactic doses of rifabutin can be associated with severe neutropenia within 2 weeks after the start of therapy, and all patients taking rifabutin, especially with clarithromycin, should be monitored carefully for neutropenia.

Clofibrate

The interaction of rifampicin with clofibrate has been reviewed (105). Rifampicin induces the metabolism of clofibrate, and in five subjects rifampicin 600 mg/day caused a 35% fall in steady-state serum clofibrate concentrations (106).

Clonidine

Rifampicin 600 mg/day had no effect on the pharmacokinetics of clonidine 0.4 mg/day in six healthy subjects (105,107).

Clozapine

Rifampicin can reduce plasma concentrations of clozapine and exacerbate psychotic symptoms (108).

Contrast media

Excretion of contrast media through the bile can be impaired by rifampicin (1,82).

Corticosteroids

Rifampicin enhances the catabolism of many glucocorticoids. For example, it increases the plasma clearance of prednisolone by 45% and may reduce the amount of drug available to the tissues by as much as 66% (SEDA-8, 288). Glucocorticoid therapy for concomitant diseases should therefore be adjusted in the light of plasma concentrations and clinical effects during rifampicin treatment (SEDA-10, 272). For example, rejection of a kidney transplant occurred after 7 weeks of rifampicin therapy (109).

Co-trimoxazole

In patients taking co-trimoxazole, rifampicin in a standard oral antituberculosis regimen (600 mg/day plus isoniazid 300 mg/day and pyrazinamide 30 mg/kg for more than 12 days) reduced the steady-state AUC of trimethoprim and sulfamethoxazole by 47 and 23% respectively (110). The same authors had previously reported reduced efficacy of co-trimoxazole in the prevention of toxoplasmosis in HIV-infected subjects (111). The reduction in prophylactic efficiency was more pronounced in subjects who took a single double-strength tablet.

There have been no reports on the risk of *Pneumocystis jiroveci* pneumonia in patients taking rifampicin plus co-trimoxazole prophylaxis. Until such time as more data are available, it is prudent to use double-strength co-trimoxazole tablets twice daily for prophylaxis of toxoplasmosis and *P. jiroveci* pneumonia in patients taking concomitant rifampicin.

Coumarin anticoagulants

Coumarin anticoagulants undergo accelerated metabolism in patients taking rifampicin (112). Rifampicin greatly increases the clearance of warfarin by inducing hepatic enzymes, and difficulty in achieving an optimal INR despite an increase in the dose of warfarin has been highlighted (113). In patients taking rifampicin, warfarin should be started in dosages of 20–30 mg/day for two days, subsequently adjusting the dose according to the prothrombin time; a daily maintenance dose of 20 mg may be required (114) and close monitoring is required during the initial weeks to achieve a therapeutic INR (115). Offset of the interaction when rifampicin is withdrawn can take as long as 4–5 weeks, during which time the dose of warfarin should be reduced gradually to avoid a high INR and bleeding complications.

Dapsone

The interaction of rifampicin with dapsone has been reviewed (105). In seven patients with leprosy, rifampicin shortened the half-life of dapsone by 50% (116).

Diazepam

The interaction of rifampicin with diazepam has been reviewed (105). The mean half-life of diazepam fell from 58 to 14 hours in seven patients who took isoniazid, rifampicin, and ethambutol (117).

Fluconazole

Fluconazole increased the AUC of rifabutin by 76% (104).

Haloperidol

Blood concentrations of haloperidol are reduced during rifampicin administration, owing to shortening of the half-life of haloperidol (SEDA-12, 258) (118).

Ketoconazole

Ketoconazole interacts with rifampicin, and the serum concentrations of both drugs are reduced (SEDA-9, 269).

Methadone

Methadone metabolism is increased and a withdrawal syndrome has been reported (1).

Mexiletine

The interaction of rifampicin with mexiletine has been reviewed (105). The mean half-life of a single dose of mexiletine 400 mg fell from 8.5 to 5 hours in eight healthy subjects who took rifampicin 600 mg/day for 10 days (119).

© 2006 Elsevier B.V. All rights reserved.

Nifedipine

The elimination of nifedipine is enhanced by rifampicin (SEDA-14, 259).

Oral contraceptives

The serum concentrations of ethinylestradiol and similar steroids used as contraceptives are reduced during rifampicin therapy; it is therefore not surprising that unexpected pregnancies have occurred (120). The effects of rifampicin have been compared with those of rifabutin (increasingly used for the treatment of atypical mycobacterial infections) in a double-blind, crossover study in 12 women who were taking a stable oral contraceptive regimen containing ethinylestradiol and norethindrone (121). Rifampicin had the greater effect in reducing the mean AUC, but none of the subjects ovulated during the cycle in which either of the rifamycins was administered.

Oral hypoglycemic agents

Oral hypoglycemic agents (glibenclamide, gliclazide, repaglinide, and rosiglitazone) undergo accelerated metabolism in patients taking rifampicin (112).

The addition of rifampicin to glimepiride (metabolized by CYP2C9) produced only a modest reduction in AUC and no significant effect on blood glucose (122).

Phenazone

Rifampicin significantly reduces the half-life of phenazone (antipyrine) (123).

Probenecid

Probenecid can increase the serum concentration of rifampicin; this can reduce costs and hepatotoxicity in long-term therapy (124). Interactions of rifampicin with probenecid have been reviewed (105).

Propranolol

The metabolism of propranolol is enhanced by rifampicin (SEDA-9, 269).

Quinidine

Quinidine plasma concentrations can be lowered by rifampicin because of enzyme induction (125).

Repaglinide

Co-administration of rifampicin with repaglinide considerably lowers the concentration of repaglinide and alters its therapeutic effect in diabetes mellitus (126). In nine healthy volunteers, the maximum reduction in blood glucose after a single 0.5 mg dose of repaglinide fell from 1.6 to 1.0 mmol/l after pretreatment with rifampicin for 5 days. This presumably occurred by induction of CYP3A4.

Statins

In healthy subjects taking rifampicin the C_{max} and AUC of simvastatin were greatly reduced (127), presumably by enzyme induction. It is likely that other HMG-CoA reductase inhibitors, including lovastatin and atorvastatin, also have clinically significant interactions with rifampicin.

Tacrolimus

An interaction of rifampicin with tacrolimus has been documented (128,129).

- A 61-year-old Chinese renal transplant recipient, who had taken tacrolimus for 1 year after an episode of rejection had failed to respond to ciclosporin, took rifampicin and 12 days later had an episode of biopsy-proven graft rejection, associated with very low serum tacrolimus concentrations.
- A 50-year-old woman, a renal transplant recipient, developed a brain abscess due to *Nocardia otitidiscaviarum* after craniotomy and was given meropenem and rifampicin. The dose of tacrolimus had to be increased three-fold to maintain adequate trough concentrations.

Theophylline

Rifampicin increases the metabolic clearance of theophylline by 45%, especially after intravenous use (130,131).

Thyroxine

Induction of cytochrome P_{450} may be the explanation for a modest increase in the clearance of levothyroxine (10–15%) which may necessitate an increase in dosage. In two cases, rifampicin led to significant increases in TSH concentrations in patients being treated for hypothyroidism (30).

Trimethoprim

The interaction of rifampicin with trimethoprim has been reviewed (105). Rifampicin has a small effect on the clearance of trimethoprim but it is not clinically significant (132,133).

Interference with Diagnostic Tests

von Jaksch test

Rifampicin metabolites in urine can cause a false positive test for melanin when assessed with the von Jaksch test (134).

Rilmenidine

General Information

Rilmenidine is an imidazoline derivative that lowers blood pressure by an interaction with imidazoline (II) receptors in the brainstem and kidneys (1).

In a number of trials in hypertension the adverse effects profile of rilmenidine was qualitatively similar to that of clonidine, although the overall incidence of adverse events appeared to be lower. The main complaints were of dry mouth, drowsiness, and constipation (2–4). In one of these reviews, in which the impact on vigilance was particularly examined, it was concluded that although there were dose-related effects there was no statistically significant difference between rilmenidine and placebo in relation to sedation and drowsiness. However, these results consistently showed a rank order among placebo, rilmenidine, and clonidine, leading to progressively greater degrees of sedation (5).

Organs and Systems

Skin

A photosensitivity reaction has been attributed to rilmenidine (6).

- A 51-year-old woman developed erythema and swelling on sun-exposed areas and complained of a local burning sensation and pruritus 10 days after she started to take rilmenidine 1 mg/day for mild hypertension. She recovered fully 1 week after rilmenidine withdrawal and treatment with prednisolone. The chronology and the results of patch and photopatch tests suggested a phototoxic reaction to rilmenidine.

The authors suggested that this may have been related to the double bond in the oxazoline ring of the drug.

Rimantadine

General Information

Rimantadine hydrochloride, an alpha-methyl derivative of amantadine (alpha-methyl-1-adamantane methylamine hydrochloride), is more active than amantadine against influenza A viruses in vitro and in laboratory animals. It is an alternative to amantadine for the prevention and treatment of influenza A virus infections in adults and for the prevention of influenza in children. Adverse effects have been considered to be less common with rimantadine (SEDA-8, 143), and it is generally tolerated better than amantadine, because it causes fewer nervous system adverse effects (1). Unfortunately, rimantadine is more costly, which has led many institutions to develop influenza treatment guidelines. Both drugs work by blocking the M2 ion channel, which is needed to affect a pH change that helps to initiate viral uncoating.

In a systematic review of seven trials of amantadine versus placebo ($n = 1797$), three of rimantadine versus placebo ($n = 688$), and two of amantadine versus

© 2006 Elsevier B.V. All rights reserved.

rimantadine ($n = 455$) in the prevention of influenza A illness, there was a relative odds reduction of illness of 64% with amantadine compared with placebo, a 75% reduction with rimantadine compared with placebo, and no significant difference between the two drugs (2). There was a significantly higher risk of central nervous system adverse reactions and premature withdrawal with amantadine compared with placebo, but not with rimantadine compared with placebo. However, there was a significant increase in the risk of gastrointestinal adverse events with rimantadine compared with placebo (OR = 3.34, 95% CI = 1.17, 9.55).

Organs and Systems

Nervous system

The major advantage of rimantadine is a lower risk of central nervous system effects, such as light-headedness, difficulty in concentrating, nervousness, and insomnia, which can be a significant problem with amantadine, particularly in older patients. The English-language literature from 1966 to 1994 has been reviewed (3). In 598 elderly patients, nervous system adverse effects were more common with higher dosages (4.9% at 100 mg/day to 12.5% at 200 mg/day).

Gastrointestinal

The English-language literature from 1966 to 1994 has been reviewed (3). Gastrointestinal effects, including nausea, loss of appetite, diarrhea, and dry mouth, occurred in 8.4% of children under 10 years of age, in 3.1% of adults, and in 2.9% of elderly patients taking 100 mg/day and 17.0% taking 200 mg/day.

Long-Term Effects

Drug tolerance

Emergence of resistance of influenza A virus to rimantadine in vivo has been reported (4), but the incidence of resistance in field isolates appears to be extremely low (5).

Rimazolium

General Information

Rimazolium is a non-narcotic analgesic that strongly potentiates the analgesic and antagonizes the respiratory depressant effect of morphine alkaloids in animals and prevents the development of tolerance to morphine in animals and humans (1). Although rimazolium is not a new drug, experience with it is very limited.

Organs and Systems

Nervous system

Vertigo, drowsiness, and nausea have been attributed to rimazolium (SED-10, 172) (SEDA-7, 117) (2).

Risperidone

See also Neuroleptic drugs

General Information

Risperidone is an atypical benzisoxazole neuroleptic drug. It is a dopamine D_2 receptor antagonist, with antagonistic actions at 5-HT_2 receptors, alpha-adrenoceptors, and histamine H_1 receptors.

Placebo-controlled studies

Patients with bipolar disorder may benefit from risperidone, but this conclusion has mostly come from open studies with small sample sizes (SEDA-23, 69). Experience with risperidone has been reviewed with data from Canadian studies (1).

In a 6-week open study of risperidone (mean dosage 4.7 mg/day) in combination with mood-stabilizing treatments (usually lithium, carbamazepine, or valproate) for the treatment of schizoaffective disorder in 102 patients, 95 of whom completed the trial, at week 4 most patients had improved symptom severity and 9.3% were completely symptom-free (2). There were no statistically significant differences between baseline and week 4 in the severity of extrapyramidal symptoms, as measured by the UKU Side-Effect Rating Scale subscale for neurological adverse effects; other adverse effects included depressive symptoms ($n = 13$), exacerbation of mania ($n = 5$), drowsiness ($n = 3$), and impotence ($n = 2$).

The efficacy and safety of risperidone (mean dose 2.9, range 1.5–4 mg/day) have been examined in a double-

© 2006 Elsevier B.V. All rights reserved.

blind, randomized, parallel-group, 6-week study of the treatment of aggression in 35 adolescents with a primary diagnosis of disruptive behavior disorder and subaverage intelligence (3). Risperidone significantly improved aggression, and extrapyramidal symptoms were absent or very mild; there was transient tiredness in 11 of the 19 drug-treated subjects compared with one of the 16 placebo-treated subjects; other adverse effects were sialorrhea ($n = 4$ for risperidone, $n = 0$ for placebo), nausea ($n = 3$ for risperidone, $n = 0$ for placebo), and weight gain (mean of 3.5% of body weight with risperidone). There were no clinically important changes in laboratory parameters, electrocardiography, heart rate, or blood pressure.

In a double-blind, placebo-controlled study of the addition of low-dose risperidone (mean dosage 2.2 mg/day) to a 5-HT re-uptake inhibitor in refractory obsessive-compulsive disorder in 70 adults, 18 of 20 risperidone-treated patients had at least one adverse effect (4). The adverse effects in both groups included sedation ($n = 17$ for risperidone, $n = 8$ for placebo), increased appetite (6 and 3), restlessness (6 and 6), and dry mouth (5 and 5).

The results of two major controlled clinical trials of risperidone in patients with dementia were not conclusive, but risperidone was more effective than placebo in agitated and demented patients (SEDA-25, 68). The long-term data have been reviewed and they suggest that although in the two pivotal previous comparisons of risperidone with placebo the risk of adverse events was similar in the two groups when risperidone was given in the optimal dosage (1 mg/day), during a 12-month open extension of these studies, the incidence of de novo tardive dyskinesia was very low, and there were no clinically important adverse events or changes in vital signs or laboratory signs (5).

Risperidone has been used in bipolar disorder, dementia, disruptive behavior disorder with subaverage intelligence, Tourette's syndrome, and autism (SEDA-23, 69) (SEDA-25, 67) (SEDA-26, 64). The efficacy and safety of low doses of risperidone in the treatment of autism and serious behavioral problems have been studied in 101 children aged 5–17 years with autistic disorder accompanied by severe tantrums, aggression, or self-injurious behavior, who were randomly assigned to risperidone for 8 weeks ($n = 49$; dosage 0.5–3.5 mg/day) or placebo ($n = 52$) (6). Risperidone produced a 57% reduction in the Irritability Score, compared with a 14% reduction in the placebo group; all other parameters were also significantly improved. Risperidone was associated with an average weight gain of 2.7 kg, compared with 0.8 kg with placebo; increased appetite, fatigue, drowsiness, dizziness, and drooling were more common with risperidone. In two-thirds of the children with a positive response to risperidone at 8 weeks, the benefit was maintained at 6 months.

Risperidone was also effective and well tolerated in 118 children aged 5–12 years with subaverage intelligence and severely disruptive behavior in a 6-week, multicenter, double-blind, randomized trial (7). Risperidone produced significantly greater improvement than placebo on the conduct problem subscale of the Nisonger Child Behavior Rating Form from week 1 (respective reductions in score of 15 and 6). The most common adverse effects of risperidone (mean dose at end-point 1.16 mg/day) were headache and somnolence; the extrapyramidal symptom profile of risperidone was comparable to that of placebo, and there were respective mean weight increases of 2.2 and 0.9 kg.

Table 1 The results of two 12-week, randomized, double-blind studies of risperidone in elderly patients with behavioral symptoms associated with dementia (28,29)

Mean age (years)	Number	Dose (mg/day)	Response (%)	Extrapyramidal symptoms (%)
81	344	Risperidone (1.1)	54	15
		Haloperidol (1.2)	63	22
		Placebo	47	11
83	625	Risperidone (1)	45	13
		Risperidone (2)	50	21
		Placebo	33	7.4

Adults with autistic disorder ($n = 17$) or pervasive developmental disorder not otherwise specified ($n = 14$) participated in a randomized, 12-week, double-blind, placebo-controlled trial of risperidone (8). Among those who completed the study, risperidone ($n = 14$) was superior to placebo ($n = 16$) in reducing the symptoms of autism, and the most prominent adverse effect was mild transient sedation during the initial phase of drug administration. Abnormal gait was reported in one patient taking risperidone.

According to a thorough review, risperidone is more effective than placebo in patients with dementia (9). Nevertheless, the results of the two major controlled clinical trials have not been conclusive (see Table 1). There was no statistical difference between the treatments in the first study, although there was in the second; extrapyramidal symptoms were notably more common with risperidone. In both studies, there was a high rate of placebo response, which implies that these patients responded favorably to the increased care that is given during a clinical trial. Long-term data in patients with dementia are lacking, but they are crucial in identifying tardive dyskinesia.

Observational studies

In a Prescription Event Monitoring study of the safety of risperidone in 7684 patients treated in general practice, information on risperidone prescriptions issued to patients in England was gathered between July 1993 and April 1996 (10). After 6 months, 76% of the patients for whom data were available were still taking risperidone. Drowsiness/sedation was the most frequent reason for stopping risperidone and the most frequently reported event (4.6 cases per 1000 patient-months). Extrapyramidal symptoms were rarely reported, the incidence being 3.2 per 1000 patient-months; they were more frequent in elderly patients (7.8 per 1000 patient-months). There were only four reports of dyskinesias and one report of tardive dyskinesia, which resulted in withdrawal of risperidone. Eight overdoses of risperidone alone were reported, with no serious clinical sequelae. Nine patients took risperidone during ten pregnancies, with seven live births and three early therapeutic terminations. There were no abnormalities among the live births.

© 2006 Elsevier B.V. All rights reserved.

Long-term data on the efficacy and tolerability of risperidone are scant, as most of the clinical trials have been of short duration (no longer than 12 weeks). However, some additional data from open studies have emerged. In one study, 386 patients with chronic schizophrenia took risperidone 2–16 mg/day for up to 57 weeks; 247 patients were treated for at least 1 year (11). All but 48 patients (88%) had been treated with antipsychotic drugs before entering the study. At the end of the study, 64% of the patients were rated as having improved on the Clinical Global Impression change scale, and extrapyramidal symptoms (scored on the Extrapyramidal Symptom Rating Scale, ESRS) tended to be lower in severity or remained unchanged over the course of risperidone treatment; 27% of the patients required antiparkinsonian medication during the study, and 6.5% discontinued treatment prematurely because of adverse events. One or more adverse events were reported by 221 patients (57%) during risperidone treatment. Extrapyramidal symptoms occurred in 23%. Insomnia and anxiety were reported by 13% and 12% of patients. Two patients died during the 1-year study: one patient drowned and another committed suicide by hanging after 3.5 months. At the end of the study the mean increase in body weight was 1.8 kg.

In a retrospective study of 97 patients taking risperidone, under 30% of the patients were still taking risperidone after a mean period of follow-up of 102 (range 13–163) weeks (12). Reasons for discontinuation included not achieving the desired therapeutic effect ($n = 39$), non-compliance ($n = 22$), adverse effects ($n = 26$), the patient's not liking the drug and requesting a change to a different medication ($n = 17$), and symptom remission ($n = 6$). The authors stated that in routine clinical practice, the use of risperidone is plagued by many of the same problems of older antipsychotic drugs.

The efficacy and safety of risperidone have been examined in special groups of patients, such as those with psychotic depression (13), autistic disorders (8), bipolar disorder (14), mental retardation (15), and children and adolescents (16).

Patients with bipolar disorders may benefit from risperidone. This has been observed in an open trial of ten patients with rapid cycling bipolar disorder who were refractory to lithium carbonate, carbamazepine, and valproate; eight improved after 6 months of treatment. One patient dropped out through non-adherence to therapy and one because of adverse effects (agitation, anxiety, insomnia, and headache) (14). There was a similar beneficial effect in eight adults with moderate to profound mental retardation (15). Risperidone was associated with a significant reduction in aggression and self-injurious behavior, whereas adverse effects were primarily those of sedation and restlessness.

Eight of a heterogeneous group of eleven children and adolescents (mean age 9.8, range 5.5–16 years) with mood disorders and aggressive behavior, improved with a low dose of risperidone (0.75–2.5 mg/day) (16). Treatment was stopped in two children because of drowsiness; the most bothersome adverse effect of risperidone was weight gain in two cases (mean increase 4 kg).

The medical records of 151 hospitalized elderly psychiatric patients (mean age 71 years) have been analysed (17). Of 114 patients treated with risperidone (mean duration of treatment 17 days; mean dose 3 mg/day), 78% responded. Adverse events were reported in 20 patients, including new-onset extrapyramidal effects in four; tremor in four; sedation in three; hypotension in three; diarrhea in two; tardive dyskinesia in two; and chest pain, anxiety, restlessness, itching, insomnia, and falls in one each.

A review of both core information and new findings concerning risperidone concluded that it can be associated with transient drowsiness (probably no greater than that observed with haloperidol), postural hypotension (which is avoided by dose titration), weight gain, reduced sexual interest, and erectile dysfunction. Risperidone can also cause dose-dependent hyperprolactinemia (which can cause amenorrhea, sexual dysfunction, and galactorrhea). Risperidone tends not to cause extrapyramidal signs at therapeutic doses (the optimal dose being 6 mg/day) but they do occur dose-dependently (18).

In an 8-week open prospective study of risperidone in 20 patients, mean age 34 (range 19–53) years, adverse effects included giddiness ($n = 3$), headache ($n = 2$), and agitation ($n = 2$); one woman reported galactorrhea and another developed obsessive-compulsive symptoms; 16 of 20 patients were taking antiparkinsonian drugs before the study, compared with 12 patients at the end (19).

Objections have been raised on the ways in which some clinical trials are interpreted (20). Furthermore, it has been stated that a major problem with the risperidone literature is that the original data can be very difficult to decipher or even obtain. Huston and Moher have described their frustration in trying to perform a meta-analysis of the effects of risperidone; they found "obvious redundancy in the results of a single-center trial being published twice," as well as problems with "changing authorship, lack of transparency in reporting, and frequent citation of abstracts and unpublished reports" (21). These concerns were reiterated in an editorial (22).

In a prospective, 6-week open trial in 31 Chinese patients with acute exacerbation of schizophrenia, risperidone doses were titrated to 6 mg/day (if tolerated) over 3 days, but were reduced thereafter if adverse effects occurred (23). Efficacy and adverse effects were assessed on days 0, 4, 14, 28, and 42. End-point steady-state plasma concentrations of risperidone and 9-hydroxyrisperidone were analysed. Of the 30 patients who completed the trial, 17 tolerated the 6 mg dose well, while the other 13 received lower final doses (mean 3.6 mg) for curtailing adverse effects. At end-point, 92% of the 13 low-dose patients had responded to treatment (a 20% or more reduction in the total score on the Positive and Negative Syndrome Scale), compared with 53% of the 17 high-dose subjects. There were no significant between-group differences in other minor efficacy measures. End-point plasma concentrations of the active moieties (risperidone plus 9-hydroxyrisperidone) were 40 ng/ml in the low-dose group and 50 ng/ml in the high-dose group; this difference was not significant, suggesting that the different responses were pharmacokinetic in origin. The results of this preliminary trial suggest that up to 6 mg/day of risperidone is efficacious in treating patients with an acute exacerbation of schizophrenia. Nearly 60% of the patients tolerated 6 mg/day; in the others, reducing the dosage to relieve adverse effects still yielded efficacy.

© 2006 Elsevier B.V. All rights reserved.

The efficacy and safety of long-term risperidone have been assessed in children and adolescents ($n = 11$) in a prospective study (24). Subjects with autism or pervasive developmental disorder not otherwise specified took risperidone for 6 months, after which their parents were given the option of continuing for a further 6 months. Weight gain was common, although the rate of increase abated with time. After 6 months two patients developed facial dystonias, which disappeared after reducing the dosage in one case and after withdrawal in the other. Amenorrhea was also observed, but there were no changes in liver function, blood tests, or electroencephalography. The authors concluded that risperidone may be effective and relatively safe in the long-term treatment of behavioral disruption in autistic children and adolescents.

Youths with behavioral disorders (25,26), and patients with disturbing neuroleptic drug-induced extrapyramidal symptoms (27) have been studied. Ten youths (aged 6–14 years) were randomly assigned to receive placebo and 10 to receive risperidone (0.75–1.50 mg/day) for conduct disorder in a preliminary study lasting 10 weeks (25). Of those assigned to risperidone, six completed the course; three completed placebo. Those who took risperidone were significantly less aggressive during the last weeks of the study than those who did not. Eight youths who took risperidone and four who took placebo had at least one adverse effect, including increased appetite ($n = 3$ for risperidone), sedation ($n = 3$ for risperidone; $n = 2$ for placebo), headache ($n = 1$ for risperidone; $n = 1$ for placebo), insomnia ($n = 1$ for risperidone), restlessness ($n = 1$ for risperidone), irritability ($n = 1$ for risperidone), enuresis ($n = 1$ for placebo), and nausea/vomiting ($n = 1$ for risperidone; $n = 1$ for placebo). These adverse effects were mild and transient.

There was marked reduction in aggression in 14 of 26 subjects (10–18 years old) in an open study of risperidone (0.5–4 mg/day) for 2–12 months (26). Two subjects had marked weight gain (8 and 10 kg) in the first 8 weeks; another participant who took lithium (1400 mg/day, serum concentration 0.9 mmol/l) presented with moderate akathisia and hand tremor; in seven, tiredness and sedation occurred after week 8.

Organs and Systems

Cardiovascular

Cardiac arrest was attributed to risperidone in a patient with no history of cardiac disease (30).

One of two children aged 29 and 23 months with autistic disorder developed a persistent tachycardia and dose-related QT_c interval prolongation while taking risperidone (31).

Cardiotoxicity of risperidone has recently been discussed (32) in the light of a death in a patient taking a therapeutic dose (SEDA-22, 68).

Nervous system

Seizures

Stuttering, a rare adverse effect of neuroleptic drugs, is thought to be a harbinger of seizures. Stuttering without seizures has been attributed to risperidone (33).

- A 32-year-old Korean man with delusions took oral risperidone 1.0 mg/day and lorazepam 0.5 mg bd. The dose of risperidone was increased to 4 mg/day over 4 days. On day 5, he began to stutter and could not articulate what he wanted to say without stuttering. The dose of risperidone was increased to 8 mg/day and the stuttering became more pronounced. However, after 1 year of continuous treatment, he did not stutter any more.

The authors suggested that since the patient had a history of stuttering risperidone had reactivated the speech pattern.

Extrapyramidal effects

Risperidone produces dose-related extrapyramidal adverse effects, but at concentrations lower than those of conventional antipsychotic drugs (SEDA-21, 58); at equieffective doses it has fewer such effects than haloperidol (SEDA-21, 57) (SEDA-22, 67) (SEDA-23, 68). The relation between the degree of receptor occupancy and the presence of extrapyramidal symptoms is not clear, as observed in a SPECT study in 20 patients (34). The frequency of risperidone-induced extrapyramidal signs, on the other hand, is intermediate between clozapine and conventional antipsychotic drugs, according to an open study in patients treated for at least 3 months with clozapine ($n = 41$; mean dose 426 mg/day), risperidone ($n = 23$; 4.7 mg/day), or conventional antipsychotic drugs ($n = 42$; 477 mg/day chlorpromazine equivalents) (35). The point prevalence of akathisia was 7.3% in those who took clozapine, 13% in those who took risperidone, and 24% in those who took conventional antipsychotic drugs; the point prevalences of rigidity and cogwheeling were 4.9% and 2.4% respectively with clozapine, 17% and 17% with risperidone, and 36% and 26% with conventional antipsychotic drugs.

A combined analysis of 12 double-blind studies in schizophrenic patients comparing the use of risperidone ($n = 2074$) with placebo ($n = 140$) or haloperidol ($n = 517$) has further stressed the dose-related extrapyramidal effects associated with risperidone (36). After covariance analysis to adjust for baseline ESRS (Extrapyramidal Symptom Rating Scale) scores, sex, race, age, height, duration of symptoms, age at first hospitalization, hospitalization status, and diagnosis, the effects of the maximum dose of risperidone on the mean shift to worse ESRS total scores were 1.4 (CI = 0.73, 2.03) at 1–4 mg/day ($n = 319$); 2.1 (CI = 1.65, 2.50) at 4–8 mg/day ($n = 932$); 3.3 (CI = 2.61, 3.89) at 8–12.5 mg/day ($n = 439$); and 3.8 (CI = 2.99, 4.55) at 13 mg/day or more ($n = 361$). The results also showed a significant dose-dependent increase in the use of antiparkinsonian drugs; the percentages of those requiring antiparkinsonian drugs were 14% at 1–4 mg/day ($n = 319$); 25% at 4–8 mg/day ($n = 900$); 27% at 8–12.5 mg/day ($n = 407$); and 31% at 13 mg/day or more ($n = 335$). Of 882 patients who took risperidone for at least 12 weeks, based on unsolicited reports, two developed tardive dyskinesia.

In an international, multicenter, double-blind study in 183 patients with a first psychotic episode treated with flexible doses of risperidone or haloperidol for 6 weeks, the severity of extrapyramidal symptoms and the use of antiparkinsonian drugs were significantly lower in patients taking low doses (up to 6 mg/day) than high doses (over

© 2006 Elsevier B.V. All rights reserved.

6 mg/day) of risperidone or haloperidol (37). These findings are consistent with the suggestion that patients with a first psychotic episode may require low doses of antipsychotic drugs. Furthermore, the severity of extrapyramidal symptoms was significantly lower in the risperidone-treated patients. Also, risperidone-treated subjects were significantly less likely than haloperidol-treated subjects to require concomitant anticholinergic drugs after 4 weeks (20 versus 63%); they had significantly less observable akathisia (24 versus 53%) and significantly less severe tardive dyskinesia. This was observed in a randomized double-blind comparison of risperidone 6 mg/day ($n = 34$) and haloperidol 15 mg/day ($n = 33$) (38).

In a 9-week open study of risperidone for agitated behavior in 15 patients with dementia (modal dose 0.5 mg/day), extrapyramidal symptoms developed at some point during the trial in 8 patients, and cognitive skills were impaired in 3 patients (39). Similarly, in 22 patients with dementia and behavioral disturbances, treated with risperidone 1.5 mg/day (range 0.5 mg qds to 3 mg bd), 50% had significant improvement, but 50% had some extrapyramidal symptoms (40). A further case of a severe extrapyramidal reaction in an old patient with dementia further illustrated these susceptibility factors (41).

Although several cases of sensitivity to risperidone with extrapyramidal signs in Lewy body dementia have been published (SEDA-20, 52), a case of successful treatment without extrapyramidal adverse effects has also been reported (42).

- A 74-year-old man with Lewy body dementia treated with a combination of donepezil (5 mg in the evening) and risperidone (0.25 mg/day) had significant improvement, objectively and subjectively, within 2 weeks.

Akathisia

Restless legs syndrome has been reported in association with risperidone (43).

- A 31-year-old woman with schizoaffective disorder taking risperidone 6 mg/day complained of uncomfortable tingling and tearing sensations deep inside the calves and less severe sensations in her arms after 5 days; the symptoms vanished after replacement by quetiapine 400 mg/day.

Parkinsonism

Intolerable exacerbation of parkinsonism with risperidone has been reported (SEDA-20, 52), and even a 12-year-old boy reportedly developed parkinsonian tremor while taking risperidone (44). However, in contrast, eight patients (five women, three men) with advanced Parkinson's disease, motor fluctuations, and levodopa-induced dyskinesia took part in an open study with a low dosage of risperidone (mean 0.187 mg/day); after an average of 11 months all the patients had moderate to pronounced reductions in levodopa-induced dyskinesias (45).

Whether risperidone should be used in patients with Parkinson's disease is a subject of debate (46,47).

The efficacy and safety of risperidone have been evaluated in 44 patients (25 women and 19 men) with Parkinson's disease (48). There was either complete or near-complete resolution of hallucinations in 23, but an unsatisfactory response ($n = 6$) or worsening of parkinsonism ($n = 6$) in 12. Excluding patients with diffuse Lewy body disease, there was no significant worsening of scores on the Unified Parkinson's Disease Rating Scale after either 3 or 6 months of treatment, and the presence of dementia did not predict the response to treatment.

The long-term effect of risperidone on basal ganglia volume, measured by MRI scanning, has been studied in 30 patients with a first episode of schizophrenia who took risperidone, 12 patients taking long-term typical neuroleptic drugs, and 23 healthy controls (49). Treatment with risperidone for 1 year (mean dosage 2.7, range 1–6 mg/day) did not alter basal ganglia volume, although there were movement disorders in both groups of treated patients, suggesting effects of both illness and medications.

Tardive dyskinesia

Tardive dyskinesia has occasionally been reported with risperidone (SEDA-20, 53) (SEDA-21, 59) (SEDA-22, 68) (50–55).

The incidence of tardive dyskinesia in patients with chronic schizophrenia taking risperidone is said to be 0.34% per year. Advanced age and dementia may be contributing factors (SEDA-21, 59) (SEDA-22, 68) (SEDA-23, 70).

Tardive dyskinesia/dystonia developed in four patients treated with risperidone at an early intervention facility for young people with psychosis (56). Other cases that have emerged were in:

- a 13-year-old young girl treated with risperidone 6 mg/day (57);
- a 21-year-old woman without previous exposure to other neuroleptic drugs or systemic illnesses that affected the central nervous system (58);
- a 58-year-old man with chronic alcoholism who developed tardive dyskinesia after exposure to risperidone that was aggravated by olanzapine (59).
- a 16-year-old girl who developed buccolingual masticatory tardive dyskinesia after taking risperidone 6 mg/day (60); when she restarted risperidone 2 mg/day, increasing to 6 mg/day later on, the dyskinesia improved.
- a 74-year-old woman who developed persistent tardive dyskinesia following a short trial (3 weeks) of a low dose (0.5 mg bd) of risperidone (61).

Tardive dyskinesia was studied in 330 elderly patients with dementia (mean age 83 years) (62). They were enrolled in a 1-year open study, in which the modal risperidone dose was 0.96 mg/day and the median duration of use was 273 days. The 1-year cumulative incidence of persistent tardive dyskinesia among the 225 patients without dyskinesia at baseline was 2.6%, and patients with dyskinesia at baseline had significant reductions in severity.

Attention deficit hyperactivity disorder (ADHD) may be a susceptibility factor for risperidone-induced tardive dyskinesia and withdrawal dyskinesia. Both conditions have occurred in patients with a past or recent history of attention deficit hyperactivity disorder.

- A 34-year-old woman developed dyskinesia after starting risperidone, with a marked increase in prolactin concentrations (63).

© 2006 Elsevier B.V. All rights reserved.

- A 13-year-old boy developed mild mouth movements, neck twisting, and intermittent upward gaze approximately 2 weeks after withdrawal of risperidone (1.5 mg and then 0.5 mg) (64).

Tardive dystonia

Dystonia and tardive dystonia have been attributed to risperidone.

- A 23-year-old man taking risperidone 8 mg/day developed blepharospasm (65).
- A 25-year-old man, who had never taken any other psychotropic medication, developed tardive dyskinesia with severe blepharospasm and tardive dystonia 2 months after withdrawal of risperidone (66).
- Possible risperidone-induced tardive dystonia has been reported in a 47-year-old man (67).

Marked improvement of tardive dystonia after replacing haloperidol with risperidone in a schizophrenic patient has been reported (68).

Pisa syndrome, a tardive axial dystonia with flexion of the trunk towards one side, is a rare reaction that occurs during treatment with neuroleptic drugs (SED-14, 146) (SEDA-24, 57). Two cases related to risperidone have been published.

- A 24-year-old woman with mental retardation and an unspecified psychosis took risperidone 2 mg/day and trihexyphenidyl 2 mg/day and after 2 weeks developed symptoms that included tilting of her body backwards and to the left and tremors and cogwheel rigidity of the limbs (69). Risperidone was withdrawn and olanzapine 5 mg/day started; after 4 weeks there was no improvement and she was then lost to follow-up.
- A 25-year-old man with auditory hallucinations took risperidone 7 mg/day for 15 months plus biperiden 6 mg/day (70). He then complained of leaning to the right and being unable to straighten up. He had tonic flexion of the trunk to the right with slight backward axial rotation. After 5 months of risperidone withdrawal, the condition had not resolved; it later improved with co-beneldopa 400/100 mg/day and then after the addition of cabergoline 0.75 mg/day.

Rabbit syndrome

Rabbit syndrome has been reported in patients taking risperidone.

- A 27-year-old man took risperidone 6 mg/day and after 4 months the dosage was reduced to 4 mg/day; 7 months after the start of treatment he developed fine rapid pouting and puckering of the lips (71). These movements were accompanied by a strange, irritating, involuntary popping sound. The dosage of risperidone was reduced to 2 mg/day and an anticholinergic drug was added. Within days, there was symptomatic improvement, but a trial withdrawal of the anticholinergic drug resulted in worsening of the symptoms and treatment was renewed.
- A 38-year-old man with major depressive disorder and psychotic features developed rabbit syndrome after taking risperidone 4 mg/day and paroxetine 40 mg/day for 4 months; he was also taking simvastatin 10 mg/day, thiamine 100 mg/day, and folic acid 1 mg/day (72).

Neuroleptic malignant syndrome

Neuroleptic malignant syndrome has been reported in patients taking risperidone (73,74); most cases occurred within the first months, and even as early as 12 hours (SEDA-22, 68) (SEDA-23, 70).

Delayed risperidone-induced neuroleptic malignant syndrome has been reported in a 27-year-old man after 21 months (75), and in a 17-year-old girl who took risperidone 0.5 mg bd (76). Risperidone-induced neuroleptic malignant syndrome has also been reported in a 63-year-old woman with probable Lewy body dementia, who had previously had an episode of neuroleptic malignant syndrome with trifluoperazine (77).

A patient with schizoaffective disorder, who developed risperidone-related neuroleptic malignant syndrome, responded satisfactorily to supportive management and vitamin E plus vitamin B6 (78).

Catatonia

Catatonia has been reported in relation to risperidone (SEDA-23, 72) (79,80).

- Catatonia occurred in a 61-year-old woman who was taking risperidone 5 mg/day for prominent paranoid delusions after a post-frontal lobotomy some 35 years ago. The catatonic disorder was dose-dependent and resolved immediately after changing to clozapine.

Pseudotumor cerebri

Two patients with hydrocephalus and learning difficulties developed headache, nausea, vomiting, drowsiness, lethargy, and episodes of collapse after starting to take risperidone for aggressive outbursts; the condition mimicked increased intracranial pressure (81). Withdrawal of the drug resulted in complete resolution of all the symptoms within 72 hours. The authors pointed out the striking degree of overlap between the adverse effects profile of risperidone and the symptoms of raised intracranial pressure due to shunt malfunction, which has not been previously highlighted.

Psychological, psychiatric

Anxiety and behavioral stimulation, characterized by anxiety, insomnia, and restlessness, during risperidone treatment have been reported (SEDA-20, 53) (SEDA-21, 59) (SEDA-23, 71) (82). Six of thirteen outpatients who took part in a 10-week open trial of risperidone had a good initial response, followed by intolerable effects, including feelings of agitation and depression and periods of crying and insomnia (83). The patients who developed this syndrome had a significantly higher mean baseline rating on the Brief Psychiatric Rating Scale anxiety subscale.

Visual distortion with generalized anxiety and panic attacks has been attributed to risperidone (SEDA-22, 69). Visual disturbance resembling hallucinogen persistent perception disorder occurred after each of three consecutive risperidone dosage increases in a 55-year-old woman; there was absence of substance abuse (84).

© 2006 Elsevier B.V. All rights reserved.

It has been speculated that the antiserotonergic properties of risperidone could lead to obsessive and depressive symptoms, since a patient taking risperidone 4 mg/day developed major depression and obsessions, which resolved with fluoxetine 29 mg/day, relapsing when fluoxetine was withdrawn (85).

Mania

Mania has rarely been associated with typical neuroleptic drugs, but has been described in patients treated with new antipsychotic drugs, especially risperidone (SEDA-22, 69) (SEDA-23, 71) (86). Risperidone-induced mania occurred in a 23-year-old man and a 21-year-old woman, who developed acute mania with euphoria, psychomotor agitation, and hypersexuality, at dosages of 4–8 mg/day (87).

Nevertheless, risperidone has been used in the treatment of mania in combination with mood stabilizers (SEDA-23, 69) (SEDA-26, 64).

Obsessive-compulsive disorder

Obsessive-compulsive symptoms associated with risperidone have been reported (SEDA-22, 69).

- Obsessive-compulsive symptoms developed in a 26-year-old Chinese woman taking risperidone for a chronic schizophrenic illness (88). She had no history of obsessive-compulsive symptoms. Risperidone 2 mg/day, benzhexol 2 mg/day, and diazepam 10 mg at night had been prescribed after she had had adverse effects with other antipsychotic drugs.
- A man who had taken risperidone 4 mg/day for 18 months developed an obsessional image of a person's face that repeatedly appeared in his mind as he went about his activities; the recurrent images disappeared after the dosage of risperidone was reduced to 3 mg/day (89).

In one case, reintroduction of risperidone did not cause obsessive-compulsive symptoms to re-emerge in a 29-year-old man who had previously developed obsessive-compulsive features when first treated with risperidone (90).

Endocrine

Prolactin

There was a significant rise in baseline serum prolactin concentration in 10 patients after they had taken risperidone for a mean of 12 weeks compared with 10 patients who were tested after a neuroleptic drug-free wash-out period of at least 2 weeks (91). A non-significant increase in serum prolactin has also been observed in an open comparison of risperidone with other neuroleptic drugs in 28 patients (92). However, in a meta-analysis of two independent studies ($n = 404$), prolactin was greatly increased by risperidone (mean change 45–80 ng/ml), a larger effect than with olanzapine and haloperidol (93).

Five patients (four women and one man, aged 30–45 years), who were evaluated for risperidone-induced hyperprolactinemia, had significant hyperprolactinemia, with prolactin concentrations of 66–209 μg/l (94). All but one had manifestations of hypogonadism, and in these four patients, risperidone was continued and a dopamine receptor agonist (bromocriptine or cabergoline) was added; in three patients this reduced the prolactin concentration and alleviated the hypogonadism.

The relation of prolactin concentrations and certain adverse events has been explored by using data from two large randomized, double-blind studies ($n = 2725$; 813 women, 1912 men) (95). Both risperidone and haloperidol produced dose-related increases in plasma prolactin concentrations in men and women, but they were not correlated with adverse events such as amenorrhea, galactorrhea, or reduced libido in women or with erectile dysfunction, ejaculatory dysfunction, gynecomastia, or reduced libido in men. Nevertheless, in five patients risperidone (1–8 mg/day) caused amenorrhea in association with raised serum prolactin concentrations (mean 122 ng/ml, range 61–230 ng/ml; reference range 2.7–20 ng/ml) (96).

Furthermore, risperidone-induced galactorrhea associated with a raised prolactin has been reported (97,98), as have amenorrhea and sexual dysfunction (18).

- Galactorrhea associated with a rise in prolactin occurred after a few weeks of treatment with risperidone in two women aged 24 and 39 (97). One of them was switched to thioridazine, with an improvement in the galactorrhea, and the other continued to take risperidone owing to a robust response; her galactorrhea was partially treated with bromocriptine.
- A 34-year-old woman, who developed amenorrhea while taking risperidone, regained her normal menstrual pattern along with a marked fall in serum prolactin concentration 8 weeks after being switched to olanzapine, whereas amantadine had failed to normalize the menses and had apparently reactivated the psychotic symptoms (99).

The authors suggested that olanzapine may offer advantages for selected patients in whom hyperprolactinemia occurs during treatment with other antipsychotic drugs.

- Galactorrhea and gynecomastia occurred in a 38-year-old hypothyroid man who took risperidone for 14 days (100).

The authors suggested that men with primary hypothyroidism may be particularly sensitive to neuroleptic drug-induced increases in prolactin concentrations.

- A 17-year-old man developed galactorrhea and breast tenderness within weeks of starting to take risperidone.

The authors suggested that patients who have galactorrhea, amenorrhea, or both while taking risperidone should be gradually switched to olanzapine, quetiapine, or clozapine (101). Indeed, when 20 women with schizophrenia who were taking risperidone and had menstrual disturbances, galactorrhea, and sexual dysfunction (SEDA-24, 72) (SEDA-26, 65) were switched from risperidone to olanzapine over 2 weeks and then took olanzapine 5–20 mg/day for 8 further weeks, serum prolactin concentrations fell significantly (102). Scores on the Positive and Negative Syndrome Scale, Abnormal Involuntary Movement Scale, and Simpson–Angus Scale for extrapyramidal symptoms at the end-point were also significantly reduced. There were improvements in menstrual functioning and patients' perceptions of sexual adverse effects.

Amenorrhea presumed to have been induced by risperidone has been successfully treated with

© 2006 Elsevier B.V. All rights reserved.

Shakuyaku-kanzo-to, a Japanese herbal medicine that contains *Peoniae radix* and *Glycyrrhizae radix* (103).

Metabolism

Diabetes mellitus

There has been a report of diabetic ketoacidosis in a 42-year-old man, without a prior history of diabetes mellitus, who took risperidone (2 mg bd) (104). The authors pointed out that in premarketing studies of risperidone, diabetes mellitus occurred in 0.01–1% of patients.

Weight gain

Pathological weight gain has been increasingly identified as a problem when atypical neuroleptic drugs are given to children (SEDA-21, 57) (SEDA-22, 69). In one case, unremitting weight gain, triggered by risperidone, was eventually curbed through the use of a diet containing slowly absorbed carbohydrates and a careful balance of carbohydrates, proteins, and fats (105).

- A 9-year-old boy with autism and overactivity was unresponsive to several drugs. Risperidone 0.5 mg bd was effective, reducing his Aberrant Behavior Checklist score from 103 to 57 by the end of the first week. Four weeks later his weight had risen from 34.6 to 37 kg. This rate of weight gain (0.6 kg/week) continued over the next 12 weeks. His weight was then contained by the use of the "Zone" diet, with an emphasis on slowly absorbed carbohydrates (examples include apples, oatmeal, kidney beans, whole-grain pasta, and sweet potatoes) in a calorie-reduced diet containing 30% proteins and 30% fats.

In 37 children and adolescent inpatients treated with risperidone for 6 months, compared with 33 psychiatric inpatients who had not taken atypical neuroleptic drugs, risperidone was associated with significant weight gain in 78% of the treated children and adolescents compared with 24% of those in the comparison group (106). Risperidone dosage, concomitant medicaments, and other demographic characteristics (such as age, sex, pubertal status, and baseline weight and body mass index) were not associated with an increased risk of morbid weight gain.

In contrast, in a multicenter, open study in 127 elderly psychotic patients (median age 72, range 54–89 years) taking risperidone (mean dose 3.7 mg/day) there was no significant weight gain after 12 months (107).

Risperidone-induced obesity can cause sleep apnea (108).

- A 50-year-old man with schizophrenia gained 29 kg over 31 months and developed diabetes while taking risperidone 6 mg/day. He reported difficulty in sleeping and frequent daytime napping that left him unsatisfied, and his wife reported prominent snoring and apnea at night.

Nasal continuous positive airway pressure produced improvement.

Electrolyte balance

Polydipsia with hyponatremia has been reported in patients taking risperidone (109,110).

- A 28-year-old man complained of unbearable thirst 2 weeks after starting risperidone 8 mg/day, and would drink 4–5 liters of water within a variable period of a few minutes to 8 hours; he did not develop hyponatremia (111). The condition lasted about 2 years and remitted after withdrawal of risperidone. After a drug-free interval of 2 weeks, clozapine was started and the condition had not recurred after 6 months.

The mechanism of this effect was unclear. The authors thought that SIADH was unlikely, considering the features of polyuria, a low urine osmolality (172 mosmol/kg), and absence of hyponatremia during polydipsia.

Hematologic

Agranulocytosis, leukopenia, neutropenia, lymphopenia, and thrombocytopenia have been reported in patients taking risperidone (112–115).

- A 40-year-old woman developed agranulocytosis after taking risperidone for 2 weeks (114). She had also developed agranulocytosis after treatment with several other antipsychotic drugs (chlorpromazine, haloperidol, and zuclopenthixol).

Mouth and teeth

Hypersalivation or sialorrhea has been reported with all neuroleptic drugs, and has been associated with risperidone as one of the most frequently mentioned adverse effects in patients with disturbing extrapyramidal symptoms during previous neuroleptic drug treatment (SEDA-25, 68). Hypersalivation is a troublesome adverse effect that can contribute to non-adherence to therapy, but it can be treated with clonidine.

- Hypersalivation in a 22-year-old man was rapidly and markedly reduced by clonidine 0.1 mg bd over 3 days (116).

Liver

Several cases of hepatotoxicity have been reported in adults (117) and boys (SEDA-22, 69) taking long-term risperidone.

- Hepatotoxicity occurred in an 81-year-old man who took only two doses of risperidone 0.5 mg (118).
- In a 25-year-old woman, liver function tests were 2.6–7.4 times higher than the upper limit of the reference range during risperidone therapy (119).
- A 13-year-old girl developed liver enzyme rises and fatty liver infiltration in the context of pre-existing obesity after taking risperidone 0.5 mg/day for 3 days (120).
- Transient increases in liver enzymes induced by risperidone occurred in two men aged 19 and 22 (121).
- Cholestatic jaundice occurred in a 37-year-old man taking risperidone (122).

Urinary tract

Hemorrhagic cystitis has been associated with risperidone (123).

- An 11-year-old boy developed acute dysuria and increased frequency accompanied by gross hematuria. He was taking fluoxetine, valproic acid, benzatropine,

© 2006 Elsevier B.V. All rights reserved.

haloperidol, clonidine, trazodone, and nasal desmopressin. One week before presentation, risperidone had been introduced instead of haloperidol to improve behavioral control. The risperidone was discontinued and haloperidol resumed, and his symptoms resolved during the following week.

Several cases of urinary incontinence have been associated with risperidone, and the manufacturers report that this adverse effect occurs in up to 1% of patients (SEDA-22, 70). The authors of a report of two patients, in both of whom the adverse effect was clearly temporally related to the drug, stated that at least 28% of patients developed transient urinary incontinence after starting risperidone (124).

Skin

Photosensitivity has been attributed to risperidone.

- A 69-year-old woman taking risperidone developed an erythematous rash with areas of blistering and early desquamation. It was most pronounced in exposed areas, although there was some spread beyond (125).

Sexual function

Prolonged erection has been reported with risperidone (126) (SEDA-24, 71).

- Priapism associated with risperidone occurred in a 19-year-old man who had taken 2 mg/day for 4 days (127).

In one case priapism followed the use of first risperidone and then ziprasidone (128). In two other cases, presumed to be due to risperidone (129,130), penile irrigation with isotonic saline and phenylephrine injection resulted in detumescence. Risperidone has a high affinity for alpha-1 adrenoceptors, and alpha-1 blockade leads to direct arteriolar dilatation, which results in increased blood inflow and reduced outflow secondary to effacement and subsequent obstruction of emissary veins.

Ejaculatory dysfunction has also been associated with risperidone in two cases.

- A 21-year-old patient with bipolar schizoaffective disorder developed absent ejaculation with normal orgasm 3 weeks after starting to take risperidone (131).
- A 37-year-old man with paranoid schizophrenia had ejaculatory difficulty during sexual intercourse with his wife, compatible with retrograde ejaculation, 1–2 weeks after starting to take risperidone (132). He reported complete failure to emit semen but a normal desire, erection, and sense of orgasm. Semen was seen in postcoital urine. The dosage of risperidone was reduced to 3 mg/day and anterograde ejaculation was partially restored.

Immunologic

Risperidone has been rarely associated with allergic reactions (SEDA-22, 70).

Long-Term Effects

Drug withdrawal

Serious withdrawal effects have occasionally been reported with risperidone (SEDA-21, 60) (SEDA-22, 70). Both manic and psychotic symptoms have been described in a patient with chronic schizophrenia after risperidone withdrawal (133).

- A 38-year-old Chinese man responded to risperidone monotherapy for 2 weeks after 19 years of resistance to typical neuroleptic drugs. Three days later he lost his medicine and 2 days later his auditory hallucinations and persecutory delusions recurred. Meanwhile, vivid manic symptoms (such as heightened mood, irritability, reduced need for sleep, hyperactivity, pressured speech, flight of ideas, and grandiosity) emerged for the first time throughout the history of his illness.
- Dyskinesia occurred for 5 days in an 82-year-old woman after withdrawal of risperidone and citalopram, which she had taken for about 3 months (134).

It is not clear whether this was a withdrawal effect or a tardive dyskinesia in response to risperidone.

Second-Generation Effects

Teratogenicity

All neuroleptic drugs cross the placenta and reach the fetus in potentially significant amounts; the best recommendation is to avoid any drug during the first trimester and only to use drugs thereafter if the benefits to the mother and fetus outweigh any possibility of risk (SED-14, 152) (SEDA-22, 54). Risperidone has been used in two women before and throughout pregnancy without developmental abnormalities in the children after 9 months and 1 year; the dosages started at 2 mg/day and were increased to 4–6 mg/day (135). In a large postmarketing study of 7684 patients who took risperidone, nine women took it during ten pregnancies; there were seven live births and three therapeutic terminations of pregnancy (SEDA-23, 69) (136).

Lactation

The distribution and excretion of risperidone and 9-hydroxyrisperidone into the breast milk of a young woman with puerperal psychosis, who was treated with risperidone, has been reported (137).

- A 21-year-old woman with a 2-year history of bipolar disorder stopped all of her medication when she discovered that she was pregnant; she was given risperidone 2.5 months after childbirth, gradually increasing to a steady-state dosage of 6 mg/day. Risperidone and 9-hydroxyrisperidone concentrations in plasma and breast milk were measured, and calculations indicated that a suckling infant would receive only 0.84% of the maternal dose as risperidone and 3.46% as 9-hydroxyrisperidone.

© 2006 Elsevier B.V. All rights reserved.

Susceptibility Factors

Genetic factors

Impaired metabolism of risperidone can increase the risk of adverse effects.

- A homozygous non-functional genotype, CYP2D6*4, was found in a 17-year-old patient with schizophrenia who developed severe akathisia, parkinsonism, and drowsiness after taking risperidone 6 mg/day for 3 months; he had high plasma concentrations of risperidone and an active metabolite (138).

Age

Elderly people

Elderly patients with dementia have been said to be at particular risk of developing extrapyramidal adverse effects, even with very low doses.

Delirium occurs in 1.6% of elderly patients newly treated with risperidone (SEDA-22, 70), and cases have been reported in patients of advanced age (139,140). It is suggested that in these patients, treatment should begin with low dosages (0.25–0.5 mg/day) and that the dosage be gradually increased over several days, with close monitoring.

The safety, tolerability, and efficacy of risperidone have been assessed in 103 patients with schizophrenia (52 men and 51 women) aged 65 years or older in an open, multicenter, 12-week study (141). The mean risperidone dose at end-point was 2.4 mg/day. Adverse events occurred in 91 patients and included dizziness ($n = 23$), insomnia ($n = 17$), agitation ($n = 15$), somnolence ($n = 15$), injury ($n = 12$), constipation ($n = 11$), and extrapyramidal disorders ($n = 10$); 11 patients withdrew because of adverse events. Among the 91 patients with normal baseline QT_c intervals (below 450 ms), 9 had a prolonged QT_c interval during the study (range 450–516 ms).

Adverse effects leading to dosage reduction or discontinuation were also observed in a retrospective study in 57 patients mean age 84 (range 66–97) years, who took risperidone (doses 0.5–4 mg/day) for more than 1 year (average 2 years) for dementia-related behavioral disturbances (142). Adverse effects included hypotension ($n = 4$), agitation ($n = 6$), and sedation ($n = 5$), and six patients developed a new movement disorder.

In a retrospective study, a substantial proportion of patients who needed antiparkinsonian medication while taking risperidone (mean daily dose 4.4 mg) were identified. Twelve of fifty-five elderly inpatients (aged over 65 years) taking risperidone received antiparkinsonian drugs (143).

A large proportion of new or worsened extrapyramidal adverse effects (32%) was observed in a review of the charts of 41 patients with dementia (mean age 75 years) treated with risperidone (mean 1.8 mg/day) (144).

Children

There was a high incidence (44%) of new movement disorders in 36 children and adolescents who were treated with risperidone (the highest dose of risperidone was 6 mg/day and the average maintenance dose was 4 mg/day) (145). The higher incidence reported in the latter series has been countered by a contrasting report that the most common adverse effect was excessive weight gain ($n = 10$) in a series of 30 children and adolescents (aged 6–21 years) taking risperidone (0.5–6 mg/day) for attention-deficit disorder (146). Vomiting and drowsiness each occurred in one patient; one patient had withdrawal dyskinesia, but the reintroduction of risperidone and slower withdrawal produced no recurrence.

Other features of the patient

Hypothermia associated with hypothalamic and thermoregulatory dysfunction has been reported in a patient with Prader–Willi syndrome taking risperidone and olanzapine (147). Hypothermia in response to these drugs is said to result from 5-HT_2 receptor blockade, and it is recommended that patients with hypothalamic dysfunction should be carefully monitored if risperidone or olanzapine are used.

Drug Administration

Drug dosage regimens

The safety and tolerability of a rapid oral loading regimen for risperidone, developed to achieve therapeutic doses within 24 hours, have been evaluated (148). Risperidone was begun in a dose of 1 mg, increasing by 1 mg every 6–8 hours up to 3 mg. Dose increases were contingent on the tolerance of the last administered dose. Of 11 consecutive inpatients who were treated with this protocol, seven tolerated the most rapid titration, achieving a dose of 3 mg bd in 16 hours; three required slightly slower titration and achieved the target dose in 24 hours; one could not tolerate the 3 mg dose but tolerated 2 mg tds; no patient had serious extrapyramidal adverse effects, sedation, or any other adverse event during the rapid titration, and in no case did risperidone have to be withdrawn. The authors concluded that aggressive dosing with risperidone is well tolerated in most psychiatric inpatients.

A randomized double-blind comparison of two dosage regimens of risperidone, 8 mg od and 4 mg bd for 6 weeks, in 211 patients has provided further information (149). Neither efficacy nor ESRS scores differed significantly. At least one adverse event was reported in 72 of the patients taking once-daily therapy and 87 of the patients taking twice-daily therapy. The most frequently reported were insomnia, anxiety, extrapyramidal symptoms, agitation, and headache. The only statistically significant difference between the groups was in the incidence of anxiety, which was reported by 31% of those taking twice-daily therapy and 17% of those taking once-daily therapy.

The optimal dose of risperidone in first-episode schizophrenia has been studied in 17 drug-naive patients (12 women, 5 men; mean age 29 years) (150). The mean optimal dosage of risperidone was 2.70 mg/day. All the patients reached the optimal dose before developing extrapyramidal adverse effects; four developed parkinsonism and one developed akathisia at a mean dosage of 5.20 mg/day. In contrast, acute exacerbations of schizophrenia may require a higher dose.

Drug overdose

During 13 months, a regional poisons center gathered information by telephone on 31 patients with reported risperidone overdose (151). Risperidone was the sole ingestant in 15 cases (1–180 mg). The major effects in this group included lethargy ($n = 7$), spasm/dystonia ($n = 3$), hypotension ($n = 2$), tachycardia ($n = 6$), and dysrhythmias ($n = 1$). One patient who co-ingested imipramine died of medical complications, but symptoms resolved within 24 hours in most of the others; all the patients were asymptomatic at 72 hours after ingestion.

- A 41-year-old man who took risperidone 270 mg developed a prolonged QT_c interval (480 ms) and sinus bradycardia (44/minute), without hemodynamic compromise. After 9 hours, he had episodes of asymptomatic supraventricular tachycardia with a maximum frequency of 150/minute. After 30 hours he was in sinus rhythm with a normal QT_c interval (360 ms). He was discharged 72 hours after admission, asymptomatic and with a normal electrocardiogram.
- A 15-year-old who took 110 mg of risperidone in a suicide attempt developed only transient lethargy, hypotension, and tachycardia without any other significant effects (152).

Drug–Drug Interactions

Carbamazepine

Carbamazepine induces CYP3A, and the metabolism of risperidone, which mainly involves CYP2D6, may also involve CYP3A. Carbamazepine can therefore reduce risperidone plasma concentrations (SEDA-22, 71). However, since carbamazepine alters the biotransformation of many agents, non-specific enzyme induction has been suggested for the risperidone and carbamazepine interaction (153).

Plasma concentrations of risperidone and 9-hydroxyrisperidone were measured in 44 patients (aged 26–63 years) treated with risperidone alone ($n = 23$) or comedicated with carbamazepine ($n = 11$) (154). Carbamazepine markedly reduced the plasma concentrations of risperidone and 9-hydroxyrisperidone.

Mean plasma concentrations of risperidone and 9-hydroxyrisperidone (5 ng/ml and 35 ng/ml) fell significantly during carbamazepine co-administration (2.5 ng/ml and 19 ng/ml) in 11 schizophrenic patients taking risperidone 6 mg/day and then carbamazepine 400 mg/day for 1 week; the changes in risperidone concentrations correlated positively with the concentration ratio of risperidone/9-hydroxyrisperidone, which was closely associated with CYP2D6 genotype (155).

Conversely, carbamazepine concentrations can increase when risperidone is added; when risperidone 1 mg/day was added in eight patients taking carbamazepine (mean dose 625 mg/day) carbamazepine plasma concentrations increased from 6.7 μg/ml at baseline to 8.0 μg/ml 2 weeks later (156).

- A 23-year-old man had raised 9-hydroxyrisperidone concentrations in association with carbamazepine dosage reduction and concomitant fluvoxamine therapy (157).
- In a 50-year-old man with deficient CYP2D6 activity, the addition of carbamazepine to pre-existing risperidone therapy resulted in a marked reduction in the plasma concentrations of risperidone and 9-hydroxyrisperidone and an acute exacerbation of his psychosis (158).

Clozapine

Risperidone increases plasma clozapine concentrations (159). The effects of risperidone 3.25 mg/day on cytochrome P450 isozymes have therefore been assessed in eight patients by determination of the metabolism of caffeine (for CYP1A2), dextromethorphan (for CYP2D6), and mephenytoin (for CYP2C19) (159). The results suggested that risperidone is a weak in vivo inhibitor of CYP2D6, CYP2C19, and CYP1A2. The authors concluded that inhibition by risperidone of those isozymes is an unlikely mechanism to explain increased clozapine concentrations.

HIV protease inhibitors

An interaction of risperidone with ritonavir and indinavir has been reported (160).

- A 34-year-old man with AIDS took risperidone 4 mg/day for a Tourette-like tic disorder. Ritonavir and indinavir were added, and 1 week later he developed significantly impaired swallowing, speaking, and breathing, and worsening of his existing tremors.

The authors hypothesized that inhibition of CYP2D6 and CYP3A4 by ritonavir and indinavir may have resulted in accumulation of the active moiety of risperidone.

Lithium

Dystonia occurred in an 81-year-old man who took lithium in addition to risperidone 1 mg/day, valproic acid 2250 mg/day, and benzatropine 4 mg/day (161).

Maprotiline

In three patients, maprotiline plasma concentrations increased when risperidone was added (162). The rise was explained by inhibition of CYP2D6, by which maprotiline is mainly metabolized.

Opioids

Two patients who were hospitalized with a diagnosis of opioid dependence received concomitant treatment with methadone 50 mg/day in one case, and levorphanol 14 mg/day in the other, each in association with risperidone. After several days, both had symptoms of opioid withdrawal despite having no change in their opioid doses (163). The withdrawal symptoms resolved soon after risperidone was withdrawn. According to the authors, this finding suggests that risperidone may precipitate opioid withdrawal in opioid-dependent patients.

Phenytoin

An interaction between risperidone and phenytoin resulted in extrapyramidal symptoms (164).

SSRIs

The possibility of a pharmacodynamic interaction between risperidone and serotonin re-uptake inhibitors has been discussed (165–167). Published cases of amelioration and deterioration have perpetuated the debate. Amelioration was observed in four patients with depression that had responded inadequately to selective serotonin re-uptake inhibitors by the addition of risperidone 1 mg bd ($n = 2$) or 0.5 mg at night ($n = 2$) (168).

Fluoxetine

A pharmacokinetic interaction of risperidone with fluoxetine has been reported (SEDA-22, 71). When 10 schizophrenic patients stabilized on risperidone 4–6 mg/day took fluoxetine 20 mg/day for concomitant depression the mean plasma risperidone concentration increased from 12 to 56 ng/ml at week 4; the concentration of 9-hydroxyrisperidone was not significantly affected (169). One patient dropped out after 1 week because of akathisia associated with a markedly increased plasma risperidone concentration.

In an open, 30-day trial, the pharmacokinetics, safety, and tolerability of a combination of risperidone 4 or 6 mg/day with fluoxetine 20 mg/day were evaluated in 11 psychotic inpatients (170). CYP2D6 genotyping showed that three were poor metabolizers and eight were extensive metabolizers. The mean AUC of risperidone increased from 83 and 398 h.ng/ml to 341 and 514 h.ng/ml when risperidone was co-administered with fluoxetine in extensive and poor metabolizers respectively. However, despite this pharmacokinetic interaction, the severity and incidence of extrapyramidal symptoms and adverse events did not increase significantly when fluoxetine was added; 10 of the 11 patients improved clinically.

- Catastrophic deterioration, with the severity of obsessive-compulsive symptoms returning to pretreatment levels, was observed in a 21-year-old man when risperidone was added to fluoxetine in a dosage that was stepped up to 3 mg/day (171).

Fluvoxamine

- A 24-year-old woman with auditory hallucinations taking risperidone 6 mg/day developed neuroleptic malignant syndrome after adding fluvoxamine 50 mg/day (172).

Paroxetine

The serotonin syndrome has been reported during treatment with paroxetine and risperidone (173). A case of edema in a patient taking risperidone and paroxetine has also been reported (174).

The effects of paroxetine 20 mg/day for 4 weeks on steady-state plasma concentrations of risperidone and its active metabolite 9-hydroxyrisperidone have been studied in 10 patients taking risperidone 4–8 mg/day (175). During paroxetine administration, mean plasma risperidone concentrations increased significantly, while 9-hydroxyrisperidone concentrations fell slightly but not significantly; after 4 weeks, the sum of the risperidone and 9-hydroxyrisperidone concentrations increased significantly by 45% over baseline, and the mean plasma risperidone/9-hydroxyrisperidone concentration ratio was also significantly changed. However, the drug combination was generally well tolerated, with the exception of one patient who developed parkinsonian symptoms during the second week, and whose total plasma risperidone and 9-hydroxyrisperidone concentrations increased by 62%.

Venlafaxine

In eight patients with major depressive disorder without psychotic features, who did not respond to serotonin re-uptake inhibitors therapy when risperidone was added, all improved within 1 week. Furthermore, risperidone also seemed to have beneficial effects on sleep disturbance and sexual dysfunction (176). In an open study in 30 healthy subjects who took risperidone 1 mg orally before and after venlafaxine dosing to steady state, the oral clearance of risperidone fell by 38% and the volume of distribution by 17%, resulting in a 32% increase in AUC; renal clearance of 9-hydroxyrisperidone also fell by 20% (177). The authors concluded that these small effects were consistent with the fact that venlafaxine is unlikely to alter the clearance of risperidone, which is mainly by CYP2D6.

Tetracycline

- A possible interaction of risperidone with tetracycline has been reported in a 15-year-old adolescent with Asperger's syndrome, Tourette's syndrome, and obsessive-compulsive disorder (178). Acute exacerbation of motor and vocal tics occurred when tetracycline 250 mg bd was introduced for acne; withdrawal of tetracycline resulted in an improvement in the tics.

Thioridazine

A 23-year-old man had high risperidone plasma concentrations secondary to concurrent thioridazine use (157).

Valproate

Plasma concentrations of risperidone and 9-hydroxyrisperidone were measured in 44 patients (aged 26–63 years) taking risperidone alone ($n = 23$) or co-medicated with sodium valproate ($n = 10$) (154). Valproate had no major effect on plasma risperidone concentrations.

However, an anecdotal report has suggested that some individuals may be susceptible to an interaction.

- Catatonia occurred in a 42-year-old woman taking valproic acid, sertraline, and risperidone (79). The catatonic features evolved for the first time after a single dose of valproate and were alleviated by lorazepam; the same catatonic signs recurred after a second dose of valproate and again remitted after lorazepam.

The authors considered that this was a possible interaction, since catatonia has not been reported with valproate alone.

The addition of risperidone 10 mg/day over 2 months to valproate and clonazepam in a 40-year-old woman

© 2006 Elsevier B.V. All rights reserved.

provoked marked edema in the legs and moderate edema in the arms (179). The authors considered that this was a possible interaction, since edema has not been reported with either of these drugs separately.

In contrast, a beneficial interaction has been observed when valproic acid was added to risperidone; the previous addition of valproic acid to treatment with chlorpromazine had no effect on psychotic symptoms (180).

Diagnosis of Adverse Drug Reactions

A therapeutic target range for serum risperidone concentrations has not been established, but in 20 of 22 patients taking 6 mg/day, which is considered the optimum dosage for most patients, risperidone serum concentrations were 50–150 nmol/l (181). Steady-state serum concentrations of risperidone and 9-hydroxyrisperidone, the active moiety, were also measured in 42 patients; there was no correlation between the serum concentration of the active moiety and adverse effects.

Ritanserin

General Information

Ritanserin, a selective 5-HT_2 receptor antagonist, increases slow-wave sleep in healthy volunteers (1). It improved sleep in middle-aged poor sleepers (2), but on withdrawal after 20 days treatment there was rebound sleep impairment, which was at its worst 3 nights after withdrawal, consistent with its long half-life (40 hours). Ritanserin is thus not a useful hypnotic, but analogues with more appropriate kinetics will be of interest.

Ritodrine

See also Beta$_2$-adrenoceptor agonists

General Information

Ritodrine is a beta$_2$-adrenoceptor agonist used in the treatment of premature labor.

The hemodynamic effects of ritodrine have been assessed in 12 fetuses by cardiac and extracardiac Doppler sonography (1). Ritodrine significantly increased maternal and fetal heart rates, left cardiac stroke volume, and cardiac output. There was also an increase in the pulsatility index of the middle cerebral artery and a fall in the pulsatility index of the umbilical artery during ritodrine infusion. The authors suggested that ritodrine vasodilates fetal vessels in the placenta.

Organs and Systems

Cardiovascular

Ritodrine can cause bradycardia instead of the expected tachycardia (SEDA-8, 145); an unexpected hypertensive crisis has also been reported (SEDA-8, 145). ST segment depression is a consistent finding in patients during ritodrine infusion, and should therefore not always be

© 2006 Elsevier B.V. All rights reserved.

interpreted as an indication of myocardial ischemia. The electrocardiographic changes are unrelated to the more generally accepted changes in heart rate, glucose, and potassium concentrations and are probably an intrinsic effect of the drug.

Endocrine

Brief infusions of ritodrine (0.15 mg/minute for 4 hours) rapidly increased plasma melatonin concentrations in healthy women (2).

Metabolism

There are two well-documented independent reports of severe ketoacidosis in non-diabetic pregnant subjects; both the beta-agonist therapy and inadequate dietary intake could have played a role (3).

Hematologic

Agranulocytosis has been documented in a pregnant woman given ritodrine (SEDA-17, 165).

Skin

Palmar erythema was observed in 12 of 209 patients who were treated with ritodrine for more than 7 days (SEDA-12, 123).

Immunologic

A petechial rash due to vasculitis has been documented in a pregnant woman given ritodrine (SEDA-17, 165).

Second-Generation Effects

Fetotoxicity

Neonatal jaundice is more frequent in the babies of mothers who received ritodrine during the second or third trimesters of pregnancy (4).

Magnetocardiography has been used to detect fetal cardiac dysrhythmias in 84 pregnant women with normal pregnancies and in 68 women receiving ritodrine for preterm labor (5). There were dysrhythmias in 3.5% of the fetuses in the normal pregnancy group and in 16% in the ritodrine-treated group.

Drug–Drug Interactions

Atropine

When ritodrine is used to alleviate fetal distress and surgical intervention (cesarean section), atropine premedication must be avoided. The vagolytic action of atropine is synergistic with the action of ritodrine, resulting in severe maternal tachycardia and systolic hypertension (6).

Rituximab

See also Monoclonal antibodies

General Information

Rituximab, a chimeric monoclonal antibody directed against the CD20 antigen of normal and malignant B lymphocytes, produces prolonged depletion of B lymphocytes. It has been used to treat refractory or relapsing follicular non-Hodgkin's lymphoma and has been tried in other B cell malignancies, including low-grade non-Hodgkin's lymphoma and diffuse large B cell lymphoma. There has also been interest in its use to treat autoimmune diseases (1–3) and in reducing anti-HLA antibodies in patients awaiting renal transplantation (4).

A wide range of adverse events has been reported in most patients (5). A transient flu-like syndrome is very common (50–90%), particularly after the first infusion of rituximab, and is often associated with various hypersensitivity-like symptoms (5–20%). In the most severe cases, patients had life-threatening cytokine release syndrome with dyspnea, bronchospasm, hypoxia, hypotension, urticaria, and angioedema. Deaths have been reported in eight of 12 000–14 000 patients after drug launch.

Severe reactions to rituximab are rare, but are seen in patients with bulky tumors or with leukemic involvement with high numbers of CD20 positive cells (6,7) and were ascribed to a rapid tumor lysis syndrome (6,8,9). In 11 patients with malignant B cell leukemia, first-dose reactions were significantly more severe in patients whose baseline lymphocyte count was higher than 50×10^6/l and were also associated with raised peak serum concentrations of tumor necrosis factor alfa and interleukin-6 (10).

Organs and Systems

Cardiovascular

Cardiac dysrhythmias have been reported in 8% of patients treated with rituximab in patients with lymphomas (11).

© 2006 Elsevier B.V. All rights reserved.

Respiratory

Desquamative alveolitis has been reported in a 55-year-old woman with mantle-cell lymphoma given rituximab (12).

Sensory systems

A variety of ocular adverse effects, including conjunctivitis, transient ocular edema, and visual changes, occurred in 7% of patients receiving rituximab (11).

Hematologic

The factors associated with toxicity in patients with B cell lymphoma receiving rituximab have been studied in Japan (13). By univariate analysis overall non-hematological toxic effects (grade 2 or greater) were more frequent in patients with extranodal disease and especially in those with bone marrow involvement. Fever was more frequent in patients with raised LDH activity, whereas chills/rigors and vomiting were more frequent in patients with extranodal disease. Patients with raised LDH activity or extranodal disease may therefore require closer monitoring. Hematological toxic effects of grade 3 or worse were more common in women.

- A 26-year-old woman with a diffuse large B cell lymphoma received CHOP (cyclophosphamide, hydroxydaunomycin, Oncovin, and prednisone), rituximab, and radiotherapy (14). She developed a transfusion-dependent anemia. Bone marrow biopsy confirmed pure red cell aplasia and parvovirus infection. She had no antibodies to parvovirus, suggesting that she never had a previous exposure. Intravenous immunoglobulin resulted in a reticulocytosis and recovery of her hemoglobin.

The authors suggested that rituximab had depleted her primary B cells, resulting in an inability to mount a primary immune response to parvovirus infection. Parvovirus is pathogenic to red cell precursors, causing their destruction before release from the bone marrow.

Depletion of B lymphocytes by rituximab was suggested as a likely explanation for the occurrence of chronic parvovirus B19 infection complicated by pure red cell aplasia in a 45-year-old patient (15).

Thrombocytopenia leading to gastrointestinal bleeding has been attributed to rituximab (16).

Skin

Stevens–Johnson syndrome has been attributed to rituximab (17).

- A 33-year-old man with a follicular non-Hodgkin lymphoma entered a phase II trial of rituximab. The first two cycles were given without infusion-related toxicity, but during the second cycle mucositis was noticed. Before the third cycle he developed a pruritic rash on the trunk, grade 2 mucositis, and weight loss. He was given oral fluconazole, aciclovir, and antihistamines, which led to improvement. One week after the third infusion of rituximab he had grade 3 orogenital mucositis and the maculopapular rash on the trunk worsened, with areas of ulceration. Rituximab was withdrawn. Stevens–Johnson syndrome was confirmed by biopsy.

Immunologic

Infusion reactions with rituximab are generally well tolerated, as with most monoclonal antibodies. Most reactions are limited to the first infusion, including nausea, chills, and fever. They occur in over 90% of patients. More serious is the cytokine-release syndrome, which occurs within 60–90 minutes and is characterized by fever, chills, rigors, bronchospasm, hypoxia, hypotension, urticaria, and angioedema. Infusion must be discontinued, and the patient carefully monitored with chest radiography and fluid and electrolyte assessment and treated with oxygen and bronchodilators.

A rapid tumor clearance syndrome can occur within 30–60 minutes, with similar symptoms. Lymphocytes rapidly disappear from the peripheral blood and uric acid and lactate dehydrogenase increase markedly. Treatment includes interruption of the infusion, hydration, allopurinol, oxygen, and bronchodilators. It mainly occurs in patients with high white blood cell counts, such as those with chronic lymphatic leukemia.

Severe viral infections/reactivation that have been reported in patients given rituximab have included fulminant hepatitis B (18), parvovirus-induced red cell aplasia (15), and fatal *Varicella zoster* infection (19). There was a high incidence of reactivation of cytomegalovirus and *V. zoster* virus when rituximab was combined with high-dose chemotherapy in high-risk patients with non-Hodgkin's lymphoma (20).

Long-Term Effects

Tumorigenicity

A second cancer is possible when treating a tumor by mutagenicity or immunosuppression. There may be a link between the therapy given and the development of Merkel cell carcinoma (21).

- A 54-year-old man with stage I follicular lymphocytic lymphoma with cervical lymph nodes underwent splenectomy followed by chemotherapy with chlorambucil and had a partial response. Five months later, when he developed generalized lymphadenopathy and bone marrow involvement, he received fludarabine, cyclophosphamide, and rituximab, with complete remission. Ten months later he developed a Merkel cell carcinoma involving the liver and lymph nodes. The disseminated tumor was chemoresistant and he died. His lymphoma remained in complete clinical remission throughout this time.

Two patients developed a peripheral T cell non-Hodgkin's lymphoma after rituximab therapy, one after 15 months and the other after 18 months (22).

Rituximab was suggested as a possible cause of aggressive peripheral T cell lymphoma in two patients 15 and 18 months after the use of rituximab for low-grade B cell non-Hodgkin's lymphoma (23,24).

© 2006 Elsevier B.V. All rights reserved.

Second-Generation Effects

Pregnancy

There are few data on the use of rituximab in pregnancy, but one case has been reported.

- A pregnant woman with relapsed follicular non-Hodgkin's lymphoma took rituximab unintentionally during the first trimester (25). The disease stabilized and following an uncomplicated pregnancy a healthy child was born at full term. Careful hematological and immunological monitoring showed no adverse effects from exposure to rituximab.

Rivastigmine

General Information

Rivastigmine (1) was the second drug after donepezil in a class of second-generation acetylcholinesterase inhibitors to become commercially available. It is now marketed in over 60 countries worldwide, including those in Europe and South America and the United Kingdom. It has central selectivity, suggesting fewer peripheral adverse effects. These include nausea, vomiting, abdominal pain, and anorexia (2,3). Daily doses up to 12 mg were tolerated and produced improvement in patients with Alzheimer's disease (4).

Although therapy with newer as well as older cholinesterase inhibitors can prevent cognitive decline, psychiatric and behavioral disturbances, and impaired ability to perform basic activities of daily living, and improve global state of patients with mild-to-moderately-severe Alzheimer's disease, more potent therapies are needed, particularly for modifying the rate of disease progression. Future research efforts need to focus on identifying predictors and better measures of response, timing of treatment, optimum dosage regimens, longer-term follow-up, and establishing how and when acetylcholinesterase inhibitors should be stopped (5,6).

A meta-analysis of various drugs approved for the treatment of Alzheimer's disease in the USA and Canada has suggested that rivastigmine can delay cognitive impairment and deterioration in global health for at least 6 months in patients with mild-to-moderate Alzheimer's disease (7). Patients taking active treatment will have more favorable ADAS-Cog (Alzheimer's Disease Assessment Scale-Cognitive) scores for at least 6 months, after which their scores will begin to converge with those who are taking placebo. The cost-effectiveness data were inconclusive.

In two studies of rivastigmine, 38% of users suffered from nausea, 23% from vomiting, and 24% from vertigo (8). Over 6 months there was a dropout rate of 25%. The gastrointestinal effects led to significant loss of weight. The positive response rate was only 10%, compared with a 6% response to placebo.

The efficacy and safety of rivastigmine have been investigated in several subsequent studies (9–12). Neurologists generally titrated this drug more slowly than recommended in the prescribing information (9). In daily practice, over 50% of the patients were unable to tolerate rivastigmine, mainly because of cholinergic gastrointestinal adverse effects (10), whereas others have found that the adverse events were most frequently mild and transient (11,12). It has been suggested that early treatment with rivastigmine (6–12 mg/day) is associated with sustained long-term (up to 52 weeks) cognitive benefit in patients with Alzheimer's disease (12).

Organs and Systems

Cardiovascular

Based on an electrocardiographic analysis of pooled data from four 26-week, phase III, multicenter, double-blind, placebo-controlled trials of rivastigmine (n = 2791), there were no adverse effects on cardiac function (13). Rivastigmine can therefore be safely given to patients with Alzheimer's disease, without the need for cardiac monitoring.

Psychological, psychiatric

Three patients with dementia, with no prior psychiatric history, deteriorated while taking rivastigmine (14). The time course suggested an association with rivastigmine, and each improved after withdrawal.

Gastrointestinal

Potentially fatal rupture of the esophagus has been associated with untitrated use of rivastigmine tablets in a patient with Alzheimer's disease (15).

- A 67-year-old Caucasian woman had a 2-year history of progressive memory loss. She had arterial hypertension successfully controlled with lisinopril and no history of ethanol abuse. A diagnosis of probable Alzheimer's disease was made, and she was given rivastigmine 1.5 mg/day, increasing to 9 mg/day by weekly increments of 1.5 mg. During the titration period, there were no significant adverse effects. After 13 weeks, weight loss was observed and rivastigmine was withdrawn. After 8 weeks she developed marked cognitive deterioration, and she and her carer were advised to restart rivastigmine 1.5 mg/day. However, she mistakenly took one tablet of 4.5 mg. About 30 minutes later she started to vomit several times. Nearly 2 hours later, she complained of severe chest pain, followed by high-grade fever. A chest X-ray showed mediastinal and soft-tissue emphysema, and a contrast X-ray showed rupture of the distal part of the esophagus. Emergency surgery was performed and she recovered.

Rivastigmine and other acetylcholinesterase inhibitors can produce chest pain because of increased esophageal contractions, although consequent rupture of the esophagus has not previously been reported. In this case, the failure to titrate the dosage of rivastigmine could have resulted in rupture secondary to severe vomiting. This confirms the need for careful titration of the dose of rivastigmine, even when restarting treatment.

The transient use of centrally acting antiemetics during rivastigmine titration may be useful in combination with dose-withholding and titration strategies to allow more patients to reach higher doses, resulting in a rapid and robust therapeutic effect. Patients who were treated with trihexyphenidyl and trimethobenzamide were more likely to be able to maintain or to increase their dose of rivastigmine than patients who were treated with glycopyrrolate or ondansetron (16).

Drug–Drug Interactions

General

Rivastigmine did not interact significantly with a wide range of concomitant medications prescribed for elderly patients with Alzheimer's disease, based on an analysis of 2459 patients (rivastigmine 1696, placebo 763) from four randomized placebo-controlled studies (17). However, the Breslow–Day analysis used in this study detected only differences in the odds ratios of rivastigmine versus

© 2006 Elsevier B.V. All rights reserved.

placebo among patients taking concomitant medications. Thus, these results have to be cautiously interpreted.

Rocuronium bromide

See also Neuromuscular blocking drugs

General Information

Rocuronium is a steroidal agent related chemically to vecuronium. It is less potent than vecuronium and has a quicker onset of action. The plasma clearance of rocuronium is primarily due to liver uptake and biliary excretion (1). About one-third of an injected dose is excreted unchanged in the urine (1). Good intubating conditions may be expected 90–120 seconds after the injection of 0.6 mg/kg rocuronium. Increasing the dose to 1 mg/kg will give acceptable intubating conditions at 60 seconds. There were no increases in plasma histamine concentrations with doses up to 1.2 mg/kg (2).

Organs and Systems

Cardiovascular

Rocuronium has virtually no cardiovascular adverse effects (2–4). Minor increases in heart rate can occur with higher doses owing to its mild vagolytic properties.

There are several reports of pain during injection of rocuronium (5,6). Eight of 10 patients complained of severe pain, one complained of moderate pain, and another reported an unpleasant sensation (5). This suggests that rocuronium will almost invariably cause pain. The mechanism of this phenomenon is not clear, but there appear to be some similarities to propofol injection pain. Several authors have suggested that rocuronium should not be given to awake patients (5,6). On the other hand, small doses of rocuronium have been used, with some success, to prevent fasciculations and myalgia after suxamethonium (7–10). With regard to the severity of injection pain, rocuronium pretreatment in awake patients does not seem advisable.

Immunologic

Several allergic reactions to rocuronium have been reported (11–20). Based on data from the UK, Australia, and France, it had been suggested that the incidence of such reactions after rocuronium administration parallels its frequency of use, as assessed by its market share, implying that rocuronium does not have unusual allergenic properties (15,21,22). In one hospital, the incidence of such reactions was 1 in 3000 (15) and in another 1 in 6000 (11). Also, the incidence of

© 2006 Elsevier B.V. All rights reserved.

hypotension, tachycardia, or reduced oxygen saturation (which might suggest an anaphylactoid reaction) was relatively low after rocuronium administration compared with other muscle relaxants in a computerized analysis of 47 295 anesthetic records in one hospital (23).

However, the French Group on the Study of Perianesthetic Anaphylactoid Reactions (GERAP) has reported that the proportion of anaphylactoid reactions to rocuronium was similar to suxamethonium in relation to the individual market shares of these agents (22). There were 41 cases among 452 reported cases of anaphylaxis due to neuromuscular blocking agents that were attributed to rocuronium (24). This would make rocuronium look unfavorable, taking into account the fact that suxamethonium is believed to trigger anaphylactoid reactions more often than any non-depolarizing neuromuscular blocker. The authors assumed that their figures might have been partly due to anesthetists' paying more attention to the effects of drugs that had become available more recently, especially in cases of mild reactions. Reporting bias has also been offered as one possible explanation of 29 reports of anaphylaxis to rocuronium among 150 000 patients in Norway, in contrast to 8 cases among 800 000 patients in the other Scandinavian countries (25). This observation has prompted the Norwegian Medicines Agency to recommend that rocuronium be temporarily withdrawn from routine practice and that it be used for rapid-sequence induction only.

It is difficult to understand why such an increase in the number of reported cases should only be observed in France and Norway and not in other countries in which rocuronium is widely used. For the time being, it is not possible to decide whether anaphylactoid reactions are more common with rocuronium than with other non-depolarizing muscle relaxants. To get a clearer picture, a large longitudinal survey would be needed (26), which is unlikely to be performed, owing to the large number of cases that would be required. We shall probably have to rely on national surveys, like the French one cited above. International networking and pooling of data might be the way forward. All of this will depend on clinicians chasing every case of a suspected anaphylactoid reaction by immunological testing and reporting all confirmed cases to appropriate bodies.

The Norwegian Medicines Agency has recommended that rocuronium bromide should be withdrawn from routine practice, referring to 29 reported cases of anaphylaxis or anaphylactoid reactions among 150 000 administrations over 2.5 years. In response, and with regard to the paucity of reported cases of anaphylaxis to rocuronium in other Nordic countries, the statistical problems of surveying such rare adverse drug reactions have been highlighted (25).

One patient died after developing multiorgan failure due to a reaction to rocuronium (27).

- A 64-year-old obese man, scheduled for a hernia repair, had had previous episodes of venous thromboembolism, for which he was still taking an oral anticoagulant. Previous general anesthesia had been uneventful. General anesthesia was induced with sufentanil 15 μg and propofol 400 mg. He was given rocuronium 50 mg to facilitate endotracheal intubation, and shortly after developed bronchospasm, severe hypotension, tachycardia, and generalized erythema. He was resuscitated with adrenaline, hydrocortisone, and colloid infusion. However, his further course after admission to the intensive care unit was complicated by persistent hypotension, acute respiratory distress syndrome, acute renal insufficiency, disseminated intravascular coagulation, and pancreatitis, and he died 7 days after the incident. Blood samples drawn at 30 and 60 minutes after the initial presentation showed increased concentrations of histamine and tryptase. Specific IgE antibodies against quaternary ammonium groups were detected, with a positive radioimmunoassay inhibition by rocuronium.

Death caused by an anaphylactic reaction to a muscle relaxant seems to be rare, although mortality rates from intraoperative anaphylaxis in the range of 3.4–6% have been reported (28–31). The incidence of cardiac arrest was 4.9% among patients with anaphylactic reactions to muscle relaxants referred to the French GERAP centers for further testing, but these patients all survived (22).

Second-Generation Effects

Fetotoxicity

The maternofetal transfer or rocuronium, as indicated by a fetal/maternal plasma concentration ratio of 0.16, is between that of vecuronium and pancuronium (32). When rocuronium was used for cesarean section, no adverse effects on the fetus were observed (32). With regard to the duration of rocuronium-induced paralysis and the relatively high incidence of failed intubations in obstetric patients, however, it was agreed that rocuronium should be considered for rapid-sequence intubation for cesarean section only if suxamethonium is contraindicated (33–35).

Susceptibility Factors

Age

In elderly patients, because of reduced hepatic elimination, the duration of action of rocuronium can be prolonged (36,37).

Renal disease

Despite the predominantly biliary elimination of rocuronium, reduced clearance and a prolonged half-life have been reported in patients with chronic renal insufficiency requiring hemodialysis (38,39); however, the duration of action was not longer than in healthy controls (38).

Hepatic disease

The duration of action of rocuronium was significantly prolonged in patients with liver cirrhosis, which might be explained either by a larger central volume of distribution or by a lower plasma clearance (40,41).

© 2006 Elsevier B.V. All rights reserved.

Drug–Drug Interactions

Anticonvulsant drugs

The duration of action of rocuronium can be reduced during long-term therapy with anticonvulsants (42). In one study the mean times to recovery of twitch height to 25% of baseline after rocuronium 0.6 mg/kg were 21 minutes in patients taking either carbamazepine or phenytoin versus 45 minutes in controls (43). It was suggested that the dose of rocuronium should be increased in patients taking antiepileptic drugs.

General anesthetics

The neuromuscular blocking effects of rocuronium are potentiated by halothane, enflurane, and isoflurane (44–46).

Rofecoxib

See also COX-2 inhibitors

General Information

Rofecoxib is a selective inhibitor of COX-2. Although it was originally introduced with the expectation that it would be safer than conventional NSAIDs, because of less gastrointestinal bleeding, the benefit to harm balance is now considered to be unfavorable during long-term treatment, mainly because of an increased risk of cardiovascular disease (heart attacks and strokes; see the monograph on COX-2 inhibitors), and it has been voluntarily withdrawn by its manufacturers.

Organs and Systems

Nervous system

Aseptic meningitis is a rare adverse effect of non-selective NSAIDs in patients with or without connective tissue disease or rheumatological disease. Rofecoxib has been implicated in five patients (four women and one man), in each case occurring within 12 days of the start of rofecoxib therapy (1). The clinical presentations and cerebrospinal fluid findings were typical of aseptic meningitis. One patient had rheumatoid arthritis. After drug withdrawal and recovery, two consecutive rechallenges in one patient led to relapses.

Urinary tract

Acute renal insufficiency has been reported after the use of rofecoxib in patients with predisposing conditions, such as chronic renal insufficiency, renal transplantation, heart disease, liver cirrhosis, and dehydration (2–5). COX-2 inhibitors should be used with great caution, if at all, in patients with medical problems that are associated with prostaglandin-dependent renal function. From this point of view they do not differ from traditional NSAIDs (6).

- Rofecoxib 12.5 mg bd for arthritic pain was associated with biopsy-proven acute tubulointerstitial nephritis in a 67-year-old woman.

Drug–Drug Interactions

Methotrexate

Methotrexate is often prescribed for the management of rheumatoid arthritis, and some NSAIDs have been reported to interact with it, causing increased plasma methotrexate concentrations, associated with impaired renal function. The safety of concurrent rofecoxib and oral methotrexate has been studied for 3 weeks in 25 patients with rheumatoid arthritis (7). Rofecoxib 12.5–50 mg/day had no effect on the plasma concentrations or renal clearance of methotrexate, but supratherapeutic doses of rofecoxib (75 and 250 mg) caused a significant increase in the plasma methotrexate AUC and reduced its renal clearance.

Warfarin

Significant increases in International Normalized Ratio (INR) have been reported in patients who took rofecoxib and warfarin; in some, the increase in INR was accompanied by a bleeding event (8,9). Careful monitoring of the INR in patients taking warfarin and concomitant rofecoxib is mandatory.

Rokitamycin

See also Macrolide antibiotics

General Information

Rokitamycin is a semisynthetic 16-membered ring macrolide. It is more hydrophobic, and has better bacterial uptake and slower release, more cohesive ribosomal binding, and a longer post-antibiotic effect than other 14-, 15- and 16-membered ring macrolides (1).

Organs and Systems

Immunologic

- Churg–Strauss syndrome has been reported in an 18-year-old woman taking cysteinyl leukotriene receptor antagonists and oral rokitamicin 400 mg bd for 10 days (2).

Romazarit

See also Non-steroidal anti-inflammatory drugs

General Information

Romazarit, a slow-acting drug for use in rheumatoid arthritis, was well tolerated in pharmacokinetic studies. It is structurally similar to clobuzarit, which was withdrawn because of four possible cases of Stevens–Johnson syndrome (SEDA-17, 114).

In a double-blind placebo-controlled study in 224 patients with rheumatoid arthritis romazarit 200 mg or 450 mg bd for up to 24 weeks reduced the rate of progress of the disease. Adverse effects were not reported (1). In a double-blind placebo-controlled in 24 patients with rheumatoid arthritis romazarit 100 mg tds, 350 mg bd, or 350 mg tds was associated with adverse events that were mainly trival and similar in incidence to placebo (2).

Ropinirole

General Information

Ropinirole is a dopamine receptor agonist.

Organs and Systems

Cardiovascular

Supraventricular extra beats have rarely been reported after low doses of ropinirole and have also been reported after pergolide and levodopa (1). Symptomatic postural hypotension has occurred after even low oral doses of ropinirole (2–5), related to peripheral dopaminergic activity. Hypotensive effects occur within 3 minutes of standing, usually between 2 and 4 hours after an oral dose, associated with non-specific malaise (2). Dizziness occurred in up to 40% of patients in clinical trials. Related symptoms include faintness, malaise, and yawning (2). Bradycardia has occasionally accompanied postural hypotension (4). Syncope has been reported.

Nervous system

Somnolence occurred in 20–40% of patients in clinical trials. Drowsiness or euphoria has occurred in some patients taking oral ropinirole (3,4,6). Dyskinesia

occurred in 34% of patients with advanced Parkinson's disease in clinical trials.

Gastrointestinal

Nausea, usually mild and not associated with vomiting, has been reported after oral doses of ropinirole, in both supine and standing positions (1–5). Nausea is related to peripheral dopaminergic activity and has been controlled by pretreatment with domperidone (20 mg) (2,3). In one study in healthy subjects, nausea was not reported in the supine position after oral ropinirole; however, nausea with malaise was common on standing (orthostatic symptoms) (2).

Sexual function

Penile erections have been described with ropinirole (7).

- A 49-year-old man with Parkinson's disease was treated with ropinirole, and the dosage eventually reaching 3 mg tds. He had penile erections 20–30 minutes after each dose, lasting for 10–15 minutes. They were not associated with arousal and were very uncomfortable: he had no history of sexual dysfunction. Their frequency diminished with a reduction in drug dosage, but they stopped completely only on drug withdrawal.

Drug–Drug Interactions

Ciprofloxacin

Ciprofloxacin, an inhibitor of CYP1A2, the major enzyme whereby ropinirole is metabolized, increased the risk of ropinirole-induced adverse effects (nausea, somnolence, dizziness) (8).

Warfarin

Ropinirole has been reported to enhance the effects of warfarin (9).

- A 63-year-old man taking co-careldopa and warfarin 4 mg/day (it is not entirely clear why) was also given ropinirole 0.75 mg/day to allow levodopa sparing. After 9 days of ropinirole his INR had increased to 4.6 from a previously stable value of 1.8–2.1, little changed in 2 years. There was no clinical evidence of bleeding. Warfarin was withheld for 4 days and then restarted at 25% of its previous dose. The ropinirole was then withdrawn because of gastrointestinal adverse effects and the warfarin dosage was restored to its previous level.

The mechanism of this interaction has not been elucidated. Ropinirole is metabolized by CYP1A2, but that is not the major isoform involved in warfarin metabolism.

Ropivacaine

See also Local anesthetics

General Information

Ropivacaine is an enantiomeric aminoamide local anesthetic, structurally related to bupivacaine but with a wider margin of safety between concentrations that cause nervous system and cardiovascular effects (1). It is mainly metabolized by CYP1A2.

The safety, pharmacokinetics and efficacy of two doses of ropivacaine (300 and 375 mg) for wound infiltration after surgical incision have been studied in an open non-randomized study of 20 men undergoing elective hernia repair (2). Efficacy was similar. There were wide variations in mean plasma concentrations of ropivacaine, the highest individual plasma concentration of total drug being 3.0 μg/ml for the 375 mg dose. One patient in the low-dose group had two episodes of bradycardia at 2 and 12 hours after drug administration. The first episode corresponded to a total plasma drug concentration of 1.3 mg/ml. Three patients in the high-dose group had several recorded episodes of sinus bradycardia. Two of these were within the first hour of ropivacaine administration and corresponded to plasma concentrations of 2.5 and 2.9 μg/ml. One patient in the 300 mg group complained of dizziness at 12 and 21 hours and of nausea at 12 hours. Another patient in the same group vomited 4 hours after the injection of ropivacaine. Two patients had transient hypesthesia in the leg on the operated side, thought to be due to partial block of the femoral nerve. The authors felt that systemic toxicity due to ropivacaine was unlikely to be a cause of any of these adverse effects and they concluded that high-dose ropivacaine is safe for wound infiltration.

© 2006 Elsevier B.V. All rights reserved.

Organs and Systems

Cardiovascular

The effects on the cardiovascular system of ropivacaine are similar to those of bupivacaine, although direct cardiotoxicity is less severe with ropivacaine than bupivacaine in both man and animals (SEDA-22, 143). Hypotension and bradycardia are prominent adverse effects when ropivacaine is used epidurally, particularly with concentrations of ropivacaine over 0.5% (SEDA-20, 129) (SEDA-22, 143); in one series, hypotension was observed in 30% of patients who received ropivacaine, but in only 13% of those given an equivalent dose of bupivacaine (3).

Nervous system

Convulsions have occurred after inadvertent intravenous injection of ropivacaine during regional anesthesia (4,5). CNS adverse effects from ropivacaine occur before or without severe cardiovascular toxicity, as there have been several similar reports of CNS toxicity, but not yet one with severe or fatal cardiotoxicity. This reinforces the claim of increased safety from cardiovascular toxicity with this enantiomeric local anesthetic compared with racemic bupivacaine.

Two episodes of central nervous system toxicity without significant cardiovascular toxicity have been described in a patient who had brachial plexus blocks with excessively high doses of ropivacaine 6 weeks apart (6).

- A 45-year-old woman with rheumatoid arthritis asked for regional anesthesia for arthrodesis of her wrist. An interscalene block was performed with ropivacaine 300 mg (6 mg/kg). After 3 minutes she complained of circumoral numbness and twitching in her throat. She developed irrational speech and perioral twitching and 15 minutes after injection developed involuntary clonic twitching in her left upper arm. She was anesthetized with thiopental and ventilated with 100% oxygen via a bag and mask. She regained consciousness within 20 minutes and at 135 minutes was fully conscious, with complete sensorimotor block of her left upper limb. Six weeks later she had an axillary nerve block with ropivacaine 225 mg (4.5 mg/kg) and lidocaine 200 mg (4 mg/kg) with adrenaline. After 25 minutes she complained of a strange feeling in her tongue and became dysarthric and unresponsive to voice. She was anesthetized with propofol and the arthrodesis was performed under general anesthetic. Postoperatively she had a complete brachial plexus block, which resolved after 6 hours. In both instances the only cardiovascular effect noted was sinus tachycardia (150–170/minute).

A single seizure after epidural ropivacaine has been reported (7).

- A 26-year-old primigravid woman in labor had an epidural anesthetic with ropivacaine (a background infusion of 18 mg/hour and three bolus doses totalling 44 mg, followed by an infusion of 24 mg/hour). She failed to progress and another three boluses totalling 150 mg were given. She received a total of 279 mg of ropivacaine over 5 hours. Immediately after the final bolus she developed oculogyric movements and slurred speech and then twitching of her face and arms. The seizure ceased with thiopental and the operation was carried out uneventfully under general anesthesia. Her serum ropivacaine concentration 1 hour later was 3.5 mg/l check units; in previous studies, symptoms of toxicity during intravenous infusions occurred at plasma concentrations of 1–2 μg/ml.

This shows that it is important to leave adequate time between bolus doses to detect adverse effects.

Inadvertent intravenous injection of ropivacaine resulted in systemic toxicity in two cases (5–8).

- A 13-year-old boy weighing 44 kg was given a bolus of 20 mg of ropivacaine through an 18 G Tuohy needle. No cerebrospinal fluid or blood had been aspirated. However, he immediately complained that his face "felt different," and within 1 minute developed a tonic-clonic seizure and a tachycardia of 160/minute. In a blood sample taken about 35 minutes later the plasma concentration of ropivacaine was 1.4 mg/ml, consistent with intravascular injection. In humans, symptoms of toxicity occur at plasma concentrations of 1–2 mg/ml. The authors thought that the rate of injection of epidural local anesthetic should be slower, which would give a greater safety margin between the onset of facial numbness and seizures.
- A ropivacaine-induced seizure occurred in a 23-year-old woman undergoing postpartum tubal ligation. An epidural that had been inserted for labor the evening before the procedure was used to give ropivacaine 120 mg in increments over 11 minutes. She complained of nervousness and within a few seconds had a generalized tonic-clonic seizure and a sinus tachycardia of 120/minute.

In both of these cases reasonable precautions had been taken to ensure correct catheter placement, but nevertheless systemic toxicity occurred. However, neither patient had any serious cardiotoxicity. However, it is worth emphasizing that large doses of local anesthetics should be given slowly and in divided doses and that lidocaine, one of the least toxic of the commonly used local anesthetics, has more obvious prodromal symptoms than ropivacaine, and could be a useful marker for intravenous injection (9).

Three patients suffered convulsions as a result of inadvertent intravascular injection of ropivacaine during placement of local blocks.

- A 75-year-old woman received ropivacaine 160 mg intravenously through an epidural catheter (10). After completion of the injection, she suddenly became unresponsive and had a generalized tonic-clonic convulsion accompanied by a sinus tachycardia of 120/minute but no other cardiac dysrhythmias.
- A 56-year-old 70 kg woman with a Colles fracture received a brachial plexus block at the humeral canal with 0.75% ropivacaine 40 ml using a nerve stimulator (11). The local anesthetic was administered slowly with negative intermittent aspiration. However, 15 minutes later she had two generalized convulsions, which were treated with diazepam. The total venous ropivacaine concentration measured 2 hours after the block was 2.3 μg/ml.
- A 25-year-old man received ropivacaine 75 mg intravenously during sciatic nerve block (12). The nerve was

© 2006 Elsevier B.V. All rights reserved.

located using a nerve stimulator and the injection was performed after elicitation of a distal extensor response. Numerous aspirations were performed during the procedure, but 1 minute after injection he suddenly became unresponsive and developed a tonic-clonic seizure, which resolved after treatment with midazolam and propofol. The only cardiovascular effect was a sinus tachycardia of 130/minute.

In the last case, the authors noted that the motor response to stimulation was maintained throughout the injection; it is generally felt that the motor response to stimulation should disappear after the injection of the first milliliters of local anesthetic; if the response does not disappear the injection should be stopped. In all three cases nervous system toxicity occurred with minimal or no cardiovascular toxicity, which is in keeping with previous reports, confirming the relative safety of ropivacaine; there has still not been one single fatal outcome reported with this agent.

Rosaceae

See also Herbal medicines

General Information

The genera in the family of Rosaceae (Table 1) include avens, cotoneasters, hawthorn, and roses, and a variety of fruits such as apples, loquats, pears, plums, quince, and strawberries.

Table 1 The genera of Rosaceae

Acaena (acaena)
Adenostoma (chamise)
Agrimonia (agrimony)
Alchemilla (lady's mantle)
Amelanchier (serviceberry)
Amelasorbus (amelasorbus)
Aphanes (parsley piert)
Argentina (silverweed)
Aruncus (aruncus)
Cercocarus (mountain mahogany)
Chaenmeles (flowering quince)
Chamebatia (mountain misery)
Chamaebatiaria (fernbush)
Chamaerhodos (little rose)
Coleogyne (coleogyne)
Comarum (comarum)
Cotoneaster (cotoneaster)
Crataegus (hawthorn)
Cydonia (cydonia)
Dalibarda (dalibarda)
Dasiphora (shrubby cinquefoil)
Dryas (mountain avens)
Duchesnea (duchesnea)
Eriobotrya (loquat)
Exochorda (pearlbrush)
Fallugia (Apache plume)
Filipendula (queen)
Fragaria (strawberry)
Geum (avens)
Heteromeles (toyon)
Holodiscus (ocean spray)
Horkelia (horkelia)
Horkeliella (false horkelia)
Ivesia (mousetail)
Kelseya (kelseya)
Kerria (kerria)
Luetkea (luetkea)
Lyonothamnus (lyononthmnus)
Malacomeles (false serviceberry)
Malus (apple)
Mespilus (mespilus)
Neviusia (snow wreath)
Oemleria (oemleria)
Osteomeles (osteomeles)
Peraphyllum (peraphyllum)
Petrophyton (rock spiraea)
Photinia (chokeberry)
Physocarpus (ninebark)
Porteranthus (porteranthus)
Potentilla (cinquefoil)
Prunus (plum)
Pseudocydonia (Chinese-quince)

Purshia (bitterbrush)
Pyracantha (firethorn)
Pyrus (pear)
Quillaja (quillaja)
Rhodotypos (rhodotypos)
Rosa (rose)
Rubus (blackberry)
Sanguisorba (burnet)
Sibbaldia (sibbaldia)
Sibbaldiopsis (sibbaldiopsis)
Sorbaria (false spiraea)
Sorbus (mountain ash)
Spiraea (spiraea)
Stephanandra (stephanandra)
Vauquelinia (rosewood)
Waldsteinia (barren strawberry)

Crataegus species

Crataegus species (hawthorn, maybush, whitethorn) contain a variety of flavonoids, including rhamnosides, schaftosides, and spiraeosides. They have a positive inotropic effect on the heart by a mechanism different from that of cardiac glycosides, catecholamines, and the phosphodiesterase type III inhibitors (1) and are effective in mild heart failure (2).

Adverse effects

The main adverse effects of *Crataegus* are dizziness and vertigo (3).

It has been suggested that the flavonoids in *Crataegus* inhibit P glycoprotein function and might therefore interact with drugs that are substrates of P glycoprotein, such as digoxin. However, in a randomized, crossover trial in eight healthy volunteers *Crataegus* special extract WS 1442 (hawthorn leaves with flowers) had no effect on the pharmacokinetics of digoxin 0.25 mg/day for 10 days (4).

Prunus species

The raw pits or kernels of various *Prunus* species (such as apricot, bitter almond, choke cherry and peach) are promoted as health foods. However, they contain the cyanogenic glycoside, amygdalin, which yields hydrogen cyanide after ingestion.

During the late 1950s, and for about 20 years afterwards, laetrile (l-mandelonitrile-beta-glucuronoside), which is related to amygdalin, was touted as a cure for cancer (http://www.quackwatch.org/01QuackeryRelatedTopics/Cancer/laetrile.html). However, in 1982 Arnold Relman, then Editor of the New England Journal of Medicine, pronounced that "Laetrile has had its day in court. The evidence, beyond reasonable doubt, is that it doesn't benefit patients with advanced cancer, and there is no reason to believe that it would be any more effective in the earlier stages of the disease. . . . The time has come to close the books." (5). Nevertheless, it is being so touted again today.

Adverse effects

When ingested in sufficient quantities *Prunus* species cause cyanide poisoning. For instance, a total consumption of about 48 apricot kernels produced forceful vomiting, headache, flushing, heavy sweating, dizziness, and faintness before vomiting was induced in the emergency room, whereafter the symptoms rapidly subsided. In another case accidental poisoning was fatal (6).

- A 67-year-old woman with lymphoma presented with a neuromyopathy following treatment with laetrile. She had high blood and urinary thiocyanate and cyanide concentrations (7). Sural nerve biopsy specimen showed a mixed pattern of demyelination and axonal degeneration, the latter being prominent. Gastrocnemius muscle biopsy specimen showed a mixed pattern of denervation and myopathy with type II atrophy.

Besides the risk that a large dose can lead to acute cyanide poisoning, there is also the question whether continued ingestion of cyanogenic pits or kernels can cause chronic intoxication.

An outbreak of congenital malformations in swine has been retrospectively associated with the eating of the fruit, leaves, and bark of *Prunus serotina* (wild black cherry) (8). Prospective experimental evidence of teratogenicity was not available at that time, but amygdalin was later reported to be teratogenic in hamsters (9).

Rotavirus vaccine

See also Vaccines

General Information

Rotavirus is the most common cause of severe gastroenteritis in infants and young children aged under 5 years in the USA, resulting in approximately 500 000 physician visits, 50 000 hospitalizations, and 20 deaths each year. Worldwide, rotavirus is a major cause of childhood death, accounting for an estimated 600 000 deaths annually among children aged under 5 years. Rotavirus vaccines offer the opportunity to reduce substantially the occurrence of this disease.

Various oral rotavirus vaccines (live attenuated rotavirus vaccines, including rhesus rotavirus and bovine rotavirus strains; serotype 1 bovine-human rotavirus reassortant vaccine; and both rhesus rotavirus monovalent and tetravalent reassortant vaccines) have been evaluated in clinical trials (SEDA-21, 292).

On August 31, 1998, a tetravalent rhesus-based rotavirus vaccine (RRV-TV) (Rotashield) was licensed in the USA. The Advisory Committee on Immunization Practices (ACIP), the American Academy of Pediatrics, and the American Academy of Family Physicians all recommended routine use of the vaccine in healthy infants. Rotashield was the first rotavirus vaccine to be licensed.

Observational studies

The safety and immunogenicity of two human-bovine reassortant rotavirus candidate vaccines have been evaluated in infants, children, and adults (1). One candidate vaccine contained a single human rotavirus gene, while the other candidate vaccine contained two human rotavirus genes. The remaining genes for both vaccines were derived from bovine rotavirus strain UK. Each of these vaccines was well tolerated and immunogenic. This was also the case in the important group of infants under 6 months of age after a single dose of vaccine.

Placebo-controlled studies

The safety, immunogenicity, and efficacy of a live oral human rotavirus vaccine 89–12 has been assessed in 213 US infants in a randomized, placebo-controlled, double-blind, multicenter trial (2). The infants received two doses of vaccine or placebo and were followed up through one rotavirus season. There was an immune response to vaccine in 94.4% of vaccinees, and vaccine efficacy was 89%. Adverse reactions were mild. Low-grade fever after the first dose was the only adverse effect that was significantly more common with the vaccine than with placebo.

Organs and Systems

Gastrointestinal

Natural rotavirus itself is a causative agent for intussusception (3). In rotavirus disease in Japan, hyperplasia of the intestinal lymphoid tissue is a common pathological finding in necropsy cases, and is identical with that observed in patients who receive the tetravalent rhesus-based rotavirus vaccine.

During the period from 1 September 1998 to 7 July 1999, 15 cases of intussusception among infants who had received rotavirus vaccine were reported to the Vaccine Adverse Event Reporting System (VAERS). Of the 15 infants, 13 (87%) had developed intussusception after the first dose of the three-dose RRV-TV series, and 12 had developed symptoms within 1 week of receiving any dose of RRV-TV. Thirteen of the 15 had received other vaccines concurrently. Intussusception was confirmed radiographically in all 15 patients. Eight infants required surgical reduction, and one required resection of 18 cm of distal ileum and proximal colon. Histopathological examination of the distal ileum showed lymphoid hyperplasia and ischemic necrosis. All the infants recovered. The dates of onset ranged from 21 November 1998 to 24 June 1999. The median age of patients was 3 (range: 2–11) months. Ten were boys. Topographically the cases were scattered, being reported from seven states. Of the 15 cases reported to VAERS, 14 were spontaneous reports and one was identified through active postlicensing surveillance.

The rate of hospitalization for intussusception among infants aged less than 12 months during 1991–97 (before RRV-TV licensure) was 51 per 100 000 infant-years in New York. The manufacturer had distributed about 1.8 million doses of RRV-TV as of June 1 1999, and estimated that 1.5 million doses (83%) had been administered. Given this information, 14–16 intussusception cases among infants would be expected by chance alone during the week after the administration of any dose of RRV-TV. Fourteen of the 15 case-patients were vaccinated before June 1 1999, and of those, 11 developed intussusception within 1 week of receiving RRV-TV.

In prelicensure studies of Rotashield, five cases of intussusception had occurred among 10 054 vaccine recipients and one of 4633 controls, a difference that was not statistically significant. Three of the five cases among vaccinated children occurred within 6–7 days of receiving rotavirus vaccine. On the basis of these data, intussusception was included in the package insert as a potential adverse reaction, and the ACIP recommended postlicensure surveillance for this adverse event following vaccination. In addition, because of concerns about the findings in prelicensing trials, VAERS data were analysed early in the postlicensure period (4).

Although the number of reported intussusception cases occurring within 1 week of receiving any dose of vaccine is in the expected range, it must be borne in mind that reporting of suspected adverse events to VAERS is far from complete, and the actual number of intussusception cases occurring among RRV-TV recipients may be substantially greater than that reported. The data available to date suggest but do not establish a causal association between receipt of rotavirus vaccine and intussusception. However, based on these results, use of the vaccine was suspended in July 1999, pending a review of the data by the Advisory Committee on Immunization Practice (ACIP) (5). In further studies more cases of intussusception (including two deaths) were associated with the administration of Rotashield. Based on the results of an expedited review of the scientific data (indicating a strong

© 2006 Elsevier B.V. All rights reserved.

association between Rotashield and intussusception) presented to the ACIP, it was recommended in 22 October 1999 that Rotashield should no longer be used. The recommendation was made in cooperation with the FDA, NIH, and Public Health Service officials, along with the manufacturer, Wyeth-Lederle (6). In late 1999 the CDC recommended postponing administration of RRV-TV to children scheduled to receive the vaccine before November 1999, including those who had already have begun the RRV-TV series (4).

The epidemiology of hospitalizations and deaths associated with intussusception among US infants has been described (7). Such data could be useful for further clinical trials with newly developed rotavirus vaccines.

Further studies have confirmed that there is an increased risk of intussusception associated with the use of rhesus rotavirus tetravalent vaccine (RRV-TV). The association has been assessed in infants in 19 states of the USA (8). Each infant hospitalized with intussusception between 1 November 1998 and 30 June 1999 was matched according to age with four healthy controls who had been born at the same hospital. The authors estimated that one case of intussusception would occur for every 4670–9474 infants immunized.

In a retrospective cohort study in 10 managed care organizations there was an increased risk of intussusception in immunized children (9). The risk was greatest at 3–7 days after the first dose of RRV-TV.

In an editorial in the journal Emergency and Office Pediatrics the critical role of physicians in the early detection of adverse events was stressed. Despite the demands of busy clinical practice, all physicians are obliged to be alert to unusual circumstances and to seek answers when unexpected findings—especially related to new drugs, vaccines, or procedures—seem to be more than just coincidence. It is incumbent on them to report these findings and to learn if their experience can be confirmed by colleagues (10).

Current prelicensure trials of newly developed rotavirus vaccines are taking into consideration the experiences gained during the licensure process of Rotashield. Phase 3 clinical trials have included over 10 000 volunteers in order to exclude the potential risk of intussusception.

Roxithromycin

See also Macrolide antibiotics

General Information

Roxithromycin is a macrolide antibiotic with actions and uses similar to those of erythromycin.

Observational studies

In 2917 adults, adverse effects of roxithromycin occurred in 4.1% at a dosage of 150 mg/day (1). Nausea (1.3%), abdominal pain (1.2%), and diarrhea (0.8%) were the most frequently reported events, whereas rash, vomiting, headache, dizziness, pruritus, urticaria, and constipation were reported only rarely. Treatment had to be withdrawn in 0.9% of the patients because of adverse effects.

In an uncontrolled study in 24 HIV-infected patients, roxithromycin (300 mg bd for 4 weeks) was effective against cryptosporidial diarrhea (2). The most limiting adverse effects were abdominal pain (two patients), raised hepatic enzymes (two patients), and abdominal pain with raised hepatic enzymes (one patient). Minor symptoms occurred in nine patients.

In 304 infants and children under 14 years adverse effects occurred in 6.9% (3). Treatment was withdrawn in 10 children (two with vomiting, two diarrhea, and six rashes).

In 480 elderly patients (over 65 years), there were adverse events in 3.1% and treatment was withdrawn in 1.9%. The gastrointestinal tract was most often affected, whereas laboratory changes (increases in bilirubin, aspartate transaminase, alanine transaminase, and alkaline phosphatase) were seen in under 0.7%.

Organs and Systems

Cardiovascular

- Torsade de pointes has been reported in an 83-year-old man who developed severe prolongation of the QT interval after taking roxithromycin 300 mg/day for 4 days (4).

Respiratory

Eosinophilic pneumonia of acute onset has been attributed to roxithromycin (5).

- A 21-year-old woman developed a fever of 39°C, a generalized pruritic macular rash, odynophagia, and intense weakness, in conjunction with respiratory difficulties 8 days after starting to take roxithromycin 150 mg bd. Her leukocyte count was 15.4×10^9/l with 9.8% eosinophils and an erythrocyte sedimentation rate of 32 mm/hour. Peripheral infiltrates were evident on the chest X-ray and CT scan, with multiple areas of consolidation and an air bronchogram, mainly peripherally distributed. Bronchoalveolar lavage showed 50% eosinophils. She improved with glucocorticoids and 6 months later was free of respiratory symptoms; a chest X-ray was normal.

Hematologic

In one study lymphopenia or eosinophilia were observed in two of 37 patients (6). However, this finding could not be confirmed in other studies.

Gastrointestinal

During long-term use of roxithromycin 300 mg/day for 2–66 months in nine patients with chronic diffuse sclerosing osteomyelitis of the mandible, diarrhea and stomach discomfort occurred in one case and liver dysfunction in another (7).

Liver

- Cholestatic and hepatocellular liver damage occurred in a previously healthy 20-year-old woman after she took roxithromycin 150 mg bd for 4 days (8).
- Hepatic failure occurred in a previously healthy 5-year-old boy after he was given roxithromycin 50 mg bd for 5 days (9). He developed a non-pruritic, non-urticarial, erythematous, maculopapular, generalized rash, and occasional vomiting. Three days later he became jaundiced, and after 8 days underwent liver transplantation.

Skin

Allergic dermatitis with characteristic distribution pattern called "baboon syndrome" has been reported (10).

- A 58-year-old man developed a pruritic skin eruption after he had taken roxithromycin 300 mg/day for 3 days. Large erythematous plaques covered his buttocks. Roxithromycin was immediately withdrawn and following treatment with oral antihistamines and topical corticosteroids the rash resolved within a few days.

Urticarial rashes have been attributed to roxithromycin.

- Roxithromycin-induced generalized urticaria and tachycardia with a positive prick test and a cross-reaction to erythromycin and clarithromycin has been reported in a 31-year-old woman (11).
- Angioedema and urticaria occurred in a 22-year-old woman a few hours after a second dose of roxithromycin 150 mg for a sore throat (12). The lesions subsided within 12 hours of drug withdrawal and there was no relapse after 3 months of follow-up. A skin prick test was positive for roxithromycin (1 mg/ml) and negative for erythromycin and clarithromycin in the same concentrations.

Immunologic

Roxithromycin had an immunomodulatory action on peripheral blood mononuclear cells in patients with psoriasis (13). The anti-inflammatory activity of roxithromycin is due to reduced production of proinflammatory mediators, cytokines, and co-stimulatory molecules, as has been shown in animal studies (14).

Drug–Drug Interactions

Antacids

Roxithromycin did not interact with antacids containing hydroxides of aluminium and magnesium (1).

Carbamazepine

Roxithromycin did not alter the pharmacokinetics of carbamazepine (15) or interact with warfarin, ranitidine, or antacids containing hydroxides of aluminium and magnesium (1).

Oral contraceptives

Plasma concentrations of oral contraceptive steroids were unchanged when roxithromycin was co-administered (16).

Ranitidine

Roxithromycin did not interact with ranitidine (1).

Statins

In an open, randomized, crossover study in 12 healthy volunteers, roxithromycin did not alter the pharmacokinetics of lovastatin in such a way that dosage adjustment of lovastatin should be necessary during co-administration (17).

- Myopathy occurred in a 73-year-old woman taking simvastatin 80 mg/day and gemfibrozil 600 mg bd 4 days after she started to take roxithromycin 300 mg/day (18).

Theophylline

Roxithromycin altered the pharmacokinetics of theophylline, mainly increasing the C_{max}, prolonging the half-life, and increasing the renal clearance (15). However, while these changes were statistically significant, they were considered clinically irrelevant. There was no effect of roxithromycin on trough concentrations of theophylline.

© 2006 Elsevier B.V. All rights reserved.

Warfarin

Roxithromycin did not interact with warfarin (1).

General Information

The genera in the family of Rubiaceae (Table 1) include cinchona and coffee.

Table 1 The genera of Rubiaceae

Anthocephalus (anthocephalus)
Antirhea (quina)
Asperula (woodruff)
Bobea (ahakea)
Bouvardia (bouvardia)
Calycophyllum (calycophyllum)
Canthium (canthium)
Casasia (casasia)
Catesbaea (lilythorn)
Cephaelis (cephaelis)
Cephalanthus (buttonbush)
Chiococca (milkberry)
Chione (chione)
Cinchona (cinchona)
Coccocypselum (coccocypselum)
Coffea (coffee)
Coprosma (mirrorplant)
Crucianella (crucianella)
Cruciata (bedstraw)
Crusea (mountain saucerflower)
Diodia (buttonweed)
Erithalis (blacktorch)
Ernodea (ernodea)
Exostema (exostema)
Faramea (false coffee)
Galium (bedstraw)
Gardenia (gardenia)
Genipa (genipa)
Geophila (geophila)
Gonzalagunia (gonzalagunia)
Guettarda (guettarda)
Hamelia (hamelia)
Hedyotis (starviolet)
Hillia (hillia)
Hintonina
Houstonia (bluet)
Ixora (ixora)
Kelloggia (kelloggia)
Lasianthus (lasianthus)
Lucya (lucya)
Machaonia (machaonia)
Mitchella (mitchella)
Mitracarpus (girdlepod)
Morinda (morinda)
Neolaugeria (neolaugeria)
Neolamarckia (neolamarckia)
Neonauclea
Nertera (nertera)
Oldenlandia (oldenlandia)
Oldenlandiopsis (creeping-bluet)
Paederia (sewer vine)
Palicourea (cappel)
Pentas (pentas)

Table 1 Continued

Pentodon (pentodon)
Phialanthus (phialanthus)
Pinckneya (pinckneya)
Psychotria (wild coffee)
Randia (indigoberry)
Richardia (Mexican clover)
Rondeletia (cordobancillo)
Rubia (rubia)
Sabicea (woodvine)
Schradera (schradera)
Scolosanthus (scolosanthus)
Serissa (snowrose)
Sherardia (sherardia)
Spermacoce (false buttonweed)
Strumpfia (strumpfia)
Timonius
Uncaria (uncaria)
Vangueria (vangueria)

Asperula odorata

Asperula odorata (sweet woodruff) is rich in coumarins.

Cephaelis ipecacuanha

The root of *Cephaelis ipecacuanha*, also known as *Psychotria ipecacuanha*, is the source of ipecacuanha, which contains the emetic alkaloids emetine and cephaeline. Ipecacuanha is covered in a separate monograph.

Hintonia latiflora

Hintonia latiflora (copalchi bark) has been advocated as a hypoglycemic agent, an effect that has been attributed to the neoflavonoid coutareagenin (1). Its use has been associated with liver toxicity but a causal relation could not be established (2).

Morinda citrifolia

Morinda citrifolia (noni) is one of the most important traditional Polynesian medicinal plants, which has a large range of therapeutic claims, including antibacterial, antiviral, antifungal, antihelminthic, antitumor, analgesic, hypotensive, anti-inflammatory, and immune enhancing effects (3,4).

Adverse effects

The juice of *M. citrifolia* has been reported to cause hyperkalemia (5).

- A man with chronic renal insufficiency who followed dietary restriction of potassium developed a raised serum potassium concentration (5.8 mmol/l). He insisted that he had followed his dietary regimen as usual, except for taking noni juice, purchased from a health food store. He was treated with sodium polystyrene sulfonate and told to stop taking noni juice. At the next check-up his potassium was still raised; he said that he would never stop taking noni juice and that his physicians did not understand its healing power.

The potassium concentration in noni juice samples was 56 mmol/l.

Rubia tinctorum

The use of herbal medicines prepared from the root of *Rubia tinctorum* (madder) is no longer permitted in Germany. Root extracts have shown genotoxic effects in several test systems, which are attributed to the presence of the anthraquinone derivative lucidin. One of the other main components, alizarin primeveroside, is transformed into 1-hydroxyanthraquinone when given orally to the rat, in which this metabolite has carcinogenic activity (6).

Uncaria tomentosa

Uncaria tomentosa (cat's claw), an herb from the highlands of the Peruvian Amazon, contains the spiroindole alkaloids isopteropodine and rynchophylline; it has immunomodulatory properties and has been used to treat arthritis and inflammatory bowel disease (7).

Adverse effects

- A 59-year-old woman with mantle-cell lymphoma and no hepatic involvement took a range of unconventional medicines (8). During a routine check-up she had raised liver enzymes, and self-medication with cat's claw was deemed the most likely cause. Cat's claw was withdrawn and her liver tests normalized within 60 days.

Rutaceae

See also Herbal medicines

General Information

The genera in the family of Rutaceae (Table 1) include citrus fruits (citrons, oranges, grapefruit, lemons, limes, tangerines, etc.), angostura, kumquat, pilocarpus, and rue.

Agathosma betulina

Agathosma betulina (buchu) contains diosmin (venosmine), and a synthetic form of diosmin is also available. It has been used to treat the pain and bleeding of hemorrhoids (1).

Adverse effects

Diosmin can rarely cause nausea and epigastric discomfort (SEDA-3, 181) and somnolence (2).

In 12 volunteers, diosmin 500 mg/day for 9 days significantly increased the AUC and C_{max} of metronidazole 800 mg without a change in t_{max}; this effect was attributed to inhibition of CYP3A4 (3).

Zanthoxylum (prickly ash)

Citrus auranticum

Volatile plant oils (often incorrectly termed "essential oils") are used in aromatherapy and are usually applied by gentle massage. The oil of *C. auranticum* (bergamot) is often used in this way. It has photosensitive and melanogenic properties and is potentially phototoxic and photomutagenic.

Adverse effects

- Two patients had localized and disseminated bullous phototoxic skin reactions 48–72 hours after exposure to bergamot aromatherapy and ultraviolet light (4). One developed bullous skin lesions after exposure to aerosolized aromatherapy oil in a sauna.

Citrus paradisi (grapefruit)

Grapefruit juice is unusual in that it is not used therapeutically but can cause many drug interactions, since an unidentified constituent of grapefruit inhibits CYP3A4. The drugs most commonly involved are dihydropyridine calcium channel blockers and HMG-CoA reductase inhibitors (5).

Both whole grapefruit and grapefruit juice have been implicated, and the wording used on a warning label in New Zealand to alert patients to potential drug interactions with grapefruit is "Do not take grapefruit or grapefruit juice while being treated with this medicine" (6). Health Canada has advised the public not to take grapefruit or its juice (fresh or frozen) with certain drugs (7). Health Canada has also issued several communication documents to remind health professionals of possible interactions of grapefruit with therapeutic drugs and has worked with drug manufacturers whose products are adversely affected by grapefruit to ensure that the relevant information is printed on the product label.

Of the several hundred chemical entities in grapefruit juice (8), psoralens, mainly 6,7-dihydroxybergamottin, are thought to be the components in grapefruit that are responsible for these interactions, although the flavonoid naringenin, which was originally suspected, cannot be excluded and may have a minor role (9).

The ability of grapefruit to increase the plasma concentrations of some drugs was accidentally discovered when grapefruit juice was used as a blinding agent in a drug interaction study of felodipine and alcohol (10). It was noticed that plasma concentrations of felodipine were much higher when the drug was taken with grapefruit juice than those previously reported for the dose of drug administered. In another study, (11) concurrent administration of grapefruit juice and felodipine increased the AUC, causing increased heart rate, and reduced diastolic blood pressure. Similarly, parallel administration of the juice with midazolam altered psychometric performance tests, while with nisoldipine or nitrendipine there was an increase in heart rate.

Table 2 lists some drugs whose effects are altered by grapefruit juice.

© 2006 Elsevier B.V. All rights reserved.

Table 2 Drug–grapefruit juice interactions

Drug	Effect of grapefruit	Reference
Benzodiazepines	Pronounced nervous system effects	(12)
Ciclosporin	Inhibits metabolism and increases blood concentration	(13,14)
Coumarins	Interferes with the analysis of coumarins	(15)
Diazepam	Increases concentration	(16)
Felodipine	Enhances the effects and can cause increased blood pressure and heart rate, headache, flushing, and light-headedness	(17)
Lovastatin	Greatly increases serum concentration	(18)
Nifedipine	Increases plasma concentration	(19)
Nisoldipine	Increases plasma concentration	(20)
Quinidine	Delays absorption and maximal effect on QT interval	(21)
Saquinavir	Increases AUC and C_{max}	(9)
Terfenadine	Increases systemic availability, with cardiotoxicity at higher doses of grapefruit juice concentration	(22)
Triazolam	Increases plasma concentrations	(23)

Dictamnus dasycarpus

Dictamnus dasycarpus (densefruit pittany) contains rutaevin, terpene glycosides (dasycarpusides), sesquiterpene glycosides (dictamnosides), and phenolic glycosides. *D. dasycarpus* is a common ingredient of the complex traditional Chinese herbal medicines that have been associated with liver damage; however, a causative role remains to be established (24–27).

Adverse effects

The UK hepatologists have described two cases of severe liver damage, one fatal, attributed to Chinese herbal mixtures for minor complaints (28). *D. dasycarpus* was implicated in one. There have been other reports of hepatotoxicity due to *D. dasycarpus* (28).

Dermatitis has been attributed to *D. dasycarpus* (29).

The root bark of *D. dasycarpus* is mutagenic in bacteria, due not to dietary flavonoids, but to the furoquinoline alkaloids dictamnine and gamma-fagarine. The clinical relevance of this finding remains to be established.

Pilocarpus species

The leaves of *Pilocarpus* species, including *Pilocarpus jaborandi* (jaborandi) and *Pilocarpus racemosus* (aceitillo), contain pilocarpine or isopilocarpine as major alkaloids as well as a variety of minor alkaloids. Pilocarpine (see separate monograph) is an agonist at acetylcholine receptors, which enhances salivary flow, sweating, and gastrointestinal motility. It can interfere with asthma therapy and the effect of anticholinergic drugs.

Ruta graveolens

Ruta graveolens (rue) contains acridone alkaloids, such as furacridone and gravacridone, quinoline alkaloids, such as graveoline and graveolinine, the furanoquinoline dictamnine, coumarins, such as gravelliferone, isorutarin, rutacultin, rutaretin, and suberenone, and the furanocoumarins 5-methoxypsoralen (bergapten) and 8-methoxypsoralen (xanthotoxine). It has been used as an abortifacient and emmenagogue (30).

Adverse effects

The essential oil of rue can cause contact dermatitis and phototoxic reactions (31,32) and severe hepatic and renal toxicity. Therapeutic doses can lead to depression, sleep disorders, fatigue, dizziness, and cramps. The sap from fresh leaves can produce painful gastrointestinal irritation, fainting, sleepiness, a weak pulse, abortion, a swollen tongue, and a cool skin.

Salbutamol

See also Beta$_2$-adrenoceptor agonists

General Information

Salbutamol (albuterol) is a beta$_2$-adrenoceptor agonist used to treat asthma. It is available in various formulations:

- oral formulations (tablets of 2 and 4 mg, a modified-release tablet of 4 or 8 mg, and a syrup 5 mg/ml);
- a multidose pressurized aerosol, which delivers 100 micrograms per puff;
- dry powder form ("Rotacaps" 200 micrograms per capsule, "Accuhaler" 200 micrograms, "Turbuhaler" 100 or 200 micrograms, "Ventodisk" 200 or 400 micrograms per delivered dose);
- individual doses for nebulization ("nebulas") containing 2.5 ml of either 1 or 2 mg/ml salbutamol;
- a multidose vial of respirator solution containing 30 ml (concentration 5 mg/ml);
- formulations for injection, 50 micrograms/ml (5 ml) and 50 micrograms/ml (1 ml), and an intravenous infusion formulation of 1 mg/ml (5 ml).

All of these formulations are used in the treatment of asthma and the intravenous infusion is also used to manage premature labor.

Since salbutamol and its congeners are not entirely selective in their beta$_2$-stimulating action, they retain some stimulant effects on the heart, central nervous system, and carbohydrate and fat metabolism; these only become troublesome with relative overdosage or in particularly susceptible subjects. Adverse effects occur through stimulation of extra-pulmonary beta$_2$-adrenoceptors; they consist of:

- vasodilatation with reflex tachycardia;
- at high doses: direct cardiac stimulation;
- tremor;
- increased blood glucose concentration;
- a fall in serum potassium concentration.

The adverse effects of salbutamol have been reviewed (1).

Organs and Systems

Cardiovascular

Peripheral vasodilatation and palpitation have been reported in patients using salbutamol. These effects usually appear with rapid administration of high doses. Inhalation of 0.4 mg did not affect the heart rate, whereas inhalation of 5 mg raised it by 15/minute (2). Infusion of salbutamol at 0.025 mg/minute had a similar effect. Slight tachycardia can result in a mild rise in blood pressure, whereas at higher doses vasodilatation was more marked and the blood pressure fell. Infusion at 0.125 mg/minute reduced blood pressure by 30 mmHg. Salbutamol 10 puffs, administered from a pressurized aerosol using a spacer, produced significant bronchodilatation without adverse effects in mechanically ventilated patients. Heart rate rose significantly after 28 puffs (SEDA-21, 182).

Patients with severe hypoxemia and low serum potassium have an increased risk of developing extra beats and cardiac dysrhythmias (SEDA-2, 121).

Salbutamol causes an increase in the activity of the MB isoenzyme of creatine kinase, which has been interpreted as meaning that it might be cardiotoxic (3).

The systemic vascular changes produced by the combination of hypoxia and inhaled salbutamol in eight healthy men with mild asthma in a randomized, double-blind, placebo-controlled, crossover trial have been briefly reported (4). Forearm blood flow was measured non-invasively to obtain a measure of forearm vascular resistance (equating with systemic vascular resistance) after inhalation of placebo or salbutamol 800 micrograms under normoxic or hypoxic conditions. Both salbutamol alone and hypoxia alone produced small non-significant falls in forearm vascular resistance, but the combination of salbutamol and hypoxia resulted in a dramatic fall (30%). The authors pointed out that this fall in forearm vascular resistance was equivalent to the effects of glyceryl trinitrate 0.6–0.9 mg sublingually or felodipine 10 mg orally. This study emphasizes the marked cardiovascular changes that can occur with even small doses of salbutamol in people with mild asthma when hypoxia is present and confirms the importance of supplementary oxygen in these patients.

Intravenous and intracoronary salbutamol (10–30 and 1–10 micrograms/minute respectively) and intravenous isoprenaline (1–5 micrograms/minute), a mixed beta$_1$/beta$_2$-adrenoceptor agonist, were infused in 85 patients with coronary artery disease and 22 healthy controls during fixed atrial pacing (5). Both salbutamol and isoprenaline produced large increases in QT dispersion (QT_{onset}, QT_{peak}, and QT_{end}), more pronouncedly in patients with coronary artery disease. Dispersion of the QT interval is thought to be a surrogate marker for cardiac dysrhythmia (6). The authors concluded that beta$_2$-adrenoceptors mediate important electrophysiological effects in human ventricular myocardium and can trigger dysrhythmias in susceptible patients.

In a blind, randomized study, 29 children aged under 2 years, with moderate to severe acute exacerbations of hyper-reactive airways disease, were treated with either a standard dose of nebulized salbutamol (0.15 mg/kg) or a low dose of nebulized salbutamol (0.075 mg/kg) plus nebulized ipratropium bromide 250 micrograms (7). Standard and low-dose nebulized salbutamol was given three times at intervals of 20 minutes and nebulized ipratropium bromide was given once. Clinical improvement, measured as oxygen saturation and respiratory distress, was similar in both groups. QT dispersion was measured at baseline and after treatment and was significantly increased only by the standard dose of nebulized salbutamol.

Respiratory

Although salbutamol generally improves respiratory activity in asthma, arterial hypoxemia can be aggravated if it is used in excess or if parenchymal lung infection is present (8). In patients with bronchiectasis, salbutamol may aggravate hemoptysis (SEDA-9, 125). A feeling of "thick neck," chest heaviness, erythema, and edema of

© 2006 Elsevier B.V. All rights reserved.

the face experienced in one reported case after the third dose could be reproduced by re-administration of the drug (SEDA-10, 116). Pulmonary edema can occur, even hours after discontinuation of $beta_2$-adrenoceptor stimulants (SEDA-13, 110).

Paradoxical bronchoconstriction has rarely been reported in patients with asthma after the inhalation of $beta_2$-agonists (9).

- A 22-year-old woman with mild asthma developed severe laryngospasm and bronchoconstriction after a fourth and subsequent doses of nebulized salbutamol, given during an acute episode of asthma. Her symptoms responded to adrenaline, but recurred after supervised rechallenge with nebulized orciprenaline (metaproterenol) sulfate. Indirect laryngoscopy excluded vocal cord dysfunction, suggesting that her symptoms of severe wheeze, respiratory distress, and hypoxia were due to bronchoconstriction.

Nervous system

Fine muscle tremor is common, especially when salbutamol is given orally or by injection. With nebulized salbutamol (2.5 or 7.5 mg) tremor was experienced by 14% of patients, and occurred more commonly with the higher doses (SEDA-21, 182). Shaking and nervousness were pronounced enough for 84% of patients taking oral salbutamol 5 mg tds to guess their treatment status correctly (SEDA-21, 180). At high doses agitation has been reported (SED-13, 362); in susceptible persons, hallucinations can develop, particularly in children, but also very occasionally in adults (10). A few patients experience headache.

The often reported observation by parents of asthmatic children that salbutamol causes hyperactivity has been investigated in 19 children before and after the inhalation of 5 ml of a nebulized solution (isotonic saline or salbutamol 5 mg); there was no statistically significant difference in activity (11). The authors hypothesized that the supposed effect on the children's activity might be dose-related or might reflect a propellant effect rather than being a consequence of salbutamol itself.

Sensory systems

Salbutamol has been applied to the eye for glaucoma, but often produces local irritation (12).

Metabolism

With inhaled salbutamol there is as a rule no significant effect on carbohydrate metabolism, but there were significant rises in blood glucose and insulin when intravenous salbutamol infusions were given to healthy pregnant women at term. The rise in blood glucose was significantly greater in pregnant women who were diabetic (SED-13, 363). Oral salbutamol 8 mg bd given for 14 days had no effect on glucose tolerance, but total cholesterol fell significantly by 9%; low-density lipoprotein cholesterol fell by 15%, and HDL increased by 10% (SEDA-21, 182).

Transient lactic acidosis/lactatemia has been reported as an adverse effect of inhaled salbutamol. In five patients who received 5 mg salbutamol by inhalation serum lactate concentrations were 3.2–8.0 mmol/l and arterial blood pH values 7.34–7.43; after 24 hours serum lactate concentrations returned to normal without specific treatment (13). In two other cases, high-dose salbutamol caused lactic acidosis, contributing to respiratory failure in one patient and complicating the assessment and management of acute severe asthma in the other (14). Respiratory compensation for this primary metabolic acidosis, characterized by increased respiratory rate and effort, may be mistaken for increased respiratory distress due to asthma. Lactic acidosis in acute asthma can therefore lead to problems in asthma management, including unwarranted intensification of $beta_2$-adrenoceptor agonist therapy and the initiation of premature or unnecessary mechanical ventilation.

Electrolyte balance

High doses of salbutamol, both intravenously and by nebulizer, can cause hypokalemia (15–17). This occurs by at least two mechanisms. First, $beta_2$-adrenoceptor agonists stimulate the Na/K pump in cell membranes, increasing the influx of potassium (18). Secondly, plasma renin activity and angiotensin II concentrations rise; angiotensin causes release of aldosterone, which is potassium-wasting in the kidney. In eight patients with mild asthma, nebulized salbutamol caused falls in serum potassium concentration from 4.4 mmol/l by a maximum of 0.85 mmol/l 45 minutes after 5 mg and by 1.16 mmol/l after 10 mg (SEDA-22, 189).

When three doses of nebulized salbutamol (0.15–0.3 mg/kg) were given at 30-minute intervals to 46 children with acute severe asthma, aged 10 months to 12 years, the mean potassium concentration fell marginally from 3.9 to 3.7 mmol/l. There was a fall in potassium concentration in 57% of the children and hypokalemia (potassium below 3.5 mmol/l) occurred in 39%. Hypokalemia was more likely to occur in children who had received oral salbutamol in the preceding 7 days. It was concluded that hypokalemia can occur in up to 33% of patients treated with three doses of nebulized salbutamol, particularly if they had previously taken oral salbutamol (SEDA-21, 182). Plasma concentrations of salbutamol correlate with changes in plasma potassium (19).

Musculoskeletal

The question of whether salbutamol can cause a myopathy has been discussed (20).

- A 76-year-old asthmatic woman developed increasing weakness, proximal muscle cramps, and fatigue. She had been using salbutamol spray (600 micrograms/day) and tablets (10 mg/day) for 2 years, and for 6 months had also used inhaled formoterol 24 micrograms/day. There were increases in creatine kinase (494 IU/l; reference range 0–130 IU/l), lactate dehydrogenase (350 IU/l; 0–300 IU/l), and aldolase (10 IU/l; 0–7.5 IU/l). Myopathy was confirmed electrophysiologically and histologically. The three medications were withdrawn and 2 days later her condition began to improve; the muscle pain and weakness disappeared within 3 weeks.

The authors concluded that $beta_2$-adrenoceptor agonist activity had been responsible for the deleterious muscle effects and they proposed that $beta_2$-adrenoceptor

© 2006 Elsevier B.V. All rights reserved.

agonists should be added to the list of drugs that can cause myopathies. However, the exact effects of beta$_2$-adrenoceptor agonists on human skeletal muscle are not clear. They have also been reported to increase muscle strength and have been used in patients with muscle weakness, including spinal muscular atrophy (21).

- A 47-year-old man presented with severe myalgia and a raised creatine kinase MM isoenzyme (from skeletal muscle) while taking salbutamol from a multidose pressurized inhaler (SEDA-21, 182). The MM creatine kinase activity returned to normal when he stopped salbutamol and rested. When salbutamol was taken by inhaler or orally, the enzyme activity rose. When salbutamol was combined with exercise, even higher concentrations of creatine kinase resulted. A muscle biopsy specimen was consistent with a myopathy.

Immunologic

Hypersusceptibility reactions to salbutamol are extremely rare, but one well-documented allergic reaction has been described (SEDA-13, 109).

Long-Term Effects

Tumorigenicity

Tumor-inducing effects have not been reported in man. Chronic administration to rats produces mesovarian leiomyomas, a form of tumor not known in human subjects. The findings might reflect a species-specific consequence of prolonged beta$_2$-adrenoceptor stimulation of the rat estrous cycle; no tumors developed in mice similarly treated (SEDA-3, 118).

Second-Generation Effects

Pregnancy

Should an abortion occur in pregnant asthmatic patients taking salbutamol, the relaxant effect on the uterine wall is likely to result in marked bleeding (22).

Fetotoxicity

When salbutamol is used to arrest premature labor, effective doses are likely to produce mild fetal tachycardia (for example an increase of 20/minute) (23). In one case, supraventricular tachycardia occurred in the fetus in the 34th week of pregnancy after the mother had been treated with salbutamol; digoxin with and without propranolol was ineffective, but amiodarone controlled the tachycardia (24).

Susceptibility Factors

Age

A modified-release formulation of salbutamol (Proventil Repitabs) 12 mg bd was well tolerated in children. There were no serious adverse events and no changes in vital signs or the electrocardiogram (SEDA-21, 182).

Continuous salbutamol nebulization is relatively safe in children with severe asthma and impending respiratory failure. No chest pain, dysrhythmias, or signs of deterioration occurred (SEDA-21, 183). In one center, children presenting to an emergency department with severe asthma were initially given nebulized salbutamol 2.5–5 mg and intravenous corticosteroids. Children who did not improve continued to receive nebulized salbutamol and in addition 0.015 mg/kg of intravenous salbutamol. There were no clinically important adverse effects, although the children who were given intravenous salbutamol developed more tremor (SEDA-22, 190).

Renal disease

In patients with renal insufficiency (creatinine clearances 7–53, average 24 ml/minute) the clearance of an intravenous dose of salbutamol was more than halved (25). The dosage of salbutamol should be reduced in patients with impaired renal function.

Other features of the patient

Because of the cardiac and metabolic effects of salbutamol, it should be given cautiously with appropriate monitoring in patients with cardiovascular disease, diabetes, and hyperthyroidism.

Drug Administration

Drug formulations

Adverse effects are generally more likely when salbutamol is given by injection. At therapeutic doses, the pressurized aerosol and dry powder inhalers produce equivalent bronchodilatation without significant adverse effects (SEDA-22, 191). Patients with severe asthma tolerate large doses of nebulized salbutamol. In severe asthma there is a reduction in early lung absorption of salbutamol after inhalation, which does not occur in mild asthma. This results in lower plasma concentrations of salbutamol and less tremor (SEDA-22, 191). This is consistent with the findings in 323 patients who attended emergency departments because of severe asthma. Initial treatment with nebulized salbutamol 7.5–10 mg or up to 3.5 mg by pressurized aerosol in 1 hour caused no serious adverse effects. Tremor was noted in about 15% of the patients. About one-third of these patients failed to achieve an adequate therapeutic response to salbutamol. The most serious adverse effect of high-dose salbutamol would be failure to intensify treatment in the non-responders, that is an error of omission (SEDA-22, 190).

The efficacy and safety of salbutamol inhaled using a dry powder inhaler has been compared with salbutamol inhaled using a pressurized metered-dose inhaler (pMDI) in a randomized, open, crossover study in 12 patients with moderate to severe asthma. A total of 1600 micrograms of salbutamol was given on two separate days in a cumulative dose fashion in increments of 100, 100, 200, 400, and 800 micrograms at 3-minute intervals. FEV_1 rose progressively with each increment. The dose–response curves showed that powdered salbutamol was 3.0 times as potent (CI = 1.8, 5.8) as salbutamol from

© 2006 Elsevier B.V. All rights reserved.

the pMDI. Systolic and diastolic blood pressures did not change. Powdered salbutamol caused a greater rise in heart rate. The maximum heart rate was seen at 25–30 minutes after the last dose on each study day. The average maximum heart rate was 95/minute (range 78–109) for the powder and 89/minute (range 76–106) for the pMDI. The relative dose potency of the powder versus the pMDI was 2.0 (CI = 1.3, 3.6) for lowering the serum potassium concentration. The lowest serum potassium concentration in an individual patient was 3.7 mmol/l after 1600 micrograms of the powder. No adverse events were reported on either study day. Four patients reported tremor. In one patient tremor was reported after each dose of powder as well as after 1600 micrograms inhaled from the pMDI. Cumulative doses of 800 and 1600 micrograms of powder caused tremor in the other three patients and two noted tremor after 1600 micrograms inhaled from the pMDI. Tremor was objectively measured and the dose–response curves showed a relative dose potency for the powder versus pMDI of 2.3 (CI = 1.5, 4.4). Thus, salbutamol powder was more potent than salbutamol pMDI for extrapulmonary effects and even more potent as a bronchodilator. It was concluded that use of the dry powder inhaler resulted in greater lung deposition of salbutamol, causing a higher concentration not only in the airways but also in the systemic circulation.

Drug additives

Additives to drug for inhalation, such as disodium edetate or benzalkonium chloride, can cause bronchoconstriction (26). This can lead to reduced therapeutic effectiveness of bronchodilators, for example salbutamol (or ipratropium). Some products do and others do not contain these additives, and an unexpected reduction in response to a bronchodilator may be the result of a change of product.

Drug overdose

After the ingestion of doses of salbutamol averaging 10 times the therapeutic oral dose, tachycardia, widened pulse pressure, agitation, nausea, and vomiting can occur (27–29).

A dose of 200 mg taken by mouth resulted in agitation, tachycardia, and peripheral vasodilatation; these effects were successfully treated with beta-blockers and benzodiazepines (SED-13, 362).

- A 28-year-old woman took an overdose of oral salbutamol (100 mg of salbutamol BP solution) (30). She developed diabetic ketoacidosis, with a serum glucose concentration of 17 mmol/l (308 mg/dl). Diabetic ketoacidosis induced by salbutamol overdose is uncommon in patients without diabetes; however, this patient had a family history of diabetes.
- A 4-year-old girl with accidental salbutamol intoxication (2.3 mg/kg) developed fever (38°C) besides the classical signs of salbutamol intoxication (31). Since she had no identifiable focus of infection the possibility of a thermogenic effect induced by increased adrenergic stimulation due to salbutamol intoxication was considered.

Drug–Drug Interactions

Beta blockers

The effects of salbutamol are antagonized by beta-blockers (32).

Corticosteroids

The risk of hyperglycemia or hypokalemia is increased if corticosteroids are given simultaneously (for example for asthma). In 24 healthy subjects randomized to salbutamol 5 mg, fenoterol 5 mg, or isotonic saline before and after a course of prednisone 30 mg/day for 1 week, changes in plasma potassium and glucose after the nebulized beta-agonist were significantly greater after treatment with prednisone (33). Baseline potassium concentration fell from 3.75 to 3.50 mmol/l. The lowest mean plasma potassium occurred 90 minutes after fenoterol with prednisone pretreatment (2.78 mmol/l).

Diuretics

Treatment with bendroflumethiazide, and presumably other diuretics, augments the hypokalemic and electrocardiographic effects of high-dose inhaled salbutamol; the dysrhythmogenic potential of this interaction can be important in patients with acute exacerbations of chronic airflow obstruction, who have concomitant hypoxemia and ischemic heart disease (SEDA-15, 134).

Formoterol and salmeterol

The interaction of formoterol and salmeterol with salbutamol has been studied in a randomized, double-blind, crossover study in 16 asthmatic patients (34). The patients were taking regular inhaled corticosteroids and were responsive to methacholine challenge, with a PD20 (that is the dose of methacholine that produced a fall in FEV_1 of 20%) of less than 500 micrograms. The patients had methacholine challenges performed 12 hours after a single dose of formoterol 12 micrograms, salmeterol 50 micrograms, placebo, and either a low dose (400 micrograms) or a high dose (1600 micrograms) of salbutamol. With placebo, challenge after high-dose salbutamol resulted in a higher PD20 than after low-dose salbutamol (as expected). However, after both formoterol and salmeterol, the higher dose of salbutamol did not give as great an increase in PD20 over the lower dose of salbutamol. This suggests that prior treatment with formoterol and salmeterol can antagonize the protective effect of salbutamol against bronchoconstriction. This effect may be important in patients with acute asthma.

Theophylline

Salbutamol has additive effects with theophylline, which can potentiate the hypokalemic effect (SEDA-17, 164). In 14 healthy volunteers, theophylline increased salbutamol-induced hypokalemia and in some individuals there was profound hypokalemia (less than 2.5 mmol/l) (35). Combining theophylline with salbutamol increased the tachycardia resulting from the salbutamol infusion. Salbutamol infusion caused a fall in diastolic and a rise in systolic blood pressure, which was not altered by theophylline.

Salicaceae

See also Herbal medicines

General Information

The family of Salicaceae contains two genera:

1. *Populus* (cottonwood)
2. *Salix* (willow).

© 2006 Elsevier B.V. All rights reserved.

Table 1 Some plant sources of salicylates

Salicylate	Plant species	Common name	Family
Methyl salicylate	*Gaultheria procumbens*	Wintergreen, Eastern teaberry	Ericaceae
	Spiraea alba	White meadowsweet	Rosaceae
Salicin	*Salix songorica*		Salicaceae
Salicylic acid	*Salix alba*	White willow	Salicaceae
	Burchardia multiflora	Milk maids	Colchicaceae
	Callicarpa integerrima		Verbenaceae
	Falcaria vulgaris	Sickleweed	Apiaceae
	Flemingia laevicarpa		Fabaceae
	Genista lucida		Fabaceae
	Populus pseudosimonii		Salicaceae
Saligenin	*Populus pseudosimonii*		Salicaceae

Salix species and salicylates

The barks of various species of *Salix* contain glycosides of saligenin (salicylalcohol), namely the simple O-glycoside salicin and more complex glycosides such as salicortin (1). When taken orally, these glycosides undergo intestinal transformation to saligenin, which is rapidly absorbed and converted by the liver to salicylic acid. When willow bark preparations are used according to current dosage recommendations, they will not provide sufficient salicylic acid to produce acute salicylate poisoning. However, the risk of hypersusceptibility reactions, such as skin reactions and bronchospasm, in sensitive individuals cannot be excluded.

Other natural sources of salicylates are listed in Table 1. There are separate monographs on acetylsalicylic acid (aspirin), benorilate, diflunisal, lysine acetylsalicylate, and salsalate. Methyl salicylate is covered under *Gaultheria procumbens* in the monograph on the Ericaceae.

Salicylanilides

See also Disinfectants and antiseptics

General Information

The halogenated salicylanilides, which include closantel, niclosamide, oxyclozanide, rafoxanide, and resorantel, have antiparasitic activity in animals (1). Closantel and rafoxanide are widely used for the control of infestation with *Hemonchus* species and *Fasciola* species in sheep and cattle and *Estrus ovis* in sheep. Niclosamide is used as an anticestode in a wide range of animals. Other parasites that are susceptible include hematophagous helminths and external parasites such as ticks and mites. Many halogenated salicylanilides, including dibromosalicylanilide, tribromosalicylanilide, and tetrachlorosalicylanilide, have been used in disinfectants.

Organs and Systems

Skin

Photocontact dermatitis can occur after the use of halogenated salicylanilides, such as tribromosalicylanilide in soaps (2) and bithionol in first-aid creams (3). Tetrachlorosalicylanilide caused many cases in the 1960s and was withdrawn, after which there was a striking reduction in the numbers of patients with positive photopatch tests (4). The authors concluded that these results were most likely to have been due to removal from the market of the more potent photosensitizing chemicals and increased familiarity of physicians with this effect. Photosensitivity has also been reported to other analogues in widespread use, such as the dibromo and tribromo derivatives. The photoallergy is localized, but transient generalized reactions can occur.

Salicylates, topical

General Information

Salicylic acid is widely used in dermatology because of its keratolytic properties. Methylsalicylate (the main constituent of oil of wintergreen) is a topical analgesic that is also a constituent of Red Flower Oil and White Flower Oil formulations, popular herbal analgesics used topically in Southeast Asia (1). Some users take small amounts of the oil orally to enhance its analgesic effects. It has been responsible for rare cases of allergic skin reactions.

Salicylism

Many reports have described "salicylism," intoxication due to percutaneous absorption of salicylates, such as methyl salicylate (2). The first symptoms of salicylism are pallor, fatigue and drowsiness, and altered respiration, which becomes more frequent and at the same time deeper, and which can be heard from a distance. Other early signs of intoxication with salicylic acid are nausea, vomiting, changes in the ability to hear, and mental confusion. Several deaths have been recorded, mainly in children.

Other signs and symptoms of salicylism (3–5) include:

fatigue, changes in hearing ability, nuchal rigidity, fever, profuse sweating, and pallor (6);
frequent deep respiration, Cheyne-Stokes respiration, dyspnea, hyperpnea;
drowsiness, mental confusion, stupor, hallucinations, headache, dizziness, tinnitus, slurred speech, agitation, disorientation, lethargy, delusions, aggression, retrograde amnesia, depression, coma, somnolence;
hypoglycemia (SEDA-16, 158) and metabolic acidosis (6); nausea, vomiting, thirst, anorexia, diarrhea.

Accidental ingestion of methylsalicylate in young children has resulted in severe salicylate poisoning, in one case with laryngeal edema (7). A suicide attempt by deliberate ingestion of about 100 ml resulted in severe salicylate poisoning (8).

Salmeterol

See also Beta$_2$-adrenoceptor agonists

General Information

Salmeterol is a selective beta$_2$-adrenoceptor agonist that is more potent and has a significantly longer duration of action than salbutamol (SEDA-21, 184). It is used as a supplement to inhaled glucocorticoids for sustained bronchodilatation. It has a much slower onset of effect than salbutamol and is not effective in acute attacks of asthma. It is available as a multidose-pressurized aerosol 0.025 mg/puff, and as a dry powder, Diskhaler or Accuhaler 0.05 mg per dose. The adverse effects profile of salmeterol is the same as that of salbutamol and other beta$_2$-agonists (SEDA-21, 185).

Observational studies

There has been a systematic review of the literature and of unpublished trials with single and chronic doses of inhaled salmeterol 100 micrograms from the GlaxoSmithKline databases (1). The analysis covered data available until early 1999. Of 44 trials that included salmeterol 100 micrograms, data on systemic effects were available from 19 trials that were subsequently included in a pooled weighted analysis. In the chronic dose studies in 1504 patients who took salmeterol for more than 7 days, tremor was reported in 5.6%, palpitation in 1.7%, reduced serum potassium in 0.9%, electrocardiographic events in 0.6%, and increased serum glucose in 0.3%. The smaller systemic effects after chronic administration compared with single salmeterol dosing possibly reflected tachyphylaxis to the systemic cardiovascular and metabolic effects of the drug. The mean systemic effects of salmeterol 100 micrograms are small and of doubtful clinical relevance; unintended use of twice the dose of salmeterol is unlikely to affect patients adversely.

Placebo-controlled studies

In a randomized, double-blind, placebo-controlled, multicenter evaluation of the clinical efficacy and safety of salmeterol 42 micrograms bd in 538 asthmatic patients, mean peak flow rate improved significantly in the patients who used salmeterol (2). The use of supplementary salbutamol, asthma symptom scores, and FEV_1 were

© 2006 Elsevier B.V. All rights reserved.

significantly improved by salmeterol. There were no clinically significant adverse events.

In a double-blind study in 49 stable asthmatic patients who were taking inhaled glucocorticoids, randomized to either salmeterol 50 micrograms or placebo bd for 4 weeks, the bronchodilator response to cumulative doses of inhaled salbutamol was measured before and 12 and 36 hours after the last dose (3). There were no significant differences between salmeterol and placebo in maximal FEV_1 or peak expiratory flow rate responses to inhaled salbutamol at 12 and 36 hours. Asthma control, as judged by lung function and diary card parameters, was significantly better in the patients who took regular salmeterol. There were no serious adverse events. The incidence of non-serious adverse events was similar in the two groups, 56% with salmeterol and 50% with placebo. The most commonly reported adverse events were headache and rhinitis.

Salmeterol 50 micrograms bd and salbutamol 400 micrograms qds have been compared in 165 patients with mild to moderate bronchial asthma in a double-dummy, placebo-controlled, crossover study (4). Relative to placebo, mean morning peak expiratory flow rate increased by 30 l/minute with salmeterol but did not change with salbutamol; evening peak expiratory flow rate increased by 25 l/minute. Salmeterol improved the asthma score compared with placebo, but salbutamol produced no overall difference. Only daytime symptoms were improved by salbutamol. The asthma score fell over time with salbutamol. Both minor and major exacerbation rates were significantly less when patients used salmeterol. Major exacerbations lasted for significantly longer in patients taking salbutamol compared with those taking placebo. Tolerance did not develop to either drug; after withdrawal there was no rebound worsening of asthma control, fall in lung function, or increase in bronchial reactivity to inhaled methacholine. Although salbutamol improved daytime symptoms, there was deterioration in asthma control over time.

The effect of salmeterol on asthma control in 506 patients requiring inhaled corticosteroids has been evaluated in a randomized, double-blind, placebo-controlled study (5). The patients received either salmeterol 42 micrograms bd via a metered-dose inhaler or placebo for 12 weeks. Salmeterol was superior to placebo when assessed by asthma quality-of-life score, global score, asthma symptoms, and improvement in FEV_1, peak expiratory flow rate, and use of supplementary salbutamol to treat exacerbations. Adverse events were reported in 53% of patients taking salmeterol and 51% of patients taking placebo. Most adverse events were not related to treatment. Treatment-related adverse events occurred in 13 patients (5%) taking placebo and 11 patients (4%) taking salmeterol. Twelve patients (2%) did not complete the study because of adverse events, five taking placebo and seven taking salmeterol. In only three patients were the adverse effects considered to be potentially related to the treatment: salmeterol—chest tightness; placebo—shortness of breath and chest pains. Respiratory failure occurred in one patient taking salmeterol and was judged to be possibly related to the drug. Exacerbation of asthma occurred in 59 patients (22%) taking placebo and 53 patients (20%) taking salmeterol. The most common reason cited for exacerbation of the asthma was respiratory infection.

In a double-blind, multicenter trial in primary care, 911 patients with asthma, who were already receiving maintenance anti-inflammatory therapy, were randomized to treatment with salmeterol (50 micrograms bd) or placebo for six months (6). As expected, the patients treated with salmeterol had higher mean peak expiratory flows, used less rescue salbutamol, and had less disturbed sleep than the patients treated with placebo. The most important result from this study was that the number of severe exacerbations was the same in both groups; in other words, salmeterol did not increase the frequency of severe exacerbations.

Salmeterol 42 micrograms bd has been compared with inhaled ipratropium bromide 36 micrograms/day and inhaled placebo in a randomized, double-blind study for 12 weeks in 405 patients with chronic obstructive pulmonary disease (6). Both salmeterol and ipratropium bromide significantly increased the peak expiratory flow rate compared with placebo. Non-specific ear, nose, and throat symptoms (for example sore throat and upper respiratory tract infections) were more common with salmeterol and ipratropium than placebo. There were no significant differences between the groups in the total number of ventricular and supraventricular extra beats. There was no tolerance to the bronchodilating effects of salmeterol.

In a randomized, double-blind, parallel-group study, 911 asthmatic patients in primary care were randomly assigned to inhaled salmeterol 50 micrograms bd or placebo bd for 24 weeks (7). They continued to use their anti-inflammatory maintenance therapy throughout. Salmeterol produced a significant improvement in peak expiratory flow rate and a reduction in the use of short-acting $beta_2$-agonists. Salmeterol did not increase the number of severe exacerbations of asthma.

Comparative studies

Salmeterol has been compared with several other bronchodilators.

Formoterol

Salmeterol dry powder 50 micrograms bd and formoterol dry powder 12 micrograms bd have been compared in 425 asthmatic patients treated for 6 months in a randomized, open, parallel-group study. Improvements were similar in the two groups, although evening predose peak expiratory flow rate showed a trend in favor of formoterol, statistically significant at 2, 3, and 4 months (8). Both treatments were well tolerated: 193 patients taking salmeterol and 190 taking formoterol reported adverse events. This was not unexpected in a 6-month trial. The most frequent adverse events included viral infections, asthma exacerbation, headache, rhinitis, and chest infections. Exacerbation of asthma was reported as an adverse event by 54 (22%) taking salmeterol and 41 patients (17%) taking formoterol. Adverse events, assessed as possibly/probably drug-related, were reported in 21 (9%) taking salmeterol and 32 (13%) patients taking formoterol. The most frequent drug-related adverse event was headache, reported by 11 patients taking salmeterol and seven taking formoterol. Other adverse events

© 2006 Elsevier B.V. All rights reserved.

included tremor in two taking salmeterol and five patients taking formoterol, exacerbation of asthma in four patients in each group, and palpitation in four patients taking formoterol.

The relative efficacy of the long-acting beta$_2$-adrenoceptor agonists formoterol and salmeterol has been studied in a randomized, double-blind, crossover trial in 15 patients with asthma taking regular corticosteroids and salbutamol (9). The patients had methacholine challenges performed after varying single doses of formoterol (12, 60, and 120 micrograms) and salmeterol (50, 250, and 500 micrograms). The maximal protective effect of salmeterol against methacholine challenge was reached at 250 micrograms, whereas formoterol showed a dose–response relation, with maximum protection at the highest dose. This confirmed the authors' hypothesis that salmeterol is a partial agonist at beta-adrenoceptors compared with formoterol. The higher affinity of formoterol for beta-adrenoceptors also produced more adverse effects. There was a significant fall in serum potassium concentration after 60 micrograms of formoterol but not after 250 micrograms of salmeterol. The serum potassium concentration was also significantly lower with the highest dose of formoterol compared with the highest dose of salmeterol (minimum concentration 3.1 mmol/l). The highest dose of formoterol also resulted in more tremor than the highest dose of salmeterol. The increases in heart rate and QT_c interval were similar with the two drugs. It should be noted that the doses used in this study were higher than recommended. It remains unclear whether the partial agonist activity of salmeterol is clinically important, but this seems unlikely.

Salbutamol

The effects of single inhaled doses of salmeterol 0.1, 0.2, and 0.4 mg and salbutamol 0.4 mg from a multidose pressurized inhaler have been compared in healthy volunteers (10). At all doses tested, salmeterol produced statistically significant changes in pulse rate, tremor, blood glucose, and plasma potassium concentrations. Tremor, awareness of heartbeat, and headache were reported by the subjects after salmeterol administration.

Theophylline

Inhaled salmeterol 50 micrograms bd has been compared with oral modified-release theophylline in 178 patients with mild to moderate chronic obstructive pulmonary disease (8). Salmeterol caused a significant improvement in mean morning peak expiratory flow rate compared with theophylline and significantly increased the percentage of symptom-free days and nights with no additional requirement for salbutamol. Adverse events occurred in 50% of the patients who took salmeterol, and 49% of those who used theophylline. Adverse events due to the pharmacological properties of the drug were less frequent with salmeterol (4%) than with theophylline (15%).

In a randomized, double-blind study, 943 patients with chronic obstructive pulmonary disease were treated over 12 weeks with either inhaled salmeterol 42 micrograms bd via a metered-dose inhaler or oral modified-release theophylline bd, titrated to serum concentrations of 10–20 micrograms/ml, or with a combination of the two drugs (11). Adverse events potentially related to the study drug were significantly more common in those who took theophylline compared with salmeterol alone. This was most evident for adverse gastrointestinal events (nausea, gastric upset, vomiting, diarrhea). Adverse cardiovascular events occurred in 1–4% and were comparable among the groups. Theophylline-related toxicity was considerable, as nearly 16% of the patients withdrew during the theophylline titration period owing to adverse events.

Organs and Systems

Cardiovascular

No cardiovascular effects are seen at the recommended daily dose. At a dose of 0.1 mg of salmeterol twice a day no change in heart rate or rhythm was seen on a 24-hour electrocardiogram (Holter). No change in blood pressure was seen and no electrocardiographic abnormality related to myocardial ischemia was recorded during 24-hour monitoring (12).

Skin

A single case of a pruritic burning maculopapular rash has been documented and confirmed by patch-testing with the active component (SEDA-17, 165).

Death

When salmeterol was given for one year to 15 407 patients there were no unexpected major adverse events. There were 1022 (6.6%) deaths; 73 patients died of asthma and 39 used salmeterol during the last month of life. Analysis showed that the majority of deaths were due to natural causes. In four of the 39 subjects who died of asthma and who had taken salmeterol the authors thought it possible that death had been related to the use of salmeterol (13).

Long-Term Effects

Drug tolerance

Current guidelines recommend the use of formoterol and salmeterol in addition to inhaled corticosteroids for optimal management of asthma. Both drugs are highly selective beta$_2$-adrenoceptor agonists, with minor pharmacological differences. Several studies have shown that regular use of both formoterol and salmeterol results in the development of tolerance to their bronchoprotective effects, even with treatment periods as short as 1 week. The significance of this tolerance is unclear, but it is potentially important clinically.

Previous studies over periods of up to 8 weeks have established that the bronchoprotective effect of salmeterol abates with regular use, even after only 1 week of regular treatment. The effects of longer-term use of salmeterol on airway hyper-responsiveness have been examined in a randomized, double-blind, placebo-controlled trial in 408 patients with mild asthma (14). These patients were not using inhaled corticosteroids and took salmeterol (42 micrograms bd) or placebo for 24 weeks. Methacholine challenges were performed at 4, 12, and 24 weeks. At 4 weeks

© 2006 Elsevier B.V. All rights reserved.

salmeterol provided protection against methacholine of about one doubling dose and there was no further change in this protection over the study period. As expected, regular salmeterol produced significant improvements in asthma symptoms. Adverse events were similar in the two groups, apart from headache, which was reported in 14 of 202 patients treated with salmeterol and seven of 206 patients taking placebo. The loss of bronchoprotection that develops with regular salmeterol did not appear to worsen over a 24-week period.

The effect of inhaled budesonide on the loss of bronchoprotection with regular salmeterol has been studied in a randomized, double-blind trial in 18 patients with mild asthma, taking no regular medications (15). After 1 week of regular salmeterol (50 micrograms bd) 12 patients developed tolerance to its protective effect against airway allergen. After another week of salmeterol combined with either inhaled budesonide (500 micrograms bd) or placebo, the patients who took budesonide showed some recovery of the protective effect of salmeterol against airway allergen compared with placebo. The authors suggested upregulation of beta-adrenoceptors as a potential mechanism.

The effect of a bolus of inhaled budesonide on formoterol-induced subsensitivity in airway beta-adrenoceptors has been studied in a randomized, double-blind, crossover study in 10 asthmatic patients taking regular inhaled glucocorticoids (16). Challenge testing with AMP was performed at baseline and after one week of regular formoterol (24 micrograms bd). Before the second challenge the patients were given either a dose of inhaled budesonide (1600 micrograms) or placebo via a dry powder inhaler. After one week of formoterol, the PC_{20} for the second challenge fell significantly (by a factor of 3.9). However, when the second challenge was performed after a bolus of budesonide, there was no fall in the PC_{20}, suggesting protection against formoterol-induced tolerance. Lymphocyte beta-adrenoceptor density fell with regular formoterol, but not after a bolus of budesonide. These results have implications for the treatment of acute severe asthma in patients taking regular long-acting $beta_2$-adrenoceptor agonists. It may be appropriate to give a bolus dose of inhaled glucocorticoids to these patients early in an acute asthma attack, particularly if they are poorly responsive to initial therapy with short-acting bronchodilators.

Drug Administration

Drug formulations

Combination formulations of fluticasone with salmeterol delivered through a dry powder inhaler are intended to provide a combination of an inhaled glucocorticoid and a long-acting $beta_2$-adrenoceptor agonist in one dose, simplifying the treatment regimen and so possibly improving compliance.

Salmeterol 50 micrograms plus fluticasone 500 micrograms bd delivered via a combination inhaler (plus a placebo inhaler) have been compared with the same drug regimen delivered by separate inhalers in a randomized, double-blind trial over 28 weeks in 503 asthmatic patients already taking inhaled glucocorticoids (17). There was also an arm treated with inhaled fluticasone alone. Outcome variables were peak flow and asthma symptoms. Both combination and concurrent therapy with fluticasone plus salmeterol resulted in significantly better symptom control and higher peak flows than fluticasone alone. There were no significant differences in the effects of fluticasone plus salmeterol delivered in a combination inhaler versus separate inhalers. Drug-related adverse effects were similar in all three treatment groups: most were asthma-related, but hoarseness, dysphonia, and throat irritation were the commonest adverse effects attributed to therapy (1–4%).

The effects of salmeterol 50 micrograms plus fluticasone 250 micrograms delivered via a combination inhaler and via separate inhalers have been compared in 371 asthmatic patients (18). There were equivalent improvements in peak flows and asthma symptoms. Candidiasis, dysphonia, and throat irritation were the commonest adverse effects attributed to treatment and occurred equally in the two groups (35%). Palpitation and tremor, which may have been related to salmeterol, occurred in 2% (for each symptom) of the combination group and in 1% and under 1% of the separate inhaler group. In both of these studies compliance was measured by dose counters on the inhalers and was equivalent in the two groups.

It appears that treatment with fluticasone plus salmeterol delivered via a combination inhaler is as effective as the same drugs given in separate inhalers and has a similar adverse effects profile. Whether treatment with a combination inhaler improves compliance is not yet proven.

Drug–Drug Interactions

Salbutamol

Experimental studies continue to show that regular treatment with either formoterol or salmeterol in patients with asthma can produce subsensitivity to the bronchodilator effects of salbutamol (19,20). This bronchodilator subsensitivity can be partly reversed by a bolus dose of inhaled or systemic corticosteroids. The clinical relevance of these experimental findings is unclear.

Salsalate

General Information

Salsalate is a compound that contains two salicylate molecules joined by a diazo bond, which is hydrolysed after absorption, yielding two molecules of salicylate.

Organs and Systems

Mouth and teeth

Salicylates can cause ulceration in the mouth from local contact (1).

- A 77-year-old man developed three ulcerated lesions on his tongue because he had difficulty in swallowing salsalate tablets. He was taught how to swallow tablets and instructed to take them with water to avoid prolonged contact of salsalate with the tongue. Three weeks later, his lesions had healed and no new ones had appeared (2).

Gastrointestinal

There is some evidence that salsalate causes less gastric toxicity than aspirin, but salsalate can produce dyspepsia and occult bleeding when used therapeutically in effective doses. In an open study in 66 patients taking salsalate 3 g/day for 6 weeks, three patients were withdrawn because of gastrointestinal upsets; the most common adverse effect was dyspepsia (3).

Saperconazole

See also Antifungal azoles

General Information

Saperconazole is an experimental, water-insoluble, lipophilic, fluorinated triazole. Its structure resembles that of itraconazole and it has a long half-life. It has a broad antifungal spectrum, including *Cryptococcus* Species and *Aspergillus* species. In early studies in cases of compassionate use, only a few adverse effects were described, including hepatotoxicity (1,2), and its adverse effects were expected to resemble those of itraconazole (3). However, the manufacturers stopped developing it because of concerns about toxicity.

Sapindaceae

See also Herbal medicines

General Information

The genera in the family of Sapindaceae (Table 1) include akee and lychee.

Blighia sapida

Blighia sapida (akee) contains a large amount of a potent hypoglycemic amino acid, glycylglycylglycine, known as hypoglycin.

Adverse effects

Akee poisoning (Jamaican winter vomiting sickness or toxic hypoglycemic syndrome) is a potentially fatal illness. During an outbreak in 1991, symptoms included vomiting (77%), coma (25%), and seizures (24%) (1). In 29 African children, all of whom died in 2–48 hours, there were intense thirst (38%) and hypotonia (97%) and the effects were more severe in those with malnutrition.

Chronic poisoning can cause cholestatic jaundice (2).

- A 27-year-old Jamaican man developed jaundice, pruritus, intermittent diarrhea, and right upper quadrant abdominal pain after chronic ingestion of akee fruit. Liver biopsy showed centrilobular zonal necrosis and cholestasis. There was no evidence of another cause.

An anaphylactic reaction to akee has been described (3).

Table 1 The genera of Sapindaceae

Paullinia cupana

Paullinia cupana (*guaraná*) contains the xanthines theobromine and theophylline as well as flavone glycosides. The crushed seeds of *P. cupana* are made into a dried paste called guaraná, from which a beverage is prepared. All of its effects are directly related to its high content of caffeine-like substances.

Adverse effects

US authors have reported two cases of ventricular extra beats associated with the intake of supplements containing guaraná (4). In both cases the supplements also contained multiple other ingredients, and causality was therefore not certain.

Saquinavir

See also Protease inhibitors

General Information

Of all protease inhibitors, saquinavir is the most potent in vitro. However, owing to poor systemic availability (less than 4%), it is the least potent of all protease inhibitors in use, although a formulation with increased availability has been marketed. However, when saquinavir is given together with ritonavir, the strong inhibitory effect on CYP3A4 of the latter results in high plasma concentrations of saquinavir. This interaction has been exploited, with favorable results, both in

© 2006 Elsevier B.V. All rights reserved.

first-line protease therapy and as salvage treatment in patients with virus resistant to a regimen containing a protease inhibitor. Using 400 mg/400 mg and 800 mg/200 mg, the saquinavir soft gelatin capsule AUC increased by 17–23 times compared with saquinavir alone (1). Saquinavir had no clinically significant effect on the pharmacokinetics of ritonavir. Ritonavir as a booster allows a much higher saquinavir concentration to be obtained, allowing twice-daily dosing and a reduced capsule burden.

General adverse effects

Hitherto, no particular or frequent adverse effects attributable to saquinavir have been reported from trials in which saquinavir was used at the licensed dosage of 600 mg tds (2). Diarrhea, usually of only moderate severity, occurring in 3–4% of patients, is the most common single adverse effect (SEDA-22, 310).

As with other HIV-1 protease inhibitors, saquinavir may be associated with drug interactions as a result of the effect of saquinavir on the hepatic cytochrome P450 oxidase system. Although compared with other HIV protease inhibitors, saquinavir has less of an inhibitory effect on cytochrome P450 isozymes; clinically relevant interactions can nevertheless occur. Drug interactions with saquinavir have been reviewed (3).

Organs and Systems

Psychological, psychiatric

Saquinavir can occasionally be associated with acute paranoid psychotic reactions (4).

- A 41-year-old woman took zidovudine and didanosine for HIV-1 infection after an acute seroconversion illness. Zidovudine and didanosine had to be withdrawn because of neutropenia and nausea, so she was given stavudine plus lamivudine without any adverse effects. Saquinavir (600 mg tds) was added 12 months later because of weight loss and a falling CD4 cell count. Within 24 hours of starting to take saquinavir she developed agitated depression with paranoid ideation. After drug withdrawal her mental health returned to normal over 5 days. Over the next 6 weeks stavudine and lamivudine were reintroduced without any adverse effects and continued for a further 11 months. Saquinavir was then reintroduced at the previous dosage, and within 2 days she again became extremely mentally agitated with paranoid ideation. Saquinavir was withdrawn and she recovered within 7 days. She was later given indinavir without problems. Her mother had a history of major depressive illness.

Endocrine

Gynecomastia has been reported in a series of men taking saquinavir (5). In these cases the association was clear (particularly since there was positive dechallenge), but this is a rare effect and has not previously been reported with either this or other protease inhibitors, although it has been associated with the nucleoside analogue reverse transcriptase inhibitor stavudine.

Gastrointestinal

Diarrhea, usually of only moderate severity, which occurs in 3–4% of patients, is the most common single adverse effect of saquinavir (6–8).

Urinary tract

A renal stone has been attributed to saquinavir (9).

- A 42-year-old HIV-positive man with a prior history of *Pneumocystis jiroveci* pneumonia who had been treated with zidovudine and dideoxycytidine started to take saquinavir 600 mg tds. His CD4 cell count rose from 28×10^3/l to 101×10^3/l and zidovudine and dideoxycytidine were replaced by stavudine and lamivudine, because of mild peripheral neuropathy. Saquinavir was continued unchanged. A few months later he developed left-sided loin pain and hematuria and a left renal calculus was seen on ultrasound. A month later the same signs and symptoms recurred and a few weeks later he passed a small black stone in the urine. Ultrasonic lithotripsy was performed, with a good result. Saquinavir was discontinued, after which he had no further renal problems.

This case suggests that saquinavir, like indinavir, may be associated with renal calculus formation in some individuals.

Skin

Adverse skin reactions to saquinavir are exceptional, but erythema multiforme has been reported (10).

- A 32-year-old HIV-positive man, who had been treated with didanosine and lamivudine, added saquinavir (600 mg tds) because of a rising plasma HIV-1 RNA viral load. Five days later he presented with a generalized maculopapular skin eruption, the lesions being centered on a bulla, and erosive lesions on the palate. Histological examination was compatible with erythema multiforme. Saquinavir was discontinued and all the mucocutaneous lesions healed within 15 days. Rechallenge was not attempted.

Long-Term Effects

Tumorigenicity

- Eruptive angiolipomata occurred in a 49-year-old woman after she had taken stavudine 30 mg bd, lamivudine 150 mg bd, and saquinavir 600 mg 8-hourly for 3 months (11). This has also been reported with other protease inhibitors (12,13) and the mechanism is not known. In one case lipomata regressed after the introduction of indinavir (14).

Drug Administration

Drug formulations

A soft gelatin capsule formulation of saquinavir with greater systemic availability than the hard gelatin capsule has been developed. Of 442 patients who used the soft gelatin capsule 1200 mg tds, for 48 weeks, 8% withdrew because of adverse events, which were not necessarily

© 2006 Elsevier B.V. All rights reserved.

related to saquinavir. No new adverse effects or laboratory abnormalities emerged compared with those previously observed with the hard gelatin capsule. The most frequent adverse effects were gastrointestinal, diarrhea being the most common (15).

Drug–Drug Interactions

Ciclosporin

In an HIV-1-positive kidney transplant recipient, saquinavir increased the trough concentration of ciclosporin three-fold, resulting in fatigue, headache, and gastrointestinal discomfort. Ciclosporin, like saquinavir, is metabolized by CYP3A. Saquinavir plasma concentrations were likewise increased by ciclosporin. All the symptoms disappeared after downward adjustment of the doses of both ciclosporin and saquinavir (16).

Cytotoxic drugs

In 37 patients with HIV-associated non-Hodgkin's lymphoma who were treated with a 96-hour continuous intravenous infusion of cyclophosphamide + doxorubicin + etoposide, severe (grade 3 or 4) mucositis occurred in eight of 12 patients who received concomitant saquinavir (600 mg tds) compared with three of 25 who did not receive saquinavir. Although the authors did not measure saquinavir plasma concentrations, they suggested that this finding may have been explained by inhibition of the metabolism of one or more of the cytotoxic drugs by saquinavir (17).

Erythromycin

In 11 healthy men, erythromycin 250 mg qds increased the AUC of saquinavir (given as a soft gel capsule 1200 mg tds) by 69% when both were given for 7 days (18).

Ketoconazole

In 12 healthy men, ketoconazole 400 mg/day increased the AUC of saquinavir (given as a soft gel capsule 1200 mg tds) by 190% when both were given for 7 days (18).

Midazolam

Saquinavir substantially potentiates the effects of midazolam by raising its blood concentrations (19).

Rifamycins

In 14 healthy men, rifampicin 600 mg/day reduced the AUC of saquinavir (given as a soft gel capsule 1200 mg tds) by 46% when both were given for 14 days; this reduction can be counteracted by the addition of ritonavir (18).

Satranidazole

General Information

Satranidazole is a highly active amebicidal agent with a slightly wider spectrum than metronidazole against micro-aerophilic and anaerobic bacteria; it is also

© 2006 Elsevier B.V. All rights reserved.

effective against *Giardia* and *Trichomonas*. It is less toxic than metronidazole, nimorazole, secnidazole, and ornidazole. Gastrointestinal tolerability was good in early studies. Therapeutic doses did not cause an adverse interaction with alcohol (SEDA-12, 707) (1,2).

Sclerosants

General Information

In sclerotherapy an irritant is introduced into varicose veins and esophageal varices, causing a local inflammatory reaction and obliteration of the veins concerned. Sclerosing agents include lauromacrogol 400, monoethanolamine oleate, sodium morrhuate, and sodium tetradecylsulfate.

Lauromacrogol 400 (polidocanol)

Lauromacrogol 400 is a solvent and non-ionic emulsifier. In medicaments it is used as topical anesthetic, an antipruritic, and a sclerosing agent (1).

Monoethanolamine oleate

Monoethanolamine oleate is an alkaline viscous liquid that is irritant and is used as a sclerosant.

Sodium morrhuate

Sodium morrhuate is a fatty acid extract of cod liver oil; its sclerosant effect was discovered with the use of the agent in treating leprosy (2). Sodium morrhuate is cytotoxic, as demonstrated by autopsy studies in 10 patients (3).

Sodium tetradecylsulfate

Sodium tetradecylsulfate is an anionic surfactant used as a sclerosant.

Treatment of esophageal varices

Bleeding esophageal varices are treated by inserting a needle-tipped catheter through an endoscope to the site of the varices, and injecting a sclerosing agent directly into the bleeding varix. The common mechanism of action of all sclerosing agents is destruction of endothelial surfaces, with subsequent thrombosis, leading to intimal fibrosis and obliteration of the vessel lumen (4).

Adverse effects occur in 10–15% of patients. These include severe local edema and necrosis at the site of sclerosis (5), bacterial peritonitis (6), and pneumococcal bacteremia (7). Fever, chest pain, and odynophagia are common after esophageal sclerotherapy, but they tend to be of short duration (8).

In one review (9) complications of endoscopic variceal sclerotherapy were studied retrospectively in 267 patients who had been treated with endoscopic variceal injection for esophageal variceal hemorrhage in the period 1988–94. Local complications were: transient dysphagia (73%), chest pain (65%), esophageal ulceration (63%), ulcerogenic bleeding (14%), post-therapeutic hemorrhage (13%), esophageal strictures (10%), pleural effusions (9%), subfebrile temperatures (6.4%), pericarditis (0.4%), and esophageal perforation (0.4%). No patient died from sclerotherapy-induced adverse effects.

Sclerotherapy has also been used in the extremities for treating varicose and telangiectatic leg veins (10,11). Telangiectatic matting can develop bluish areas due to post-treatment neovascularization, in which new blood vessels, less than 0.2 mm in diameter, appear distally to the treated site, most commonly on the thigh. The incidence of this has been reported to be between 5 and 35%. Resolution often occurs spontaneously over 3–12 months, although in some patients it may be permanent or require further sclerotherapy to which it can be resistant (12).

Organs and Systems

Cardiovascular

Vascular thrombosis due to sclerosants is due to direct damage to vascular endothelium and red cells, aggregation of platelets, and aggregation of granulocytes at the venous wall endothelium. Where sodium morrhuate is concerned, these effects probably derive from its surfactant properties and its high arachidonate content (13). Other sclerosant agents in current use (lauromacrogol 400, monoethanolamine oleate, and sodium tetradecylsulfate) cause effects similar to sodium morrhuate.

Cardiac arrest has been reported in a child who received lauromacrogol 400 to sclerose a symptomatic peripheral venous malformation (14).

- A 5-year-old child with Klippel–Trenaunay syndrome, a cutaneous capillary malformation in the right leg, and a venous malformation of the lateral and posterior aspects of the right thigh and buttock had an injection of 4 ml of 1% lauromacrogol 400 into the malformation in the leg after oral premedication with midazolam 5 mg and atropine 0.5 mg and anesthesia with thiopental 80 mg and vecuronium bromide 2 mg for tracheal intubation. Shortly after the injection the patient developed rapidly progressive sinus bradycardia with eventual asystolic cardiac arrest. Anesthesia was discontinued and cardiopulmonary resuscitation, with 100% oxygen, external cardiac message, and intravenous orciprenaline 0.05 mg, was successful.

Respiratory

Fever and pneumonia have been reported after the use of sodium morrhuate sclerosant solution (SEDA-14, 456).

© 2006 Elsevier B.V. All rights reserved.

Gastrointestinal

Following the use of sclerosants, such as monoethanolamine oleate 5%, to treat esophageal varices, patients commonly experience early dysphagia and retrosternal pain, as might be expected. More serious complications can arise later if the fibrosis that is a natural consequence of the treatment extends too far, or if the sclerosant escapes from the veins that are being treated. Complications can include fibrosis (leading, for example, to esophageal stricture) as well as perforation, sepsis, and respiratory problems. Mediastinal pain can be precipitated by excessively deep or large injections. Mesenteric thrombosis has been claimed to occur as a complication and would not be unexpected; chylothorax and cerebral embolism have also been described.

Immunologic

Contact allergic reactions to lauromacrogol 400 have been reported (15). Patch testing with lauromacrogol 400 may yield irritant reactions. In a retrospective study of 8739 patients tested with a topical drug patch test series, 3186 patients were tested with 0.5% lauromacrogol 400 in water (16). There was slight irritation in 0.88%, weakly positive reactions in 0.97%, and strongly positive reactions in 0.25%. In 6202 patients tested with lauromacrogol 400 3% in petrolatum, there was slight skin irritation in 0.48%, weakly positive reactions in 1.77%, and strongly positive reactions in 0.34%. Among the 649 patients tested with both formulations, concurrence was moderate.

Long-Term Effects

Tumorigenicity

A number of case reports have suggested that sclerosant therapy could be carcinogenic (SEDA-15, 401).

Secnidazole

General Information

Secnidazole is more active and gives more prolonged blood concentrations than metronidazole; it is effective in hepatic amebiasis. Gastrointestinal adverse effects are less common (SEDA-11, 597) (1).

Secretin

General Information

Secretin is a peptide hormone that stimulates pancreatic secretion. It has been used to treat autism, without success (1–3).

© 2006 Elsevier B.V. All rights reserved.

Synthetic porcine secretin and biologically derived porcine secretin have been compared in a double-blind, randomized, crossover study in 12 volunteers (4). The two formulations had identical effects and were safe and well tolerated. One subject reported transient mild flushing with both formulations. Otherwise, physical examination, clinical laboratory assessments, and electrocardiograms were normal.

In 10 healthy volunteers secretin suppressed peptone-stimulated gastric acid secretion and serum gastrin and inhibited acid output (5). There was a significant correlation between percentage inhibition of acid secretion and plasma secretin concentrations, which were greatly above those seen physiologically. Serum lipase and trypsin activities increased significantly. Most of the subjects lost fluid from diuresis and diarrhea, and serum sodium and total protein concentrations increased significantly.

Organs and Systems

Mineral balance

In seven healthy controls, seven patients with duodenal ulcer, seven with primary hyperparathyroidism, and one with an excluded gastric antrum, intravenous secretin 3 U/kg/hour for 90 minutes increased total protein and the protein-bound calcium fraction but did not alter the ionized calcium fraction (6).

Selaginellaceae

See also Herbal medicines

General Information

The family of Selaginellaceae contains the single genus *Selaginella*.

Selaginella doederleinii

Selaginella doederleinii (spike moss) has been used as an alternative anticancer treatment.

Adverse effects

- A 52-year-old woman with cholangiocarcinoma developed severe bone marrow suppression after taking *S. doederleinii* daily for 2 weeks (1). She developed severe pancytopenia with skin ecchymoses and gum bleeding. A bone marrow smear and biopsy showed severe hypocellularity without malignant cell infiltration. One week after withdrawal her blood count became normal.

Selective serotonin re-uptake inhibitors (SSRIs)

See also Individual agents

General Information

The selective serotonin re-uptake inhibitors (SSRIs) that are currently available are fluoxetine, fluvoxamine, paroxetine, sertraline, citalopram, and escitalopram. They are widely marketed and are in many countries a major alternative to tricyclic antidepressants in the treatment of depression. The SSRIs are structurally diverse, but they are all inhibitors of serotonin uptake, with much less effect on noradrenaline. They have slight or no inhibitory effect on histaminergic, adrenergic, serotonergic, dopaminergic, and cholinergic receptors (1).

The SSRIs are eliminated mainly through hepatic metabolism. Their half-lives are about 1 day for fluvoxamine, paroxetine, and sertraline (2–5), 1.5 days for citalopram (6), and 2–3 days for fluoxetine (7). Norfluoxetine, the main metabolite of fluoxetine, is a potent and selective serotonin re-uptake inhibitor, and since this metabolite also has a very long half-life (7–15 days) it contributes significantly to the clinical effect. Norsertraline, the desmethylated metabolite of sertraline, is also an inhibitor of serotonin re-uptake, but

© 2006 Elsevier B.V. All rights reserved.

with much lower potency than sertraline; although its half-life is about 2.5 times longer than that of sertraline, it is not considered to contribute to the clinical effect (3). The main metabolite of citalopram, desmethylcitalopram, is pharmacologically active but has much lower potency than the parent compound (1). The metabolites of fluvoxamine and paroxetine are inactive with respect to monoamine uptake (2). Escitalopram oxalate is the *S*-enantiomer of citalopram (8). The therapeutic activity of citalopram resides in the *S*-isomer and escitalopram binds with high affinity to the human serotonin transporter; *R*-citalopram is about 30-fold less potent. The half-life of escitalopram is 27–32 hours. Escitalopram and citalopram have negligible effects on CYP isozymes.

The major advantages of SSRIs over the tricyclic antidepressants are their less pronounced anticholinergic adverse effects and lack of severe cardiotoxicity. However, some studies have shown some degree of nervousness or agitation, sleep disturbances, gastrointestinal symptoms, and perhaps sexual adverse effects more commonly in patients treated with SSRIs than in those treated with tricyclic antidepressants. SSRIs may also be associated with an increased risk of suicide, particularly in children under 16 (9).

There seems to be little difference between SSRIs with respect to frequency and severity of adverse effects. The most common adverse effects are gastrointestinal disturbances (nausea, diarrhea/loose stools, constipation; incidence 6–37%), nervous system effects (insomnia, somnolence, tremor, dizziness and headache; 11–26%), and effects on the autonomic nervous system (dryness of the mouth and sweating; 9–30%) (2,10). Weight gain or weight loss have been documented relatively infrequently (2). A high frequency of sexual disturbances has been reported. SSRIs may selectively inhibit hepatic enzymes, causing pharmacokinetic interactions with other drugs that are metabolized by these enzymes; a pharmacodynamic interaction can also occur when SSRIs are given in combination with other serotonergic drugs, which may give rise to serotonergic hyperstimulation, the "serotonin syndrome." The SSRIs are safer than the tricyclic antidepressants in overdose.

A meta-analysis of 20 short-term studies of five SSRIs (citalopram, fluoxetine, fluvoxamine, paroxetine, and sertraline) has been published (11). There were no overall differences in efficacy, but fluoxetine had a slower onset of action. Analysis of tolerability showed the expected adverse effects profile, the most common adverse event being nausea, followed by headache, dizziness, and tremor. The rate of withdrawal from treatment because of adverse effects was significantly greater with fluvoxamine (RR = 1.9; CI = 1.2, 3.0). Data available from the UK Committee on Safety of Medicines suggested that withdrawal reactions were most common with paroxetine and least common with fluoxetine (presumably because of the long half-life of its active metabolite norfluoxetine). There were more gastrointestinal reactions to fluvoxamine and paroxetine. This pattern was reflected in prescription-event monitoring data. Citalopram and sertraline were least likely to cause drug interactions, but citalopram was implicated more often in fatal overdoses.

Organs and Systems

Nervous system

Movement disorders

Extrapyramidal symptoms (including akathisia, dystonia, dyskinesia, tardive dyskinesia, parkinsonism, and bruxism) have been reported in association with SSRIs, especially in the presence of predisposing factors (SEDA-14, 14) (12). Current data suggest that SSRIs should be used with caution in patients with parkinsonism (see the monograph on fluoxetine). Concomitant treatment with neuroleptic drugs and high concentrations of SSRIs seems to predispose to extrapyramidal symptoms. Elderly patients and women are also at increased risk.

It is believed that SSRIs produce movement disorders by facilitating inhibitory serotonin interactions with dopamine pathways. While all SSRIs are potent inhibitors of serotonin re-uptake, they have other pharmacological actions that might contribute to their clinical profile. Sertraline has an appreciable affinity for the dopamine re-uptake site, and for this reason might be presumed less likely to cause movement disorders than other SSRIs. However, there is little clinical evidence to support this suggestion and a case of sertraline-induced parkinsonism has been reported (13).

SSRI-induced movement disorders have been comprehensively reviewed (14). The use of SSRIs was associated with a range of movement disorders, the most frequent of which was akathisia. However, clinician-based reports of adverse events solicited from SSRI manufacturers suggested that parkinsonism might occur with an equal frequency but with a later onset during treatment. As suggested before (SEDA-22, 12), concomitant treatment with antipsychotic drugs and lithium, as well as pre-existing brain damage, predisposes to the development of movement disorders with SSRIs. Case reports have suggested that akathisia can be associated with suicidal impulses.

Spontaneous reports received by the Netherlands Pharmacovigilance Foundation between 1985 and 1999 have been analysed in a case-control study (15). Relative to other antidepressants, SSRIs were about twice as likely to be implicated in spontaneous reports of extrapyramidal reactions (OR = 2.2; 95% CI = 1.2, 3.9). The risk was greater in patients who were also taking neuroleptic drugs. This result suggests that SSRIs have a modestly increased risk of producing extrapyramidal reactions compared with other antidepressants. However, increased reporting can be influenced by increased awareness. In addition, no account was apparently taken in this study of relative prescription rates of different antidepressants.

Withdrawal of SSRIs usually results in remission of symptoms of extrapyramidal movement disorders. However, occasionally, SSRIs can unmask a vulnerability to Parkinson's disease, and can also worsen established Parkinson's disease (SEDA-22, 23) (see monographs on citalopram and sertraline) (16).

Serotonin syndrome

The serotonin syndrome is a well-established complication of SSRI treatment. It is usually associated with high

© 2006 Elsevier B.V. All rights reserved.

doses of SSRIs or the use of SSRIs in combination with other serotonin-potentiating agents, such as monoamine oxidase inhibitors (SEDA-22, 24).

- A 45-year-old man had definite symptoms of serotonin toxicity (hypomania, myoclonus, sweating, and shivering), first when taking a low therapeutic dose of citalopram (20 mg/day) and then with low-dose sertraline (25 mg/day); he was also taking zolpidem (17).

The authors speculated that the combination of zolpidem with an SSRI might have predisposed to the serotonin syndrome. It is also possible that some people (for example poor metabolizers) are idiosyncratically vulnerable to serotonin toxicity at low doses of SSRIs.

Sleep

SSRIs can cause insomnia and daytime somnolence; however, the symptoms seem to reflect a sleep–wake cycle disorder. It is conceivable that disruptions in the normal pattern of melatonin secretion, particularly a delay in the normal early morning fall in plasma concentrations could be involved in the pathophysiology of these symptoms. The fact that fluvoxamine is the SSRI that is most likely to cause sleep disorders supports a role of melatonin, which is increased by fluvoxamine but not by other SSRIs (18).

Sensory systems

Tricyclic antidepressants can precipitate acute glaucoma through their anticholinergic effects. There are also reports that SSRIs can cause acute glaucoma, presumably by pupillary dilatation (see the monograph on paroxetine and fluoxetine).

Psychological, psychiatric

Like other antidepressants, SSRIs are occasionally associated with manic episodes, even in patients with no history of bipolar disorder. Some argue that the affected patients may have had an underlying predisposition to bipolar illness.

In a retrospective chart review of 167 patients with a variety of anxiety disorders, excluding patients with evidence of current or previous mood disorder, manic episodes were recorded in five patients, a rate of 3% (19). While this might suggest a clear effect of SSRIs to induce mania, two of the patients were taking clomipramine, a tricyclic antidepressant, albeit a potent serotonin reuptake inhibitor. In addition, all the affected patients had additional diagnoses of histrionic or borderline personality disorder, known to be associated with mood instability. It is still therefore plausible that SSRIs cause mania only in patients with an underlying predisposition, although this may be more subtle than a personal or family history of bipolar illness.

Visual hallucinations are rare during antidepressant drug treatment, except after overdosage.

- A 38-year-old man with a history of chronic depression developed on waking visual hallucinations of different geometric shapes after treatment with both sertraline and fluoxetine. Eventually he responded to treatment with nefazodone, which did not cause hallucinations (20).

Many drugs that cause visual hallucinations (for example lysergic acid diethylamide) have agonist activity at 5-HT_2 receptors, and it is conceivable that in these patients both sertraline and fluoxetine caused sufficient activation of post-synaptic 5-HT_2 receptors to produce this visual disturbance. Although nefazodone can increase 5-HT neurotransmission, it is also a 5-HT_2-receptor antagonist, so presumably does not activate 5-HT_2 receptors.

Endocrine

Serotonin pathways are involved in the regulation of prolactin secretion. Amenorrhea, galactorrhea, and hyperprolactinemia have been reported in patients taking SSRIs (see the monographs on fluoxetine, fluvoxamine, paroxetine, and sertraline).

Electrolyte balance

SSRIs can reportedly cause hyponatremia (SEDA-18, 20) (SEDA-26, 13). In a case-control study of hyponatremia in 39 071 psychiatric inpatients and outpatients, the incidence of antidepressant-induced hyponatremia was 2.1% (21). SSRI users had a three times higher risk of developing hyponatremia relative to users of other antidepressant drugs (OR = 3.1; 95% CI = 1.3, 8.6). Additional risk factors included older age and concomitant treatment with diuretics.

SSRIs can cause hyponatremia in elderly patients (SEDA-18, 20, 21).

- A 45-year-old woman developed hyponatremia complicated by rhabdomyolysis while taking citalopram and the antipsychotic drug chlorprothixene for depressive psychosis (22). The hyponatremia became apparent 2 weeks after the dose of citalopram was increased to 40 mg/day, when she complained of weakness and lethargy.

SSRI-induced hyponatremia is unusual in non-geriatric populations, but the chlorprothixene may have played a role in this case.

There have been other reports of hyponatremia with SSRIs (23,24). Hyponatremia is probably more common with SSRIs than with tricyclic antidepressants and predominantly but not exclusively affects older patients. Most reports involve fluoxetine, but this might represent greater patient exposure. All SSRIs and venlafaxine can produce this adverse effect (SEDA-23, 21) (SEDA-25, 14). According to published reports, the median time to the onset of hyponatremia is 13 days (range 3–120) and the presentation is of inappropriate secretion of antidiuretic hormone (23). Symptoms, such as lethargy and confusion, can be non-specific, so awareness of the possibility of SSRI-induced hyponatremia, particularly in elderly people, is needed.

Fluid balance

The syndrome of inappropriate secretion of antidiuretic hormone (SIADH) is a possible adverse effect of the SSRIs (SEDA-14, 14) (SEDA-18, 20) (SEDA 21, 11) (25). The mechanism is not known. Several of the affected

© 2006 Elsevier B.V. All rights reserved.

patients have been elderly, and old people may be at greater risk.

Hematologic

SSRIs have in rare cases been reported to produce bruising, bleeding, prolonged bleeding time, increased prothrombin time, and other hematological disturbances (SEDA-24, 15) (see the monographs on fluoxetine, fluvoxamine, paroxetine, and sertraline). The suggested mechanism of these adverse effects is reduced granular storage of serotonin in platelets, leading to disturbances of platelet function, especially in predisposed patients with mild underlying platelet disorders (26,27). An alternative mechanism is increased capillary fragility. Some patients appear to have a pre-existing susceptibility, for example, by virtue of treatment with other medications that might predispose to bleeding.

Five children, aged 8–15 years, developed bruising or epistaxis 1–12 weeks after starting SSRI treatment (28). In all cases the bleeding problem resolved when the SSRI was withdrawn or the dose lowered. In a review of 30 cases of SSRI-induced bleeding disorders the most common events were bruising, petechiae, purpura, and epistaxis, though gastrointestinal hemorrhage was also reported (29). The mean age of the affected patients was 42 years and the female:male ratio was 3:4. Symptoms were sometimes associated with prolonged bleeding time or platelet aggregation disorders, but often these indices were normal.

Gastrointestinal

Gastrointestinal adverse effects are one of the major disadvantages of SSRIs. The most common is nausea, and the incidence is said to be 20% or more for paroxetine (30,31), sertraline (32), fluvoxamine (5), fluoxetine (33), and citalopram (10,34). Although nausea can lead to drug withdrawal, it usually disappears after a few weeks. Other gastrointestinal symptoms that occur commonly with fluoxetine and sertraline are loose stools and diarrhea (32,33,35), while constipation has been more often reported with fluvoxamine (5) and paroxetine (30,31).

In a case-control study, current exposure to SSRIs was associated with an increased risk of upper gastrointestinal bleeding (RR = 3.0; CI = 2.1, 4.4) (36). The risk was substantially greater in subjects taking both SSRIs and non-steroidal anti-inflammatory drugs (NSAIDs) (RR = 16; CI = 6.6, 37). However, there was also an increased risk of bleeding with trazodone (RR = 8.6; CI = 2.1, 35), which does not block the uptake of 5-HT in therapeutic doses. Thus, the association between certain kinds of antidepressant drugs and upper gastrointestinal bleeding appears to be real.

Liver

SSRIs are rarely hepatotoxic and have only occasionally been reported (see the monographs on fluoxetine, paroxetine, and sertraline).

Skin

Skin reactions to SSRIs have been reported (SEDA-17, 20) (SEDA-18, 20), including Stevens–Johnson syndrome (37), and rash due to fluoxetine occurs in a few percent of patients (38) (see also the monographs on fluoxetine, fluvoxamine, and sertraline).

Sexual function

Impaired sexual function

The adverse sexual effects of SSRIs have been reviewed (39). The use of SSRIs is most often associated with delayed ejaculation and absent or delayed orgasm, but reduced desire and arousal have also been reported. Estimates of the prevalence of sexual dysfunction with SSRIs vary from a small percentage to over 80%. Prospective studies that enquire specifically about sexual function have reported the highest figures. Similar sexual disturbances are seen in patients taking SSRIs for the treatment of anxiety disorders (40), showing that SSRI-induced sexual dysfunction is not limited to patients with depression. It is not clear whether the relative incidence of sexual dysfunction differs between the SSRIs, but it is possible that paroxetine carries the highest risk (39).

The ability of SSRIs to cause delayed ejaculation has been used in controlled trials of men with premature ejaculation (41,42). Of the SSRIs, paroxetine and sertraline produced the most benefit in terms of increase in time to ejaculation, but fluvoxamine did not differ from placebo. Clomipramine was more effective than the SSRIs but caused most adverse effects. From a practical point of view many patients might prefer to take medication for sexual dysfunction when needed rather than on a regular daily basis, and it would be of interest to study the beneficial effects of SSRIs on premature ejaculation when used in this way.

Laboratory studies have shown that fluvoxamine differs from paroxetine, sertraline, and fluoxetine in not delaying the time to ejaculation. The effect of citalopram to delay ejaculation is also relatively modest (43). There are, however, many other ways in which SSRIs can interfere with sexual function, for example by causing loss of sexual interest and erectile difficulties. In an open, prospective study of 1000 Spanish patients taking a variety of antidepressants, there was an overall incidence of sexual dysfunction of 59% (44). The highest rates, 60–70%, were found with SSRIs (including fluvoxamine) and venlafaxine. The lowest rates were found with mirtazapine (24%), nefazodone (8%), and moclobemide (4%). Spontaneous resolution of this adverse effect was uncommon—80% of subjects had no improvement in sexual function over 6 months of treatment. This study suggests very high rates of sexual dysfunction in patients taking SSRIs and venlafaxine. However, in investigations of this nature, it can be difficult to tease out the effect of the drug from that of the underlying disorder. Nevertheless, while depressive symptoms should improve in most patients over 6 months of treatment, the sexual dysfunction in these subjects tended not to remit, suggesting that the antidepressant was the main culprit.

Increased sexual function

Occasionally, SSRIs are associated with increased sexual desire and behavior.

- A 27-year-old married woman with a borderline personality disorder was admitted to hospital with

© 2006 Elsevier B.V. All rights reserved.

depression and suicidal ideation (45). Over 3 weeks she was given fluvoxamine in doses up to 150 mg/day, but because of lack of response the dosage was increased to 200 mg/day; 3 days later she reported that her sex drive was greater than it had ever been before and that she felt she could not control it. There was no evidence of mania. Within a week of withdrawal of fluvoxamine her sexual desire had returned to its previous level.

Patients with borderline personality disorder may behave in a sexually disinhibited manner and have mood swings. In this patient, however, it did not appear as though the hypersexuality was part of a manic syndrome, and she was clear that the sexual feelings were unusually great for her. Support for a role of the SSRI in this adverse effect comes from a series of five patients (four taking citalopram and one paroxetine) who had an unusual increase in sexual interest, with preoccupation with sexual thoughts, promiscuity, and excessive interest in pornography (46). In some of the cases symptoms such as diminished need for sleep suggested the possibility of a manic syndrome.

These reports suggest that occasionally SSRIs can be associated with increased sexual desire and behavior. This might be associated with mood instability, for example in a manic or mixed affective state, but in some people personality factors are likely to be important.

Treatment of sexual dysfunction due to SSRIs

Various treatments have been advocated to ameliorate sexual dysfunction in SSRI-treated patients, including 5-HT_2-receptor antagonists (cyproheptadine, mianserin, nefazodone) and 5-HT_3-receptor antagonists such as granisetron (39). One of the most popular remedies is the use of dopaminergic agents, such as amfebutamone.

In a prospective study, 47 patients who complained of SSRI-induced sexual dysfunction took amfebutamone (bupropion) 75–150 mg 1–2 hours before sexual activity (47). If this was unsuccessful they were titrated to a dosage of 75 mg tds on a regular basis. Amfebutamone improved sexual function in 31 patients (66%). Anxiety and tremor were the most frequently reported adverse events, and seven patients discontinued for this reason. However, it should be noted that more serious adverse events (panic attacks, delirium, and seizures) have been reported when amfebutamone (bupropion) and SSRIs are combined (39).

In a placebo-controlled, parallel-group study of buspirone and amantadine in 57 patients with fluoxetine-induced sexual dysfunction, there was an overall improvement in all three treatment groups and no significant differences between them (48). These data suggest that anecdotal reports of treatment benefit in SSRI-induced sexual dysfunction should be regarded with caution.

Reproductive system

Vaginal bleeding and menorrhagia have been rarely reported with SSRI treatment and the mechanism is uncertain. SSRIs have been associated with bleeding diatheses, which might explain these observations (SEDA-24, 15) (SEDA-25, 14). Another possibility is an action of serotonin pathways on the neural regulation of gonadotropin release. More cases have been reported.

- A 67-year-old woman developed vaginal bleeding after taking sertraline 25 mg/day for 3 days (49). The sertraline was withdrawn and the bleeding stopped 48 hours later.
- A 41-year-old woman developed vaginal bleeding after taking venlafaxine 75 mg/day, a dose at which selective serotonin blockade is the predominant pharmacological action (50). The vaginal bleeding stopped 24 hours after venlafaxine withdrawal and occurred again on rechallenge.

Immunologic

Infection risk: three cases of *Herpes simplex* reactivation associated with fluoxetine have been described (SEDA-16, 10).

Death

Severe adverse reactions to SSRIs that were reported to Health Canada's database in 1986–1996 have been reviewed (51). There were 295 severe adverse reactions with 87 deaths. Of the fatal cases, 65 were due to intentional overdose. The other 22 deaths were due chiefly to other forms of suicide or were accidental or indeterminate (12 cases). Of the rest there were three cases of neuroleptic malignant syndrome and individual cases of cardiac or respiratory disease in which the role of SSRIs was less clear.

This report shows that the major causes of death in patients taking SSRIs are related to the risks of depression itself, particularly self-harm. SSRIs themselves appear to be relatively safe. It is possible, however, that the cases of neuroleptic malignant syndrome could have been misdiagnosed forms of the serotonin syndrome, which, like the neuroleptic malignant syndrome, can present with hyperthermia and changes in consciousness and is usually produced by pharmacodynamic interactions between SSRIs and other serotonin-potentiating compounds (SEDA-25, 24). In general, the risks of SSRIs are increased by co-prescription, and fatal overdose with SSRIs usually involves a mixture of psychotropic drugs and/or alcohol.

Sudden death has been reported in three elderly women with pulmonary disease and atrial fibrillation who had recently started taking fluoxetine. The authors recommended caution in such patients, although no causal link with fluoxetine was established (SEDA-17, 19).

Long-Term Effects

Drug withdrawal

Reports of withdrawal reactions after abrupt withdrawal of SSRIs continue to accumulate, and several reviews have summarized case reports of withdrawal symptoms (52,53).

SSRIs with shorter half-lives, such as fluvoxamine and paroxetine (qv), have a higher incidence of withdrawal symptoms than long-acting ones, but withdrawal effects have been reported, albeit rarely, after withdrawal of

© 2006 Elsevier B.V. All rights reserved.

fluoxetine (qv) (SEDA-20, 8) (54) and citalopram (55). Patients taking high doses, long-term treatment, or both are at increased risk of developing withdrawal symptoms (54,56).

In a randomized, placebo-controlled trial, sudden withdrawal of paroxetine produced significant withdrawal symptoms by as early as the second day, while patients taking fluoxetine remained asymptomatic for the five-day withdrawal period (57). Patients taking sertraline had an intermediate level of abstinence symptoms. Both paroxetine- and sertraline-treated patients reported impaired functioning during the withdrawal period, while those taking fluoxetine did not. These findings are consistent with earlier reports that suggested that acute withdrawal symptoms after fluoxetine withdrawal are unusual, presumably because of the long half-life of its active metabolite, norfluoxetine.

Second-Generation Effects

Teratogenicity

Tricyclic antidepressants appear to be generally free of teratogenic effects, but the status of newer antidepressants is unclear. Since 1993 four controlled prospective studies of antidepressant exposure during pregnancy have been published, involving about 400 women, most of whom took fluoxetine at various stages during pregnancy (58). There was no evidence that fluoxetine or other SSRIs caused an increase in intrauterine death, significant birth defects, or growth impairment. Follow-up behavioral studies of infants exposed to SSRIs during pregnancy also showed no difference from controls.

Fetotoxicity

An increasing number of women are being exposed to SSRIs during pregnancy. It is therefore important to establish as carefully as possible whether SSRIs have teratogenic effects (SEDA-24, 15). In a retrospective study of the impact on birth outcome of the timing of fluoxetine exposure in 64 pregnant women there were no major differences between infants exposed to fluoxetine early in pregnancy (the first or second trimesters only) and those exposed to fluoxetine throughout the third trimester and delivery (59). However, the infants in the late-exposed group were about twice as likely to be admitted to a special-care nursery. No specific pattern of neonatal difficulties could be found to account for this difference, and it is possible that the excess of neonatal problems in the late-onset treatment group was due to worse depression in the women who took antidepressants at around the time of delivery.

Withdrawal effects of SSRI treatment may be apparent in neonates shortly after delivery. These include jitteriness, hypoglycemia, hypothermia, and respiratory distress (60).

Lactation

The benefit : harm balance of breast-feeding during antidepressant treatment is difficult to compute and must be done on an individual basis. In general, breast-feeding with SSRIs is regarded as safe, as the amount of drug ingested by the infant is very low. However, adverse effects in the child are reported occasionally (SEDA-25, 15) and it is difficult to exclude completely the possibility of long-term effects on brain development in the infant. Clearly, the lower the concentration of SSRI in the infant the less likely are problems of acute and longer-term toxicity. In two cases treatment of breast-feeding mothers with fluvoxamine (300 mg/day) was associated with undetectable concentrations of fluvoxamine (below 2.5 ng/ml) in the plasma of both infants (61). These results are encouraging, but further data will be needed before it can be concluded that fluvoxamine has an advantage over other SSRIs in this respect. Because fluoxetine has a long half-life it may be advisable not to use it in breast-feeding women.

Drug Administration

Drug overdose

The SSRIs are in general considered to be less toxic in overdose than tricyclic antidepressants. From a review of cases of overdose with SSRI during 10 years it was concluded that SSRIs are rarely fatal in overdose when taken alone (62). In moderate overdoses of up to 30 times the daily dose, symptoms were either minor or absent. In higher doses, typical symptoms included drowsiness, tremor, nausea, and vomiting. At extremely high doses (over 75 times the usual daily dose), there were more serious toxic effects, including seizures, electrocardiographic changes, and disturbances of consciousness. When an SSRI overdose was taken in combination with alcohol or other drugs, toxicity increased, and almost all deaths involving SSRIs were in combination with other drugs.

Drug–Drug Interactions

General

For the SSRIs there are two types of interaction of major concern: SSRIs can selectively inhibit hepatic drug metabolizing enzymes, giving rise to pharmacokinetic interactions (SEDA-22, 13), and pharmacodynamic interactions can occur when SSRIs are given in combination with other serotonergic drugs, which can cause serotonergic hyperstimulation: the "serotonin syndrome." Fluoxetine gives rise to special concern, since reactions can occur weeks after withdrawal, owing to the long half-life of both parent compound and metabolite. Of the various SSRIs, citalopram seems the least likely to produce this effect. Paroxetine and fluoxetine can cause interactions with tricyclic antidepressants, neuroleptic drugs, and some antidysrhythmic drugs that are metabolized by CYP2D6.

In 31 healthy men and women (mean age 28 years) the ability of four SSRIs (fluoxetine, fluvoxamine, paroxetine, and sertraline) to inhibit CYP2D6 activity was assessed in vivo, as judged by the dextromethorphan test (63). All were extensive metabolizers of dextromethorphan. After 8 days treatment at therapeutic doses, four of eight paroxetine-treated and five of eight fluoxetine-treated subjects had become poor metabolizers, presumably because of the inhibitory effect of the two SSRIs

© 2006 Elsevier B.V. All rights reserved.

on CYP2D6 activity. In contrast, none of the eight fluvoxamine-treated or seven sertraline-treated subjects showed this effect. This in vivo study has confirmed the potent inhibitory effect of fluoxetine and paroxetine on CYP2D6 and the relative sparing by fluvoxamine and sertraline. However, fluvoxamine is a potent inhibitor of CYP1A2 and CYP3A3/4 (SEDA-22, 13). In addition, at higher doses (over 100 mg/day at steady state) sertraline can inhibit CYP2D6.

The drugs that can cause a serotonin syndrome when they are combined with SSRIs include monoamine oxidase inhibitors (including reversible inhibitors of monoamine oxidase types A and B), dextromethorphan, tryptophan, lithium, pentazocine, and carbamazepine (SEDA-17, 23) (SEDA-18, 22) (64).

Buspirone

The serotonin syndrome can occur with therapeutic doses of SSRIs (see above), but it occurs most commonly when SSRIs are co-administered with other drugs that also potentiate serotonin function. Recent case reports have suggested that there is a risk of the serotonin syndrome when SSRIs are combined with buspirone (65).

Dextromethorphan

SSRIs inhibit hepatic CYP isozymes and can thereby increase the activity of co-administered drugs that are metabolized by this route (SEDA-22, 13) (SEDA-24, 15). In healthy volunteers randomly allocated to fluoxetine (20 mg/day), sertraline (100 mg/day), or paroxetine (20 mg/day) the activity of CYP2D6 was measured by dextromethorphan testing once steady state had been achieved and the medication was withdrawn (66). Extrapolated calculations showed that the mean time for full CYP2D6 recovery after fluoxetine (63 days) was significantly longer than that for sertraline (25 days) or paroxetine (20 days). Accordingly, even after SSRIs have been withdrawn, the potential for drug interactions persists for substantial periods of time, particularly in the case of fluoxetine.

Monoamine oxidase inhibitors

Monoamine oxidase inhibitors, including reversible inhibitors of monoamine oxidase types A and B, can cause a serotonin syndrome when they are combined with SSRIs (SEDA-17, 23) (SEDA-18, 22) (64).

Nefazodone

The serotonin syndrome can occur with therapeutic doses of SSRIs (see above), but it occurs most commonly when SSRIs are co-administered with other drugs that also potentiate serotonin function. Recent case reports have suggested that there is a risk of the serotonin syndrome when SSRIs are combined with nefazodone (67).

Neuroleptic drugs

Interactions of SSRIs with neuroleptic drugs have been reported (68–70).

Sibutramine

The serotonin syndrome has been attributed to a combination of citalopram and sibutramine.

- A 43-year-old woman who had taken citalopram 40 mg/day for 2 years was given sibutramine for obesity and a few hours after the first dose of 10 mg had irritability, racing thoughts, pressure of speech, agitation, shivering, and sweating (71). These symptoms persisted for 3 days, during which time she continued to take sibutramine. The day after sibutramine was withdrawn the symptoms resolved.

The serotonin syndrome can present with hypomanic features, and the clinical picture and rapid onset in this case suggested that the addition of sibutramine to citalopram provoked serotonin toxicity. Sibutramine blocks the re-uptake of serotonin, dopamine, and noradrenaline. Whether the serotonin toxicity seen here resulted purely from the combined effects of both citalopram and sibutramine in blocking serotonin re-uptake is unclear. It is possible, for example, that potentiation of dopamine and noradrenaline activity by sibutramine might also have been involved.

Tricyclic antidepressants

Interactions of SSRIs with tricyclic antidepressants have been reported. For example, plasma concentrations of tricyclic antidepressants rise after the addition of fluoxetine (72,73), fluvoxamine (74,75), and sertraline (76).

Triptans

Drugs used in the treatment of acute migraine, such as sumatriptan and rizatriptan, are 5-$HT_{1B/1D}$-receptor agonists and could theoretically interact pharmacodynamically with SSRIs to cause serotonin toxicity. Triptans are metabolized mainly by monoamine oxidase, which makes pharmacokinetic interactions with SSRIs unlikely. Although case series have suggested that sumatriptan can be safely combined with SSRIs (SEDA-22, 14), there are occasional reports of toxicity.

Selegiline

See also Monoamine oxidase inhibitors

General Information

Selegiline is a relatively selective and irreversible inhibitor of monoamine oxidase type B, which has been used in the treatment of Parkinson's disease. It was originally suggested that selegiline may be neuroprotective. However, in a prospective double-blind study no such action was seen (1). On the other hand, selegiline does delay the start of disability, determined by the need for levodopa and progression of parkinsonian signs and symptoms (2).

However, the Parkinson's Disease Research Group in the UK reported that after a mean follow-up period of 5.6 years, mortality was increased in randomized patients with Parkinson's disease who took levodopa together with selegiline compared with patients who took levodopa alone (2). This unexpected conclusion was interpreted as a result of methodological failures. In a meta-analysis of five long-term, prospective, randomized trials of selegiline, the treated group did not have an increase in mortality (3).

Organs and Systems

Cardiovascular

Unwanted effects of selegiline on cardiovascular regulation have been investigated as a potential cause for the

© 2006 Elsevier B.V. All rights reserved.

unexpected mortality in the UK Parkinson's Disease Research Group trial (4). Head-up tilt caused selective and often severe orthostatic hypotension in nine of 16 patients taking selegiline and levodopa, but had no effect on nine patients taking levodopa alone. Two patients taking selegiline lost consciousness with unrecordable blood pressures and another four had severe symptomatic hypotension. The normal protective rises in heart rate and plasma noradrenaline were impaired. The abnormal response to head up tilt was reversed by withdrawal of selegiline. The authors proposed that these findings might be due to either non-selective inhibition of monoamine oxidase or effects of amfetamine and metamfetamine.

Nervous system

Selegiline is metabolized to amfetamine and metamfetamine, and can therefore cause insomnia (SEDA-17, 167).

Gastrointestinal

Selegiline has rarely re-activated pre-existing peptic ulcer disease (5).

Sexual function

Hypersexuality has been attributed to selegiline (6).

- A 72-year-old man who had taken levodopa for over 20 years started to take selegiline 10 mg/day. He developed a strong impulse for cross-dressing, which he had never experienced before. The behavior ceased when the selegiline was withdrawn.

It is not clear whether this effect was due to an interaction of levodopa with selegiline or due to a direct effect of selegiline itself.

Drug–Drug Interactions

Dopamine

An interaction of selegiline with dopamine has been described (7).

- A 75-year-old critically ill man taking selegiline 10 mg/day was given intravenous dopamine 3.5 micrograms/kg/minute. Within 50 minutes his systolic pressure had risen from 105 to 228 mmHg. Within 30 minutes of stopping the infusion his systolic blood pressure fell to 121 mmHg. Rather surprisingly, two rechallenges were attempted on that day and the next, at doses of 1.03 and 0.9 micrograms/kg/minute. Severe hypertension occurred on both occasions, with return to normal pressures very soon after the dopamine was discontinued.

As the authors pointed out, the selectivity of selegiline for monoamine oxidase type B may be less than was once thought, and co-administration of the drug with dopamine may be risky.

Fluoxetine and paroxetine

When given alongside fluoxetine selegiline can produce a sudden increase in blood pressure. The combined use of selective serotonin re-uptake inhibitors, such as fluoxetine or paroxetine, with selegiline has reportedly caused muscle rigidity, autonomic instability, and agitation or delirium. However, these possibilities are rare, and the serotonin syndrome is even rarer.

Levodopa

The Parkinson's Disease Research Group in the UK have reviewed an earlier report that there was excess mortality in patients with early disease treated with a combination of levodopa and selegiline (8). They have confirmed that there was about a 35% greater mortality in those on combined treatment compared with patients treated with levodopa alone. The excess deaths were all attributed to Parkinson's disease. The authors did not present any explanation for these findings, but they very reasonably suggested that the combination is inappropriate in early disease and should be used only with caution if at all in the later stages of the disease.

Tricyclic antidepressants

The combined use of tricyclic antidepressants and selegiline has been associated with hyperpyrexia, tremors, agitation, restlessness, reduced level of consciousness, and in rare instances death (9).

Selenium

General Information

Selenium is a non-metallic element (symbol Se; atomic no. 34) that was discovered by Berzelius in 1817.

The major functions of selenium can be attributed to its antioxidative properties and its role in the regulation of thyroid hormone metabolism. Selenium is important as a nutritional factor, and the US Food and Nutrition Board's Committee on Dietary Allowances has, perhaps somewhat arbitrarily, proposed a recommended daily intake of 50–200 micrograms/day.

Selenium has functions in many selenoproteins and also in relation to the immune response. There is an association between low plasma selenium concentrations and oral cancer (1). Selenium compounds inhibit tumorigenesis in a variety of animal models, and added selenium in human diets might reduce the risk of cancer (SEDA-21, 240).

Uses

Selenium-based drugs show some promise in several diseases, as orally active antihypertensive, anticancer, antiviral, antimicrobial, and immunosuppressive drugs, and organoselenium compounds reduce oxidative tissue damage and edema (2).

Selenium sulfide is used as an antiseborrheic agent and as a shampoo in the treatment of *Tinea versicolor*. Selenite is also found in mineral supplements and is used in parenteral nutrition. However, selenium has gained undeserved popularity as a constituent of health foods and alternative tonics, perhaps because selenium deficiency has been implicated in the pathogenesis of some forms of malnutrition in children. However, even in children with selenium deficiency the benefit to harm balance has not been established. Indeed, in protein deficiency it seems to be particularly toxic. Nor is there any serious basis for its reputation as a remedy for cystic fibrosis, to prevent aging, or as a sexual stimulant.

General adverse effects

As is evident from veterinary practice and animal studies, selenium has both acute and chronic toxic effects on many organs. Endemic selenium poisoning of populations in an area of China produced a picture resembling arsenic poisoning (3). It is not possible to say what effects have gone unrecorded, or perhaps what effects irregular use in alternative medicines might have at various ages. In countries where selenium is in vogue, physicians should be aware of its potential risks and should enquire about the possible use of selenium products in the home, either in adults or children.

An FDA overview has described 12 cases of selenium intoxication in the USA due to ingestion of "superpotent" selenium tablets, the estimated total ingested doses ranging from 27 to 2310 mg (4). Nausea, vomiting, nail changes, fatigue, and irritability were the most common symptoms; some subjects had watery diarrhea, abdominal cramps, dry hair, paresthesia, and a garlic-like odor on the breath. Many of these symptoms resembled the pattern of endemic poisoning seen in China (3). In one case, selenium poisoning resulted from a gross underestimation of the selenium content of a nutritional supplement.

Various aspects of selenium have been reviewed, including its toxicology and selenium deficiency (5–7) and its protective effects against cancer (8).

Organs and Systems

Neuromuscular function

The incidence of amyotrophic lateral sclerosis has been studied in some 5000 residents in an area of Italy in which they had accidentally been exposed to drinking water with a high selenium content for 9 years (9). The findings pointed to a possible association between overexposure to environmental selenium and amyotrophic lateral sclerosis.

Endocrine

One report suggests that therapeutic use of selenium in the form of selenite could precipitate hypothyroidism, but the circumstances were complex and iodine deficiency seems to have played a major role (10).

Urinary tract

Selenium 400 micrograms/day for 2 weeks in a boy of 17 and 25 micrograms/day for 2 weeks in an 11-month-old infant were thought to have caused renal damage, manifested primarily by sodium loss (11). However, there is little evidence that selenium is nephrotoxic, and the patients in question had cystic fibrosis, which could have caused sodium depletion.

Skin

Selenium sulfide can cause local irritation (SED-12, 685). Photosensitive dermatitis (pityriasis versicolor) occurred in an adult man after a second application of 2.5% selenium sulfide (12).

Reproductive system

Suppression of lactation has been ascribed to the use of selenium sulfide shampoo, but the causal relation was not proven (SEDA-16, 158).

Immunologic

Selenium can cause allergic reactions (12–14).

Drug Administration

Drug overdose

Fatal suicidal selenium poisoning has been described (15), although the patient had ingested not only selenious acid 90 mg/kg but also cupric sulfate 60 mg/kg. At autopsy, pulmonary edema, congestion of the kidneys, and hemorrhagic and erosive gastric mucosa were found.

© 2006 Elsevier B.V. All rights reserved.

Drug–Drug Interactions

Cisplatin

Selenium appears to accentuate the nephrotoxic effects of cisplatin and its vascular toxicity (SEDA-21, 241).

Sertindole

See also Neuroleptic drugs

General Information

Sertindole is an antipsychotic drug that was approved in several countries in 1997, but was suspended in January 2000, following concerns about reports of cardiac dysrhythmias and sudden death (SEDA-22, 71) (SEDA-25, 71) (1). To gather further information, data collected for prescription-event-monitoring (PEM) studies have been analysed (2). Patients taking sertindole ($n = 462$; 5482 months of observation) were compared with patients taking risperidone or olanzapine ($n = 16\,542$; 139 987 months of observation). There were seven deaths in the sertindole group and 415 in the other, and the death rates were not significantly different, although the confidence intervals were wide because of the relatively small number of patients in the sertindole group. There were six cases of prolonged QT_c interval in the patients taking sertindole and one in the controls. The authors concluded that the sertindole group was too small to rule out an association between sertindole and cardiovascular deaths.

On 28 June 2001 an ad hoc expert committee was convened to review the available clinical and preclinical data related to the cardiovascular activity of sertindole and to consider whether such data supported the then current marketing authorization status of sertindole (3). Based on a re-evaluation of all the available data, including additional data submitted by the Marketing Authorization Holder, it was concluded that the re-introduction of sertindole could be supported by further clinical safety data, strong safeguards (including extensive contraindications and warnings for patients at risk of cardiac dysrhythmias), a reduction in the recommended maximum dose from 24 mg to 20 mg in all but exceptional cases, and extensive electrocardiographic monitoring before and during treatment. The Committee for Proprietary Medicinal Products (CPMP) of The European Agency for the Evaluation of Medicinal Products later recommended lifting the ban on sertindole-containing medicinal products on the basis of additional data provided by the marketing authorization holders (see monthly report from October, 2001: www. emea.eu.int).

Organs and Systems

Cardiovascular

Sertindole was associated with 27 deaths (16 cardiac) in 2194 patients who were enrolled in premarketing studies; further fatal cases have been collected, and the Committee on Safety of Medicines has described reports of 36 deaths (including some sudden cardiac deaths) and 13 serious but non-fatal dysrhythmias also associated with sertindole (4).

Sertraline

See also Selective serotonin re-uptake inhibitors (SSRIs)

General Information

Sertraline hydrochloride has an average half-life of about 26 hours, and mean peak plasma concentrations occur at 4.5–8.4 hours. The dosage is 50–200 mg/day orally. Its major metabolite, *N*-desmethylsertraline, is less active than sertraline. Adverse effects are as for the SSRIs in general.

Organs and Systems

Cardiovascular

Angina occurred in an elderly woman shortly after she started to take sertraline and on rechallenge (1).

Nervous system

Parkinsonism

Sertraline has an appreciable affinity for the dopamine re-uptake site, and for this reason might be presumed less likely to cause movement disorders than other SSRIs. However, there is little clinical evidence to support this suggestion and cases of sertraline-induced parkinsonism have been reported (2).

- A 70-year-old woman, who had been taking sertraline 100 mg/day for 7 months, gave a 6-month history of resting tremor and loss of dexterity in the right hand. She had mild bradykinesia and cogwheel rigidity in the right arm and leg. She had not taken any other medications. A brain MRI scan was normal. The sertraline was withdrawn and within 1 month all the neurological symptoms and signs had remitted.
- An 81-year-old woman took sertraline 100 mg/day for depression and 6 months later presented with tremor and difficulty in moving her right arm and leg (3). A diagnosis of right hemiparkinsonism was made and the sertraline was withdrawn. Her extrapyramidal symptoms resolved within 3 months, but 14 months later she developed parkinsonism and was treated with levodopa and carbidopa.
- A 70-year-old man developed parkinsonian symptoms 1 month after starting to take sertraline 100 mg/day (4). Withdrawal of sertraline resulted in amelioration but not complete remission of his symptoms which then required treatment with carbidopa and levodopa.

In these cases presumably the sertraline prematurely precipitated Parkinson's disease. Two cases of sertraline-induced akathisia have been reported (SEDA-18, 19).

Serotonin syndrome

Treatment with serotonin-potentiating drugs in usual therapeutic doses can sometimes produce the serotonin syndrome. There are also case reports of this reaction with single doses of SSRIs (see also the monograph on fluvoxamine) (5).

Serotonin syndrome after a single dose of sertraline 100 mg has been reported in a 16-year-old girl (6). It responded to a single 4 mg dose of the serotonin antagonist cyproheptadine.

There was therapeutic benefit from cyproheptadine in a case of serotonin syndrome in a 2-year-old girl who accidentally swallowed ten 50 mg tablets of sertraline (7).

Endocrine

Serotonin pathways are involved in the regulation of prolactin secretion. Galactorrhea has also been reported in a patient taking sertraline, in whom lactation ceased after withdrawal (SEDA-18, 20) and in another case (8).

Hematologic

Prolonged bleeding time has been reported with sertraline (9).

Sertraline has been associated with agranulocytosis (10).

Liver

Hepatitis has been associated with sertraline (11).

Hepatitis has also been reported with paroxetine (SEDA-21, 12).

Skin

Stevens–Johnson syndrome has been reported in a 96-year-old woman who had taken sertraline (dosage not stated) for 3 weeks (12). The lesions involved the skin, oral mucosa, and conjunctiva. The eruption disappeared within 7 days of sertraline withdrawal.

Hair

Hair loss has been associated with sertraline (13).

Sexual function

Sexual disturbance has also been associated with sertraline (14), and a high frequency of such adverse effects has been reported in studies in which high doses were used. In a double-blind, placebo-controlled study of sertraline and amitriptyline in patients with major depression, male sexual dysfunction, mainly ejaculatory disturbance, was reported significantly more often with sertraline (in 21% of the patients) (15). Male sexual dysfunction in 15% of sertraline-treated patients has also been reported (16).

Priapism is occasionally associated with the use of psychotropic drugs, such as trazodone, that are α_1-adrenoceptor antagonists. It has also been reported in a man taking sertraline (17).

- A 47-year-old man presented with a 4-day history of priapism and moderate pain. Several brief but otherwise similar episodes had occurred during the previous month. He had a history of depression and had been taking sertraline 200 mg/day and dexamfetamine 10 mg/day. He received intracorporeal methoxamine, but when this proved ineffective he was treated with intracorporeal adrenaline and a shunt procedure. However, detumescence was incomplete. At follow-up after several weeks the priapism had resolved and he had not become impotent (a significant risk in cases of

© 2006 Elsevier B.V. All rights reserved.

prolonged priapism). He was given nefazodone with no recurrence of erectile dysfunction.

The dosage of sertraline used in this case was high and the combined use of dexamfetamine may also have been relevant.

Long-Term Effects

Drug withdrawal

Withdrawal symptoms have been reported with sertraline (18). All the symptoms, including gastrointestinal discomfort, insomnia, and influenza-like symptoms, remitted when sertraline was reinstituted.

Drug Administration

Drug overdose

In 40 patients who took up to 8 g of sertraline there were no serious sequelae (19).

One of the largest overdoses of sertraline has been reported (20).

- A 51-year-old woman took about 8 g of sertraline, about 80 times the usual daily dose. On admission to hospital she was somnolent but rousable. Her electrocardiogram showed a transiently prolonged QT_c interval (510 ms falling to 470 ms). On the third day she developed agitation, disorientation, myoclonus, and pyrexia (38.5 °C), was treated with supportive measures, and recovered over the next 3 days.

While cardiac toxicity was not prominent in this case, the patient developed clear evidence of the serotonin syndrome, which proved self-limiting.

Drug–Drug Interactions

Carbamazepine

Sertraline is a substrate for a number of CYP450 isozymes, including CYP2C9, CYP2C19, and CYP3A4. Several case reports have shown loss of antidepressant activity of sertraline at usual therapeutic doses when depressed patients have also taken drugs that induce CYP3A4, including carbamazepine (21).

Erythromycin

Drug interactions leading to the serotonin syndrome usually result from pharmacodynamic mechanisms. However, the antibiotic erythromycin may have precipitated the serotonin syndrome in a patient taking sertraline by a pharmacokinetic mechanism (22).

- A 12-year-old boy, who had taken sertraline 37.5 mg/day for 5 weeks for obsessive-compulsive disorder, started to take erythromycin 200 mg bd. Within 4 days he began to feel anxious; this was followed over the next 10 days by panic, restlessness, irritability, tremulousness, and confusion. These symptoms resolved within 72 hours of withdrawal of sertraline and erythromycin.

The authors proposed that in this case erythromycin had inhibited sertraline metabolism by inhibiting CYP3A. This could have led to increased concentrations of sertraline and signs of serotonin toxicity. Unfortunately sertraline concentrations were not measured to confirm this suggestion.

Rifampicin

Sertraline is a substrate for a number of CYP450 isozymes, including CYP2C9, CYP2C19, and CYP3A4. Several case reports have shown loss of antidepressant activity of sertraline at usual therapeutic doses when depressed patients have also taken drugs that induce CYP3A4, including rifampicin (23).

Sevoflurane

See also General anesthetics

General Information

Sevoflurane is an isoflurane-related anesthetic, which is pleasant to breathe and has a rapid onset and offset of action. It can be used for both the induction and maintenance of anesthesia.

It has become popular in day surgery, despite little evidence of clear advantages over current alternatives.

Inhalational induction of anesthesia is common in children, and sevoflurane is challenging the tradition of halothane induction in children. Deep anesthesia with sevoflurane can be obtained rapidly, and recovery is also faster than with halothane.

Compound A

Compound A is a haloalkene degradation product of sevoflurane metabolism by carbon dioxide absorbers, and it has been suggested that prolonged low-flow closed-circuit anesthesia with sevoflurane may maximize exposure to the degradation product. Compound A can cause convulsions and neural damage in rats (1). It also causes nephrotoxicity and hepatotoxicity in rats, particularly if barium hydroxide lime is used (2).

Organs and Systems

Cardiovascular

In 28 subjects given either sevoflurane + nitrous oxide or enflurane + nitrous oxide anesthesia, sevoflurane caused fewer cardiodepressant effects than enflurane (3). Nevertheless, in 10 healthy subjects atrial contraction and left ventricular diastolic function, including active relaxation, passive compliance, and elastic recoil were impaired by sevoflurane (1 MAC) (4).

Sevoflurane has a similar effect on regional blood flow to other halogenated anesthetics, although it is perhaps slightly less of a coronary artery vasodilator than isoflurane. It reduces myocardial contractility and does not potentiate adrenaline-induced cardiac dysrhythmias (5). It also reduces baroreflex function, and in that respect is similar to other halogenated anesthetics. Coronary artery disease is not a risk factor for the use of these agents (6).

In contrast to isoflurane and desflurane, sevoflurane tends not to increase the heart rate, and is usually well tolerated for induction of anesthesia in young children. However, profound bradycardia was reported in four unpremedicated children aged 6 months to 2 years during anesthesia induction with sevoflurane 8% and nitrous oxide 66% (7). The episodes were not associated with loss of airway or ventilation. In three of the children there was spontaneous recovery of heart rate when the sevoflurane concentration was reduced; the other child received atropine because of evidence of significantly reduced cardiac output. In a previous study of sevoflurane induction of anesthesia in children with atropine premedication there was also a low incidence of this complication (8), which is probably due to excessive sevoflurane concentrations.

The effects of sevoflurane on cardiac conduction have been studied in 60 healthy unpremedicated infants (9). They received sevoflurane either as a continuous concentration of 8% from a primed circuit or in incrementally increasing doses. Nodal rhythm occurred in 12 cases. The mean duration of the nodal rhythm was 62 seconds in the incremental group and 90 seconds in the 8% group. All of the dysrhythmias were self-limiting and there were no ventricular or supraventricular dysrhythmias. No adverse events occurred as a result of the dysrhythmias. This study highlights the importance of using electrocardiographic monitoring when inducing anesthesia with volatile agents.

- Complete atrioventricular block occurred in a 10-year-old child with a history of hypertension, severe renal dysfunction, incomplete right bundle branch block, and a ventricular septal defect that had been repaired at birth (10). After slow induction with sevoflurane and nitrous oxide 66%, complete atrioventricular block occurred when the inspired sevoflurane concentration was 3% and reverted to sinus rhythm after withdrawal of the sevoflurane. The dysrhythmia recurred at the end of the procedure, possibly caused by lidocaine, which had infiltrated into the abdominal wound, and again at 24 hours in association with congestive cardiac failure following absorption of peritoneal dialysis fluid.

Congenital or acquired forms of the long QT syndrome can result in polymorphous ventricular tachycardia (torsade de pointes). Many drugs, including inhalational anesthetics, alter the QT interval, and sevoflurane prolongs the rate-corrected QT interval (QT_c). In a randomized study of whether sevoflurane-associated QT_c prolongation was rapidly reversed when propofol was used instead, 32 patients were randomly allocated to one of two groups (11). All received sevoflurane induction and maintenance for the first 15 minutes. In one group, sevoflurane was then withdrawn, and anesthesia was maintained with propofol for another 15 minutes; the other group continued to receive sevoflurane for 30 minutes. Sevoflurane-associated QT_c prolongation was fully reversed within 15 minutes when propofol was substituted.

A case of torsade de pointes has been attributed to sevoflurane anesthesia (12).

© 2006 Elsevier B.V. All rights reserved.

- A 65-year-old woman, who had had normal preoperative serum electrolytes and a normal QT interval with sinus rhythm, received hydroxyzine and atropine premedication followed by thiopental and vecuronium for anesthetic induction. Endotracheal intubation was difficult and precipitated atrial fibrillation, which was refractory to disopyramide 100 mg. Anesthesia was then maintained with sevoflurane 2% and nitrous oxide 50%. Ten minutes later ventricular tachycardia ensued, refractory to intravenous lidocaine, disopyramide, and magnesium. DC cardioversion resulted in a change to a supraventricular tachycardia, which then deteriorated to torsade de pointes. External cardiac massage and further DC cardioversion were initially unsuccessful, but the cardiac rhythm reverted to atrial fibrillation 10 minutes after the sevoflurane was switched off. Two weeks later she had her operation under combined epidural and general anesthesia, with no changes in cardiac rhythm.

In this case the role of excessive sympathetic drive as a result of the difficult intubation and the lack of opioid use during induction must be considered, even if sevoflurane played a role in precipitating the dysrhythmia.

Respiratory

In a randomized study of the respiratory effects of high concentrations of halothane and sevoflurane in 21 healthy boys undergoing inguinal or penile surgery, there was similar respiratory depression with each agent (13). Minute ventilation fell by about 50% as a result of a reduction in tidal volume, despite an increase in respiratory rate.

Nervous system

Despite a fall in mean arterial pressure, with a consequent reduction in cerebral perfusion pressure, sevoflurane should be a suitable agent for neuroanesthesia (14). Even in patients with ischemic cerebrovascular diseases, both the CO_2 response and cerebral autoregulation were well maintained during sevoflurane anesthesia (0.88 MAC) (15).

A case of acute dystonia has been reported during induction of anesthesia with sevoflurane (16).

- A 19-year-old man with schizophrenia, who was taking cyamemazine (a phenothiazine) 75 mg/day, and dihydroergotamine 180 mg/day to avoid neuroleptic drug-induced hypotension, had no history of involuntary movements, and neurological examination was normal preoperatively. Anesthesia was induced with midazolam 5 mg oral premedication and an inhalational induction using 4–5 maximum breaths of sevoflurane 8% and nitrous oxide 50% in oxygen. One minute after loss of consciousness, he developed a torticollic posture and stiffness, rapidly extending to the left trapezius and scalene muscles. There was severe rotation of the head accompanied by trismus and opisthotonos. An intravenous injection of the muscle relaxant atracurium 30 mg resolved the muscle spasms. Subsequent anesthesia was uneventful.

Dystonia after inhalational anesthesia is rare and is presumably due to an alteration in the dynamic relation between dopaminergic and other receptors in the brain.

Sevoflurane can cause epileptiform activity on the electroencephalogram, especially during emergence from anesthesia. It has also been associated with epileptiform discharges in volunteer studies, but clinical convulsions appear to very be rare. Two cases of epileptiform activity during sevoflurane anesthesia have been reported in healthy volunteers (17). They were taking part in a study of the effects of sevoflurane on regional cerebral blood flow and received twice the minimum alveolar concentration (MAC) of sevoflurane (4.4%). The only other drug administered was rocuronium, a muscle relaxant. Sevoflurane was used at up to twice its MAC, to induce burst suppression of the electroencephalogram. One of the subjects had partial motor seizure activity in the form of slight clonic movements in the right and then later in the left leg. There was an associated increase in heart rate (from 65 to 79 beats/minute) and systolic blood pressure (from 85 to 106 mmHg) and rhythmic epileptiform discharges on the electroencephalogram. The second subject had epileptiform activity on his electroencephalogram, consisting of partial and secondarily generalized discharges lasting for 2 and 3 minutes respectively. There were no clinical signs of an epileptic seizure. Burst suppression appeared on the electroencephalogram in both subjects before the seizure activity, and the Bispectral Index increased dramatically during the epileptiform discharge to maximum values of 44 and 73 respectively. As expected, regional cerebral blood flow and regional metabolism of the epileptic focus fell interictally and increased ictally. Although the concentrations of sevoflurane used in this study were high compared with usual anesthetic practice, further human studies are warranted, because prolonged epileptiform discharge is known to be harmful.

In another case, epileptiform activity was reported during sevoflurane anesthesia, but not with propofol in the same individual (18).

- A 62-year-old woman with no personal or family history of seizures had general relaxant anesthesia for plastic surgery using a total intravenous anesthetic technique with propofol, remifentanil, and cisatracurium, after benzodiazepine premedication. Routine electroencephalographic monitoring showed continuous slowing followed by burst suppression (consistent with very deep anesthesia), but no epileptiform activity. At a second procedure, and following identical benzodiazepine premedication and induction with propofol, anesthesia was maintained with sevoflurane (plus remifentanil for analgesia and cisatracurium for neuromuscular blockade). During the procedure, sevoflurane was increased from 2% to 8%. After 5 minutes, at an end-tidal concentration of 5.9%, there was epileptiform activity on the electroencephalogram. There were no hemodynamic changes.

Epileptiform activity on the electroencephalogram in association with sevoflurane induction has also been reported in a prospective study of 20 non-premedicated healthy children in whom electroencephalographic monitoring was started before sevoflurane induction (19). At 2

© 2006 Elsevier B.V. All rights reserved.

MAC there was epileptiform activity in two boys, with spontaneously resolving myoclonic movements.

Epileptiform activity on the electroencephalogram in association with sevoflurane has also been reported in two children aged 3 and 5 years in a center in which electroencephalographic monitoring is routine (20). In both cases the activity occurred after several minutes of anesthesia, when the sevoflurane concentrations were increased to 7–8%. The epileptiform activity resolved after a reduction in sevoflurane concentrations. No seizure activity was noted.

In a prospective, observational study in 30 children undergoing adenoidectomy anesthesia was induced with midazolam and thiopental (both potent anticonvulsants) and maintained with sevoflurane; no electroencephalographic epileptiform activity was observed (21).

Generalized tonic–clonic seizures have been reported in association with the use of sevoflurane.

- Generalized tonic–clonic seizure-like movements lasting 40 seconds occurred in a healthy 32-year-old man after emergence from sevoflurane-based anesthesia (22).
- A 19-year-old man with a history of metamfetamine abuse 3 weeks earlier, but no personal or family history of seizure activity had anesthesia induced with midazolam 1 mg, nitrous oxide 50%, and sevoflurane 8% (23). The sevoflurane was subsequently reduced to 2%. After radical orchidectomy the sevoflurane and nitrous oxide were withdrawn and oxygen 100% was given and 2 minutes later rhythmic jerking movements began in the legs and quickly spread to the rest of the body. The movements were accompanied by an arched back and a stiff neck. Arterial oxygen saturation dropped to 50% and ventilation was controlled, again using sevoflurane 8%. The duration of the seizure was about 4 minutes. The sevoflurane was again withdrawn 3 minutes later, and a similar seizure occurred. This time it was controlled with midazolam 1 mg and propofol 30 mg. Recovery was marked only by mild disorientation. Postoperative computerized tomography showed a ganglioneuroma in the posterior cortex. The electroencephalogram was normal.

These reports show that clinicians need to be aware of the possibility of generalized seizures, especially in patients who are predisposed to seizures.

Peripheral neuropathy has been reported in two healthy men anesthetized with 1.25 MAC sevoflurane at 2 l/minute fresh gas flow for 8 hours. Their average concentrations of compound A were 45 and 28 ppm. Both had had previous minor injuries in the regions in which the neuropathies were reported. The authors suggested that compound A, or other factors associated with sevoflurane anesthesia, may predispose patients to peripheral neuropathy. Both men were volunteers for earlier published studies comparing the nephrotoxic properties of sevoflurane and desflurane, sponsored by Baxter PPD, New Jersey, the manufacturer of desflurane, a rival inhalational anesthetic agent; these reports need to be regarded with caution.

Neuromuscular function

Prolongation of rapacuronium-induced neuromuscular blockade by sevoflurane has been studied in a randomized, placebo-controlled comparison with suxamethonium in 40 children (24). Patients received sevoflurane and nitrous oxide anesthesia followed by rapacuronium 2 mg/kg. The study was stopped after only seven patients had been recruited, because the mean time to return of twitch height to 25% of baseline was 26 minutes. This time represents a stage at which neuromuscular blockade can be reversed and in this case it was twice as long as predicted from experience in adult patients. The authors suggested that the prolonged neuromuscular relaxation was due to the interaction of sevoflurane with rapacuronium, because such prolongation has not been observed using other inhalation agents.

Psychological, psychiatric

Delirium during emergence from sevoflurane anesthesia has often been documented. Four patients, an adult and three children aged 3–8 years, who were able to recount the experience, have been reported (25). They had full recall of postoperative events, were terrified, agitated, and distressed, and hence presented with acute organic mental state dysfunction which was short-lived. Two were disoriented and had paranoid ideation. They were not in any pain or were not distressed by pain if it was present. The authors hypothesized that misperception of environmental stimuli associated with sevoflurane's particular mode of action may have been the underlying cause of this phenomenon. Anxiolytic premedication and effective analgesia did not necessarily prevent the problem.

The effect of intravenous clonidine 2 micrograms/kg on the incidence and severity of postoperative agitation has been assessed in a double-blind, randomized, placebo-controlled trial in 40 boys who had anesthetic induction with sevoflurane after oral midazolam premedication (26). There was agitation in 16 of those who received placebo and two of those who received clonidine; the agitation was severe in six of those given placebo and none of those given clonidine.

The effects of intravenous and caudal epidural clonidine on the incidence and severity of postoperative agitation have been assessed in a randomized, double-blind study in 80 children, all of whom received sevoflurane as the sole general anesthetic for induction and maintenance (27). A caudal epidural block was performed before surgery for analgesia with 0.175% bupivacaine 1 ml/kg. The children were assigned randomly to four groups: (I) clonidine 1 microgram/kg added to the caudal bupivacaine; (II) clonidine 3 micrograms/kg added to the caudal bupivacaine; (III) clonidine 3 micrograms/kg intravenously; and (IV) no clonidine. The incidences of agitation were 22, 0, 5, and 39% in the four groups respectively. Thus, clonidine 3 micrograms/kg effectively prevented agitation after sevoflurane anesthesia independent of the route of administration.

The effect of a single preoperative dose of the opioid oxycodone on emergence behavior has been studied in a randomized trial in 130 children (28). Oxycodone prophylaxis had no effect on post-sevoflurane delirium.

The effect of a single bolus dose of midazolam before the end of sevoflurane anesthesia has been investigated in a double-blind, randomized, placebo-controlled trial in 40 children aged 2–7 years (29). Midazolam significantly

© 2006 Elsevier B.V. All rights reserved.

reduced the incidence of delirium after anesthesia. However, when it was used for severe agitation midazolam only reduced the severity without abolishing agitation. The authors concluded that midazolam attenuates, but does not abolish, agitation after sevoflurane anesthesia.

Liver

Sevoflurane can be used to induce hypotension during neurosurgery. Hypotensive anesthesia has little effect on postoperative liver function (30).

- A 3-day-old boy underwent inguinal herniorrhaphy under sevoflurane anesthesia, and 2 days later developed vomiting, anorexia, and fever (31). His aspartate transaminase, alanine transaminase, and lactate dehydrogenase activities were increased and peaked 12–16 days after the operation. Viral markers were negative, as was a lymphocyte stimulation test with sevoflurane. Toxic (not allergic) liver damage due to exposure to sevoflurane was considered to be the most probable diagnosis.

In a randomized study of the renal and hepatic effects of prolonged low-flow anesthesia with sevoflurane or isoflurane in patients undergoing prolonged operations (over 8 hours), using a technique that maximized compound A production, there were no differences in markers of hepatocellular injury at 24 or 72 hours (32).

The effect of minimal-flow (as opposed to low-flow) anesthesia with sevoflurane and isoflurane has been examined in a randomized trial in 76 patients (33). There were no significant differences between the groups in blood chemistry markers of hepatic function, despite high exposure to Compound A in the patients who received sevoflurane.

Plasma activity of alpha-glutathione *S*-transferase activity (αGT) is a more sensitive and specific marker of hepatocellular injury than transaminase activity and it correlates better with hepatic histology. Anesthesia with halothane leads to transiently raised αGT activity, but propofol and isoflurane do not. In a randomized study of plasma αGT activity during and after low-flow anesthesia with sevoflurane or isoflurane, there were no significant differences in αGT activities between the two groups during or after anesthesia (34).

Thus, the evidence suggests that sevoflurane is as safe as isoflurane in low-flow anesthesia with respect to liver dysfunction.

Urinary tract

The effects of sevoflurane, isoflurane, and desflurane on macroscopic renal structure have been studied in 24 patients undergoing nephrectomy (35). All anesthetics were administered using a fresh gas flow of 1 l/minute and a sodium hydroxide absorber and had an average duration of 3 hours. No injury to nephrons was observed by pathologists blinded to which anesthetic agent had been used. Postoperative creatinine concentrations and urine volumes did not differ significantly between the groups.

- Transient renal tubular dysfunction has been reported in a patient with asthma requiring mechanical ventilation who received sevoflurane for 9 days (36). Soda lime was not used, and the cumulative dose was 298 MAC-hours. Serum and urinary inorganic fluoride concentrations reached maximum concentrations of 71 and 2047 μmol/l respectively. Markers of renal tubular injury were also greatly raised (urinary *N*-acetyl-beta-D-glucosaminidase and $beta_2$-microglobulin). However, urine volume, creatinine clearance, and serum creatinine and urea concentrations were unaffected.

There has been a meta-analysis of 22 controlled trials in 3436 patients (82% ASA I or II, 16% ASA III, and 2% ASA IV) (37). The trials had compared sevoflurane for anesthesia maintenance with isoflurane, propofol, or enflurane. Serum creatinine and blood urea nitrogen were used to assess preoperative and postoperative renal function. The duration of anesthesia was 0.5–11 hours. Most patients (97%) were exposed to less than 4 MAC-hours of volatile agent. Falls in the serum creatinine and blood urea nitrogen were significantly smaller with isoflurane than with sevoflurane. In patients who received concurrent aminoglycosides, sevoflurane was associated with a small increase in serum creatinine. The following factors had no effect on renal function: the type of anesthetic circuit, the choice of carbon dioxide absorber, the inorganic fluoride ion concentration, the duration of anesthesia, the use of nitrous oxide, or how sick patients were. When all patients were considered, the incidences of clinically significant increases in serum creatinine were the same between agents. In patients with baseline creatinine values greater than 132 μmol/l (1.5 mg/dl), the incidence of clinically important increases in serum creatinine was significantly higher in both treatment groups compared with baseline. This meta-analysis has provided strong evidence that sevoflurane does not contribute to clinically significant renal insufficiency.

Renal impairment often follows cardiac surgery, but in a randomized trial in elective coronary artery surgery in 354 patients, sevoflurane did not produce greater increases in serum creatinine concentrations than isoflurane or propofol (38).

The role of compound A

Sevoflurane is metabolized to compound A by carbon dioxide absorbers. It is nephrotoxic in rats, but nephrotoxicity in humans has not been proven. The accumulation of compound A is greatest with low fresh gas flows and barium hydroxide absorbers, both of which cause higher temperatures in the absorber. Current anesthetic practice is to use sodium hydroxide for carbon dioxide absorption, because it produces less compound A than barium hydroxide.

There has been controversy over whether compound A causes significant renal damage in humans. The potential for renal damage using sevoflurane was investigated in 42 patients without renal disease scheduled for surgery lasting more than 4 hours (39). The patients were given low-flow sevoflurane or isoflurane (fresh gas flow 1 l/minute/m^2) or high-flow sevoflurane (6 l/minute/m^2). None of these increased blood urea nitrogen concentrations, creatinine concentrations, or creatinine clearance.

© 2006 Elsevier B.V. All rights reserved.

There were no significant differences in $beta_2$-microglobulin, a marker of tubular function, or urinary glucose concentrations. However, there was an increase in the 24-hour urinary excretion of *N*-acetyl-beta-glucosaminidase, a marker of proximal tubular necrosis, with both doses of sevoflurane but not with isoflurane. There were no significant differences in the serum and urinary fluoride concentrations between the two sevoflurane groups, despite the higher concentration of compound A (29 versus 3.9 ppm) in the expired gases of those who received low-flow sevoflurane. The maximum 24-hour protein excretion was higher with low-flow sevoflurane compared with the other two groups.

The effect of the nephrotoxic aminoglycoside antibiotic amikacin on renal function during low-flow sevoflurane anesthesia has been studied in a randomized study in 37 men undergoing orthopedic surgery (40). Markers of renal tubular injury (urinary *N*-acetyl-beta-D-glucosaminidase and $beta_2$-microglobulin) were not abnormally raised, and urine volume, creatinine clearance, and serum creatinine and urea concentrations were unaffected. The duration of anesthesia and compound A concentrations were similar in the two groups.

In a randomized study of the renal and hepatic effects of prolonged low-flow anesthesia with sevoflurane or isoflurane in patients undergoing prolonged operations (over 8 hours), using a technique that maximized compound A production, there were no significant differences between the groups in serum creatinine or urea concentrations, creatinine clearance, or urinary protein or glucose excretion at 24 or 72 hours (32). Proteinuria and glycosuria were common in both groups. There was no correlation between exposure to compound A and any measure of renal function. There were no differences in markers of hepatocellular injury. There was no evidence of nephrotoxicity of sevoflurane even at high degrees of exposure to compound A for as long as 17 hours.

The effect on renal function of minimal-flow (as opposed to low-flow) anesthesia with sevoflurane and isoflurane has been examined in a randomized trial in 76 patients (33). There were no significant differences between the groups in blood chemistry markers of renal or hepatic function or in urinary markers of tubular injury, despite high exposure to compound A in the patients who received sevoflurane.

These studies have confirmed earlier findings that although there is biochemical evidence of renal damage after sevoflurane anesthesia, there are no clinically significant effects.

The role of fluoride

Serum and urinary inorganic fluoride concentrations can rise after inhalation of sevoflurane, because of hepatic metabolism (41). The authors concluded that lengthy sevoflurane anesthesia could alter renal function, although there was no other evidence of nephrotoxicity. Although patients with normal renal function are probably not at risk during normal anesthesia with sevoflurane, those with pre-existing renal impairment may be at risk.

A randomized, open study in 26 patients with renal dysfunction who received either isoflurane or sevoflurane for operations lasting up to 6 hours showed no significant differences in postoperative creatinine clearances. However, there was a significant increase in the plasma fluoride ion concentration with sevoflurane (42). In 10 adults who were given repeat high-flow sevoflurane anesthesia there was no evidence of renal or hepatic injury and no increases in serum or urine fluoride concentrations that would indicate an increase in sevoflurane metabolism with repeated use (43).

Renal function has been assessed after low fresh gas flow anesthesia (1 l/minute or less) with either sevoflurane or isoflurane in a multicenter study of 254 patients (44). The mean duration of anesthesia was 3.0 MAC-hours in both groups. Peak serum fluoride concentrations were significantly higher (40 μmol/l) after sevoflurane compared with isoflurane (3 μmol/l), and 26 patients had peak fluoride concentrations over 50 μmol/l, a concentration that is associated with renal dysfunction after methoxyflurane anesthesia. There were no significant differences in the renal function of the two groups, as measured by serum creatinine, urea, glycosuria, proteinuria, urine pH, or specific gravity. Absence of renal dysfunction, despite high serum fluoride concentrations after sevoflurane anesthesia, was consistent with previous reports. It appears that low fresh gas flow anesthesia with sevoflurane is not associated with clinically significant renal damage.

The role of aquaporins

Aquaporin-2 is a protein involved in regulation of water permeability in the kidneys. The effects of sevoflurane- and propofol-based anesthesia on urine concentrating ability and aquaporin-2 concentrations have been compared in 30 patients undergoing major surgical procedures given sevoflurane + nitrous oxide or propofol + nitrous oxide (45). Sevoflurane caused a transient 25% fall in aquaporin-2 concentrations 90 minutes after surgery, rather than the usual 40% increase, which occurred in the propofol group. By 3 hours after surgery the aquaporin concentrations in the sevoflurane group had increased and were similar to those in the propofol group. There was a 40% fall in urine osmolarity in the sevoflurane group, but recovery occurred by 3 hours postoperatively. This effect is the likely cause of the occasional cases of polyuria reported in association with sevoflurane anesthesia, rather than nephrotoxicity caused by fluoride ion or compound A.

Musculoskeletal

There have been reports of rhabdomyolysis after anesthesia with halothane, enflurane, and isoflurane in patients with muscular dystrophy, in whom suxamethonium was not used. Rhabdomyolysis has also been reported after sevoflurane anesthesia (46).

- An 11-year-old boy with Duchenne's muscular dystrophy underwent strabismus repair. He also had asthma, for which he was taking prednisone 25 mg/day and theophylline. He underwent inhalational induction with sevoflurane 4% and nitrous oxide 64%; tracheal intubation was then performed without the use of a muscle relaxant. Anesthesia was maintained using sevoflurane 1.5–3.0% and nitrous oxide 64%. He also

© 2006 Elsevier B.V. All rights reserved.

received hydrocortisone 100 mg and diclofenac 25 mg. The operation lasted 51 minutes and anesthesia was uneventful. He suffered heel pain during the first few hours postoperatively, and 3 hours postoperatively passed 300 ml of dark red urine, containing large amounts of myoglobin. His serum enzymes increased from preoperative values, serum aspartate transaminase from 76 to 458 IU/l, alanine transaminase from 136 to 254 IU/l, and creatine kinase from 4430 to 55 700 IU/l. He was treated with dantrolene 1 mg/kg and recovered over the next day.

The history and finding in this case are strongly diagnostic of rhabdomyolysis. The most likely cause of rhabdomyolysis in this patient was thought to be inhalation of sevoflurane.

Rhabdomyolysis triggered by sevoflurane in a child with Duchenne muscular dystrophy has been reported in one case (47).

Body temperature

Malignant hyperthermia has occurred in people treated with sevoflurane.

- In the case of a 4-year-old girl, dantrolene was effective; susceptibility to malignant hyperthermia was later confirmed by muscle biopsy (48).
- A 28-year-old man, who developed malignant hyperthermia after anesthesia induced with isoflurane and maintained with sevoflurane, died 4 days later, despite cooling and intravenous dantrolene (49).

Other cases of malignant hyperthermia have been reported in patients who received sevoflurane (50,51). Although it is highly likely that sevoflurane caused malignant hyperpyrexia in these cases, suxamethonium was also given and was also a suspect.

Of two other cases (52,53), the second was remarkable, in that the specific-treatment dantrolene was not available, and yet the patient survived with aggressive active cooling and general supportive measures, including sodium bicarbonate.

In more than 3000 cases in Japan, there were two cases of malignant hyperthermia, one fatal (49). In this case isoflurane had been used early in anesthesia, and could have been at least in part responsible. There was some reason to consider that the patient, a 12-year-old girl, had a family propensity to malignant hyperthermia, as indicated by higher resting Pi/Pcr values. However, sevoflurane itself can trigger malignant hyperthermia in swine (54).

Susceptibility Factors

Renal disease

It has been thought that patients with chronically impaired renal function might be at increased risk of nephrotoxicity due to sevoflurane, because of an increased fluoride load due to reduced excretion. However, this was not confirmed in 41 patients undergoing elective surgery, with a stable increased preoperative serum creatinine concentration, who were randomly allocated to receive sevoflurane ($n = 21$) or enflurane ($n = 20$) at a fresh gas inflow rate of 4 l/minute for maintenance of anesthesia (55). Peak serum inorganic fluoride concentrations were significantly higher after sevoflurane than after enflurane anesthesia. Laboratory measures of renal function remained stable throughout the postoperative period in both groups. No patient had permanent deterioration of pre-existing renal insufficiency and none required dialysis.

Other features of the patient

Insulinoma

- A 56-year-old woman with insulinoma, operated under sevoflurane anesthesia, had an uneventful perioperative course, and the authors suggested that sevoflurane suppressed the spontaneous release of insulin (56).

Sevoflurane may therefore be useful for anesthesia in patients with insulinoma.

Transplantation

- A 29-year-old man was anesthetized after renal transplantation with sevoflurane + nitrous oxide + oxygen for replacement of the head of the left femur (57). His serum fluoride concentration was always below 40 μmol/l and sevoflurane had little effect on the transplanted kidney.

It seems therefore that sevoflurane might be suitable for patients with renal transplants.

Drug–Drug Interactions

Dexmedetomidine

In 45 adult patients undergoing elective surgery, the α_2-adrenoceptor agonist dexmedetomidine in a concentration of 0.7 ng/ml reduced the minimum alveolar concentration of sevoflurane required to suppress movement to skin incision by 17%, but a plasma concentration of 0.39 ng/ml had no effect (58). The larger reductions in isoflurane requirements found in earlier studies of dexmedetomidine were probably due to the use of potent opioids and intravenous induction as part of the anesthetic.

Fentanyl

The minimum alveolar concentrations of sevoflurane required to suppress movements and adrenergic responses to surgery in the presence of the potent opioid fentanyl have been quantified in 226 adults (59). Fentanyl 3 ng/ml and 6 ng/ml reduced sevoflurane requirements to suppress movement to pain by 61% and 74%, respectively, and requirements to suppress the adrenergic responses to pain by 83% and 91%, respectively. There was no further reduction in sevoflurane requirements at concentrations of fentanyl above 6 ng/ml. The degree of interaction was similar to that seen in previous studies of other volatile anesthetic + opioid combinations.

Ketorolac

Ketorolac, which can cause renal vasoconstriction by inhibiting cyclo-oxygenase, is often given to patients anesthetized with sevoflurane, which is also potentially

© 2006 Elsevier B.V. All rights reserved.

nephrotoxic. The effect of ketorolac has been assessed in a placebo-controlled, randomized study in 30 women undergoing breast surgery with sevoflurane anesthesia (60). There were no differences in several markers of renal injury in those who did or did not receive ketorolac.

Probenecid

The effect of the uricosuric agent probenecid in prolonged sevoflurane anesthesia has been examined in 64 patients randomized to receive high-flow or low-flow anesthesia with sevoflurane with or without preoperative oral probenecid (61). There were no differences in urea, creatinine, or creatinine clearance among the treatments. However, patients who received low-flow sevoflurane had some evidence of renal tubular injury (raised urinary markers) compared with those who received either high-flow anesthesia or probenecid.

Sfericase

General Information

Sfericase is a crystallized alkaline protease that breaks down various protein bases. It is given in enterolytic tablets containing 10 000 units of sfericase. It is prescribed in a dose of two tablets to be taken three times a day. In 73 patients with chronic respiratory diseases there were no significant adverse effects (1).

Sibutramine

See also Anorectic drugs

General Information

Sibutramine is an appetite suppressant that inhibits the re-uptake of noradrenaline and serotonin. It is used in the adjunctive management of obesity in individuals with a body mass index (BMI) of 30 kg/m^2 or more (and no associated co-morbidity) or in individuals with a BMI of 27 kg/m^2 or more in the presence of other risk factors such as type 2 diabetes or hypercholesterolemia.

The safety and efficacy of sibutramine 10 mg/day in 109 obese patients (BMI over 30 kg/m^2, ages 16–65 years) has been evaluated in a double-blind, placebo-controlled, parallel-group, prospective study over a period of 6 months (1). There was a significant loss of body weight and significantly reduced BMI and waist measurement. There were 45 adverse events in 32 patients taking sibutramine; the most frequent were dry mouth ($n = 19$), increased blood pressure ($n = 5$), constipation ($n = 5$), and tachycardia ($n = 5$); two patients withdrew owing to adverse events. There were 29 adverse events in 23 patients taking placebo, mainly increased blood pressure ($n = 11$) and dry mouth ($n = 10$). In contrast, in an earlier study (2) there was no significant increase in systolic or diastolic blood pressures or heart rate.

Although serious adverse events have not been reported, there is no evidence of the long-term safety of sibutramine (3). Several new randomized clinical trials have assessed long-term weight reduction efficacy, tolerability, and safety of sibutramine. In a 1-year placebo-controlled study in primary care, sibutramine 10 mg/day ($n = 122$) or 15 mg/day ($n = 123$) with dietary advice produced and maintained more weight loss than dietary advice alone (4). None of the patients taking sibutramine or placebo ($n = 114$) was withdrawn because of a raised blood pressure.

There were comparable results in 44 patients who took sibutramine 10 mg/day for 12 months in a double-blind, placebo-controlled, crossover design (5). After sibutramine withdrawal, the patients gained weight but did not reach baseline body weight. There were no significant adverse events of sibutramine withdrawal. Early sibutramine administration produced better effects than administration after a period of dieting.

Further trials have confirmed the efficacy of sibutramine as a weight-loss agent in doses of 10–20 mg/day. The benefit of sibutramine is not only in its ability to induce weight loss, but also in its ability to maintain the weight loss effect for up to 2 years. However, once sibutramine is withdrawn, weight gain commonly occurs. Thus, sibutramine is considered effective in the management of obese patients who require pharmacotherapy as part of a multimodal approach to weight reduction (6).

In a multicenter, double-blind, randomized, parallel-group, placebo-controlled trial in 22 European centers for specialist diabetes care over 6 months, sibutramine, in conjunction with moderate caloric restriction, enabled obese patients with type 2 diabetes taking sulfonylureas to achieve clinically significant weight loss (7). This was associated with additional improvement in glycemic control in a limited number of patients who lost at least 10% of their baseline body weight.

Sibutramine was approved in Italy in April 2001 but was taken off the market there on 6 March 2002, after 50 reported adverse reactions (mainly tachycardia, hypertension, and dysrhythmias, in seven cases serious), and two deaths from cardiac arrest (8). Subsequently, the Secretariat of the European Medicines Evaluation Agency began a comprehensive benefit : harm balance assessment of sibutramine, which remains on the market in several European countries; these include the UK (where there were 215 reports of 411 adverse events, 95 serious and 2 deaths) and France (where there were 99 reports of adverse events, 10 serious but no deaths). From February 1998 to September 2001, the Food and Drug Administration (FDA) in the USA received reports of 397 adverse events (143 cardiac dysrhythmias and 29 deaths, 19 due to cardiovascular causes, 10 involving people under 50 years of age, and 3 involving women under 30 years of age) (9). In Canada, 28 adverse reactions (mainly hypertension and dysrhythmias, but no deaths) were reported from December 2000 to February 2002, including one case of chest pain, one of stroke, and two of eye hemorrhage; in three of these cases, the patients were concurrently taking a contraindicated antidepressant (10). The safety of sibutramine needs further postmarketing surveillance.

In a placebo-controlled study, sibutramine 10 mg/day for 6 months caused weight loss and a reduction in left ventricular mass in 86 obese hypertensive patients, with no changes in blood pressure or antihypertensive therapy (11). Baseline investigations included echocardiography, 24-hour ambulatory blood pressure monitoring, and hepatic enzyme measurements. Compared with placebo, sibutramine produced a greater weight loss, an increase in heart rate, and a reduction in left ventricular mass/height index. The two groups had comparable increases in alkaline phosphatase activity and comparable adjustments in antihypertensive therapy. The most frequent adverse effects associated with sibutramine were dry mouth and arthralgia; higher frequencies of insomnia and irritability, as suggested in other studies, were not found. The alterations reported in alkaline phosphatase may be associated with mobilization of visceral adipose tissue (12) and cannot be attributed to the use of sibutramine.

Organs and Systems

Cardiovascular

Cardiovascular risk factors associated with obesity, including dyslipidemia, particularly raised triglyceride concentrations and reduced high-density lipoprotein concentrations, can be improved with weight loss during sibutramine treatment (4,5,13). In general, improvements in serum lipids are proportional to the degree of body weight loss, whether that weight loss occurs with sibutramine or with placebo (13,14).

In a study of the efficacy and safety of sibutramine in obese white and African Americans with hypertension, the most common adverse event resulting in withdrawal

© 2006 Elsevier B.V. All rights reserved.

among those taking sibutramine was hypertension (5.3 versus 1.4% of patients taking placebo) (15).

The observation that sibutramine, which blocks the re-uptake of noradrenaline and serotonin and to a lesser extent dopamine (6), causes a raised blood pressure has been a cause of concern (1,16). Some insight into this problem and its magnitude comes from two recent studies (17,18). Most studies have shown a positive relation between blood pressure and weight (19). The failure of the blood pressure to fall with weight loss in normotensive and hypertensive patients treated with sibutramine differs from the fall seen with orlistat (20–22) or weight loss induced by life-style modifications (23,24). In the case of sibutramine, the potentially detrimental effect due to the failure of the blood pressure to fall with weight loss may be offset by the reductions in lipids, insulin, and uric acid that occur with weight loss (25).

Intermittent use of sibutramine has been proposed to reduce potential concerns about its effect on blood pressure. An alternative strategy would be to identify those patients who respond to sibutramine with weight loss but who have minimal changes in blood pressure (25).

The effects of sibutramine on weight loss, blood pressure, and pulse rate in hypertensive obese patients, whose blood pressure was well controlled with a beta-blocker either alone or with a thiazide diuretic, have been evaluated in a 12-week, double-blind, placebo-controlled, parallel-group, randomized study in 69 patients (17). Sibutramine was effective and well tolerated and did not exacerbate pre-existing hypertension controlled with beta-blockers. Despite the presence of apparently effective beta-blockade, there were modest increases in pulse rate in those who took sibutramine, suggesting that mechanisms other than increased sympathetic tone may, at least in part, mediate this effect. Based on the potential for increased blood pressure and pulse rate, obese patients with well-controlled hypertension who are taking sibutramine should be monitored periodically (17).

In a 52-week, multicenter, randomized, double-blind, placebo-controlled, parallel-group study in 220 hypertensive patients with obesity (BMI 27–40 kg/m^2), whose hypertension was well controlled with an angiotensin converting enzyme (ACE) inhibitor with or without a thiazide diuretic, sibutramine 20 mg/day safely and effectively achieved weight loss without compromising blood pressure control (18). Blood pressure remained in the target range in patients who took sibutramine or placebo, although sibutramine was associated with a small mean increase in blood pressure and a modest increase in pulse rate.

Drug–Drug Interactions

Citalopram

Hypomania in a unipolar depressed woman has been attributed to concomitant use of sibutramine and citalopram (26). The close temporal relation between the onset and the disappearance of hypomania with the introduction and withdrawal of sibutramine suggested a causal link. This report suggests that combining sibutramine with a serotonin re-uptake inhibitor could cause hypomania in people with unipolar major depressive disorder with a family history of bipolar disorder.

Finasteride

Soon after the introduction of finasteride to treat alopecia, a 30-year-old man taking sibutramine developed paranoid psychotic behavior (27). This drug interaction was demonstrated by careful clinical follow-up and the use of Naranjo's algorithm.

Sildenafil

General Information

Sildenafil is a potent inhibitor of phosphodiesterase type V, and therefore of the breakdown of cyclic guanosine monophosphate (cGMP) in the corpora cavernosa. The increased concentration of cGMP leads to nitric oxide-mediated relaxation of the smooth muscle cells and vasodilatation in the corpus cavernosum, which is essential for normal erection. Thus, sildenafil increases the penile response to sexual stimulation and is effective in erectile dysfunction (1,2).

The main adverse effects reported in clinical studies were flushing, headache, dyspepsia, visual disturbances, and rhinitis, some of which show that vasodilatation is not confined to the corpora cavernosa. They were mild, and only 1–2% of the patients discontinued sildenafil because of adverse effects.

The adverse effects of a single dose of sildenafil 50 mg have been evaluated in a placebo-controlled study in 40 young healthy volunteers (3). The most commonly reported adverse effects with sildenafil and placebo respectively were flushing (75 and 0%), headache (50 and 5%), and dyspepsia (15 and 5%). This adverse effects profile was similar to that observed in clinical trials. Heart rate changed significantly, but blood pressure did not.

There have been several case reports of the use of sildenafil to ameliorate rebound pulmonary hypertension (4).

- A six-week-old 3.1 kg girl developed severe pulmonary hypertension and systemic hypotension after the removal of a bilateral pulmonary vein obstruction due to a left atrial membrane. Nitric oxide 20 ppm reduced the pulmonary arterial pressure from 57 to 33 mmHg, and plasma cGMP concentrations increased from 12 nmol/l at baseline to 28 nmol/l with nitric oxide. After three unsuccessful weaning attempts, due to rebound, sildenafil 1 mg was given via a nasogastric tube and nitric oxide was withdrawn 90 minutes later, with minimal increase in pulmonary artery pressure and a rise in cGMP concentration to 45 nmol/l.
- A 3.5 kg newborn girl, who underwent corrective surgery for an infradiaphragmatic totally anomalous pulmonary venous connection, had postoperative systemic hypotension, low cardiac output, and pulmonary hypertension. Inhaled nitric oxide 20 ppm improved her pulmonary hemodynamics but could not be withdrawn by the third postoperative day, owing to reflex pulmonary hypertension. Sildenafil 1 mg via nasogastric tube again allowed withdrawal of nitric oxide, with preservation of plasma cGMP concentrations above baseline.
- A 4-month-old 4.1 kg boy with severe bilateral pulmonary vein stenosis developed moderate pulmonary hypertension after surgical revision. Sildenafil 1.1 mg via nasogastric tube did not increase the plasma cGMP concentration or reduce the rebound effect.

The authors suggested that in this case the effect of sildenafil may have been reduced by impaired gastrointestinal absorption. They speculated that exogenous nitric oxide inhibits nitric oxide synthase activity, with a consequent reduction in pulmonary vascular smooth muscle cGMP concentration. Phosphodiesterase type V inhibitors, such as sildenafil, increase cGMP concentration and ameliorate the rebound effect.

Organs and Systems

Cardiovascular

In several reviews, in which the same data have been analysed, sildenafil has been rated as being well tolerated

© 2006 Elsevier B.V. All rights reserved.

(5,6) and extremely safe (7). Concerns about its cardiovascular safety profile have stemmed primarily from sporadic reports of myocardial infarction and stroke.

- One patient without a history of previous chest pain or risk factors for cardiovascular disease, developed a well-documented myocardial infarction 30 minutes after he took sildenafil 50 mg and before any attempt at sexual intercourse (8).

The interpretation of these sporadic cases is controversial, although some have argued that the reported cardiovascular adverse effects occur more often with sildenafil than with other pharmacological treatments of erectile dysfunction. It is at present unclear whether there is an increased risk with sildenafil. For example, in placebo-controlled trials there have been no differences in the incidences of myocardial infarction, angina, or coronary artery disorders between sildenafil and placebo (9). Exclusion criteria in clinical trials may have prevented the inclusion of patients who are at increased risk of adverse events. On the other hand, sexual activity itself increases cardiac workload and the risk of myocardial infarction. Patients with cardiovascular disease should be cautious in their use of sildenafil.

Cardiac dysrhythmias have been reported in patients who have taken sildenafil.

- A 54-year-old man with hypertrophic cardiomyopathy, for which he took verapamil, felt unwell after a single tablet of sildenafil (10). Holter monitoring after repeat sildenafil showed an increase in ventricular extra beats and episodes of non-sustained ventricular tachycardia. On echocardiography, left ventricular dimensions were reduced and the subaortic gradient was markedly increased.
- Two other patients with severely depressed left ventricular function developed ventricular tachycardia (11).

Ear, nose, throat

Two men developed prolonged epistaxis a few hours after taking sildenafil 50 mg to enhance their sexual performance (before the nose bleeding started); both had well-controlled hypertension (12). Epistaxis is not an unusual problem in elderly people with hypertension, and venous engorgement is thought to be the main causative factor. Whether this is amplified by sildenafil (and/or by sexual activity) is an open question.

Nervous system

Clinical trials of sildenafil have not shown increased risks of stroke or myocardial infarction. However, postmarketing drug surveillance programs have mentioned strokes associated with sildenafil, and case reports have been published.

- A 50-year-old man took sildenafil 50 mg, and 2 hours later developed a right-sided hemiparesis and altered hemibody sensation, a right-facial paresis, and slurred speech (13). The symptoms gradually disappeared 4 hours later, but recurred the next week when he took sildenafil 100 mg. On the second occasion the symptoms did not resolve, and an MRI scan showed a recent infarct in the left internal capsule and lateral thalamus. No other cause of the stroke was found by evaluation of the heart and extracranial vessels. The symptoms gradually improved over 6 months.
- A 44-year-old man developed a severe headache and vomiting after taking four tablets of sildenafil (of unknown strength) followed by sexual intercourse (14). A CT scan showed a left-sided temporal intracranial hemorrhage. He died of cerebral edema and pneumonia a few days later. Autopsy showed no vascular abnormality.
- A 67-year-old man took two tablets of sildenafil 25 mg 1 hour apart (15). He complained of headache, confusion, and nervousness after the first tablet, his symptoms increased, and he developed language difficulty after the second tablet. He did not have sexual intercourse. A few days later, an MRI scan showed a large left temporal subcortical hemorrhage. The symptoms resolved partially over a few days.

Whereas the suspected mechanism for ischemic stroke is analogous to that leading to myocardial infarction (hypoperfusion distal to a critical lesion), intracerebral bleeding (14,15) may be more difficult to explain. The authors considered the likelihood of sildenafil-induced spontaneous intracerebral hemorrhage due to the vasodilatory effects of the drug on the cerebral vasculature (as evidenced by headache, flushing, and nasal congestion).

- A third-nerve palsy occurred 36 hours after a second dose of sildenafil in a 56-year-old man.

The authors suggested that sildenafil had caused systemic hypotension sufficient to cause neurological dysfunction, but 36 hours is a long lag time for a drug with a half-life of only a few hours (16).

Unexpected functional disturbances, which occur shortly after the use of sildenafil, are likely to be attributed to the drug.

- A 51-year-old man had transient global amnesia 30 minutes after taking sildenafil 25 mg (17).
- A 79-year-old man had acute vertigo, vomiting, and tinnitus resembling vestibular neuronitis 2 hours after first taking 50 mg; the symptoms lasted for 24 hours (18).
- Generalized tonic-clonic seizures have been reported after a first 50 mg tablet in two men aged 54 and 63, neither of whom had organic brain lesions on imaging; one had tonic-clonic seizures again on rechallenge with the drug 3 months later (19).

Sensory systems

Sildenafil has weak inhibitory effects on phosphodiesterase type V in the retina, leading to temporary changes in the perception of color hue and brightness. The importance of reversible changes in the electroretinogram observed in volunteers after sildenafil 100 mg, ascribed to inhibition of phosphodiesterase type 5 in the retina, is unclear (20–22).

There have been reports of a temporal association between vascular events in the eye and sildenafil administration.

- A fit, healthy, 69-year-old man presented with sudden painless loss of vision in the left eye a few hours after taking sildenafil 100 mg (23). Fundus examination

© 2006 Elsevier B.V. All rights reserved.

showed occlusion of a branch of the retinal artery. No cardiovascular abnormality was detected.
- A 52-year-old man developed sweating, headache, and blurred vision in his left eye 1 hour after a first dose of sildenafil 50 mg (24). The same symptoms recurred on the next night, after a second dose of sildenafil. Fundoscopy a few days later showed an ischemic optic neuropathy.
- A 42-year-old man presented with anterior ischemic optic neuropathy, leading to a visual field defect in that eye within 24 hours of having taken sildenafil (25).

Anterior ischemic optic neuropathy is a disorder whose pathophysiology is poorly understood. The difference between the intraocular pressure and the perfusion pressure in the posterior ciliary arteries determines the circulation in the optic disc, and a reduction in this difference may contribute to ischemia.

Several other cases of non-arteritic ischemic optic neuropathy have been reported in men taking sildenafil (26,27).

Liver

- A 68-year-old man with alcoholic cirrhosis and small esophageal varices (degree of severity classified as Child I) started bleeding after taking sildenafil 25 mg for the first time (28).

Sudden overload of the portal venous system related to splanchnic vasodilatation was a possible provoking factor in this case. Gastroesophageal reflux secondary to a lower esophageal sphincter tone and causing mucosal erosion was an alternative explanation.

Sexual function

Whereas priapism has not been reported with sildenafil in controlled clinical trials, it is being mentioned in postmarketing drug surveillance programs, and two case reports have appeared in a healthy young man and a patient with sickle cell trait (29,30).

Death

There has been debate on the risk of death after sildenafil: can it be entirely attributed to co-existing cardiovascular disease with an inherent high risk of mortality, particularly during sexual activity, or does the drug contribute (31,32).

- A 44-year-old man developed an acute myocardial infarction after taking sildenafil but before sexual intercourse (33).

This case appears to point to the drug as a potential trigger in people with unknown critical coronary lesions

A postmarketing survey over the first 6 months of sales of sildenafil in the USA (April to the middle of November 1998) has reported details on 130 patients who died after having been given sildenafil (over 3.5 million having received a prescription for it). As expected, deaths were mostly cardiovascular. There was a close time relation to the administration of sildenafil (within 4–5 hours) in 44 patients, 27 of whom died during or immediately after sexual intercourse. The disturbing finding was that 16 men also either took or were given glyceryl trinitrate, contrary to product labeling and to several warnings (34). A survey conducted in the UK on recreational use of sildenafil among night-club customers detected combined use of sildenafil with amyl nitrate. As both drugs are vasodilators, combined use may expose users to the same risk as the combination with glyceryl trinitrate (35).

Long-Term Effects

Drug tolerance

Potential tachyphylaxis with long-term use of sildenafil has been discussed following a survey in which 200 patients were questioned twice, 2 years apart, about the effects of sildenafil; on the second occasion 20% of them reported needing an increased dose, and 17% had discontinued therapy because of lack of effect (36). However, others have commented that more likely reasons for the loss of effect over time included worsening of the disease (37–41), reducing testosterone concentrations with age (38,39), or lack of proper arousal (42). Although the mRNA for phosphodiesterase type 5 is down-regulated in the retina by long-term administration of sildenafil in rats (43), it is not known whether that happens in human corpus cavernosum, nor whether long-term sildenafil use is associated with tachyphylaxis.

Drug Administration

Drug overdose

A case of suspected overdose of sildenafil has been reported (44).

- A 56-year-old man with a history of diabetes mellitus and hypertension was found dead at home, with an empty package of sildenafil (12 tablets of 50 mg) near the body. The concentration of sildenafil in postmortem blood was high. Autopsy showed a dilated cardiomyopathy and diffuse coronary atherosclerosis, but an overdose of sildenafil was suspected to have provoked a fatal ventricular dysrhythmia.

Drug–Drug Interactions

Calcium channel blockers

Retrospective analysis of clinical trials has suggested that the concomitant use of antihypertensive drugs did not lead to an increase in adverse events in patients also taking sildenafil (45).

Hypertensive patients taking amlodipine, in contrast to glyceryl trinitrate, had only a minor supplementary fall in blood pressure when challenged with a single dose of sildenafil, and a few had a mild to moderate headache (46).

Diltiazem is metabolized by CYP3A4 and was held responsible for unanticipated prolonged hypotension after sublingual glyceryl trinitrate in a patient who underwent coronary angiography 2 days after last using sildenafil (47).

© 2006 Elsevier B.V. All rights reserved.

Indinavir

A drug interaction between sildenafil and HIV antiretroviral drugs is suspected, since both are metabolized by and act as inhibitors of the same cytochrome P450 isoforms (48). A pharmacokinetic study of sildenafil in HIV-positive patients taking indinavir has shown that the AUC of sildenafil was 4.4 times higher than data from historical controls (49). The magnitude of the interaction suggested that a lower starting dose of sildenafil may be more appropriate in patients taking indinavir.

Nitrates

The concomitant use of nitrates and sildenafil can precipitate a hypotensive reaction, and this combination should therefore be avoided (50,51). More than 3.6 million prescriptions for sildenafil were issued as of August 1998; of 69 deaths, 12 were attributable to the interaction with nitrates, as reported to the FDA.

Potentiation by sildenafil of the hypotensive effects of glyceryl trinitrate and amlodipine has been investigated. The fall in systolic blood pressure with glyceryl trinitrate was amplified four-fold by sildenafil in healthy subjects.

The pressure-lowering effect of a step-wise intravenous infusion of glyceryl trinitrate was significantly increased in 12 healthy volunteers treated for 4 days with sildenafil 25 mg tds; episodes of symptomatic hypotension were also more frequent with sildenafil (52). When sublingual glyceryl trinitrate was used, the reduction in systolic blood pressure was fourfold greater in association with sildenafil.

Tacrolimus

The effects of sildenafil can be potentiated by drugs that are metabolized by CYP3A4. Tacrolimus is an example. When sildenafil was given to patients with kidney transplants taking regular tacrolimus, peak concentrations were much higher and the half-life much longer than expected from data in healthy volunteers (53). However, an effect of the underlying disease and other concomitant drugs obviously could not be excluded.

Silicone

General Information

Silicones are polymers of alternating atoms of silicon and oxygen, whose viscosity depends on the molecular weight: the longer the molecule the more viscous.

When silicones were used for the first time, more than 35 years ago, they were proposed as excellent, inert, seemingly harmless compounds (1) and they have been used in various medical applications, including the construction of joint prostheses and breast implants and in tissue augmentation procedures. However, reports of silicone-induced granulomatous reactions in man and animals subsequently appeared (2,3) and silicones were prohibited in many countries as cosmetic materials. However, silicones are nevertheless still used (4). The FDA has issued a ruling requiring the filing of a premarket approval application or a notice of completion of a product development protocol for silicone inflatable breast prostheses, a generic type of medical device intended to or reconstruct the female breast. This device is made of a silicone shell that is inflated with sterile isotonic saline (5). The agency has taken this action because the requirement of premarket approval will provide an opportunity to assess more fully the risks and benefits of these devices, in order to determine whether there is reasonable assurance of their safety and effectiveness, or what regulatory course should be taken in the absence of such assurance. Silicone gel-filled breast prostheses have already been subjected to this requirement.

Local complications have been associated with both types of breast prostheses, including rupture, pain, capsular contracture, disfigurement, and serious infection, which may lead to medical interventions and repeated surgery. The practice of injecting liquid silicone has largely been abandoned by plastic surgeons (6), but unfortunately there are still people who perform these injections injudiciously (7).

- A 26-year-old male-to-female transsexual received an injection of 100 ml of liquid silicone of unknown grade into her upper lateral thighs to gain female contours (8). Four years later she developed pain and a massively swollen right ankle with signs of inflammation. An MRI scan showed massive diffuse and localized silicone infiltration throughout the soft tissues of the legs.

This case provides further evidence that severe morbidity can be associated with the subcutaneous injection of large volumes of liquid silicone.

Silicone implants sometimes provoke systemic adverse effects. More than 20 women developed muscle pain, joint pain and swelling, pulmonary disease including pleural effusions, pulmonary infiltrates, and reduced pulmonary diffusing capacity, dry eyes, dysphagia, bladder dysfunction, neurological abnormalities, and skin disease (including localized and diffuse scleroderma-like changes) (9).

Organs and Systems

Sensory systems

Silicone oil injection has been used to treat retinal detachment. Six patients who had had previous silicone oil injection had the oil extracted, partial introduction of perfluorocarbon liquids, extraction of epiretinal membranes, endodiathermy, retinotomy, retinectomy, complete filling of the intraocular cavity with perfluorocarbon, endophotocoagulation, and silicone oil injection (10). All maintained the reattached retina. One developed a macular epiretinal membrane. Another developed a macular epiretinal membrane with subfoveal perfluorocarbon and a relapse of the retinal re-detachment when the silicone oil was extracted and it had to be re-introduced. Four of the patients developed different degrees of cataracts; the other two were aphakic.

Other reported complications include pupillary block glaucoma, secondary glaucoma, and corneal complications, including band-shaped keratopathy (11). Pupillary block in aphakic eyes can be prevented by placing peripheral iridectomy at the 6 o'clock position, since silicone is lighter than water.

After silicone injection, glaucoma is more common in diabetic aphakic eyes than in phakic or non-diabetic eyes; on the other hand, corneal complications are less frequent in diabetic than in non-diabetic eyes; in non-diabetic eyes the complications are more frequent in aphakic than in phakic eyes (11). In a 2-year-follow up study of 105 eyes (including 27 aphakic eyes), operated on for retinal detachment by silicone oil injection after pars plana vitrectomy, cataract was a constant complication in all phakic eyes (12). Intraocular hypertension was common in both phakic and aphakic eyes (30 and 33% of cases respectively) and responded poorly to medical or surgical treatment. Other complications occurred less often; they were corneal edema, conjunctival hyperemia, and uveitis. Pain required evisceration of 2 eyes.

A heavier-than-water fluorinated silicone oil was used in the treatment of 30 selected cases of complicated retinal detachment due to proliferative vitreoretinopathy ($n = 19$), proliferative diabetic retinopathy with traction detachment ($n = 2$), giant retinal tears ($n = 5$), ruptured globe with retinal detachment ($n = 2$), massive choroidal effusion with retinal detachment ($n = 1$), and acute retinal necrosis with retinal detachment ($n = 1$) (13). Initial retinal reattachment was achieved in all cases. Complications included redetachment ($n = 7$), cataract ($n = 6$), raised intraocular pressure ($n = 4$), hypotony ($n = 4$), keratopathy ($n = 3$), uveitis synechia formation ($n = 3$), phthisis ($n = 2$), choroidal hemorrhage ($n = 1$), and vitreous hemorrhage ($n = 1$).

Skin

Foreign body giant cell granulomas were first reported after liquid silicone injection in 1965 (14) and are usually observed near silicone-injected areas (15). There have been many reports of cysts and granulomatous reactions to silicone at application sites and distal sites after hematogenous or lymphatic migration (15–17).

- An otherwise healthy 59-year-old woman had received acupuncture for a sprained ankle several times over the previous year (18). She had numerous 2–5 mm waxy orange-brown papules on the dorsal aspects of both feet and ankles. A punch biopsy of one of these showed a mixed lichenoid, spongiotic, and granulomatous dermatitis. Macrophages, including many foreign body-type giant cells, were arranged in a granuloma annulare-like pattern around dermal collagen with focal mucinous alteration. Ultrastructural examination showed macrophages containing amorphous foreign material consistent with silicone. The acupuncturist had switched to silicone-plated acupuncture needles over the recent months, and she was believed to have cutaneous granulomas secondary to silicone deposition (18). She was treated with potent topical steroids and continued acupuncture with non-coated needles. The lesions slowly resolved over the ensuing months.

This case raises the possibility of silicone deposition from cutaneous manipulation with silicone-coated instruments over a relatively short duration of time. In addition, the case is remarkable in that the latency from exposure to the foreign material to the onset of lesions was relatively short (6–12 months).

Facial granulomatous lesions and a connective tissue-like disorder have been attributed to silicone deposition following injection of silicone into the breasts (19).

- A 56-year-old Japanese woman developed eyelid edema and erythema on her face and arms and 2 weeks later annular erythema on both arms, sicca syndrome, and progressive loss of sweating on her forehead. Laboratory studies, including muscle enzymes, antinuclear antibodies, and serum immunoelectrophoresis, were unremarkable. One month later, she developed skin lesions around the eyelids that resembled lupus miliaris disseminatus faciei. A biopsy showed non-caseating epithelioid granulomas in the mid-dermis, especially around the sweat glands. A CT scan of the chest showed fibrous implant capsules in each breast, due to silicone injections 30 years before. Electron microscopy of a nodule from the lower eyelid showed particles of silicone within the granulomas. The silicone was thought to have been derived from the material that had been injected into her breasts. After subcutaneous mastectomy and axial lymphadenectomy the facial edema disappeared rapidly, but the nodules remained.

Silicone gel breast prostheses are associated with a mild foreign body response resulting in the formation of a collagenous capsule around the prosthesis (20,21). Although many such patients may have evidence of a microscopic granulomatous foreign body reaction on examination of the capsular material at explantation of a prosthesis, it is unusual to have large palpable granulomas, even in the presence of rupture or leakage (22). Nevertheless, rare patients have had severe local inflammation and complications resulting from silicone migration to the axilla, arm, or abdominal wall (23,24). Three patients had significant problems with deforming granulomas after implant rupture (25). More importantly, they suffered the consequences of silicone gel migrating down the arm. Once silicone gel leaves the implant it is not biologically inert and in some people it can elicit profound pathological responses.

Silicone granulomas are usually observed near silicone-injected areas (15).

Siliconized dressings can cause pigmentation abnormalities (26).

Musculoskeletal

Foreign-body reactions to silicone can complicate silicone elastomer joint prostheses, manifesting as synovitis and/or lymphadenopathy, sometimes at remote locations (27).

Silicone can cause fibromyalgia (SEDA-22, 526).

Immunologic

There is a possible association between silicone breast implants and underlying connective tissue diseases (9,28–30).

In patients with symptoms of connective tissue diseases it has been assumed that rupture of the gel-filled prosthesis was the most likely cause of the symptoms. Although the prosthesis was intact in some patients, amorphous silicone-like material was identified by light microscopy in surgically removed fibrous tissue. In one study (31), granulomatous inflammatory reactions developed when silicone elastomers were used as skin expanders. This was attributed to leakage of particles of the plastic material through the expander wall. Lymphadenitis and destructive synovitis following silicone implants (especially joint prostheses) have been described before (32,33), while use of silicone in dialysis tubing also led to dissemination of silicone causing splenomegaly and deposits in liver, bone marrow, skin and visceral lymph nodes. Exposure for less than 53 months did not elicit these complications (34,35).

Immunological abnormalities in the form of increased autoantibodies, specifically antinuclear antibodies, antithyroid antibodies, rheumatoid factor, and increased immune complexes, have been evaluated and documented (36). In addition, abnormalities in lymphocyte subsets have been reported, with reduced lymphocytic mitogenic response, as well as abnormalities in the ratios of T-helper to T-suppressor cells (37). Several mechanisms have been suggested, among them that silicone oozes through the intact capsule of the implants, enters the lymphatic system, and causes an immunological reaction (38); this reaction causes further development of autoimmune disease through an adjuvant effect, with possible immune dysregulation (39).

More evidence for the antigenicity of silicone has been provided in studies that have shown specific silicone antibodies directed against silanized albumin in the sera of two patients exposed to silastic tubing (40). In 520 patients, aged 28–65 years, who had had silicone breast implants for 3–22 years, the most common symptoms were fatigue (96%), myalgia (86%), morning stiffness (86%), insomnia (77%), attention deficit (74%), night sweats (43%), cervical lymphadenopathy (78%), and axillary lymphadenopathy (55%).

Clinical, histopathological, and fibroblast studies have been carried out in 30 patients given subcutaneous injections of silicone (41). The mean time between the injection and the onset of symptoms was 6 years. All the patients had sclerodermatous skin changes, subcutaneous nodules, edema, and/or hyperpigmentation at the site(s) of injection(s); five individuals also had skin changes at sites far from the injection; 13 patients had clinical features of an autoimmune disease; 11 patients gave a history of arthralgias, including four who had symmetrical non-erosive polyarthritis; 20 of 28 patients had positive antinuclear antibodies. This report confirms the association between the injection of silicon and the development of autoimmune disease (human adjuvant disease). Pneumonitis and pulmonary edema following subcutaneous injection of silicone have been reported earlier (42–44).

In an evaluation of the frequency and clinical characteristics of the underlying connective tissue disorders associated with silicone breast implants, 300 women with silicone breast implants were studied (45). In addition to a history and physical examination, C reactive protein, rheumatoid factor, and autoantibodies were determined. Criteria for fibromyalgia and/or chronic fatigue syndrome were met by 54%; connective tissue diseases were detected in 11%; and undifferentiated connective tissue disease or human adjuvant disease in 10.6%. A variety of disorders, such as angioedema, frozen shoulder, and a multiple sclerosis-like syndrome, were also found. Several other miscellaneous conditions, including recurrent and unexplained low grade fever, hair loss, skin rash, symptoms of the sicca syndrome, Raynaud's phenomenon, carpal tunnel syndrome, memory loss, headaches, chest pain, and shortness of breath were also seen. Of 93 patients who underwent explantation, 70% reported improvement in their systemic symptoms.

Silver salts and derivatives

General Information

Silver is a white precious metal (symbol Ag; atomic no. 47). The symbol derives from the Latin word argentum. It is found in various minerals, including argyrodite, cerargyrite, chlorargyrite, dyscrasite, iodyrite, and sylvanite.

Silver compounds are still used in medicine to a limited extent, notably in dermatological formulations, nose-drops,

© 2006 Elsevier B.V. All rights reserved.

and eye-drops, the essential effect being to precipitate protein. If sufficient silver is absorbed, for example from long use or application to extensive burns, there can be accumulation in many tissues (1). Although silver is well tolerated, the frequency of exposure results in frequent reports of complications (SEDA-22, 250).

Silver nitrate

Silver nitrate is used as a caustic, antiseptic, and astringent agent. The silver ion is precipitated by the chloride in tissue fluids, so that it does not readily penetrate.

Silver nitrate is effective in vitro against *Neisseria gonorrheae* and *Staphylococcus aureus* in a concentration of about 0.1% and against *Escherichia coli* in a concentration of about 0.01%. It is effective in vivo against most strains of *Staphylococcus aureus* and *Staphylococcus epidermidis* and also has activity against *Pseudomonas aeruginosa*, but is less active against other gram-negative species, such as *Enterobacter* and *Klebsiella* (2). It does not penetrate eschar to any significant degree. The non-histotoxic concentrations of 0.5% used in burns are bacteriostatic. Thick cotton dressings saturated with the solution are applied to thoroughly debrided areas. The dressings must be re-wetted every 23 hours with fresh solution to prevent development of histotoxic concentrations over 2% at the wound surface. In the treatment of burns, silver nitrate has been largely replaced by silver sulfadiazine.

Silver sulfadiazine

Silver sulfadiazine (3) is a white, highly insoluble compound synthesized from silver nitrate and the sulfonamide sodium sulfadiazine. It is used in burns as a 1% formulation in a water-soluble cream base. It has in vitro activity against a wide range of burn wound microbial pathogens, including *S. aureus*, *E. coli*, *Klebsiella* species, *P. aeruginosa*, *Proteus* species, other Enterobacteriaceae, and *Candida albicans*. Its penetration into eschar is considered to be better than that of silver nitrate. Silver from silver sulfadiazine cream is rapidly absorbed and deposited in large amounts throughout the body (4).

Uses of silver compounds

Silver nitrate and silver sulfadiazine are used to treat burns (5,6).

Ophthalmic use of silver nitrate solution for prophylaxis of ophthalmia neonatorum due to gonorrhea should be considered as obsolete; silver nitrate is highly irritant and antibiotics provide better alternatives.

Silver is used in various medical devices. There is concern about the use of silver-containing formulations of uncontrolled composition (for example colloidal silver) with supposed activity in a host of microbial diseases. Despite the supposed anti-infective efficacy of silver-coated medical prostheses, in the majority of studies these prostheses have not been proven to be infection-resistant (7).

Silver fluoride has been used in dental care for the treatment of deep caries. However, application of 40% silver fluoride to deep carious lesions or its use as a spot application agent can cause 3–4 mg of fluoride to reach the systemic circulation (8). It has therefore been suggested that solutions of lower strength (1–4%), which may be as effective as a 40% solution, should be used. Similarly, the high concentration is contraindicated in children because of systemic access of fluoride (9).

Silver has been used in anti-smoking formulations designed to alter taste sensation. In 21 adults who use silver acetate chewing gum for 12 weeks as a smoking deterrent, serum concentrations of silver rose and quickly returned to normal after withdrawal (10). In most cases the number of silver granules in skin biopsies, observed by autometallography, increased after the gum had been used for 12 weeks. However, no-one developed clinical signs of argyria.

Over-the-counter products containing colloidal silver or silver salts have been marketed for use in adults and children for a wide variety of diseases, including AIDS, cancer, tuberculosis, malaria, systemic lupus erythematosus, syphilis, scarlet fever, herpesvirus infections, pneumonia, typhoid, tetanus, and many others. The US Food and Drug Administration has issued a ruling that a colloidal silver product for any medical use will first have to be approved by the FDA under drug application procedures (11).

Argyria

Argyria is a characteristic smoke-gray discoloration of the skin and a bluish discoloration of the mucous membranes reminiscent of cyanosis (12,13). The discoloration is permanent. The deposited pigment may be partly silver sulfide and partly metallic silver, formed by photoactivated reduction.

Accumulation in the deeper tissues occurs at the same time, but as a rule has no clinical consequences (14). One disputed report dating from 1984 (15) concerned two patients with what was regarded as systemic argyria following the uncontrolled use for several years of nose-drops containing silver salts; they had dyspnea, palpitation, weakness, a slightly reduced CO_2 diffusion capacity and in one case "functional adrenal hypofunction."

Delayed wound healing has been suggested as one adverse effect of presence of silver in the system.

Argyria has followed the use of dietary supplements containing colloidal silver protein (16).

- A 56-year-old man developed blue color changes of his fingernails. His face had a dusky appearance, and there was no scleral or conjunctival discoloration or hyperpigmentation of the gums. His fingernails had a blue-gray proximal band of discoloration, as did the lunulae of both thumbnails. His toenails were not involved and the rest of his skin showed no discoloration. His serum silver concentration was 85 (reference range below 5) ng/ml. He had taken colloidal silver for the previous 3 years as an allergy and cold medication, following the recommended regimen of 1 teaspoon of a 200 ppm silver solution tds.

Generalized argyria has occurred in patients treated with eye-drops containing silver nitrate. In one case the diagnosis was confirmed by a skin biopsy showing deposits of metallic silver in the dermis (17). Argyria should be considered in the differential diagnosis of focal pigmented conjunctival lesions (18).

© 2006 Elsevier B.V. All rights reserved.

- An 82-year-old woman with strabismus amblyopia, for which she had had surgery as a child, developed an asymptomatic pigmented conjunctival lesion in the right eye, mainly involving the underlying subconjunctival connective tissue and the insertion of the lateral rectus muscle; there was no scleral thinning. Biopsy of the conjunctiva and lateral rectus muscle showed numerous extracellular black pigment granules, many of which were aligned in a linear array along the muscle fibers. Energy dispersive X-ray microanalysis showed the pigmentation to be due to silver deposits. During strabismus surgery a silver clip had probably been used to shorten the lateral rectus muscle.

Vaginal argyria has been attributed to a combination of silver sulfadiazine and Aci-Jel (a buffered acid jelly containing acetic acid) (19).

- A 67-year-old woman with a sore vulva applied Flamazine cream (containing 1% silver sulfadiazine) topically for nearly 10 years and then Aci-Jel. She developed widespread black deposits in the vagina consistent with argyria. There were dark pigmented areas around the urethral meatus, Skene's ducts, and hymeneal remnants, and a circumferential deposit around the upper third of the vagina. Biopsies showed mild acanthosis and a mild chronic inflammatory infiltrate in the upper dermis, with black pigment granules 0.5–2 μm in size in the superficial dermis. Electron probe analysis confirmed the presence of silver. The creams were withdrawn and 6 months later the vagina showed no signs of argyria.

It is likely that reducing agents in the gel base of Aci-Jel interacted with the silver sulfadiazine, causing deposition of silver and discoloration of the vagina.

- A patient with schizophrenia developed systemic argyria from chronic and excessive ingestion of an anti-smoking formulation that contained silver (20). Seizures developed after he had taken the pills for 40 years. There was an extremely high concentration of silver in the serum.

The authors suggested that systemic silver can cause seizures.

Argyria and hepatotoxicity has been reported after the use of a silver-coated wound dressing, Acticoat, in the treatment of 30% mixed depth burns in a 17-year-old boy (21). Silver concentrations were high in the plasma (107 μg/kg) and urine (28 μg/kg).

Organs and Systems

Cardiovascular

A chronic inflammatory reaction in a prosthetic valve has been attributed to silver (22).

- A prosthetic mitral valve (St Jude Medical Silzone) that had been implanted in a 72-year-old woman became partially detached 4 months later, causing acute cardiac failure. The mitral annulus was ulcerated and there were multiple erosions in the tissues in contact with the valve. Histology showed chronic inflammation, with hemosiderin deposits and giant cells. She was not allergic to silver.

The silver-coated sewing cuff had caused a chronic inflammatory reaction because of a toxic reaction to silver. The Silzone valve was withdrawn from the market in January 2000.

Nervous system

Peripheral neuropathy from long-term treatment of venous leg ulcers with silver sulfadiazine cream has been observed in one patient (13).

Sensory systems

The use of 1% silver nitrate eye-drops in prophylaxis of ophthalmia neonatorum has been periodically reviewed and compared with other prophylactic measures. There seems to be no case in which permanent damage to the eye was actually proven to have been caused by a single application of a correctly used 1% silver nitrate solution (23). However, silver nitrate has largely been replaced by antimicrobial drugs.

The reaction of the tissues in the front of the eye during the first 5 days after delivery has been examined in a double-blind study in 40 neonates with and without prophylaxis with silver nitrate solution (24). There was no significant difference in the frequency of pathological changes in the palpebrae, conjunctiva bulbi et tarsi, or cornea between the two groups and the same frequency of palpebral edema and conjunctival hyperemia. Repeated application of silver nitrate solutions in low concentrations can cause discoloration of the conjunctiva due to argyria (25).

Several cases of chemical burns of the eyes in newborn babies have been reported (26) but most of these complications followed incorrect administration of the formulation.

The clinical significance and incidence of chemical conjunctivitis due to silver nitrate has been investigated in 1000 newborn infants (27). Rinsing after instillation does not reduce the conjunctival irritation. Although 90% of the infants had conjunctivitis in the first 6 hours of life, in most cases it cleared within 24 hours. Chemical conjunctivitis did not increase the incidence of secondary infections. In 1980 the American Academy of Pediatrics pointed out the need for continued prophylaxis for all newborn infants, and proposed a 1% silver nitrate solution in single dose ampules or single-use tubes of an ophthalmic ointment with 1% tetracycline or 0.5% erythromycin. However, in infants of mothers with clinically apparent gonorrhea aqueous crystalline penicillin G should be injected.

In a double-blind, controlled study of a possible causal relation between 1% silver nitrate solution and 1% tetracycline solution in prophylaxis of ophthalmia neonatorum there was no statistically significant difference in the incidence of nasolacrimal duct obstruction between the two groups at either 2 weeks or 2 months of age (28).

Concentrations of silver nitrate of 5–50% applied accidentally to the eye have caused severe injuries with permanent corneal opacification and cataract in some cases (25).

Psychological, psychiatric

In one case there was a rapid decline in mental function at silver concentrations of 191 ng/ml, but the patient was seriously ill in other respects and although high concentrations of silver were found in the brain postmortem, it is not at all clear that the silver was responsible for the mental state (29).

Nutrition

Failure to thrive in a child has been attributed to silver toxicity (30).

- A 12-month-old girl with failure to thrive had been treated with various supplements and alternative therapies (including a blend of kelp, *Lactobacillus acidophilus*, wheat, rye, and barley) or colloidal silver. The silver was given in the form of a suspension and was thought to be effective in boosting immunity. The serum silver concentration was 3.4 (reference range below 0.02) μmol/l. Silver was withdrawn and her serum silver concentrations normalized some months later.

Electrolyte balance

Electrolyte disturbances are the major adverse effect of the use of silver nitrate in burns, since the distilled water vehicle used to carry the silver nitrate is hypotonic, and since the silver salts that are formed in the tissues, primarily silver chloride and silver sulfide, are insoluble (31). The hypotonicity produces absorption of large amounts of water into the body, with a dilutional effect and the leaking of significant quantities of body minerals, including sodium, potassium, magnesium, calcium, and chloride. Deficiency of chloride is caused by the formation of silver chloride on the treated surface. Up to 350 mmol/day of sodium can be lost per square meter of treated body surface area. Problems occur particularly in patients with burns that exceed 20% of the body surface and in infants, unless a regular replacement schedule is established. Maximum deficiency can occur within a matter of 6–8 hours after the start of therapy. Continuous oral or intravenous electrolyte supplementation and careful monitoring of electrolyte balance are necessary.

Hematologic

Methemoglobinemia due to silver nitrate occurs via bacterial reduction of nitrate to nitrite, which is subsequently absorbed (32). The diagnosis should be suspected if the skin or blood appears cyanotic or gray in the presence of normal arterial PO_2. The diagnosis should always be confirmed with measurement of blood methemoglobin concentration. In the treatment of burns with silver nitrate solutions, the possible occurrence of methemoglobinemia must be considered, especially when organisms are cultured from the wounds. The silver nitrate should be withdrawn if this complication occurs. Treatment of the methemoglobinemia with reducing agents is rarely required.

- Fatal methemoglobinemia occurred in a 3-year-old Caucasian girl who had burns involving 82% of the body surface and had been treated by painting the burns with silver nitrate solution (33). By the fourth day, low-grade fever was evident and *Aerobacter cloacae*, which was resistant to silver nitrate 0.5%, was cultured from the scar tissue. The child became cyanotic and died after 27 days. Methemoglobin constituted 70% of her hemoglobin; there was no other evident cause of death. The *A. cloacae* cultured from the skin was tested and reduced nitrate to nitrite.
- A 12-month-old girl, with necrotizing fasciitis at the site of a cutaneous infection on her left trunk, became unresponsive, lethargic, and in shock, and underwent immediate aggressive tissue debridement (34). Later wound irrigation was carried out with a solution of silver nitrate 0.5% and 20 days later she became cyanotic and dyspneic. Her methemoglobin concentration was 38%. Intravenous methylene blue restored her oxygen saturation and reduced the dyspnea and cyanosis. Her methemoglobin concentration fell to 0.8%.

Transient leukopenia with a disproportionate reduction in neutrophilic leukocytes has been reported during treatment with sulfadiazine silver (35). This adverse effect appears to run a typical course: sulfadiazine-induced leukopenia reaches a nadir within 2–4 days of starting therapy, with a characteristic fall in the neutrophil count and a relative increase in the number of band forms. The erythrocyte count is not affected. By 2–3 days after the onset of leukopenia, the leukocyte count returns to normal. The leukocyte count tends to recover whether or not the silver sulfadiazine is withdrawn and may also be an intrinsic response to burn injury and unrelated to the use of silver sulfadiazine.

The use of silver sulfadiazine has been associated with acute hemolytic anemia (22).

Fatal pancytopenia has been reported from the extensive use of topical silver sulfadiazine.

- An 11-month-old infant with second- and third-degree burns over 30% of the body was treated topically with silver sulfadiazine (36). From day 2 there was significant neutropenia, maximal at day 3. The silver sulfadiazine was withdrawn. The neutropenia was followed by anemia, which was maximal on day 5. Finally, thrombocytopenia developed. In spite of blood transfusions and recovery of the neutropenia and thrombocytopenia, infection occurred and the patient died from respiratory failure.

Mouth and teeth

In one case severe ulceration of the anterior ventral surface of the tongue was caused by ill-advised cautery of a small ulcer with a silver nitrate stick (37). Only silver nitrate solutions of 5–10% should be used to cauterize mucous membranes or when a strong germicidal action is desired.

Urinary tract

Intrapelvic instillation of silver nitrate is sometimes still used in the treatment of essential hematuria. In one case ureteric stenosis developed as a consequence (38).

Nephrotic syndrome following topical therapy with silver sulfadiazine has been reported once (39).

Anuria has occurred after silver nitrate irrigation for intractable bladder hemorrhage caused by cyclophosphamide chemotherapy (40). The level of obstruction was the ureterovesical junction on the one hand, and the collecting ducts of the renal papillae on the other. Therapy

© 2006 Elsevier B.V. All rights reserved.

consisted of rigorous endoscopic evacuation of deposited coagulate from the bladder, after which the urinary output rapidly returned to normal.

Skin

Three infants treated for umbilical granuloma with silver nitrate suffered chemical burns to the periumbilical area; conservative treatment led to good outcomes (41).

- A 29-year-old woman complained of increasing black discoloration of the tip of her left middle finger, resembling gangrene (42). She had been applying silver nitrate to her finger for the treatment of a small granuloma and had developed localized tissue necrosis, secondary to application of the silver nitrate, on withdrawal of which she recovered completely.

In consequence, it is recommended that the practice of unsupervised local application of silver nitrate to the fingers should be discontinued.

Höllensteinstift 10 (Pharma Winter, Leipzig, Germany) is a stick that contains 90% silver nitrate and 10% potassium nitrate, and has corrosive, germicidal, and astringent characteristics; it is used in the treatment of hypergranulation and common warts.

- A 28-year-old woman used Höllensteinstift 10 inappropriately (43). Intending to treat her periorbital folds, she removed the outside layer of paraffin, moistened the tip, and applied the stick to the lower parts of the lids, accidentally transferring parts of the corrosive agent to the skin in the periorbicular region. After some time, she felt a burning sensation, rinsed her face with water, and so distributed the agent widely to both cheeks and increased the pain. Self-treatment with several ointments did not bring relief. On the next day she developed brown discoloration of the facial skin, particularly in the periorbital region, pain, and torsion of the skin in the affected area. Initial treatment consisted of soap solution (to wash out the silver particles) and panthenol ointment (to support the process of healing). The lesions disappeared completely.

Cutaneous sensitivity reactions, typically maculopapular rashes, occur in under 5% of patients who use silver sulfadiazine and rarely require withdrawal (44).

Immunologic

A meta-analysis of the clinical and economic effects of chlorhexidine and silver sulfadiazine antiseptic-impregnated catheters has been undertaken (45). The costs of hypersensitivity reactions were considered as part of the analysis, and the use of catheters impregnated with antiseptics resulted in reduced costs. The analysis used the higher estimated incidence of hypersensitivity reactions occurring in Japan, where the use of chlorhexidine impregnated catheters is still banned (46).

Susceptibility Factors

Renal disease

If silver sulfadiazine is used in a patient with impaired renal function, accumulation of silver can occur.

- In a patient with end-stage renal disease, there was a marked increase in serum silver concentration during treatment with silver sulfadiazine cream 200 g/day for 2 weeks (29). The serum concentration of silver reached a maximum of 291 ng/ml and there was rapid deterioration of mental status. Silver sulfadiazine was withdrawn, but the patient died after 4 months. At autopsy, there were very high concentrations of silver in the brain tissues (617 and 824 ng/g in the cerebrum and cerebellum respectively).

In this patient both plasma exchange and hemofiltration were effective in reducing the serum silver concentration, and their effects were additive, but hemodialysis was ineffective. However, none of these maneuvers affected brain silver concentrations.

Drug Administration

Drug formulations

A modification of silver sulfadiazine by the incorporation of cerium nitrate is believed to enhance its efficacy. In 60 patients with moderate and severe burns randomly assigned to topical silver sulfadiazine either alone ($n = 30$) or in combination with cerium nitrate ($n = 30$), there were four deaths in those who were given sulfadiazine alone and only one in those who were given the combination (47). Wound infection did not differ significantly between the groups. The rate of re-epithelialization of partial thickness burns was faster by 8 days in those given the combination, and the relatively dry shell-like eschar allowed planned excisions with immediate autologous grafting and the tissue underneath was ready to accept grafting 11 days earlier. There was a higher incidence of transient stinging pain with the combination, but this was effectively managed with analgesics when necessary.

Simvastatin

See also HMG Co-A reductase inhibitors

General Information

Simvastatin is an HMG Co-A reductase inhibitor. Its most serious adverse effect is rhabdomyolysis, which is enhanced by other drugs that inhibit CYP3A4 (1).

© 2006 Elsevier B.V. All rights reserved.

Organs and Systems

Cardiovascular

Transient hypotension attributable to simvastatin may have been related to reduced production of corticosteroids (2).

Respiratory

Hypersensitivity reactions can occur with statins (SEDA-13, 1328) (3), and an otherwise unexplained case of interstitial lung disease and pleural effusion developed during treatment with simvastatin for 6 months; the number of eosinophils in the bronchoalveolar lavage fluid normalized a few days after withdrawal (4).

Psychological, psychiatric

In the 4S study there were five suicides in the simvastatin group and four in controls (5).

Endocrine

In 521 patients taking simvastatin 40–80 mg/day, serum cortisol concentrations were on average reduced by 3–7% (6). In the men there was a 10% fall in serum testosterone. However, there were no reports of sexual dysfunction.

Simvastatin up to 40 mg/day was given to 98 boys and 75 girls, aged 10–17 years, for 48 weeks without any adverse effects beyond a small fall in dehydroepiandrosterone (7). Of special note was the observation that simvastatin had no adverse effects on growth or pubertal development.

Metabolism

- A 53-year-old man taking simvastatin 40 mg/day developed rhabdomyolysis and hepatitis and had a raised serum lactate concentration (8.3 mmol/l; reference range 0.5–2.2) (8). Everything resolved 7 days after drug withdrawal.

Lactic acidosis in this patient supports the view that interference with the mitochondrial respiratory chain may play a role in the toxicity of the statins.

Hematologic

Thrombocytopenia is a rare adverse effect of simvastatin (9).
