In rats, intracerebroventricular injection of various cephalosporins produced markedly different responses in epileptogenic potential (10), later confirmed with a total of 15 compounds (11). Compounds with two heterocyclic rings at both position 3 and position 7 of the cephalosporin molecule, for example ceftriaxone, cefoperazone, and ceftazidime, were even more epileptogenic than benzylpenicillin, while others, with only one heterocyclic ring at position 7, for example cefotaxime and cefonicid, were less potent. Cefazolin, a tetrazole derivative, similar to the convulsant phenyltetrazole, was most potent.

Neurotoxicity has been reported with intracerebroventricular cefazolin (12) and with systemic cefazolin (13–15), cefepime (16), cefotaxime (17–19), ceftazidime (20,21), and cefuroxime (22). Ceftazidime also caused truncal asterixis (23) and absence status and toxic hallucinations (24). Even the least epileptogenic of 15 cephalosporins, namely cefonicid (11), caused seizures (25), although this effect was disputed (26). As expected, seizures after systemic treatment were predominant in uremic patients, and neurotoxicity has been associated with intraperitoneal ceftazidime therapy in a patient

© 2006 Elsevier B.V. All rights reserved.

undergoing CAPD (27). Of practical interest was a patient treated with intravenous cefmetazole in whom the CSF concentration was twice as high as the corresponding blood concentration (236 versus 103 μg/ml) (28). Uremia may have contributed to this unusual distribution pattern.

- A 66-year-old woman had several episodes of recurrent aseptic meningitis associated with cefalexin, cefazolin, and ceftazidime (29). Intrathecal ceftazidime-specific IgG antibodies were isolated and a skin test with cefazolin provoked recurrence of the aseptic meningitis.

Two patients developed status epilepticus during treatment with cefepime for *Pseudomonas aeruginosa* sepsis (30).

- A 44-year-old man, who had previously had bilateral lung transplantation and who was on hemodialysis for chronic renal insufficiency, was given cefepime 2 g/day. Within 24 hours he started to become confused and developed diffuse hyper-reflexia. Two days later an electroencephalogram showed nearly continuous, generalized sharp-wave/slow-wave activity. After lorazepam 2 mg the status epilepticus resolved, but he remained confused. A follow-up electroencephalogram showed recurrence of generalized sharp-wave activity. Cefepime was withdrawn, and within hours he rapidly recovered his mental status. An electroencephalogram showed absence of epileptiform discharges.
- A 28-year-old woman with a thoracic spina bifida was given cefepime 1 g bd for an infection with *P. aeruginosa*. After a time (not stated) an electroencephalogram showed a continuous generalized spike and wave pattern. She was given lorazepam 2 mg, which resulted in resolution. Cefepime was withdrawn and she promptly recovered.

In the first case the dose was inappropriate for the degree of renal impairment and in the second case the dose was inappropriate for the patient's body weight. The authors underlined the importance of giving cefepime with great care, especially to patients with renal impairment and low body weight.

Five patients developed severe symptoms after receiving cefepime (31). The patients, three men and two women, aged 16–75 years, received 2 g/day ($n = 3$) 4 g/day ($n = 1$) or 9 g/day ($n = 1$). The symptoms started 12–16 days after the start of therapy. In all cases, the initial neurological symptoms (disorientation, confusion, and reduced consciousness) were progressive and were attributed to the infection. Facial or multifocal myoclonic movements occurred subsequently and were rapidly followed by convulsive or non-convulsive status epilepticus. The dose of cefipime had not been adjusted for renal function in any of the patients. Cefepime serum concentrations were measured in three cases, and were 72, 73, and 134 μg/ml. All the patients underwent hemodialysis, and the serum concentrations of cefepime fell to 4.3, 21, and 25 μg/ml respectively. In the other two patients, the serum concentrations after dialysis were 14 and 54 μg/ml, suggesting high concentrations before dialysis. There was complete recovery in four of the patients. One, a 73-year-old woman, died of multiorgan failure with refractory status epilepticus and coma. The authors referred to four other reports of cefepime-induced generalized seizures. They seriously questioned whether the actual frequency of this complication might not be underestimated, owing to insufficient knowledge, underreporting, and/or lack of specificity of clinical features.

- An 82-year-old man on chronic hemodialysis had pneumonia, for which he was given intravenous cefepime 1 g/day (32). After 4 days he developed a seizure and cefepime was withdrawn. Hemodialysis was started and his conscious level improved. On the next day, after a second hemodialysis, he recovered completely.

The authors recommended that in elderly patients with severe renal impairment, other agents than cefepime should be considered.

Psychological, psychiatric

It has long been known that intramuscular procaine penicillin can cause some peculiar psychological adverse reactions, and that other penicillin derivatives, such as amoxicillin, can cause psychiatric reactions, such as hallucinations (SEDA-21, 259). In a report from the Netherlands, neuropsychiatric symptoms occurred in six patients who received cefepime for febrile neutropenia (33). The patients, two men and four women, aged 32–75 years, received 6 g/day ($n = 5$) or 3 g/day ($n = 1$). The symptoms started 1–5 days after the first dose and varied from nightmares, anxiety, agitation, and visual and auditory hallucinations to coma and seizures. After withdrawal of cefepime, they recovered within 1–5 days. The causality between their neuropsychiatric symptoms and cefepime was considered as probable (WHO criteria) because of the temporal relation, lack of other causal neurological explanations, and positive rechallenge in five patients.

The mechanisms of these adverse effects are unknown, although it might be of value to take a closer look at the theory that drug-induced limbic kindling may be the principal pathogenic factor (SEDA-21, 259).

Hematologic

Since the days when chloramphenicol was more commonly used, it has been recognized that many antimicrobial drug are associated with severe blood dyscrasias, such as aplastic anemia, neutropenia, agranulocytosis, thrombocytopenia, and hemolytic anemia. Information on this association has come predominantly from case series and hospital surveys (34–36). Some evidence can be extracted from population-based studies that have focused on aplastic anemia and agranulocytosis and their association with many drugs, including antimicrobial drugs (37,38). The incidence rates of blood dyscrasias in the general population have been estimated in a cohort study with a nested case-control analysis, using data from a General Practice Research Database in Spain (39). The study population consisted of 822 048 patients aged 5–69 years who received at least one prescription (in all 1 507 307 prescriptions) for an antimicrobial drug during January 1994 to September 1998. The main outcome measure was a diagnosis of neutropenia, agranulocytosis, hemolytic anemia,

© 2006 Elsevier B.V. All rights reserved.

thrombocytopenia, pancytopenia, or aplastic anemia. The incidence was 3.3 per 100 000 person-years in the general population. Users of antimicrobial drugs had a relative risk (RR), adjusted for age and sex, of 4.4, and patients who took more than one class of antimicrobial drug had a relative risk of 29. Among individual antimicrobial drugs, the greatest risk was with cephalosporins (RR = 14), followed by the sulfonamides (RR = 7.6) and penicillins (RR = 3.1).

Hemolytic anemia

Autoimmune hemolytic anemia has rarely been reported with the older cephalosporins, including cefalexin (40), cefalotin (41,42), cefazolin (43), and cefaloridine (44). The main laboratory findings correspond to the "drug adsorption" mechanism classically found in benzylpenicillin-induced immune hemolysis. Antibodies cross-reacting with cefalotin and benzylpenicillin were found in both benzylpenicillin-induced and cefalotin-induced hemolysis (43,45) Cases have also been reported with cefamandole (46), cefalexin (47), ceftriaxone (48), cefotaxime (49,50), cefotetan (51,52) and ceftazidime (53).

Cefotetan-induced hemolytic anemia has been discussed in a review of 35 cases, eight of which were discussed in greater detail (54). All eight cases were associated with the prophylactic use of cefotetan in gynecological or obstetric procedures. The patients had received 1–4 doses of cefotetan, and they left hospital in good shape, but all were re-admitted with hemolytic anemia within 2 weeks after the last dose. All needed several blood transfusions and two underwent plasmapheresis twice. They all survived, but the authors underlined the seriousness of this adverse effect. Of 43 cases of drug-induced hemolytic anemia that had been referred to their laboratory in the previous 8 years, 35 had been caused by cefotetan and three by ceftriaxone; 11 had a fatal outcome, eight and three caused by cefotetan and ceftriaxone respectively.

Hemolytic anemia has also been attributed to ceftizoxime (55).

- A 76-year-old Japanese man, who had been given 23 courses of intravenous antibiotic therapy over 2 years for chronic bronchitis, was given intravenous ceftizoxime 1 g/day. He developed anaphylactic shock and hemolysis. Despite very extensive therapy he died 2 weeks later.

The patient's serum was tested for antibodies against five penicillins and 30 different cephems (that is all types of cephalosporins), using protocols to detect drug adsorption as well as immune-complex mechanisms. His serum contained an IgM antibody that formed immune complexes with 10 of the 30 cephems. The 10 drugs were classified as oxime-type cephalosporins, that is they had a common structural formula at the C7 position on 7-aminocephalosporinic acid. This antibody did not show any cross-reactivity with five kinds of penicillins (ampicillin, aspoxicillin, carbenicillin, piperacillin, sulbenicillin). The authors asked a difficult question: Why did anaphylactic shock accompany acute hemolysis? Their answer was that the complex of ceftizoxime with IgM anti-ceftizoxime might act like anti-A or anti-B. This hypothesis will surely be further tested. In the meantime, it would be wise not to use the newer cephalosporins too freely.

Ceftriaxone has been associated with autoimmune hemolytic anemia, erythroblastocytopenia, and acute hepatitis (56). The ceftriaxone in this case was given intravenously and not orally, as erroneously published (written communication from the authors). Other cases of hemolysis have been reported after ceftriaxone (57).

- A 38-year-old man with no known disease rapidly developed disturbed consciousness 4 days after having taken co-amoxiclav for sinusitis (58). On admission, he was given intravenous ceftriaxone 2 g bd for purulent meningitis. On the 10th day of therapy, he developed icterus and hemolytic anemia. Despite vigorous resuscitative efforts, he died with evidence of multiple organ failure on day 5.
- A 48-year-old woman who had been given ceftriaxone 2 g/day intravenously for 7 days for Lyme disease developed severe hemolytic anemia (59). She had previously been given ceftriaxone twice without any adverse effects. An immune complex mechanism was suggested.
- A 14-year-old girl, perinatally infected with HIV, had a medical history of recurrent infections that had been treated with several antibiotics, including ceftriaxone. She was given ceftriaxone (60 mg/kg intravenously) for pneumonia and 30 minutes later complained of severe back pain, became nauseated, vomited, and collapsed. Despite intensive medical care she died within a few hours with massive intravascular hemolysis and disseminated intravascular coagulopathy. Autopsy was refused.

Of 10 patients with hemolysis due to ceftriaxone, seven died, six of them children (48,57,60–62).

- A 5-year-old girl, who had taken co-trimoxazole prophylaxis for recurrent urinary tract infections since the age of 1 year, received ceftriaxone intramuscularly for 7 days at the age of 5 years, uneventfully (63). Six months later she was given intramuscular ceftriaxone 50 mg/kg/day and amikacin 20 mg/kg for a new urinary tract infection. After 3 days she became unexpectedly ill and had a generalized seizure 30 minutes after the administration of both drugs. A day later, her seizures recurred, she rapidly became worse, and she was referred to an ICU for ventilatory support. There, she had two cardiac arrests and was resuscitated successfully. Her hematocrit and reticulocyte count were eight and 0.2% respectively. A direct antiglobulin test was strongly positive. She was given methylprednisone 5 mg/kg/day and three units of red blood cells. The direct antiglobulin test became negative on day 3, and the dose of methylprednisone was reduced to 3 mg/kg/day but then had to be increased again to 5 mg/kg/day because of recurring hemolysis. The steroid was withdrawn uneventfully after 8 weeks. She remained well and had no neurological deficit.

The authors stated that in children, hemolysis usually starts within minutes to some few hours after the administration of the drug, whereas in adults it starts after a period of days.

Mechanism

In addition to the "drug-adsorption" mechanism, the findings in some instances of anemia associated with cephalosporins were consistent with concomitant formation of

© 2006 Elsevier B.V. All rights reserved.

auto-antibodies (51) or the so-called "innocent bystander" mechanism, leading to acute intravascular hemolysis, one with ceftriaxone being fatal (48). After this, another six cases were reported, of which five were fatal (57,60,61,64–66). All were due to ceftriaxone and all were in children aged 2–14 years, who were immunocompromised and/or had a hematological disease. All had been previously exposed to ceftriaxone and in some instances also to other cephalosporins. The hemolysis occurred abruptly within 5–54 minutes. However, it is not settled whether the risk reflected by those observations is specific to ceftriaxone or occurs with all cephalosporins. Ceftriaxone has a large share of the cephalosporin market, and three of the reports (61,65,66) were stimulated by a foregoing one (60), which may point to publication bias. Cross-reactivity of ceftriaxone antibodies with other cephalosporins was not studied. The significance of the underlying immunological or hematological diseases and the youth of the patients is also uncertain. Cefalotin and other cephalosporins can cause a positive direct antiglobulin test (67,68). This phenomenon is due to non-specific serum protein adsorption on to the erythrocyte membrane and is not related to immune hemolytic processes. Detection of non-immunologically bound serum proteins improves if reagents used in the direct antiglobulin test include additional antialbumin activity (69). The phenomenon is a known source of difficulties in evaluating suspected immune hemolysis or in routine cross-matching of blood products (70). The true frequency with many individual cephalosporins is unclear, since it has not been positively sought. However, it may depend on daily doses and in particular on the duration of treatment. For example, in a study with cefepime there were positive direct antiglobulin tests in 43% (71). The mean duration of treatment was 19 days and positive direct antiglobulin tests were principally seen in patients taking long-term treatment for osteomyelitis (mean duration of treatment 32 days). On the other hand, ceftazidime given for 9 days induced positive direct antiglobulin tests in 12% of patients (72). Positive direct antiglobulin tests can turn negative again while treatment with cephalosporins continues (71).

In a case of hemolysis associated with ceftriaxone the causative antibodies appeared to be stimulated solely by a degradation product of ceftriaxone (62).

- A 16-year-old girl with craniofacial dysplasia was given ceftriaxone 4 g/day for pneumococcal meningitis. On the seventh day of therapy she developed neck muscle spasms, dizziness, and tachypnea immediately after the administration of ceftriaxone. On the next day, the same symptoms occurred about 30 minutes after the end of the infusion of ceftriaxone. Her plasma was red and her hemoglobin had fallen to 2.4 g/dl. A direct antiglobulin test was positive only for C3d and no ceftriaxone-dependent antibodies were detected. Her serum reacted strongly with erythrocytes in the presence of ex vivo antigen related to ceftriaxone (urine samples from patients receiving ceftriaxone). All therapeutic attempts were unsuccessful and she developed renal insufficiency and died.

The authors concluded that this was the first reported case in which the causative antibodies appeared to be stimulated solely by a degradation product of ceftriaxone. Unfortunately, they were not able to characterize the degradation products. They ended their report by advising that degradation products should be taken into account in all suspected cases of drug-dependent hemocytopenia in which the antibody remains undetectable.

Neutropenia

Virtually all cephalosporins can cause neutropenia and agranulocytosis (73). This has been associated with cefapirin (74), cefepime (75), cefmenoxime (76), cefmetazole (77), ceftriaxone (78–81), moxalactam (82), and others. All of these cases were seen after high cumulative doses given in one treatment course. In one series, cefapirin-induced neutropenia occurred in five of 19 patients who took a total of 90 g or more, but not in 113 patients who took smaller cumulative doses (74). It has not been settled whether toxic mechanisms, immunological mechanisms, or both are involved.

Thrombocytopenia

Thrombocytopenia has rarely been reported, always associated with cefalotin (83–85). In one case there were drug-dependent antibodies. In two other cases the role of drug-dependent antibodies was further evaluated. In one case the antibodies only reacted with platelets in the presence of exogenous cefotetan, but not with cefotetan-coated platelets (86). In another case associated with cefamandole, antibodies cross-reacted with two cephalosporins that had a thiomethyltetrazole group at position 3 but not with other cephalosporins (87). In an additional case, cefuroxime has been implicated (88). In about one-third of cases with cephalosporin-induced neutropenia, slight concomitant thrombocytopenia has been found (73).

Impaired hemostasis

As with other beta-lactam antibiotics, cephalosporins can cause impaired hemostasis and bleeding by altering coagulation and platelet function.

Pseudolymphoma

Pseudolymphoma leukemia (Sézary syndrome) has been reported to occur mainly after the use of phenytoin and other anticonvulsant drugs (89,90), but cefixime has also been implicated (91).

- A 48-year-old woman developed fever and cough, for which she was given oral cefixime. After 48 hours she developed an itchy diffuse erythematous maculopapular rash all over her body. Her white blood cell count was 20×10^9/l, with 8% eosinophils; 5 days later it was 12.5×10^9/l, with atypical, so-called Sézary-like, cells and 64% eosinophils. A bone marrow aspirate showed 20% atypical lymphocytes with a Sézary-like appearance, having large cerebriform nuclei. An increase in eosinophil precursors was also noted. Cefixime was withdrawn, and as she continued to be febrile with a rash and her eosinophil count increased to 72% she was given corticosteroids. Her fever fell to 37.5°C, the rash improved, and her white cell count fell. At follow-up 12 months later her leukocytosis and eosinophilia had

© 2006 Elsevier B.V. All rights reserved.

completely resolved and she did not have any other problems.

The authors stressed that, like patients with phenytoin-induced pseudolymphoma, this patient will need long-term follow-up to differentiate true prelymphoma. This case can be taken as a reminder that every new beta-lactam coming on the market may have an adverse effects profile of its own.

Mouth and teeth

Three children receiving cefaclor developed intraoral ulcers covered with a thick pseudomembrane together with various skin lesions, suggesting a viral disease at first sight (92).

Gastrointestinal

Acute hemorrhagic colitis without pseudomembranes has been reported after oral cefuroxime (SEDA 21, 261). In mice, some cephalosporins accelerated gastric emptying, in some instances even more effectively than erythromycin or metoclopramide (93). The relevance of this to the gastrointestinal adverse effects of cephalosporins, such as nausea and vomiting, is uncertain.

Liver

As with all beta-lactam antibiotics, slight increases in serum transaminases and alkaline phosphatase have been reported with cephalosporins. However, in contrast to the isoxazolylpenicillins and co-amoxiclav, only very sporadic cases with more severe liver disease have occurred (94–98). Very prolonged cholestasis was reported in isolated cases with cefmenoxime (99) and ceftibuten (98).

Biliary tract

Ceftriaxone has been associated with mostly asymptomatic and reversible biliary sludge. The condition is defined by the presence of low amplitude echoes with absent postacoustic shadows in the gallbladder on ultrasonography and has also been called "biliary pseudolithiasis" (100). Findings consistent with the presence of cholelithiasis (high amplitude echoes with acoustic shadowing) have also been reported (101).

The frequency of biliary sludge in 37 children treated for serious infections was 40% and was lower in adults (about 20%) (100,102,103). The condition usually runs a benign course and ultrasound becomes normal after withdrawal of ceftriaxone within a mean of 15 days (100). However, clinical evidence of cholecystitis has been reported (104). Gallstones containing mostly ceftriaxone have been described (105). In a case-control study of patients treated with ceftriaxone for Lyme disease, more serious biliary complications (cholecystitis and cholelithiasis) were observed in 2%. Age over 18 years and female sex were risk factors (106).

Ceftriaxone does not seem to predispose to subsequent gallbladder stone formation, as assessed 6 and 12 months later (107). The pathogenesis relates to ceftriaxone's high rate of biliary excretion and the subsequent formation of calcium-containing precipitates (108). Thus, apart from the risk factors mentioned above, the risk of biliary sludge may increase with the use of high doses, rapid bolus injection, gall bladder stasis, and renal insufficiency associated with enhanced biliary excretion. Routine ultrasound scans are not required in patients taking ceftriaxone. In the presence of symptoms possibly due to ceftriaxone-associated sludge or cholelithiasis, confirmed by ultrasonography, the drug should be withdrawn. Surgery is mostly unnecessary.

Pancreas

Ceftriaxone has been reported to have caused pancreatitis (109).

- A 13-year-old boy received long-term intravenous ceftriaxone after surgical drainage of a right frontal subdural empyema secondary to sinusitis. After about 5 weeks he developed abdominal pain with profuse emesis; his serum amylase was 1133 U/l and lipase 3528 U/l. Abdominal ultrasound showed cholelithiasis, and he had an uncomplicated cholecystectomy. The material in the gallbladder was 100% ceftriaxone.

The authors ended by stating that patients taking long-term ceftriaxone may be at risk of cholelithiasis and pancreatitis. Ultrasound screening might be useful for monitoring such patients.

Urinary tract

Two of the older cephalosporins, cefaloridine and cefalotin, are nephrotoxic and have often caused renal dysfunction (110,111). The nephrotoxicity of cefaloridine is related to its unusual renal transport, resulting in higher intracellular concentrations in the proximal tubular cells than with other cephalosporins (112). Since less toxic cephalosporins are available, the clinical use of cefaloridine is no longer justified.

Cefalotin can cause two types of renal disease in man (111): acute tubular necrosis, similar to that seen with cefaloridine, although less often; and acute interstitial nephritis, often accompanied by a rash, fever, or eosinophilia, resembling the same disorder as that caused by methicillin.

Beta-lactam nephrotoxicity has been reviewed, particularly considering structure-activity relations (112). Acute proximal tubular necrosis as a consequence of beta-lactam toxicity develops in proportion to:

- uptake by the cupular cell
- acylation inactivation of mitochondrial substrate transporters
- in the case of cefaloridine, lipid peroxidation.

For example, cefaloglycin, which is no longer used, is highly nephrotoxic because of its reactivity, while cefalexin, being comparably sequestered in the tubular cells, is not (112).

Broad clinical use of second- and third-generation cephalosporins has not produced clear evidence of significant nephrotoxicity. In two groups of 10 and 17 patients treated with ceftazidime 3 or 4 g/day, falls in glomerular filtration rate of about 10 ml/minute were seen after treatment courses of 4–9 days or 7–31 days respectively (113,114). For many other cephalosporins comparable data are lacking. Furthermore, an increase

© 2006 Elsevier B.V. All rights reserved.

in aminoglycoside nephrotoxicity have only been documented with cefalotin and cefaloridine when used in combination (110,115). Nevertheless, adjustment of cephalosporin dosages in renal insufficiency is justified, and acute tubular necrosis can occur with very high doses of cephalosporins other than cefaloridine and cefalotin (116). Isolated cases of acute interstitial nephritis with newer compounds have been related to cefaclor (117), cefamandole (118), cefotaxime (119,120), cefotetan (121), cefoxitin (122), ceftazidime (123), ceftriaxone (124), and cefuroxime (125). Ceftriaxone, on the other hand, protects against tobramycin nephrotoxicity in rats (126). In addition to biliary sludge and stone formation with ceftriaxone, occasional patients developing urinary stones have been described (127,128).

In a report of acute tubulointerstitial nephritis in a patient receiving cefdinir, it was stated that among 41 kinds of cephalosporins available in Japan, this complication has been reported with 12 (129).

- A 58-year-old woman developed acute renal insufficiency soon after a 7-day course of cefdinir 300 mg/day for acute bronchitis. Renal histology showed tubular atrophy and interstitial fibrosis accompanied by moderate lymphocyte infiltration. A lymphocyte stimulation test with cefdinir was positive. Serum creatinine concentrations continued to rise even after withdrawal of cefdinir, but steroid therapy normalized renal function.

The outcome of drug-induced acute tubulointerstitial nephritis can be life-long dialysis or renal transplantation if it is not adequately treated in time. The authors therefore concluded that it is important to look out for this complication when using any cephalosporin.

Skin

Generalized pustular eruptions, histologically presenting as leukocytoclastic vasculitis with neutrophils forming subcorneal pustules, have been reported with different cephalosporins, such as cefaclor (130), cefazolin (131,132), cefalexin (133), and cefradine (134).

Isolated cases of the following syndromes have been reported more recently in connection with cephalosporins:

- pseudolymphoma leukemia syndrome after cefixime presenting with itchy rash, atypical Sézary-like cells, and lymphadenopathy (91);
- pemphigus vulgaris with cefadroxil (135) and cefalexin (136);
- erythema multiforme with cefotaxime (137) and cefalotin (138);
- adult linear IgA disease associated with an erythema multiforme-like reaction with cefamandole (139);
- Stevens–Johnson syndrome with cefalexin (140);
- toxic epidermal necrolysis with cefsulodin (141) and cefazolin (142);
- photosensitivity due to intravenous ceftazidime in a patient with cystic fibrosis (143);
- fixed drug eruption with cefalexin (144);
- occupational contact allergy with ceftiofur (145).

The frequencies of rashes have been retrospectively investigated in 5923 children (146). All the children who developed a rash after treatment with one or more of the commonly used oral antibiotics were identified, 472 in all. Significantly more rashes were documented with cefaclor (4.79%) compared with sulfonamides (3.46%), penicillins (2.72%), and other cephalosporins (1.04%). Based on the numbers of patients for whom the antibiotics were prescribed, the frequencies of rashes were 12.3% for cefaclor, 8.5% for sulfonamides, 7.4% for penicillins, and 2.6% for other cephalosporins.

Telangiectasiae in a light-exposed distribution have rarely been reported with cephalosporins.

- An otherwise healthy 57-year-old man developed telangiectatic skin lesions after receiving intramuscular cefotaxime 1 g bd for 7 days for a urinary tract infection (147). He had used no other medications, and there was no history of photosensitivity or rosacea. He had several asymptomatic telangiectasiae widely distributed on the forehead and on the backs of both hands. Antinuclear antibodies and antineutrophil cytoplasmic antibodies were negative. Skin biopsy showed dilated capillaries without signs of vasculitis. A light provocation test produced telangiectatic lesions at 36 hours. Because of the relation between the administration of cefotaxime and the onset of the telangiectasiae, confirmed by light testing, cefotaxime was withdrawn, with progressive improvement and complete resolution after 2 months; rechallenge was not performed.

Iatrogenic telangiectasis is a poorly understood dermatological adverse effect of several drugs, including cephalosporins (143,148). Telangiectasiae localized to light-exposed areas, as in this case, have been described with some calcium channel blockers (149,150).

Immunologic

Type I reactions

Immediate hypersensitivity reactions, mediated through IgE antibodies to cephalosporin determinants, are a major factor limiting their use. Early cases of anaphylaxis to cephalosporins were probably due to contamination with trace amounts of penicillin (151). These studies may therefore have over-reported cross-sensitivity.

In a retrospective study the frequency of systemic anaphylaxis to cefaloridine, cefalotin, or cefalexin was two out of 9388 patients (0.02%) without a history of penicillin allergy, and two out of 450 patients (0.4%) with a history of penicillin allergy (152). In the first group, two of the 1983 patients treated with cefalotin accounted for the adverse event.

Two of 178 prospective patients, of whom 151 had a history of penicillin allergy but were negative on penicillin skin testing, had reactions to a cephalosporin (153). There were 27 who had a positive penicillin skin test but did not react to a cephalosporin. Similar results were found by others (154).

However, a history of penicillin allergy is often vague, and many studies have suggested that it is an unreliable indicator, which has been confirmed (155). In 62 penicillin skin-test-positive patients, cephalosporins produced only one reaction of mild urticaria and bronchospasm (156).

Primary cephalosporin allergy in patients not allergic to penicillin has been reported, but the exact frequency is

© 2006 Elsevier B.V. All rights reserved.

not known (157,158). The true incidence of allergic reactions may differ among the cephalosporins. Several reports implicating particular compounds have been published (159–163).

An accurate molecular definition of cephalosporin allergy is not currently available. Relevant determinants of cephalosporin-induced anaphylaxis may not reside in the bicyclic core, but rather in the side chain (164,165).

Neither in vitro tests nor skin tests reliably predict cephalosporin allergy (166). The true frequency of allergic reactions in penicillin-allergic patients exposed to cephalosporins has been estimated to be 1 or 2% (167). Nevertheless, when there is a history of penicillin anaphylaxis or other severe IgE-mediated reactions, it is wise to avoid cephalosporins.

An acute, life-threatening, anaphylactic reaction has been described in a child who received his first intravenous injection of ceftriaxone (168).

- A 3-year-old boy developed a high fever and a petechial rash. In the past he had been treated four times with amoxicillin for upper respiratory tract infections without allergic reactions. At presentation he had multiple petechiae over the trunk and limbs. There were no signs of meningeal irritation. He was given intravenous ceftriaxone 100 mg/kg and after 1 minute developed excitation and a generalized papular urticarial rash. His heart rate increased to 160/minute and the blood pressure was not measurable. He was given subcutaneous adrenaline 0.15 mg plus intravenous clemastine fumarate 2 mg, dexamethasone 3 mg, and fluids. Within 15 minutes his circulation was restored and the urticarial rash abated. Instead of ceftriaxone, he was given chloramphenicol for 7 days, and no further allergic reaction was observed. *Neisseria meningitidis*, sensitive to chloramphenicol and ceftriaxone, was cultured from his blood and spinal fluid. He was discharged well 12 days after admission. One month later, skin tests for ceftriaxone and benzylpenicillin were negative, as was a test for ceftriaxone-specific IgE. Because hypersensitivity could not be demonstrated, a controlled intravenous challenge with ceftriaxone 100 mg/kg was performed, and 20 seconds later there was again excitation and a generalized papular urticarial rash. He was treated as before and recovered within 15 minutes.

According to the authors, anaphylaxis after a single injection of ceftriaxone without previous exposure to the drug is very rare, and they referred to only one previous report (169). However, despite the fact that hypersensitivity could not be demonstrated by skin testing or the presence of ceftriaxone-specific IgE, the outcome of the challenge to ceftriaxone very clearly pointed to an anaphylactic reaction.

An anaphylactic reaction to a subconjunctival injection of cefazolin has been described.

- A 70-year-old white woman with a history of penicillin allergy underwent an uncomplicated eye operation, at the end of which she received a subconjunctival injection of cefazolin 50 mg (170). About 90 minutes postoperatively she developed acute respiratory distress and an erythematous macular rash over the face, neck, chest, forearms, and lateral thighs. The rash became urticarial without pruritus. She was given bronchodilators and intravenous glucocorticoids, with little improvement, but repeated subcutaneous injections of adrenaline gave some improvement in breathing. However, she had to be intubated, and was weaned from the ventilator only after some hours.

The main lesson from this case is that a small amount of a beta-lactam antibiotic anywhere in the body can cause life-threatening anaphylaxis.

Type III reactions

Serum sickness was first described by von Pirquet and Schick in 1905 and was regarded as a syndrome resulting from the administration of heterologous serum or other foreign proteins. The immunopathology of classic serum sickness results from antigen-antibody complex formation with a foreign protein as the antigen. Characteristic symptoms include fever, cutaneous eruptions, edema, arthralgias, and lymphadenopathy. The incidence of classical serum sickness has fallen secondary to the refinement of foreign proteins. However, a serum sickness-like reaction that is clinically similar to classical serum sickness can result from the administration of a number of non-protein drugs, such as tetracyclines, penicillins, cephalosporins (171). The reaction typically occurs within 1 month of the start of therapy and resolves after withdrawal.

Most cephalosporins have sporadically been reported to cause reactions closely resembling classical serum sickness (172,173), and intriguingly comparable syndromes were seen in the majority of a series of volunteers treated for up to 4 weeks with high doses of cefalotin and cefapirin (174). There is so far no clear evidence of drug-specific antibodies. The outcome has always been benign. Earlier suspicions that cefaclor increases the risk of serum sickness-like syndromes (175) have subsequently been confirmed (176–181). The true incidence is still a matter of debate. Data suggest that it is several-fold higher than with other cephalosporins or comparator antimicrobials, such as amoxicillin-containing products, penicillin, flucloxacillin, trimethoprim, and others (182,183). More children are affected, which might at least in part reflect preferential use of cefaclor in this age group (184,185).

Serum sickness has been attributed to cefaclor (186).

- A 2-year-old girl was given cefaclor for an infection, having been given it on one previous occasion without any adverse effects. However, on this occasion, after 6 days she developed a rash, edema, and joint swelling. Her symptoms were thought to be due to serum sickness caused by cefaclor, which was withdrawn. The rash resolved within 2 days and the arthralgia settled within 1 week.

It is still uncertain whether cefaclor-associated serum sickness-like reactions correspond to true hypersensitivity. It has indeed been suggested that they may result from inherited defects in the metabolism of reactive intermediates and may be a unique adverse reaction requiring biotransformation of the parent drug (187). A lymphocyte-based cytotoxicity assay has shown that cefaclor metabolites, as generated by murine hepatic microsomes, mediated cytotoxicity among patients with

© 2006 Elsevier B.V. All rights reserved.

cefaclor-induced serum sickness-like disease, but not with other immediate or delayed hypersensitivity reactions (188). The positive tests were not shared with loracarbef, a carbacephem with a methylene (instead of a sulfur) substituent at position 5, but otherwise structurally identical to cefaclor. It is not known whether the chemical degradation of cefaclor in vivo (189) contributes to the pathophysiology of serum sickness-like reactions.

Second-Generation Effects

Teratogenicity

Sporadic reports of findings in cell cultures (190) and animals (191) have suggested potential second-generation effects of cephalosporins; however, no such effects are known in man.

Drug Administration

Drug administration route

Thrombophlebitis is a common reaction to the administration of cephalosporins into peripheral veins. The use of buffered solutions mitigated the reaction with cefalotin (192). Published trials have mainly compared older cephalosporins, but the overall results are still contradictory (193,194). Pain and inflammatory reactions after intramuscular injection are also common. Ceftriaxone is probably given more often intramuscularly now than any other cephalosporin. Its local tolerability does not differ from that of other compounds (195).

Drug–Drug Interactions

ACE inhibitors

Intestinal absorption of beta-lactams occurs at least in part by an active mechanism involving a dipeptide carrier, and this pathway can result in interactions with dipeptides and tripeptides (196,197), which reduce the rate of absorption of the beta-lactams. In particular, angiotensin-converting enzyme (ACE) inhibitors, which have an oligopeptide structure, are absorbed by the same carrier (198) and interact with beta-lactams in isolated rat intestine (199). However, there might be a second site of interaction between ACE inhibitors and beta-lactams. Both groups of substances are excreted by the renal anionic transport system, and concomitant administration of both drugs sometimes results in pronounced inhibition of the elimination of beta-lactams (200). In the case of cefalexin, it may not lead to toxic effects. However, when more toxic beta-lactams are used, the possibility of this interaction has to be kept in mind.

In rats, ACE inhibitors reduced renal cefdinir excretion, probably by competition at the tubular anionic carrier (201).

Alcohol

Cephalosporins that contain a methyltetrazole-thiol side chain (as in cefamandole, cefmenoxime, cefmetazole, cefonizid, cefoperazone, ceforanide, cefotetan, cefotiam, latamoxef, and moxalactam) and chemically similar structures (cefepime, ceftriaxone) co-administered with alcohol can produce a disulfiram-like syndrome by inhibiting aldehyde dehydrogenase (195,202,203).

Transient toxic reactions to cefepime and alcohol in the inner ear have been reported (204). Alcohol intolerance needs some time to build up and has been described for up to 5 days after the ingestion of the antibiotic (205,206). It has to be kept in mind that many pharmacological formulations contain alcohol.

Sudden but reversible bilateral labyrinthine hearing loss occurred after cefepime therapy for one-sided otitis and simultaneous intake of alcohol (204). An abortive form of the acetaldehyde syndrome was assumed.

Ciclosporin

Ceftriaxone reportedly increases ciclosporin blood concentrations (207).

Iron

There was a more than 10-fold reduction in AUC when cefdinir was given concomitantly with iron (208). Since the formation of a chelation complex is believed to account for this effect, similar interactions with aluminium- and magnesium-containing antacids are likely.

Vancomycin

Ceftazidime formed microprecipitates when it was mixed with vancomycin (209).

Verapamil

Competitive albumin binding of drugs with high serum protein affinity can increase pharmacologically active unbound concentrations and enhance the metabolism of low clearance drugs. Acute verapamil toxicity with ceftriaxone and clindamycin may be explained by this mechanism (210).

Interference with Diagnostic Tests

Galactose absorption

Some cephalosporins non-competitively inhibited the active absorption of D-galactose by reducing the activity of Na/K-ATPase (211). Theoretically, this effect might interfere with galactose tolerance testing.

Jaffee Test

Certain cephalosporins (cefoxitin, cefpirome, cefacetrile, cefaloglycin, cefaloridine, cefalotin) react with alkaline picrate solution, forming a chromogen with the same spectrum of absorbance as that formed by creatinine and alkaline picrate, producing falsely high serum

© 2006 Elsevier B.V. All rights reserved.

creatinine values (212,213). This reaction occurs at therapeutic concentrations. Other cephalosporins (cefamandole, cefazolin, cefoperazone, cefotaxime, ceftazidime, ceftriaxone, cefuroxime, latamoxef) do not interfere with this assay (214).

Cerivastatin

See also HMG Co-A reductase inhibitors

General Information

Weight for weight, cerivastatin is the most potent statin. Like other statins, the chance of rhabdomyolysis increases when cerivastatin is taken together with certain other drugs (1). Although cerivastatin is degraded by two different isoforms of P_{450} in the liver, and therefore should be less likely to take part in drug interactions than most of the other statins, clinically important interactions do occur, and reports of drug interactions in 2001 triggered its withdrawal, after 31 people in the USA taking cerivastatin, 12 of whom had also taken gemfibrozil, died of severe rhabdomyolysis (2).

In other respects, the adverse effects of cerivastatin are similar to those of other statins (3), and a pooled analysis of studies of cerivastatin 100–400 micrograms/day taken for at least 8 weeks showed no differences in drug-related adverse events between cerivastatin and placebo (4). There was no association between plasma transaminase or creatine kinase activities and cerivastatin dosages. Cerivastatin 800 micrograms/day for 4 weeks had only mild transient adverse effects (5).

Organs and Systems

Liver

There were increases in serum transaminase activities to more than three times the top end of the reference range in under 1% of patients taking cerivastatin, which is similar to findings with other statins (6).

Musculoskeletal

There were no cases of myalgia in 94 patients taking cerivastatin 50–300 micrograms/day for 72 weeks, whereas in the same study, two of 59 patients taking simvastatin had myalgia (7). At dosages of 300–400 micrograms/day for 8 weeks in 349 patients there were no rises in creatine kinase activity above 10 times the upper limit of the reference range, and asymptomatic increases (to over three times the upper limit of the reference range) occurred more often with placebo (2.8%) than with cerivastatin (1.4% with 0.4 mg; none with 0.3 mg) (8).

Drug–Drug Interactions

Ciclosporin

Cerivastatin 0.2 mg/day was well tolerated when given together with ciclosporin, although there were 3- to 5-fold increases in the plasma concentrations of cerivastatin and its metabolites when single-dose cerivastatin was given to 12 kidney transplant recipients taking ciclosporin 200 mg bd and to 12 healthy controls (9). Ciclosporin may have affected both the distribution of cerivastatin and its biotransformation in the liver.

Gemfibrozil

Cerivastatin was withdrawn in 2001 after 31 people in the USA taking cerivastatin, 12 of whom had also taken gemfibrozil, died of severe rhabdomyolysis (2).

- Myalgia and a marked increase in creatine kinase was precipitated in a 74-year-old woman with normal renal function who took gemfibrozil 1200 mg/day 3 weeks after she had started to take cerivastatin 300 μg/day (10).

Ceruletide

General Information

Ceruletide is a synthetic decapeptide that resembles cholecystokinin and causes contraction of the gallbladder. It has sometimes been used instead of the traditional "fatty meal" in cholecystography. After intramuscular injection, nausea, vomiting, diarrhea, and cramps have been reported.

Intravenous injection can cause spasm of the gall-bladder neck and severe pain with tingling sensations, sweating, and mild hypotension (1).

Cetirizine

See also Antihistamines

General Information

Cetirizine is a non-sedating metabolite of hydroxyzine (SEDA-18, 181) (SEDA-19, 172) (SEDA-21, 172) (SEDA-22, 178). There is only minor hepatic metabolism of cetirizine (1), which is excreted unchanged in the urine. It has not been associated with dysrhythmias. Skin reactions have been reported, and the anticoagulant activity of acenocoumarol may be potentiated (SEDA-22, 178).

Seasonal allergic rhinitis affects about 10% of school-age children, and there is evidence of a significant impact of the disease on health-related quality of life. The effect on health-related quality of life of once-daily of cetirizine syrup 10 mg/day for 4 weeks has been studied in 544 children with seasonal allergic rhinitis in a multicenter, open, non-comparative study (2). In addition to improvements in symptom scores the authors also reported significant improvements in health-related quality of life, with good tolerability of the drug. Treatment-related adverse effects were reported in 22 subjects, of which somnolence was the most frequent problem, reported by six of the subjects. Only 12 of subjects discontinued treatment owing to an adverse effect.

Health-related quality of life and clinical outcomes in 865 adult patients with seasonal allergic rhinitis treated with cetirizine or placebo for 2 weeks have been evaluated in a double-blind, randomized, parallel-group study (3). Cetirizine significantly improved both symptoms and health-related quality of life, while treatment-related adverse effects were comparable with those in the placebo group.

Organs and Systems

Cardiovascular

In a prospective, double-blind, parallel-group study for 18 months in 817 children with atopic dermatitis aged 12–24 months, cetirizine 0.25 mg/kg bd had no effect on the QT_c interval (4).

In a double-blind, randomized, placebo-controlled study in 85 infants aged 6–11 months there were no differences in the frequencies of adverse events between those who were given cetirizine or placebo, and no electrocardiographic changes, particularly in the QT interval (5).

Nervous system

Oculogyric crisis has been described in nine patients treated with cetirizine; eight cases occurred in children (6).

The effects of cetirizine (5, 10, and 15 mg) on sleep latency, subjective sleepiness, and performance from 0.5 to 7.5 hours after ingestion have been studied (7). Cetirizine produced shortened sleep latencies, increased subjective sleepiness, and impaired tracking. The authors considered that cetirizine should not be used by personnel involved in critical occupations.

Psychological, psychiatric

In a double-blind, crossover study levocetirizine 5 mg once daily for 4 days was compared with cetirizine 10 mg, loratadine 10 mg, promethazine 30 mg, and placebo in terms of nervous system inhibitory effects in 20 healthy volunteers (8). With the exception of promethazine, none of the drugs had disruptive or sedative effects on objective measurements in a comprehensive battery of psychomotor and cognitive tests.

The Early Treatment of the Atopic Child (ETAC) Study has provided evidence that cetirizine may be able to halt the progression to asthma in high-risk groups of young children and infants with atopic dermatitis (9). However, the study involved giving relatively high doses of cetirizine to very young children (aged 1–2 years at study entry) over a long period of time. Therefore, the impact of prolonged use of high-dose cetirizine (0.25 mg/kg bd over 18 months) on behavior and cognitive ability in young children and infants has been assessed in a double-blind, randomized, placebo-controlled study (10). Well-validated and standardized assessments of behavior or cognition were used, and the ages at which psychomotor milestones were attained were established. The authors concluded that, compared with placebo, cetirizine had no significant effects on behavior, cognition, or psychomotor milestones in young children with atopic dermatitis.

© 2006 Elsevier B.V. All rights reserved.

Liver

Severe hepatitis has been reported in a 23-year-old man taking cetirizine (11) and cholestasis in a 28-year-old man who had taken cetirizine for 2 years (12). However, a causal relation between these uncommon events and cetirizine was difficult to confirm.

Skin

Cutaneous reactions have been reported with cetirizine (13).

- A man taking cetirizine developed a multifocal fixed drug eruption (14).
- In a 45-year-old man cetirizine caused multiple fixed erythematous lesions on the trunk (15). Cetirizine was withdrawn for 15 days and an oral challenge test was performed. The same skin lesions developed in the previously affected skin sites when cetirizine was taken.
- A 14-year-old girl with house dust mite allergy had generalized skin eruptions after taking cetirizine. She also had symptoms of acute hepatitis, which also resolved after withdrawal of cetirizine (16).
- A 73-year-old man had skin eruptions associated with cetirizine and hydroxyzine therapy, which healed after drug withdrawal (17).

There have been several case reports of urticaria due to cetirizine.

- Generalized urticaria developed in a woman 2 hours after she took cetirizine (18).
- Acute generalized urticaria occurred in a 42-year-old woman taking cetirizine for seasonal allergic rhinitis and conjunctivitis, which had previously been treated with loratadine (19).
- A 32-year-old woman with recurrent idiopathic urticaria, asthma, and metal-induced contact dermatitis had 5–10 episodes of urticaria a year, with pruritic wheals of less than 24 hours duration (20). Cetirizine 10 mg/day was associated with the appearance of pruritic wheals on her neck, forehead, and arms. The symptoms resolved on drug withdrawal and reappeared on rechallenge. Double-blind challenge tests with mizolastine, loratadine, fexofenadine, dexchlorphenamine, ebastine, ketotifen, and placebo were negative, whereas hydroxyzine and its active metabolite, cetirizine, reproduced the urticaria.
- A 36-year-old woman noted intense exacerbation of urticarial wheals and facial edema 3–4 hours after taking cetirizine 10 mg (21). Skin tests with cetirizine produced an urticarial reaction 5 hours after challenge. Placebo-controlled oral challenge resulted in generalized urticaria, edema of the hands, and intense pruritus 90 minutes after administration of cetirizine, with symptoms lasting up to 12 hours. Skin biopsies showed inflammation typical of urticaria.

Susceptibility Factors

Age

The long-term safety of cetirizine (0.25 mg/kg bd) has been studied in children with atopic dermatitis (22). The mean duration of exposure to cetirizine in 399 children was 17 months. The frequency of dropouts and serious events did not differ between cetirizine and placebo. There were no clinically important differences in neurological or cardiovascular events, growth, or behavioral or cardiovascular assessments between the groups. No child taking cetirizine had prolongation of the QT_c interval.

The effects of cetirizine 0.25 mg/kg bd for 18 months have been investigated in a prospective, double-blind, parallel-group study in 817 children with atopic dermatitis aged 12–24 months (4). Dropouts and serious events, including hospitalization, were infrequent and were less common in the children who took cetirizine, although the differences were not statistically significant. Most of the adverse events were mild and were not related to medication.

Drug–Drug Interactions

Alcohol

Cetirizine did not potentiate the effects of ethanol on psychomotor and driving performance (SEDA-20, 163), but did affect tracking speed and performance in divided attention tests.

Cetrimonium bromide and cetrimide

See also Disinfectants and antiseptics

General Information

Cetrimonium bromide and cetrimide are quaternary ammonium antiseptics, trimethylammonium derivatives, with similar structures. Cetrimonium bromide is hexadecyltrimethylammonium. Cetrimide is a mixture of tetradecyltrimethylammonium (mostly), dodecyltrimethylammonium, and hexadecyltrimethylammonium. They dissociate in aqueous solution, forming a relatively large and complex cation, which is responsible for their surface activity, and a smaller inactive anion. They are emulsifiers and detergents and have bactericidal activity against Gram-positive and, at higher concentrations, some Gram-negative bacteria.

In three hospitals, 378 patients with hydatid cysts were treated surgically, including irrigation with cetrimide solutions in concentrations between 0.05 and 1% (1). No adverse effects were observed.

Organs and Systems

Sensory systems

Accidental use of cetrimide solution 0.1% as an irrigation solution during cataract surgery in two cases resulted in immediate corneal edema, which in turn resulted in a severe bullous keratopathy (2).

Acid–base balance

Severe metabolic acidosis without signs of peritonitis occurred after more than 1 liter of 1% cetrimide was instilled into hydatid cysts (SEDA-11, 490) (3).

Hematologic

Severe methemoglobinemia has been reported after excision of hydatid cysts and liberal irrigation of the cysts in the liver with a 0.1% solution of cetrimide (4).

Skin

Eighteen cases of an ichthyosiform contact dermatitis caused by antiseptic solutions containing 3% cetrimide and 0.3% chlorhexidine have been reported (5,6). Biopsies showed hyperkeratosis with striking vesiculation of lamellar bodies in the granular cells and upper spinous cells, premature secretion of lamellar bodies, and abundant remnants of lamellar bodies and retention of desmosomes between corneocytes. Cetrimide, and not chlorhexidine, was said to be the cause of the dermatitis.

Suckleya (suckleya)
Zuckia (zuckia)

Chenopodium ambrosioides

Chenopodium ambrosioides (American wormseed) contains the diterpenoid aritasone and the toxic principle ascaridole, which was formerly used as an antihelminthic drug, but has now been superseded.

Chloral hydrate

General Information

Chloral hydrate, which was synthesized by Justus Liebig in 1832, continues to be used for sleep disorders and for sedation before surgery or radiology, especially in children (1). As an alternative to the benzodiazepines, it has essentially similar properties and problems, but is associated with perhaps rather more frequent gastrointestinal disturbances, up to 7% in one large sample of children. Chloral hydrate had a reputation for safety, which has been challenged by data that suggest that it and short-acting barbiturates are particularly lethal when taken in overdose (2). Liver damage and cardiac toxicity, consistent with the chemical similarities between trichloroethanol, chloroform, and alcohol, can occur.

Organs and Systems

Cardiovascular

A single dose (1.2 g) in a 4-year-old girl gave rise to a reversible ventricular dysrhythmia (SEDA-21, 39).

Nervous system

Two generalized seizures occurred in a 2-year-old boy after he was sedated before echocardiography (SEDA-22, 42).

Gastrointestinal

A 78-year-old woman and a 45-year-old man developed pneumatosis cystoides coli. Both were taking chloral hydrate (3). It was speculated that chloral hydrate had caused the abdominal symptoms in these patients.

- A 69-year-old man had daily loose stools with mucous discharge. Repeated stool cultures were negative. Histology confirmed the appearances of pneumatosis cystoides coli. Various treatments had little effect on his symptoms. He had taken chloral hydrate for insomnia for 10 years. Subjectively, his symptoms were worse while taking the drug and resolved after withdrawal. With his consent, an unblinded controlled challenge with chloral hydrate was performed. The results, recorded meticulously in a symptoms diary, were dramatic. Before chloral hydrate, his bowels opened 18 times per week and only two motions contained mucus. After one tablet of chloral hydrate on days 1, 2, 5, and 7 he passed 49 stools in one week, 35 containing mucus. Two weeks later his bowel habit had returned to normal, with 15 movements per week, and only one stool contained mucus. Subsequently his bowel frequency fell to 8–10 times per week with considerable colonoscopic improvement.

Liver

Hyperbilirubinemia in neonates associated with chloral hydrate (4) may be due to the more prolonged half-life of trichloroethanol in newborns compared with adults (37 versus 14 hours).

Skin

Allergic skin reactions continue to be reported (5).

Immunologic

Several reports have highlighted the importance of gelatin allergy in young children, with some deaths due to anaphylaxis.

- A 2-year-old boy and a 4-year-old boy developed anaphylactic symptoms after being given a chloral hydrate suppository, which contained gelatin, for sedation before electroencephalography (6).

© 2006 Elsevier B.V. All rights reserved.

Chloral hydrate suppositories are often used to sedate children during various examinations and the authors suggested using gelatin-free formulations.

Long-Term Effects

Drug dependence

Chloral hydrate dependence can occur (7), the most famous case being that of Anna O. (Bertha Pappenheim), who was treated by Breuer from 1880 to 1882, and whose pathology was discussed by him and Freud in 1895 (8).

Tumorigenicity

Concerns about carcinogenicity are not supported by its persisting and generally successful therapeutic use.

Drug Administration

Drug formulations

Several reports have highlighted the importance of gelatin allergy in young children, with some deaths due to anaphylaxis. Some formulations of chloral hydrate contain gelatin.

- A 2-year-old boy and a 4-year-old boy developed anaphylactic symptoms after being given a chloral hydrate suppository, which contained gelatin, for sedation before electroencephalography (6).

Chloral hydrate suppositories are often used to sedate children during various examinations and the authors suggested using gelatin-free formulations.

Drug overdose

Chloral hydrate toxicity can cause a number of dysrhythmias, including supraventricular tachycardia, ventricular tachycardia, ventricular fibrillation, and torsade de pointes.

- A 27-year-old man with a history of psychiatric illness became unconscious after taking about 20 g of chloral hydrate, 1000 mg of loxapine, and 180 mg of fluoxetine (9). He became unresponsive and hypotensive and had intermittent episodes of ventricular tachycardia, which was successfully treated with intravenous propranolol.

Chloramphenicol

General Information

Chloramphenicol is one of the older broad-spectrum antibiotics. It was introduced in 1948 and grew in popularity because of its high antimicrobial activity against a wide range of Gram-positive and Gram-negative bacteria, *Rickettsiae*, *Chlamydia*, and *Mycoplasma* species. It is particularly useful in infections caused by *Salmonella typhi* and *Haemophilus influenzae*. It is mainly bacteriostatic. It readily crosses tissue barriers and diffuses rapidly into nearly all tissues and body fluids.

The main route of elimination of chloramphenicol is metabolic transformation by glucuronidation. The microbiologically inactive metabolites are excreted rapidly and only a small proportion of unchanged drug is excreted in the urine. The usual daily dose is 50 mg/kg for adults and children over 2 months. The total dose should not exceed 3.0–3.5 g/70 kg. The statement that neither the dose nor the interval of chloramphenicol administration needs to be adjusted in patients with significant renal dysfunction (1) probably has to be modified in view of recent findings (2).

By 1950 it became evident that chloramphenicol could cause serious and fatal blood dyscrasias. Its use has therefore steadily fallen during the past 50 years. Since the risk of serious chloramphenicol toxicity is so small (1:18 000 or probably less) it is of more than historical interest. There are still many areas in which its benefits outweigh its risks. These include:

- typhoid and paratyphoid fever;
- other septic forms of *Salmonella* infections;
- meningitis due to *H. influenzae*, *Streptococcus pneumoniae*, and *Neisseria meningitidis* when the patient is allergic to beta-lactam antibiotics or when the strains (*H. influenzae*, Enterobacteriaceae) are resistant to aminopenicillins and cephalosporins;
- brain abscess;
- serious infections caused by *Bacteroides fragilis* (as an alternative to clindamycin or metronidazole).

Since chloramphenicol is still one of the cheapest antibiotics, this list of indications is longer in developing

© 2006 Elsevier B.V. All rights reserved.

countries, where chloramphenicol may be more readily available than newer expensive antibiotics. However, most infections can be readily, safely, and effectively treated with alternative drugs. Therefore, the role of chloramphenicol in the treatment of infectious diseases is likely to diminish further.

Chloramphenicol and its metabolites act primarily on the 50S ribosomal subunit, with suppression of the activity of the enzyme peptidyltransferase. It inhibits mitochondrial membrane protein synthesis, leading to suppression of mitochondrial respiration and ultimately to cessation of cell proliferation (3). Analogous mechanisms may operate in the production of the reversible type of bone marrow depression, which is the most prominent toxic effect in patients taking chloramphenicol. Its potency to induce toxic effects on mitochondria in maturing or rapidly proliferating eukaryotic cells is very close to that for inhibiting prokaryotic cells (bacteria and blue-green algae). However, little progress has been made in elucidating the pathogenesis of irreversible bone marrow aplasia (3–5).

Observational studies

The response to chloramphenicol has been assessed in cases of bacteremia due to vancomycin-resistant enterococci, of whom 65% received chloramphenicol (6). Among those in whom a response could be assessed, 61% had a clinical response and 79% had a microbiological response. Mortality was non-significantly lower in patients treated with chloramphenicol. In cases with central line-related bacteremia, there was no difference in mortality among those treated with chloramphenicol, line removal, or both. No adverse effect could be definitely attributed to chloramphenicol.

General adverse effects

Chloramphenicol has been associated with two serious but rare toxic effects, each with a high mortality. One is the "gray syndrome," vasomotor collapse in neonates caused by excessive parenteral doses. The second is bone marrow aplasia, which is a hypersusceptibility reaction. Prolonged use can result in neuropathies. Mild gastrointestinal disturbances are common. Chloramphenicol can cause a Jarisch–Herxheimer reaction, for example in patients with louse-borne relapsing fever (7). Hypersensitivity reactions are commonly mild and more frequent with topical use (allergic contact dermatitis, rashes, glossitis). The late, severe type of bone marrow reaction may be of allergic origin. Tumor-inducing effects have not been described; a statement that chloramphenicol might cause cancer in the fetus appears to have been purely speculative.

Organs and Systems

Cardiovascular

The "gray syndrome" is the term given to the vasomotor collapse that occurs in neonates who are given excessive parenteral doses of chloramphenicol. The syndrome is characterized by an ashen gray, cyanotic color of the skin, a fall in body temperature, vomiting, a protuberant abdomen, refusal to suck, irregular and rapid respiration, and lethargy. It is mainly seen in newborn infants, particularly when premature. It usually begins 2–9 days after the start of treatment.

Inadequate glucuronyl transferase activity combined with reduced glomerular filtration in the neonatal period is responsible for a longer half-life and accumulation of the drug. In addition, the potency of chloramphenicol to inhibit protein synthesis is higher in proliferating cells and tissues. The most important abnormality seems to be respiratory deficiency of mitochondria, due, for example to suppressed synthesis of cytochrome oxidase. The dosage should be adjusted according to the age of the neonate, and blood concentrations should be monitored. In most cases of gray syndrome, the daily dose of chloramphenicol has been higher than 25 mg/kg (8,9). Occasionally, treatment of older children and teenagers with large doses of chloramphenicol (about 100 mg/kg) has resulted in a similar form of vasomotor collapse (10).

Nervous system

Peripheral neuropathy has been seen after prolonged courses of chloramphenicol (11).

Retrobulbar optic neuritis and polyneuritis have been attributed to prolonged chloramphenicol therapy (12).

Sensory systems

Eyes

Optic neuropathy has been seen after prolonged courses of chloramphenicol (13). Alterations in color perception and optic neuropathy, in some cases resulting in optic atrophy and blindness, have been observed, especially in children with cystic fibrosis receiving relatively high doses for many months (12,14). Most of these complications were reversible and were attributed to a deficiency of B vitamins.

Ears

Local application of chloramphenicol can cause hearing defects. Asymmetrical hearing loss with lowered perception of high tones has been documented after treatment of chronic bilateral otitis media with chloramphenicol powder (15). Propylene glycol is often used as a vehicle for chloramphenicol ear-drops, and ototoxicity may be due to chloramphenicol and/or propylene glycol, which is itself strongly ototoxic. Ototoxic effects can also occur after systemic drug administration (16).

Hematologic

The first death resulting from bone marrow aplasia induced by chloramphenicol eye-drops was described in 1955 (17). Chloramphenicol causes two types of bone marrow damage (18).

- A frequent, early, dose-related, reversible suppression of the formation of erythrocytes, thrombocytes, and granulocytes (early toxicity).
- A rare, late type of bone marrow aplasia, a hypersusceptibility reaction, which is generally irreversible, and has a high mortality rate (aplastic anemia) (19–21).

Chloramphenicol inhibits mRNA translation by the 70S ribosomes of prokaryotes, but does not affect 80S eukaryotic ribosomes. Most mitochondrial proteins are encoded by

© 2006 Elsevier B.V. All rights reserved.

nuclear DNA and are imported into the organelles from the cytosol where they are synthesized. Mitochondria retain the capacity to translate, on their own ribosomes, a few proteins encoded by the mitochondrial genome. True to its prokaryotic heritage, mitochondrial ribosomes are similar to those of bacteria, meaning that chloramphenicol inhibits protein synthesis by these ribosomes. Chloramphenicol-induced anemia is believed to result from this inhibition (22). Chloramphenicol can also cause apoptosis in purified human bone marrow CD34+ cells (23).

Dose-related bone marrow suppression

The early, dose-related type of chloramphenicol toxicity is usually seen after the second week of treatment, and is characterized by inhibited proliferation of erythroid cells and reduced incorporation of iron into heme. The clinical correlates in the peripheral blood are anemia, reticulocytopenia, normoblastosis, and a shift to early erythrocyte forms. The plasma iron concentration is increased. Early erythroid forms and granulocyte precursors show cytoplasmic vacuolation. After withdrawal, complete recovery is the rule. Leukopenia and thrombocytopenia are less frequent.

Although there is no evidence that these abnormalities progress to frank bone marrow aplasia, continuation of chloramphenicol after the appearance of early toxicity is thought to be hazardous. Pre-existing liver damage (for example due to infectious hepatitis or alcoholism) and impaired kidney function can lead to reduced elimination of chloramphenicol and its metabolites, thereby aggravating marrow toxicity. As a rule, this is not the irreversible type.

Aplastic anemia

Although bone marrow aplasia has not been related with certainty to either the daily or the total dose of chloramphenicol or to the sex or age of the patients, it has occurred almost exclusively in individuals who were taking prolonged therapy, particularly if they were exposed to the drug on more than one occasion (24). The condition is rare, occurring about once in every 18 000–50 000 subjects in various countries. These variations may in part depend on ethnic factors (25,26). For example, there have been very few cases reported in blacks (27). Bone marrow aplasia due to chloramphenicol has usually resulted in aplastic anemia with pancytopenia; other forms, such as red cell hypoplasia, selective leukopenia, or thrombocytopenia, are less common.

When bone marrow aplasia was complete, the fatality rate approached 100%. As a rule, it has been found that the longer the interval between the last dose of chloramphenicol and the appearance of the first sign of a blood dyscrasia, the more severe the resulting aplasia. Nearly all patients in whom the interval was longer than 2 months died as a result of this complication. However, fatal aplastic anemia can also occur shortly after normal doses of chloramphenicol (28).

The pathogenesis of bone marrow aplasia after chloramphenicol is still uncertain. Compared with normal cells, bone marrow aspirates from patients with bone marrow aplasia are relatively resistant to the toxic effects of chloramphenicol in vitro. This has been explained by the hypothesis that during treatment with chloramphenicol, chloramphenicol-sensitive cells were eliminated, leaving behind only a chloramphenicol-insensitive population of blood cell precursors with poor proliferative capacity (29). Chloramphenicol can induce apoptosis in purified human bone marrow CD34+ cells; however, there was no protection from a variety of antioxidants on chloramphenicol-induced suppression of burst-forming unit erythroid and colony-forming unit granulocyte/monocyte in vitro (30). In contrast, a caspase inhibitor ameliorated the apoptotic-inducing effects of chloramphenicol.

Since thiamphenicol, which causes very few cases of aplastic anemia, differs from chloramphenicol by substitution of the para-nitro group by a methylsulfonyl group, interest has been focused on the para-nitro group and metabolites of that part of the molecule, nitrosochloramphenicol and chloramphenicol hydroxylamine. In human bone marrow, nitrosochloramphenicol inhibited DNA synthesis at 10% of the concentration of chloramphenicol required for the same effect, and proliferation of myeloid progenitors was irreversibly inhibited. The covalent binding of nitrosochloramphenicol to marrow cells was 15 times greater than that of chloramphenicol (31). This has lent support to the hypothesis that abnormal metabolism may contribute to the susceptibility to bone marrow aplasia. The production of reduced derivatives by intestinal microbes may contribute to toxicity, but oral administration of chloramphenicol is not essential for the development of aplastic anemia (32). There is evidence that genetic predisposition may play a role (33,34). The wide geographical variations in the incidence of aplastic anemia may also reflect environmental factors.

For many years it had been said that there were no cases of aplastic anemia after parenteral administration of chloramphenicol; however, a few cases of aplastic anemia have been reported (35). There have also been reports of bone marrow hypoplasia after the use of chloramphenicol eye-drops (36,37).

There is controversy about the risk of aplastic anemia with topical chloramphenicol. In a prospective case-control surveillance of aplastic anemia in a population of patients who had taken chloramphenicol for a total of 67.2 million person-years, 145 patients with aplastic anemia and 1226 controls were analysed. Three patients and five controls had been exposed to topical chloramphenicol, but two had also been exposed to other known causes of aplastic anemia. Based on these findings, an association between ocular chloramphenicol and aplastic anemia could not be excluded, but the risk was less than one per million treatment courses (38). In another study, a review of the literature identified seven cases of idiosyncratic hemopoietic reactions associated with topical chloramphenicol. However, the authors failed to find an association between the epidemiology of acquired aplastic anemia and topical chloramphenicol. Furthermore, after topical therapy they failed to detect serum accumulation of chloramphenicol by high performance liquid chromatography. They concluded that these findings support the view that topical chloramphenicol was not a risk factor for dose-related bone marrow toxicity and that calls for abolition of treatment with

© 2006 Elsevier B.V. All rights reserved.

topical chloramphenicol based on current data are not supported (39).

In a study using general practitioner-based computerized data, 442 543 patients were identified who received 674 148 prescriptions for chloramphenicol eye-drops. Among these patients, there were three with severe hematological toxicity and one with mild transient leukopenia. The causal link between topical chloramphenicol and hematological toxicity was not further evaluated in detail (40).

Leukemia

In a small fraction of patients who survive the chronic type of bone marrow damage, myeloblastic leukemia develops (41,42). In most instances this complication has appeared within a few months of the diagnosis of aplasia and was considered to be a sequel of chloramphenicol treatment. Sometimes the delay was shorter. The majority were either children or adults aged 50–70 years.

The occurrence of acute leukemia has been studied in relation to preceding use of drugs (before the 12 months preceding the diagnosis) in a case-control study of 202 patients aged over 15 years with a diagnosis of acute leukemia and age- and sex-matched controls (43). Among users of chloramphenicol or thiamphenicol the odds ratio for any use was 1.1 (0.6–2.2) whereas the odds ratio for high doses was 1.8 (0.6–5.3). Other systemic antibiotics showed no substantial relation with the occurrence of leukemia.

Gastrointestinal

Mild gastrointestinal disturbances are common in patients taking chloramphenicol. In 51 children with Mediterranean spotted fever randomized for 7 days to either clarithromycin, 15 mg/kg/day orally in two divided doses, or chloramphenicol, 50 mg/kg/day orally in four divided doses, the two drugs were equally well tolerated and there were no major adverse effects; there was vomiting in two patients treated with clarithromycin and in one treated with chloramphenicol (44). None of the patients required drug withdrawal.

Skin

Hypersensitivity occurs about four times more often after topical than after oral use (45). In fact, there has been a continuous increase in chloramphenicol hypersensitivity, owing to the use of dermatological formulations (46). Allergic contact dermatitis and macular or vesicular skin rashes are usually limited to skin areas previously exposed to the drug. Contact conjunctivitis has also been reported.

A case of a facial contact dermatitis due to chloramphenicol with cross-sensitivity to thiamphenicol has been reported (47).

Immunologic

Systemic reactions with collapse, bronchospasm, angioedema, and urticaria occur rarely (48,49).

Infection risk

The number and types of microorganisms that constitute the normal microflora of the alimentary, respiratory, and genital tracts change during therapy with chloramphenicol. Superinfections can then develop with *Staphylococcus aureus*, *Pseudomonas*, *Proteus*, and fungi. The changes in intestinal flora may be partly responsible for a reduction in the synthesis of vitamin K-dependent clotting factors, especially in patients with severe illnesses and malnutrition or during the administration of oral anticoagulants.

Long-Term Effects

Drug tolerance

There have been reports of chloramphenicol-resistant *H. influenzae* from various countries, but there have been few cases (50). Outbreaks of chloramphenicol-resistant *S. typhi* have been observed in several countries (51,52).

High-level chloramphenicol-resistant strains of *N. meningitidis* serogroup B were isolated from 11 patients in Vietnam and one patient in France. Resistance was due to the presence of the catP gene on a truncated transposon that has lost mobility because of internal deletions (53).

Salmonella typhimurium DT104 is usually resistant to ampicillin, chloramphenicol, streptomycin, sulfonamides, and tetracycline. An outbreak of 25 culture-confirmed cases of multidrug-resistant *S. typhimurium* DT104 has been identified in Denmark (54). The strain was resistant to the above-mentioned antibiotics and nalidixic acid and had reduced susceptibility to fluoroquinolones. A swineherd was identified as the primary source (54). The DT104 strain was also found in cases of salmonellosis in Washington State, and soft cheese made with unpasteurized milk was identified as an important vehicle of its transmission (55).

A high rate of resistance of non-typhoid *Salmonella* to commonly used antimicrobial agents was found in Taiwan; 67% of the isolated strains were resistant to chloramphenicol (56).

Streptococcus pneumoniae was isolated in 30% of 40 HIV-infected and 50% of 162 HIV-negative children living in a Romanian orphanage (57). Multidrug-resistant streptococci were highly prevalent, and 21% of the isolates were resistant to chloramphenicol.

Esterases in serum from rabbits and to a lesser extent humans can convert diacetyl chloramphenicol back to an active antibiotic. Therefore, in vitro findings may not accurately reflect the level of chloramphenicol resistance by chloramphenicol acetyltransferase-bearing bacteria in vivo, when growth media supplemented with serum are used (58).

The flo gene that confers resistance to chloramphenicol and the veterinary antibiotic florfenicol have previously been identified in *Photobacterium piscicida* and *Salmonella enterica serovar typhimurium* DT104 (59). Florfenicol-resistant isolates of *Escherichia coli* were tested and found to contain large flo-positive plasmids, suggesting that several of these isolates may have a chromosomal flo gene. The *E. coli* flo gene also specifies non-enzymatic cross-resistance to both florfenicol and chloramphenicol (60). Florfenicol resistance has emerged among veterinary isolates of *E. coli* incriminated in bovine diarrhea.

Second-Generation Effects

Teratogenicity

In the large population-based dataset of the Hungarian Case Control Surveillance of Congenital Abnormalities, of 38 151 pregnant women who had babies without any defects and 22 865 pregnant women who had neonates or fetuses with congenital abnormalities, 51 and 52 had been treated with oral chloramphenicol respectively. Treatment during early pregnancy presented little, if any, teratogenic risk to the fetus (61).

Fetotoxicity

Chloramphenicol penetrates the fetal circulation and should therefore be avoided during the last phase of pregnancy (62,63). The gray syndrome has been observed in babies born to mothers who had received chloramphenicol in the final stage of pregnancy.

Lactation

Chloramphenicol has been found in relatively large amounts in breast milk. It should therefore be avoided during breast-feeding (62,63).

Susceptibility Factors

Age

In children, a high cumulative dose seems to be an important risk factor. As leukopenia can occur in the early phase of treatment, a complete blood count every third day is recommended (SEDA-15, 267).

Renal disease

Impaired kidney function, with reduced clearance of chloramphenicol, may be a risk factor for toxicity.

Hepatic disease

Liver damage, with reduced clearance of chloramphenicol, may be a risk factor for toxicity.

Other features of the patient

In a retrospective study of 30 consecutive children with sepsis treated with oral chloramphenicol, weight, albumin, and white blood cell count were the most important determinants for chloramphenicol distribution volume, whereas age, white blood cell count, and serum creatinine were most important for drug clearance (64). A preexisting blood dyscrasia is generally considered to be an absolute contraindication to the use of chloramphenicol.

Drug Administration

Drug administration route

In 1993 the American National Register of Drug Induced Ocular Side Effects received reports of 23 patients with blood dyscrasias that could have been related to topical ocular administration of chloramphenicol (65).

Of the two types of bone marrow toxicity that chloramphenicol can cause, it may cause the late type only in genetically predisposed patients. The overall risk of aplastic anemia after oral administration of chloramphenicol is 1:30 000 to 1:50 000, which is 13 times greater than the risk of idiopathic aplastic anemia in the population as a whole. Since topical administration achieves systemic effects by absorption through the conjunctival membrane or through drainage down the lacrimal duct, with eventual absorption from the gastrointestinal tract, the risk may be similar to that after oral administration. However, based on two case-control studies and a cohort study, the incidence of blood dyscrasias due to chloramphenicol eye-drops was estimated to be somewhat lower, namely 1:100 000 treated patients (40,66).

It is difficult to justify subjecting patients to this small potential risk, in view of the availability of other antibiotics for use in the eye. In the USA the Physician's Desk Reference emphasizes with repeated warnings the importance of not using ocular chloramphenicol unless there is no alternative, and this warning should be respected on both sides of the Atlantic (67,68).

Allergic reactions to chloramphenicol eye-drops include conjunctivitis, keratitis, and palpebral and periocular eczema (47).

Erythema multiforme caused by local treatment with chloramphenicol eye-drops has been described (47). The possible role of an allergic mechanism in this reaction was suggested, based on a positive mast cell degranulation test (69).

Drug–Drug Interactions

Ciclosporin

A possible interaction between ciclosporin and chloramphenicol has been observed (70).

- A morbidly obese 17-year-old Hispanic girl, who had a cadaveric renal transplantation 5 years before, took ciclosporin and prednisone for stabilization. She was treated with chloramphenicol 875 mg qds and ceftazidime 2 g tds for vancomycin-resistant enterococcal sinusitis. There was a substantial and sustained increase in ciclosporin concentrations after chloramphenicol was added. Normalization was achieved after withdrawal of chloramphenicol.

Cyclophosphamide

Chloramphenicol inhibits the biotransformation of cyclophosphamide (71).

Cytochrome P450

Chloramphenicol can interfere with the elimination of drugs that are inactivated by hepatic metabolism, probably through a mechanism involving inhibition of microsomal enzymes. The mechanism has been claimed to be inactivation of microsomal enzymes via an intermediate reactive metabolite that binds covalently to the protein moiety of cytochrome P450 (71). Assuming such a mechanism, chloramphenicol would be expected to interact with the metabolism of other drugs dealt with by cytochrome P450.

© 2006 Elsevier B.V. All rights reserved.

Oral anticoagulants

Chloramphenicol inhibits the biotransformation of oral anticoagulants (71).

Paracetamol (acetaminophen)

Paracetamol altered the pharmacokinetics of chloramphenicol in some studies but not in others.

In six adults the half-life of chloramphenicol, 1 g intravenously was increased from 3.3 to 15 hours by paracetamol 100 mg intravenously (72).

In contrast, in five children aged 2.5–5 years paracetamol 50 mg/kg/day for several days significantly lowered the C_{max} of chloramphenicol, increased its apparent volume of distribution and clearance, and slightly shortened its half-life (73).

Other studies have failed to show any interaction in children (74) or adults (75).

Phenobarbital

Phenobarbital can increase the rate of chloramphenicol metabolism and so lead to abnormally low serum chloramphenicol concentrations. In 17 children receiving chloramphenicol succinate alone, mean peak and trough serum concentrations were 25 and 13 μg/ml respectively. In six patients phenobarbital reduced these concentrations to 17 and 7.5 μg/ml respectively (76).

Phenytoin

The ability of chloramphenicol to inhibit the biotransformation of phenytoin is well established and clinically relevant (77).

Conversely, phenytoin can increase the rate of chloramphenicol metabolism and so lead to abnormally low serum chloramphenicol concentrations, as has been anecdotally reported (78). However, contrary to expectation, in another study serum chloramphenicol concentrations rose during concomitant phenytoin therapy (76).

Rifampicin

Rifampicin can increase the rate of chloramphenicol metabolism and so lead to abnormally low serum chloramphenicol concentrations (79,80).

Tacrolimus

Inhibition of tacrolimus clearance has been observed in an adolescent renal transplant recipient who was treated with standard doses of chloramphenicol for vancomycin-resistant enterococci. Toxic concentrations of tacrolimus were observed on the second day of chloramphenicol treatment, requiring an 83% reduction in the dose of tacrolimus (81).

A significant interaction has also been reported in an adult (82).

- A 47-year-old white man with a cadaveric liver transplant took chloramphenicol for a urinary tract infection due to a vancomycin-resistant *Enterococcus* and inadvertently received 1850 mg qds (roughly twice the maximum recommended dose). On day 4 he had a 12-hour trough tacrolimus concentration of over 60 ng/ml, and complained of fatigue, lethargy, headache, and tremor, symptoms consistent with tacrolimus toxicity.

It was suggested that the underlying mechanism might be inhibition of CYP3A4 by chloramphenicol.

Tolbutamide

Chloramphenicol inhibits the biotransformation of tolbutamide (71).

Warfarin

An interaction of warfarin with ocular chloramphenicol (5 mg/ml; 1 drop qds in each eye), which led to an increase in INR, has been suspected in an 83-year-old white woman (83). The authors suggested that the effect may be due to chloramphenicol inhibition of hepatic microsomal CYP2C9, since the pharmacologically active enantiomer *S*-warfarin is metabolized by this enzyme).

Chlordiazepoxide

See also Benzodiazepines

General Information

Chlordiazepoxide, which has a long duration of action ($t_{1/2}$ = 10–25 hours), is useful for the management of alcohol withdrawal and is arguably better tolerated than other benzodiazepines when used for this indication. As with diazepam, loading doses are possible and simplify clinical management.

Organs and Systems

Metabolism

A San Francisco woman with a history of diabetes and high blood pressure was hospitalized in January 2001 with a life-threatening low blood sugar concentration after she consumed Anso Comfort capsules (1). The authors conjectured that hospitalization may have been necessitated by a drug interaction of chlordiazepoxide with medications that she was taking for other medical conditions.

Hematologic

- A 68-year-old man, who had been taking lorazepam, perphenazine, and amitriptyline for many years, developed acute thrombocytopenic purpura after combination therapy of chlordiazepoxide 5 mg and clidinium 2.5 mg tds for irritable bowel syndrome (2). His disease

© 2006 Elsevier B.V. All rights reserved.

improved after withdrawal of chlordiazepoxide and clidinium and treatment with intravenous prednisolone.

In this case it was not clear which of the two compounds caused the purpura; it is possible that it was due to the combination.

Drug Administration

Drug formulations

The California State Health Director has warned consumers to stop using the herbal product Anso Comfort capsules immediately, because the product contains the undeclared prescription drug chlordiazepoxide (1). Anso Comfort capsules, available by mail or telephone order from the distributor in 60-capsule bottles, are clear with dark green powder inside. The label is yellow with green English printing and a picture of a plant. An investigation by the California Department of Health Services Food and Drug Branch and Food and Drug Laboratory showed that the product contains chlordiazepoxide. The ingredients for the product were imported from China and the capsules were manufactured in California. Advertising for the product claims that the capsules are useful for the treatment of a wide variety of illnesses, including high blood pressure and high cholesterol, in addition to claims that it is a natural herbal dietary supplement. The advertising also claims that the product contains only Chinese herbal ingredients and that consumers may reduce or stop their need for prescribed medicines. No clear medical evidence supports any of these claims. The distributor, NuMeridian (formerly known as Top Line Project), has voluntarily recalled the product.

Drug–Drug Interactions

Heparin

In normal non-fasting subjects, 100–1000 IU of heparin given intravenously caused a rapid increase in the free fractions of diazepam, chlordiazepoxide, and oxazepam (3,4), but no change in the case of lorazepam (3). The clinical implications of this finding are not known.

Oral contraceptives

In 7 healthy young women who had taken oral contraceptives for more than 6 months the protein binding of chlordiazepoxide was reduced and its volume of distribution increased (5). The clearance of chlordiazepoxide is also reportedly reduced by oral contraceptives (6).

Mid-cycle spotting occurred in a large proportion of 72 women taking oral contraceptives and chlordiazepoxide; however, there were no pregnancies (7).

Chlorhexidine

See also Disinfectants and antiseptics

General Information

Chlorhexidine (1,1′-hexamethylene-*bis*[5-(*p*-chlorophenyl) biguanide]) is a widely used antibacterial agent with activity against Gram-positive bacteria, Gram-negative bacteria (less against *Pseudomonas* species), and yeasts. It was introduced as an antiseptic in the early 1950s. It has been primarily used for topical antisepsis, for example in preoperative skin disinfection, and for disinfection of materials, mainly in combination with cetrimide. Long-term experience has shown a low incidence of sensitization and a low irritant potential (SEDA-11, 480).

Unwanted effects have resulted from undue reliance on the disinfecting properties of chlorhexidine. Hospital-acquired infections have been caused by infected chlorhexidine used for bladder irrigation and for storage or disinfection of catheter spigots and needles (SEDA-11, 480) (1,2). A microbiological analysis of chlorhexidine-cream tubes, repeatedly used by patients with indwelling urethral catheters, showed high contamination with potential pathogens in 32% of cream samples and in 35% of swabs taken from the outside of the tubes beneath the screw cap (SEDA-11, 480) (3).

Use of chlorhexidine in dentistry

Chlorhexidine has been used as an adjuvant for plaque control and in the treatment of gingival inflammation. It is generally considered to be effective in the control of plaque and can be helpful in the treatment of gingivitis. It can be applied in the form of a solution, used as a mouth rinse or with a toothbrush, in dentifrice or as a gel. The concentrations used are 0.05–2%.

It is very difficult to summarize the effect of chlorhexidine on oral hygiene, since studies differ markedly as regards the population studied, the occurrence of gingival lesions, the use of other oral hygiene regimens, previous scaling, and polishing of the teeth. The most frequently reported adverse effects of oral use are discoloration of the teeth, tongue, and buccal mucosa, taste disorders, and desquamation of the oral mucosa. A mild increase in

© 2006 Elsevier B.V. All rights reserved.

gingival bleeding was reported after the use of chlorhexidine mouthwash compared with mechanical cleaning methods.

Use of chlorhexidine in neonatal skin care

The withdrawal of hexachlorophene-containing products for routine neonatal skin care stimulated investigations into the possible use of chlorhexidine in this field. Its activity range includes effectiveness of high dilutions against Gram-positive and Gram-negative bacteria, yeasts, and molds. In studies of nursery populations, chlorhexidine appears to be as effective as hexachlorophene in preventing staphylococcal colonization and infection. However, there is no evidence that chlorhexidine promotes Gram-negative colonization in neonates bathed in water-containing chlorhexidine (SEDA-11, 482).

Data presented in three studies have provided substantial evidence that there is very low percutaneous absorption in full-term infants and also in excessively exposed newborn rhesus monkeys. However, traces of chlorhexidine were found in adipose tissue (two of five monkeys), kidneys (five of five), and liver (one of five), suggesting some absorption percutaneously or by oral ingestion, following the rigorous bathing procedure in the above study. The grooming habits of the monkeys could have played a role (SEDA-12, 578) (4).

Use of chlorhexidine in routine neonatal cord care

About 0.2 ml of undiluted 4% chlorhexidine solution with a detergent was included in the daily routine of rubbing the dry cord stump and the surrounding skin, which were then rinsed and dried. No chlorhexidine was detectable in the blood samples of the neonates, taken on the fifth day (5).

Use of chlorhexidine in spermicides

The use of chlorhexidine in spermicides has been promoted as a strategy for protecting against sexually transmitted diseases, including HIV infection. However, both the claim of protection and the cytotoxicity of chlorhexidine, with a risk of damage to the epithelia of the vagina, cervix, and glans penis due to chronic exposure, have to be further validated (6).

Vaginal use of chlorhexidine

Five studies of the prophylactic intravaginal use of chlorhexidine vaginal suppositories before delivery and in obstetrics have been reviewed (7). No severe adverse reactions were reported.

Accidental ingestion

A newborn had cyanotic spells associated with sinus bradycardia but not with apnea on the third day of life(8). The mother had used a chlorhexidine spray on her breasts from the third feed onwards. Bradycardia became less frequent and less severe from day 4 after the spray was stopped, and had abated completely by day 6.

Five healthy newborn breast-fed babies were accidentally fed a dilute antiseptic solution containing chlorhexidine 0.05% with cetrimide 1% instead of sterile water (9). They developed caustic burns of the lips, mouth, and tongue within minutes. One baby became severely ill due to acute pulmonary edema, but all survived without sequelae.

Organs and Systems

Respiratory

Chlorhexidine gluconate when ingested usually causes relatively mild symptoms, with poor gastrointestinal absorption, and is considered relatively safe. However, a rare fatality, with acute respiratory distress syndrome, has been reported (10).

- An 80-year-old woman with dementia accidentally took about 200 ml of chlorhexidine gluconate 5%. She aspirated her gastric contents and despite intensive treatment died of acute respiratory distress syndrome 12 hours later. The serum concentration of chlorhexidine gluconate was markedly high (25 μg/ml).

It is possible that in this case, although chlorhexidine was poorly absorbed from the gastrointestinal tract, absorption occurred through the pulmonary alveoli.

Occupational asthma caused by chlorhexidine alcohol disinfectant spray was well documented in three nurses (11).

Ear, nose, throat

Reversible hyposmia occurred after Hardy's operation for pituitary adenomas following preoperative disinfection of the nasal cavity with chlorhexidine (12). The olfactory disturbance improved after 3–7 weeks. Degeneration of the olfactory epithelium was also seen in guinea pigs when the nasal cavities were irrigated 3 times with 5 ml 0.5% chlorhexidine solution; regeneration of the epithelium started after 14 days and the surfaces appeared normal after 1 month.

Nervous system

The middle ear should be carefully protected against chlorhexidine solutions in preoperative skin disinfection in otolaryngology. Severe sensorineural deafness occurred in 14 of 97 patients who underwent myringoplasty (13). The only common factor in all these patients was the preoperative skin disinfection of the ear with 0.5% chlorhexidine in a 70% alcoholic solution.

In extensive investigations of the ototoxicity caused by chlorhexidine after introducing it into the middle ear of guinea pigs, the extent of severe vestibular and cochlear damage was related to the concentration of chlorhexidine, to the duration of exposure, and to the time-lapse after exposure (14–16).

Sensory systems

Eyes

Accidental contamination of the eye with chlorhexidine can cause adverse effects. Care should be taken during preoperative skin preparation to keep chlorhexidine out of the eye and to flush copiously with sterile saline solution or sterile water if contact accidentally occurs.

- Accidental use of chlorhexidine solutions (1:666 and 1:1000) as irrigation during cataract surgery resulted in

© 2006 Elsevier B.V. All rights reserved.

immediate corneal edema, which resulted in a bullous keratopathy (17).
- Chlorhexidine disinfectant was accidentally used to irrigate the eyes of four patients; despite immediate treatment, corneal burns occurred in all (18).
- In four patients, accidental corneal exposure to Hibiclens (4% chlorhexidine formulated with a detergent) resulted in keratitis, with severe and permanent corneal opacification (19).
- Epithelial and stromal edema of the cornea and a diffuse bullous keratopathy developed in a 39-year-old woman 2 weeks after a preoperative disinfection of the face with an alcoholic chlorhexidine solution. This led to penetrating keratoplasty 10 months later (20).

The histopathological findings in the cornea have been described in such cases; they include epithelial edema with bullous changes, marked loss of keratocytes, thickening of Descemet's membrane, and an attenuated disrupted cell layer (21).

Chlorhexidine has also been accidentally irrigated into the anterior chamber of the eye, instead of balanced salt solution, during cataract surgery (22). Later in the operation, a decrease in corneal clarity was noted and an epithelial abrasion had to be performed. The inadvertent use of chlorhexidine in this patient resulted in reduced endothelial function and loss of corneal clarity.

Progressive ulcerative keratitis related to the use of chlorhexidine gluconate 0.02% eye-drops has been reported (23).

- A 45-year-old woman was treated for presumed *Acanthamoeba* keratitis with chlorhexidine gluconate 0.02% and propamidine 0.1% eye-drops. After using the eye-drops for 8 weeks she developed a near total loss of the corneal epithelium and progressive ulcerative keratitis, which eventually required penetrating keratoplasty. Histopathological examination of the corneal button showed ulceration and loss of Bowman's membrane, massive loss of keratocytes with apparent apoptosis, and loss of endothelial cells, with inflammatory cells adherent to the remaining cells. These findings were similar to those seen in chlorhexidine 4% keratopathy. No organisms were seen in stained sections and immune histochemistry showed no significant findings.

Taste

Taste impairment and/or disturbance is especially seen with chlorhexidine mouthwashes (SEDA-11, 481) (SEDA-12, 577) (24). It occurs in about one-third of subjects and is perhaps the main complaint. Symptoms include a burning sensation, a feeling of soreness, a dry mouth, and a bitter aftertaste lasting from a few minutes up to several hours. However, these types of symptoms also occur, albeit to a lesser extent, in placebo or control groups.

Mouth and teeth

Desquamation and ulceration of the oral mucosa has been observed after the use of chlorhexidine mouthwashes. The frequency of this adverse effect must be very low. Histological and histochemical examination of mucosal biopsies taken after 18 months of daily exposure to chlorhexidine did not show any adverse effect on the oral mucosa. There was increased keratinization of human gingival cells in vitro in cell cultures if the chlorhexidine concentration exceeded 25 μg/ml, and the same acceleration of keratinization of human gingival cells in gingival swabs occurred after rinsing with 0.025, 0.05, and 0.1% chlorhexidine solutions (25). In one case there was excessive impairment of wound healing after daily rinses with a 0.1% chlorhexidine solution after oral surgery.

Staining of the teeth was the first and principal adverse effect observed with the dental use of chlorhexidine. In a 4-month study of soldiers who used chlorhexidine mouthwashes in concentrations of 0.1 and 0.2%, 15% of the interproximal surface and 62% of the fillings, especially the old and porous ones, were discoloured (26,27). The stain intensity seems to be directly correlated to the concentration of the chlorhexidine and to the frequency and duration of use. The type of administration (0.2% mouthwash, 0.2% spray, or 1% gel) does not seem to influence the amount of tooth-staining. The initial discoloration is yellow-brown, but prolonged use and stronger concentrations result in a dark-brown color. Extensive investigations have been performed to evaluate factors that influence tooth-staining and the possibility of avoiding it. The cause of extrinsic tooth discoloration is not fully understood. However, the available evidence suggests that browning and formation of pigmented metal sulfides are the most likely causes, while dietary factors (such as beverages or red wine) and smoking may play an aggravating role only (SEDA-10, 427).

A discoloration of the dorsum of the tongue occurs in up to one-third of subjects using chlorhexidine mouth rinses. It does not occur during the use of chlorhexidine-containing dentifrices or gels (SEDA-11, 481) (27,28).

Reversible swelling of the parotid glands has been reported occasionally after the use of chlorhexidine mouthwashes; this is probably due to mechanical obstruction of the parotid duct by over-rigorous rinsing (SEDA-11, 481) (29).

Gastrointestinal

- Atrophic gastritis was reported in a 72-year-old man with Parkinson's disease who had used a 4% chlorhexidine solution as a daily mouthwash but had also swallowed it. Gastroscopy showed multiple erosions in the lower part of his stomach and the first part of the duodenum (30).

Skin

Of 551 patients with venous or traumatic ulcers of the leg who were patch-tested with chlorhexidine, 10 developed severe dermatitis and 4 developed skin infections on the face and/or scalp (31).

Serosae

Sclerosing peritoneal disease occurred in peritoneal dialysis patients in whom the tubing connection had been disinfected with chlorhexidine (32–34); 214 cases were

© 2006 Elsevier B.V. All rights reserved.

reported from 112 centers in European countries up to 1984 (SEDA-15, 250).

Musculoskeletal

Chlorhexidine is not normally used in arthroscopy, but it is a common irrigating fluid for surgical wounds. In three of five patients with pain, swelling, crepitus, and loss of range of movement following arthroscopy of the knee, there had been accidental irrigation with 1% aqueous chlorhexidine. Histological examination showed partial necrosis of the cartilage, with slight non-specific inflammation and fibrosis of synovial specimens (35). This shows that particular care is needed in checking irrigation fluids.

Even very dilute solutions of chlorhexidine can cause marked chondrolysis of articular cartilage, leading to severe permanent damage of the knee (36).

- A 20-year-old woman, a 30-year-old man, and a 62-year-old woman all had arthroscopic reconstruction of the anterior cruciate ligament performed by the same surgeon. The only difference in technique in these three cases, compared with the rest of his cases, was the use of chlorhexidine 0.02% for irrigation throughout the procedure. All had good immediate postoperative recovery with no sign of infection, and none had preceding rheumatoid or other inflammatory joint disease, systemic disease, or chronic use of drugs. However, they all developed pain, swelling, stiffness, and loud crepitus at 2–4 months after the procedure and had radiological evidence of loss of joint space, especially in the medial compartment. Arthroscopy in all three cases showed a large amount of loose chondral material, a "snowstorm" appearance, which could be washed out. Severe erosion of the articular cartilage and a mild synovitis were also demonstrated. The ligaments were all intact and culture of the synovial fluid was sterile. Histopathology of the fragments of cartilage showed non-viable chondrocytes, with an absence of acute inflammatory cells and very few chronic inflammatory cells. The synovial biopsies showed evidence of fibrosis. All three patients had severely damaged knees which required total knee replacement.

These cases of chondrolysis did not result from accidental use of relatively concentrated solutions of chlorhexidine, but from the use of a very low concentration, 0.02%, which is widely used as an irrigation solution during surgical procedures. Chlorhexidine has a damaging effect on the articular cartilage of the knee, and should not be used, even in low concentrations, to irrigate exposed articular cartilage.

Immunologic

Allergic reactions, including anaphylaxis, from chlorhexidine are reported with all types of use and are well documented. However, chlorhexidine may still not be suspected as a possible cause of anaphylaxis when several agents are used in the anesthetized surgical patient, and hypersensitivity to chlorhexidine may not be tested for (37). If a reaction occurs during anesthesia, there is often doubt about the exact agent responsible; patch-testing will help if there is doubt about causality.

Mechanism

The molecular basis of the recognition of chlorhexidine in a sensitive patient has been examined (38).

- A 75-year-old man had three anaphylactic events after the use of chlorhexidine. The first occurred in September 1995 during general anesthesia for coronary artery bypass grafts. Ten minutes after induction he developed a marked fall in blood pressure, bronchospasm, tachycardia, and increased pulmonary artery pressure. In July 1996, a transurethral resection of the prostate was performed under spinal anesthetic. At cystoscopy he developed a headache, a rash, and bronchospasm, which settled after treatment. He had a further cystoscopy in February 1998, during which he became flushed, wheezy, and hypotensive, and had a cardiac arrest. He was successfully resuscitated. He had raised serum tryptase activities (60.4 and 26.6 μg/l at 3.5 and 9.5 hours after the event), suggesting a true anaphylactic reaction. Since the only pharmacological agent common to all three procedures was urethral jelly containing lidocaine 2% and chlorhexidine 0.05%, he subsequently had skin prick tests, intradermal tests, and sequential subcutaneous challenges to lidocaine without any positive or adverse effects. Because he had developed profound anaphylaxis with cardiac arrest after the topical administration of chlorhexidine, skin tests were deemed unethical, and an in vitro method for detecting sensitivity to chlorhexidine was pursued. Detailed quantitative hapten inhibition studies were carried out with chlorhexidine-reactive IgE antibodies identified in the serum of the patient.

The authors concluded that unlike most drug allergic determinants the whole chlorhexidine molecule is complementary to the IgE antibody combining sites and that the 4-chlorophenol, biguanide, and hexamethylene structures together comprise the allergenic component.

Frequency and susceptibility factors

In a collaborative Danish study, 2061 patients were patch-tested with chlorhexidine gluconate 1% in water. There was a positive reaction in 2.3% of the patients. This was more common in patients with leg eczema (6.8%) or leg ulcer (10.6%) than in those with eczema of the hands (1.9%) or at other sites (1.6%). Of the 14 patients who were retested with chlorhexidine, only one was positive to the 1% solution and none to a solution of 0.01%. This apparent loss of sensitivity may be due to irritable skin at the initial testing, the so-called excited skin syndrome. This study suggests that the sensitizing potential of chlorhexidine is very low, but that it should be used with caution in dressings for leg ulcers.

In 1063 consecutive eczema patients tested with the ICDRG standard series, supplemented with chlorhexidine gluconate 1% in water and 1% in petrolatum, the frequency of positive reactions was similar to that in the collaborative study (39).

Application to the skin

In a report of generalized urticaria after skin cleansing with and urethral instillation of chlorhexidine-containing products, the authors suggest that there is under-reporting

© 2006 Elsevier B.V. All rights reserved.

of such reactions and that alternative antiseptics should be considered in urological and gynecological procedures (40).

- Life-threatening anaphylactic reactions with generalized urticaria, dyspnea, and shock occurred in six patients after the use of 0.05, 0.5, or 1% chlorhexidine (41), and in one patient after topical use of an alcoholic 0.5% chlorhexidine digluconate solution (42). A severe systemic allergic response was observed in a patient in whom the large donor area of skin graft was dressed with Bactigras, which contains 0.5% chlorhexidine acetate (43).
- An acute anaphylactic reaction occurred in a 19-year-old man after cleaning of burns on the left arm (44). A scratch test with chlorhexidine acetate 0.05% was positive.
- Anaphylaxis occurred in four surgical patients after the use of chlorhexidine as a skin disinfectant. All four had a history of minor symptoms, such as rashes or faints, in connection with previous surgery or invasive procedures (45).
- Following disinfection of a drain insertion site with chlorhexidine digluconate 2% solution, a 43-year-old man had severe anaphylaxis, manifest as dyspnea, shock, and ST segment elevation (46). In the past he had had two episodes of contact dermatitis with chlorhexidine antiseptics.
- A 14-year-old girl had combined delayed and immediate types of allergy, with urticarial rash and syncope, after long-term use of an antiacne formulation containing chlorhexidine in an unknown concentration.
- When chlorhexidine was used as a skin disinfectant in a 53-year-old man undergoing lung resection for adenocarcinoma, anaphylaxis was complicated by coronary artery spasm (47). He had two anaphylactic reactions accompanied by severe myocardial ischemia. Immunological testing indicated chlorhexidine as the causative substance.

In the last two cases, epicutaneous tests with 1% chlorhexidine gluconate and acetate, and prick tests with 0.05 and 0.01% of the acetate solution were positive (48).

Local hypersensitivity reactions to chlorhexidine-impregnated patches occur in neonates (49). In a randomized comparison of povidone-iodine and a chlorhexidine gluconate impregnated dressing for the prevention of central venous catheter infections in neonates, the risk of local contact dermatitis limited the use of the chlorhexidine dressing (50).

Application to mucous membranes

Anaphylaxis has been reported after nasal application of chlorhexidine.

- Anaphylactic circulatory arrest occurred in a 53-year-old man with acromegaly when his nasal mucosa was cleaned with an aqueous solution of chlorhexidine gluconate 0.05% (51).

A report to the Japanese Ministry of Welfare about reactions observed between 1967 and 1984 included 22 cases with a fall in blood pressure, 13 with dyspnea, 9 with anaphylactic shock, 4 with cyanosis, 19 with erythema, 11 with urticaria, 9 with pruritus, and 7 with facial wheals; following this report, in 1984, the Japanese Ministry of Welfare recommended that the use of chlorhexidine on mucous membranes be prohibited because of the evidence of the risk of anaphylactic shock (41).

Application to wounds

Application of chlorhexidine to wounds is generally safe, but it should be used at the lowest bactericidal concentration of 0.05% (41).

Application to the urethra

Anaphylaxis after cystoscopy or urinary catheterization has been reported repeatedly (SEDA-18, 255) (SEDA-19, 235) (SEDA-20, 225) (52).

- A 64-year-old man had severe anaphylaxis induced by intraurethral chlorhexidine gel 0.05% (53). Previous hypersensitivity reactions during urethral dilatation had been thought to be due to lidocaine. Chlorhexidine-specific IgE antibodies were demonstrated, and the chlorhexidine gel had been used in all the preceding urological procedures the patient had undergone.

Severe allergic reactions occurred in five patients after the insertion of an intra-urethral lidocaine jelly containing chlorhexidine gluconate and instrumentation of the urethra (54). All had a positive response to chlorhexidine gluconate (0.0005%) and a negative response to lidocaine (0.2%).

Impregnated intravenous catheters

Chlorhexidine-coated catheters have been developed in the hope of reducing the incidence of central venous line sepsis. Package inserts warn that these should not be used in individuals who are thought to be sensitive to chlorhexidine.

It is possible that the potential benefit of reducing the incidence of central venous sepsis by using chlorhexidine-coated catheters is outweighed by the risk of sudden and profound anaphylaxis. Certainly a high degree of suspicion of chlorhexidine allergy should be exercised and skin tests performed.

In a randomized clinical study of the efficacy of catheters impregnated with antiseptics for the prevention of central venous catheter-related infections in intensive care units in 204 patients with 235 central venous catheters between November 1998 and June 1999, a standard triple-lumen polyurethane catheter and a catheter impregnated with chlorhexidine and silver sulfadiazine were indistinguishable from each other (55). Compared with standard polyurethane catheters, antiseptic catheters were less likely to be colonized by micro-organisms when they were cultured at removal (8 versus 20 colonized catheters per 100 catheters; relative risk 0.34 (95% CI = 0.15, 0.74). There were no significant differences between the groups in catheter-related infections (0.9 versus 4.9 infections per 100 catheters; relative risk 0.17 (95% CI = 0.03, 1.15)). Gram-positive cocci and fungi were more likely to colonize the standard polyurethane catheters than antiseptic catheters. Two of the cases in the control group died because of catheter-related candidemia. There were no adverse reactions such as hypersensitivity or leukopenia with the antiseptic catheters. The authors concluded that central venous catheters with antiseptic coating are safe and carry less risk of

© 2006 Elsevier B.V. All rights reserved.

colonization of bacteria and fungi than standard catheters in critically ill patients.

However, although randomized studies have failed to show an association between hypersensitivity reactions and chlorhexidine-impregnated central venous catheters, there have been reports of anaphylaxis after insertion of these catheters (SEDA-22, 262) (56,57), and two life-threatening episodes of anaphylaxis in the same patient were attributed to a central venous catheter that had been impregnated with chlorhexidine and sulfadiazine (58).

- In a 51-year-old man, two episodes of pronounced, refractory cardiovascular collapse accompanied the insertion of a chlorhexidine-coated central venous catheter (59). Sensitivity to chlorhexidine was not at first suspected, but 5 months later, a skin prick test with chlorhexidine resulted in a characteristic sustained wheal and flare response, strongly suggesting IgE-mediated sensitivity. The patient subsequently underwent uneventful surgery following strict avoidance of chlorhexidine exposure.

Bronchospasm was not a feature in any of these cases.

The FDA has issued a public health notice to inform health-care professionals about the potential for serious hypersensitivity reactions to medical devices impregnated with chlorhexidine. The Agency is also seeking information and reports to better evaluate the potential health hazard these products might pose, and to decide on what action, if any, should be taken. Devices that incorporate chlorhexidine that the FDA has cleared for marketing include intravenous catheters, topical antimicrobial skin dressings, and implanted antimicrobial surgical mesh. The notice describes non-US reports of systemic reactions to chlorhexidine-impregnated gels or lubricants used during urological procedures and similarly impregnated central venous catheters. It also describes other types of reactions that have been reported in the USA, including localized reactions to impregnated patches in neonates and occupational asthma in nurses exposed to chlorhexidine and alcohol aerosols (49).

A meta-analysis of the clinical and economic effects of chlorhexidine and silver sulfadiazine antiseptic-impregnated catheters has been undertaken (60). The costs of hypersensitivity reactions were considered as part of the analysis, and the use of catheters impregnated with antiseptics resulted in reduced costs. The analysis used the higher estimated incidence of hypersensitivity reactions occurring in Japan, where the use of chlorhexidine-impregnated catheters is still banned (61).

Polyhexanide

Caution also seems to be warranted concerning polyhexanide, a chlorhexidine polymer, used in disinfectants for a relatively short time.

- Polyhexanide caused severe anaphylaxis in two young patients (62). Both were exposed to the disinfectant Lavasept®, containing polyhexanide, on surgical wounds during orthopedic interventions. They had never been exposed to polyhexanide before, but had been exposed to chlorhexidine. However, skin prick tests were positive for polyhexanide in both cases, while chlorhexidine was negative. Negative skin prick tests to polyhexanide were obtained from controls.

Chlormezanone

General Information

Chlormezanone is a tranquillizer with central muscle relaxant effects. In reaction to some case reports of serious, sometimes fatal, cutaneous toxicity and after intervention by drug regulatory authorities in some European countries, all major manufacturers have stopped production of chlormezanone. It may still be available in combination products in some Asian countries.

For the most part chlormezanone causes only minor adverse effects, such as sedation, dizziness, nausea, and headache, which clear on stopping the drug.

Organs and Systems

Hematologic

Rarely, thombocytopenia can occur in a patient taking chlormezanone (1).

Liver

Rarely, cholestatic hepatitis can occur with chlormezanone.

- A 46-year-old woman with rheumatoid arthritis developed cholestatic liver disease while taking chlormezanone and paracetamol (2).
- Fulminant liver necrosis requiring liver transplantation occurred in a young pregnant woman who had taken chlormezanone 600 mg/day for 3 weeks (SEDA-17, 157).

Skin

Toxic epidermal necrolysis and Stevens–Johnson syndrome have been attributed to chlormezanone (3).

Drug–Drug Interactions

Paracetamol

The concomitant use of paracetamol may increase the chance of adverse effects, especially erythema and urticaria (4).

Chloroform

See also General anesthetics

General Information

Chloroform (SED-8, 250) should no longer be used, because of its toxic effects on the heart, liver, and kidneys, although the exact nature and extent of these complications has been debated (1). The very serious adverse effects of chloroform anesthesia when poorly administered have been briefly reviewed (2).

Chloroprocaine

See also Local anesthetics

General Information

Chloroprocaine is a local anesthetic, an aminoester of para-aminobenzoic acid. Its systemic toxicity is low, owing to rapid hydrolysis by plasma pseudocholinesterases (1).

Organs and Systems

Cardiovascular

Of 25 patients who received epidural chloroprocaine for various day procedures, 23 had a fall in arterial blood pressure of 15%, and in two it fell by 25% (2).

Neuromuscular function

Prolonged neuromuscular blockade has been reported after epidural chloroprocaine (3).

- A 29-year-old woman in labor was given an epidural infusion of bupivacaine 0.04% plus fentanyl 1.66 micrograms/ml, running at 15 ml/hour for 7 hours. She then required an urgent cesarean section and 15 ml of chloroprocaine 3% was given, followed 20 minutes later by 12 ml of 2% lidocaine. Half an hour later she showed signs of high epidural blockade with dyspnea followed by unresponsiveness, and required immediate intubation with suxamethonium. She then developed prolonged neuromuscular blockade with a first-twitch response occurring after 1.75 hours. It took 3.75 hours before she could be extubated. Her plasma cholinesterase activity was low immediately postpartum, with a concentration of 1.3 U/ml (reference range 2.8–11), returning to normal within 7 weeks.

The authors believed that the high epidural blockade and the prolonged neuromuscular block had resulted from reduced pseudocholinesterase activity.

Second-Generation Effects

Pregnancy

Reduced pseudocholinesterase activity has been described both in pregnancy and with magnesium therapy. As most ester local anesthetics (with the exception of cocaine) are metabolized by this enzyme, caution should be exercised when using ester local anesthetics in pregnancy, especially with the increasing use of magnesium sulfate in this field.

Susceptibility Factors

Genetic factors

When there is an atypical pseudocholinesterase, complications can occur, notably convulsions (1).

Drug Administration

Drug formulations

Chloroprocaine does not itself appear to be neurotoxic at clinical concentrations. However, formulations that contain EDTA can cause burning back pain when used in epidurals (SEDA-22, 142).

Local neural irritation can occur when large doses of formulations containing sodium bisulfate as a preservative are used epidurally or intrathecally, probably because of the low pH and the sodium bisulfate content rather than the local anesthetic (SEDA-14, 111). Prolonged neural deficits have been described, the pathophysiology of which is controversial (SEDA-10, 105).

Drug–Drug Interactions

Suxamethonium

Because it is hydrolysed by plasma cholinesterase, chloroprocaine may competitively enhance the action of suxamethonium (4).

Chloroquine and hydroxychloroquine

General Information

Chloroquine is rapidly and almost completely absorbed from the intestinal tract, peak serum concentrations being reached in 1–6 hours (average 3 hours). It is extensively distributed and redistribution follows. It is slowly metabolized by side-chain de-ethylation. The half-life is 30–60 days. Elimination is mainly via the kidney. Malnutrition can slow down the rate of metabolism.

Comparative studies

Amodiaquine and chloroquine have been compared in an open, randomized trial in uncomplicated falciparum malaria in Nigerian children (1). The doses were amodiaquine ($n = 104$) 10 mg/kg/day for 3 days and chloroquine ($n = 106$) 10 mg/kg/day for 3 days. After 28 days, the cure rate was significantly higher with amodiaquine than chloroquine (95% versus 58%). The rates of adverse events, most commonly pruritus (10%) and gastrointestinal disturbances (3%), were similar in the two groups. Cross-resistance between the two aminoquinolines is common, and there are concerns regarding toxicity of amodiaquine with repeated use.

General adverse effects

There are relatively few adverse effects at the doses of chloroquine that are used for malaria prophylaxis and standard treatment doses. However, the use of higher doses than those recommended, for example because of problems with resistance, can cause problems. Infants are very easily overdosed (SEDA-16, 302). In the treatment of rheumatoid arthritis and lupus erythematosus, larger doses are used, often for long periods of time, and with this use the incidence of adverse effects is high. Neuromyopathy, neuritis, myopathy, and cardiac myopathy can cause serious problems. Retinopathy can lead to blindness. Chloroquine has a long half-life and accumulates in the tissues, including the brain. Concentrations in the brain can have a bearing on mental status and psychotic syndromes. Chloroquine interferes with the action of several enzymes, including alcohol dehydrogenase, and blocks the sulfhydryl–disulfide interchange reaction. Allergic reactions are generally limited to rashes and pruritus.

Organs and Systems

Cardiovascular

Electrocardiographic changes, comprising altered T waves and prolongation of the QT interval, are not uncommon during high-dose treatment with chloroquine. The clinical significance of this is uncertain. With chronic intoxication, a varying degree of atrioventricular block can be seen; first-degree right bundle branch block and total atrioventricular block have been described. Symptoms depend on the severity of the effects: syncope, Stokes–Adams attacks,

and signs of cardiac failure can occur. Acute intoxication can cause cardiovascular collapse and/or respiratory failure. Cardiac complications can prove fatal in both chronic and acute intoxication.

Third-degree atrioventricular conduction defects have been reported in two patients with rheumatoid arthritis after prolonged administration of chloroquine (2,3).

Intravenous administration can result in dysrhythmias and cardiac arrest; the speed of administration is relevant, but also the concentration reached: deaths have been recorded with blood concentrations of 1 μg/ml; concentrations after a 300 mg dose are usually 50–100 μg/ml (SEDA-13, 803).

Long-term chloroquine can cause cardiac complications, such as conduction disorders and cardiomyopathy (restrictive or hypertrophic), by structural alteration of the interventricular septum (4). Thirteen cases of cardiac toxicity associated with long-term chloroquine and hydroxychloroquine have been reported in patients with systemic autoimmune diseases. The cumulative doses were 600–2281 g for chloroquine and 292–4380 g for hydroxychloroquine.

- A 64-year-old woman with systemic lupus erythematosus took chloroquine for 7 years (cumulative dose 1000 g). She developed syncope, and the electrocardiogram showed complete heart block; a permanent pacemaker was inserted. The next year she presented with biventricular cardiac failure, skin hyperpigmentation, proximal muscle weakness, and chloroquine retinopathy. Coronary angiography was normal. An echocardiogram showed a restrictive cardiomyopathy. A skeletal muscle biopsy was characteristic of chloroquine myopathy. Chloroquine was withdrawn and she improved rapidly with diuretic therapy.
- Chloroquine cardiomyopathy occurred during long-term (7 years) treatment for rheumatoid polyarthritis in a 42-year-old woman, who had an isolated acute severe conduction defect, confirmed by histological study with electron microscopy (5).

Regular cardiac evaluation should be considered for those who have taken a cumulative chloroquine dose of 1000 g, particularly elderly patients.

More than one mechanism may underlie the cardiac adverse effects of chloroquine. Severe hypokalemia after a single large dose of chloroquine has been documented, and some studies show a correlation between plasma potassium concentrations and the severity of the cardiac effects (6).

Light and electron microscopic abnormalities were found on endomyocardial biopsy in two patients with cardiac failure. The first had taken hydroxychloroquine 200 mg/day for 10 years, then 400 mg/day for a further 6 years; the second had taken hydroxychloroquine 400 mg/day for 2 years (SEDA-13, 239). A similar case was reported after the use of 250 mg/day for 25 years (SEDA-18, 286).

Respiratory

Respiratory collapse can occur with acute overdosage.

Acute pneumonitis probably due to chloroquine has been described (7).

- A 41-year-old man with chronic discoid lupus erythematosus was given chloroquine 150 mg bd for 10 days followed by 150 mg/day. After 2 weeks he developed fever, a diffuse papular rash, dyspnea, and sputum. A chest X-ray showed peripheral pulmonary infiltrates. He improved on withdrawal of chloroquine and treatment with cefpiramide and roxithromycin. No organism was isolated. A subsequent oral challenge with chloroquine provoked a similar reaction.

Nervous system

The incidence of serious nervous system events among patients taking chloroquine for less than a year has been estimated as one in 13 600.

Chloroquine, especially in higher doses, can cause a marked neuromyopathy, characterized by slowly progressive weakness of insidious onset. In many cases this weakness first affects the proximal muscles of the legs. Reduction in nerve conduction time and electromyographic abnormalities typical of both neuropathic and myopathic changes can be found. Histologically there is a vacuolar myopathy. Neuromyopathy is a rare adverse effect and is usually limited to patients taking 250–750 mg/day for prolonged periods. The symptoms can be accompanied by other manifestations of chloroquine toxicity (SEDA-11, 583). An 80-year-old woman developed symptoms after taking chloroquine 300 mg/day for 6 months (8), once more demonstrating that a standard dosage can be too much for elderly people.

A spastic pyramidal tract syndrome of the legs has been reported. In young children the features of an extrapyramidal syndrome include abnormal eye movements, trismus, torticollis, and torsion dystonia.

Chloroquine can cause seizures in patients with epilepsy. The mechanism is uncertain, but it may include reductions in inhibitory neurotransmitters and pharmacokinetic interactions that alter anticonvulsant concentrations. Tonic–clonic convulsions were reported in four patients in whom chloroquine was part of a prophylactic regimen. Antiepileptic treatment was required to control the seizures. None had further seizures after withdrawal of the antimalarial drugs (9).

Chloroquine and desethylchloroquine concentrations have been studied in 109 Kenyan children during the first 24 hours of admission to hospital with cerebral malaria (10). Of the 109 children 100 had received chloroquine before admission. Blood chloroquine and desethylchloroquine concentrations were no higher in children who had seizures than in those who did not, suggesting that chloroquine does not play an important role in the development of seizures in malaria.

- A 59-year-old woman had a generalized convulsion 24 hours after returning from a trip to Vietnam (11). She had a history of partial complex seizures (controlled with carbamazepine) due to a previous ruptured cerebral aneurysm. For the preceding 3 weeks she had been taking chloroquine 100 mg/day and proguanil 200 mg/day. A blood film was negative for malaria. A CT scan of the brain showed changes compatible with the previous hemorrhage. She was successfully treated

© 2006 Elsevier B.V. All rights reserved.

with clobazam (dose not stated) until withdrawal of chemoprophylaxis.

The interaction between chloroquine and carbamazepine was not examined. Chloroquine should not be given to adults with a history of epilepsy.

Neuromuscular function

Severe neuromyopathy has been reported in patients taking chloroquine (SEDA-21, 295).

Chloroquine-induced neuromyopathy is a complication of chloroquine treatment of autoimmune disorders or long-term use of chloroquine as a prophylactic antimalarial drug (12).

Sensory systems

Eyes

Chloroquine and its congeners can cause two typical effects in the eye, a keratopathy and a specific retinopathy. Both of these effects are associated with the administration of the drug over longer periods of time.

Keratopathy

Chloroquine-induced keratopathy is limited to the corneal epithelium, where high concentrations of the drug are readily demonstrable. Slit lamp examination shows a series of punctate opacities scattered diffusely over the cornea; these are sometimes seen as lines just below the center of the cornea, while thicker yellow lines may be seen in the stroma. The keratopathy is often asymptomatic, fewer than 50% of patients having complaints. The commonest symptoms are the appearance of halos around lights and photophobia. Keratopathy can appear after 1–2 months of treatment, but dosages of under 250 mg/day usually do not cause it. Dust exposure can lead to similar changes. The incidence of keratopathy is high, occurring in 30–70% of patients treated with higher dosages of chloroquine. The condition is usually reversible on withdrawal and does not seem to involve a threat to vision (SEDA-13, 805). There are differences in incidence between chloroquine and hydroxychloroquine. In a survey of 1500 patients, 95% of the patients taking chloroquine had corneal deposition of the drug, while less than 10% of patients taking hydroxychloroquine showed any corneal changes (SEDA-16, 303).

Retinopathy

The retinopathy encountered with the prolonged use of chloroquine or related drugs is a much more serious adverse effect and can lead to irreversible damage to the retina and loss of vision. However, it is not possible to predict in which patients and in what proportion of patients an early retinopathy will progress to blindness. The typical picture is that of the "bull's eye," an intact foveal area surrounded by a depigmented ring, the whole lesion being enclosed in a scattered hyperpigmented area. At this stage the retinal vessels are contracted, there are changes in the peripheral retinal pigment epithelium, and the optic disk is atrophic. In the early stages there are changes in the macular retinal pigment epithelium. However, the picture is not always clear, and peripheral retinal changes may appear as the first sign. Another sign may be unilateral paramacular retinal edema. The macular changes and the "bull's eye" are occasionally seen in patients who have never been treated with chloroquine or related drugs (SED-13, 805). Retinopathy can occur after chloroquine antimalarial chemoprophylaxis for less than 10 years: the lowest reported total dose was 110 g (13). A case of hydroxychloroquine-induced retinopathy in a 45-year-old woman with systemic lupus erythematosus has illustrated that maculopathy can be associated with other 4-aminoquinolines (14).

The resulting functional defects are varied: difficulty in reading, scotomas, defective color vision, photophobia, light flashes, and a reduction in visual acuity. Symptoms do not parallel the retinal changes. By the time that visual acuity has become impaired, irreversible changes will have taken place.

Testing of visual acuity, central fields (with or without the use of red targets), contrast sensitivity, dark adaptation, and color vision provides no early indication of chloroquine retinopathy. Careful ophthalmoscopic examination of the macula can be a sensitive index when visual acuity remains intact. More sophisticated tests, such as the measurement of the critical flicker fusion frequency and the Amsler grid test (detection of small peripheral scotoma), can be useful. It is important to trace, if at all possible, the results of a pretreatment ophthalmological examination after dilatation of the pupils, thus reducing the possibility of confusing senile degenerative changes with chloroquine-induced abnormalities.

Despite the fact that the retinopathy has been known for many years, it is still not clear why certain patients develop these changes while others do not. There is a clear relation to daily dosage: the retinopathy is rarely seen with daily doses below 250 mg of chloroquine or 400 mg of hydroxychloroquine; the daily dose seems to be more important than the total dose. Nevertheless, cases of retinopathy have been described after the use of small doses for relatively short periods of time, while prolonged treatment and total doses of a kilogram or more have been used in many other patients without any evidence of macular changes. In the published cases there is usually no information about other treatments given previously or concomitantly. More cases are seen in older people. Patients with lupus erythematosus are more susceptible than patients with rheumatoid arthritis. The presence of nephropathy increases the likelihood of retinopathy, as does the concomitant use of probenecid. Exposure to sunlight may be of importance, since light amplifies the risk of retinopathy. The retinopathic changes are probably connected with the concentrating capacity of the melanin-containing epithelium. Chloroquine inhibits the incorporation of amino acids into the retinal pigment epithelium.

Little is yet known about the development of the retinopathy after withdrawal of treatment. Retinal changes in the early stages are probably reversible if the drug is withdrawn, and progression of a severe maculopathy to blindness seems to be less frequent than feared. In 1650 patients with 6/6 vision and relative scotomas there was no further decline in visual acuity after drug withdrawal, but 63% of patients who presented with absolute scotomas lost further vision over a median period of 6 years.

© 2006 Elsevier B.V. All rights reserved.

This suggests that withdrawal of chloroquine at an early stage halts progression of the disease (SEDA-17, 327).

Three patients with chloroquine retinopathy have been studied with multifocal electroretinography (15). All three had been taking chloroquine for rheumatological diseases and all had electroretinographic changes that were more sensitive than full field electroretinography. It may be that multifocal electroretinography will be a useful technique in the assessment of suspected cases of subtle chloroquine retinopathy.

The need for routine ophthalmological testing of all patients who take chloroquine is under discussion, an obvious element being the cost/benefit ratio. The best current opinion seems to be that at doses not exceeding 6.5 mg/kg/day of hydroxychloroquine, given for not longer than 10 years and with periodic checking of renal and hepatic function, the likelihood of retinal damage is negligible and ophthalmological follow-up is not required (SEDA-16, 303) (SEDA-17, 327). However, patients taking chloroquine or higher doses of hydroxychloroquine should be checked.

Other adverse effects on the eyes

Rhegmatogenous retinal detachment and bitemporal hemianopsia have both been seen in association with chloroquine retinopathy. Bilateral edema of the optic nerve occurred in a woman who took chloroquine 200 mg/day for 2.5 months. Diplopia and impaired accommodation (characterized by difficulty in changing focus quickly from near to far vision and vice versa) also affect a minority of patients (SEDA-13, 806).

Ears

Ototoxicity has been mentioned occasionally over the years; tinnitus and deafness can occur in relation to high doses; symptoms described after injection of chloroquine phosphate include a case of cochlear vestibular dysfunction in a child (16). However, there is insufficient evidence to attribute ototoxicity to chloroquine in humans, except as a rare individualized phenomenon. In guinea pigs given chloroquine 25 mg/kg/day intraperitoneally, one of the first signs of intoxication was ototoxicity (SEDA-11, 586).

- Unilateral sensorineural hearing loss occurred in a 7-year-old girl with idiopathic pulmonary hemosiderosis after she had taken hydroxychloroquine 100 mg bd for 2 years (17).

Taste

Disturbances of taste and smell have been attributed to chloroquine (18).

Psychological, psychiatric

Many mental changes attributed to chloroquine have been described, notably agitation, aggressiveness, confusion, personality changes, psychotic symptoms, and depression. Acute mania has also been recognized (SEDA-18, 287). The mental changes can develop slowly and insidiously. Subtle symptoms, such as fluctuating impairment of thought, memory, and perception, can be early signs, but may also be the only signs. The symptoms may be connected with the long half-life of chloroquine and its accumulation, leading to high tissue concentrations (SEDA-11, 583). Chloroquine also inhibits glutamate dehydrogenase activity and can reduce concentrations of the inhibitory transmitter GABA.

In some cases with psychosis after the administration of recommended doses, symptoms developed after the patients had taken a total of 1.0–10.5 g of the drug, the time of onset of behavioral changes varying from 2 hours to 40 days. Most cases occurred during the first week and lasted from 2 days to 8 weeks (SEDA-11, 583).

Transient global amnesia occurred in a healthy 62-year-old man, 3 hours after he took 300 mg chloroquine. Recovery was spontaneous after some hours (SEDA-16, 302).

In one center, toxic psychosis was reported in four children over a period of 18 months (SEDA-16, 302). The children presented with acute delirium, marked restlessness, outbursts of increased motor activity, mental inaccessibility, and insomnia. One child seemed to have visual hallucinations. In each case, chloroquine had been administered intramuscularly because of fever. The dosages were not recorded. The children returned to normal within 2 weeks.

Metabolism

Hypoglycemia was reported in a fatal chloroquine intoxication in a 32-year-old black Zambian male (SEDA-13, 240). Hypoglycemia has also been seen in patients, especially children, with cerebral malaria (SEDA-13, 240). Further studies have shown that the hypoglycemia in these African children was usually present before the antimalarial drugs had been started; in a study in Gambia hypoglycemia occurred after treatment with the drug had been started, although it was not necessarily connected with the treatment (SEDA-13, 240). Convulsions were more common in hypoglycemic children. This commonly unrecognized complication contributes to morbidity and mortality in cerebral *Plasmodium falciparum* malaria. Hypoglycemia is amenable to treatment with intravenous dextrose or glucose, which may help to prevent brain damage (SEDA-13, 804).

Although hydroxychloroquine has been used to treat porphyria cutanea tarda (19), there are reports that it can also worsen porphyria (20,21).

Electrolyte balance

Severe hypokalemia after a single large dose of chloroquine has been documented, and some studies show a correlation between plasma potassium concentrations and the severity of the cardiac effects. In a retrospective study of 191 consecutive patients who had taken an overdose of chloroquine (mean blood chloroquine concentration 20 μmol/l; usual target concentration up to 6 μmol/l), the mean plasma potassium concentration was 3.0 mmol/l (0.8) and was significantly lower in those who died than in those who survived (6). Plasma potassium varied directly with the systolic blood pressure and inversely with the QRS and QT intervals. Plasma potassium varied inversely with the blood chloroquine.

© 2006 Elsevier B.V. All rights reserved.

Hematologic

Chloroquine inhibits myelopoiesis in vitro at therapeutic concentrations and higher. In a special test procedure, a short-lasting anti-aggregating effect could be seen with chloroquine concentrations of 3.2–32 μg/ml (SEDA-16, 303). These effects have clinical consequences. Chloroquine and related aminoquinolines have reportedly caused blood dyscrasias at antimalarial doses. Leukopenia, agranulocytosis, and the occasional case of thrombocytopenia have been reported (SEDA-13, 804) (22). There is some evidence that myelosuppression is dose-dependent. This is in line with the hypothesis that 4-aminoquinoline therapy merely accentuates the cytopenia linked to other forms of bone marrow damage (SEDA-11, 584) (SEDA-16, 302).

Some studies have pointed to inhibitory effects of chloroquine on platelet aggregability. In an investigation, this aspect of chloroquine was studied in vitro in a medium containing ADP, collagen, and ristocetin. There was a highly significant effect at chloroquine concentrations of 3.2–32 μg/ml. However, there were no significant differences in platelet responses to ADP or collagen 2 or 6 hours after adding chloroquine, compared with pre-drug values. The investigators believed that these data provided no cause for concern in using chloroquine for malaria prophylaxis in patients with impaired hemostasis (SEDA-16, 303).

Mouth and teeth

Pigmentation of the palate can occur as a part of a more generalized pigmentation in patients taking chloroquine (23).

Several patients seen with chloroquine retinopathy in Accra have been observed to present with depigmented patches in the skin of the face. This may be associated with a greyish pigmentation of the mucosa of the hard palate. Two such cases are reported here to illustrate the condition. Stomatitis with buccal ulceration has occasionally been mentioned (SEDA-11, 584).

Gastrointestinal

Gastrointestinal discomfort is not unusual in patients receiving chloroquine, and diarrhea can occur. Changes in intestinal motility may be to blame; intramuscular injection of chloroquine caused a shortened orofecal time in the five cases in which this was measured. Overdosage can cause vomiting.

Skin

Skin lesions and eruptions of different types have been attributed to chloroquine, including occasional cases of epidermal necrolysis (24).

The most common dermatological adverse event associated with chloroquine is skin discomfort (often called pruritus). It is much more common in people with darker skins and has been ascribed to chloroquine binding to increased melanin concentrations in the skin. In a pharmacokinetic study, the ratio of $AUC_{0–48}$ for chloroquine and its major metabolite desethylchloroquine was significantly higher in the plasma and urine of 18 patients with chloroquine-induced pruritus than in that of 18 patients without (25). These results imply that differences in metabolism and higher chloroquine concentrations may be partly responsible for chloroquine-induced pruritus.

Pruritus begins about 10 hours after the start of treatment, with a maximum intensity at about 24 hours. These times correspond to maximum serum concentrations of chloroquine and its metabolites after oral ingestion. In many cases, the itch is confined to the palms of the hands and the soles of the feet. In a study in Nigeria, the incidence of pruritus was 60–75%; the itch was considered unbearable in 40%, and 30% refused further chloroquine (26). In a second study, there was an even higher incidence. In a study elsewhere, the incidence of pruritus was 27% (SEDA-16, 304). Not surprisingly, pruritus is a major cause of non-adherence to treatment, and it may contribute largely to the emergence and spread of resistant *P. falciparum* (SEDA-16, 304). Pruritus is more often seen in black-skinned than in white-skinned people in Africa, a difference that has been ascribed to the binding of chloroquine to melanin, and hence a racial predisposition. No such reports have come from America (SEDA-11, 584) (SEDA-16, 303) (SEDA-17, 327) (SEDA-18, 288). Antihistamine treatment can have a preventive effect on pruritus. Other treatments that have been mentioned include prednisone and niacin, but the results were not impressive (27).

A few cases of psoriasis, or severe exacerbation of psoriasis shortly after the start of treatment, have been reported (SEDA-13, 804) (SEDA-16, 304) (SEDA-17, 327).

Photosensitivity and photo-allergic dermatitis have been seen, particularly during prolonged therapy with high doses.

Blue–black pigmentation involving the palate and facial, pretibial, and subungual areas occurs rarely, but it has been associated with retinopathy (SEDA-11, 584). The nail bed can turn blue–brown and the nail itself may develop longitudinal stripes and show a blue–grey fluorescence (SEDA-11, 584).

Chloroquine can cause vitiligo (SEDA-17, 327).

Fatal toxic epidermal necrolysis has been associated with hydroxychloroquine (28).

- A 39-year-old woman with rheumatoid arthritis took hydroxychloroquine 200 mg bd for painful synovitis, in addition to meloxicam, co-dydramol, and Gaviscon. She inadvertently took twice the prescribed dose of hydroxychloroquine, but stopped it after 2 weeks because of nausea. The next day she developed a widespread blotchy erythema and 2 weeks later was admitted to hospital with clinical and histological toxic epidermal necrolysis and deteriorated rapidly with multiorgan failure; she died 1 week later.

There have been only a few isolated reports of Stevens–Johnson syndrome associated with hydroxychloroquine. Recently, a clear temporal relation to the start of treatment with hydroxychloroquine has been documented in a patient with rheumatoid arthritis (29).

An increased frequency of skin reactions to hydroxychloroquine was noted in 11 patients (seven of whom had systemic lupus erythematosus, two discoid lupus, and two a lupus-like syndrome) when a coloring agent (sunshine yellow E110) was removed from the formulation; the authors were unable to explain this unexpected finding (30).

© 2006 Elsevier B.V. All rights reserved.

There have been four case reports of photosensitivity associated with hydroxychloroquine (31) which has an estimated incidence of about 10 per 1000 patient-years (32).

Hydroxychloroquine causes skin reactions such as urticaria. There is some support for the contention that hydroxychloroquine causes skin reactions more often than chloroquine.

Nails

Chloroquine can turn the nail bed blue–brown and the nail itself can develop longitudinal stripes and show a blue–grey fluorescence (SEDA-11, 584).

Immunologic

- Allergic contact dermatitis, which progressed to generalized dermatitis and conjunctivitis, followed later by severe asthma, occurred in a 60-year-old worker in the pharmaceutical industry after exposure to hydroxychloroquine (33). Patch-testing showed delayed sensitivity to hydroxychloroquine. Equivalent tests in five healthy volunteers were negative. The patch test reactions were pustular, and a biopsy was interpreted as multiform contact dermatitis. Bronchial exposure to hydroxychloroquine dust produced delayed bronchial obstruction over the next 20 hours, progressing to fever and generalized erythema (hematogenous contact dermatitis).

Long-Term Effects

Drug tolerance

Chloroquine-resistant falciparum malaria was first reported in 1960. As of 1996, chloroquine resistance became widespread throughout the world and in many areas there is multidrug resistance. Preventive administration of drugs such as chloroquine, primaquine, and pyrimethamine, as well as the use of various sulfonamide mixtures and combinations of sulfonamides with trimethoprim, has progressively lost its usefulness. Currently, hardly half a century after the therapeutic breakthroughs occurred, quinine is once more one of the most valuable drugs in the treatment of malaria and there is a desperate need for other effective drugs.

Alongside the well-known development of resistance by *P. falciparum* to chloroquine, the emergence of chloroquine-resistant *Plasmodium vivax* is now clear (SEDA-13, 801). An increased frequency of cerebral malaria appears to coincide with the growing emergence of the chloroquine-resistant strains in Francophone Africa.

Second-Generation Effects

Pregnancy

Chloroquine inactivates DNA, and crosses the placenta in animals. Caution has generally been advised with respect to the use of chloroquine and related compounds during pregnancy, but except for one (perhaps coincidental) case, there have been no reports of complications to mother or child from treatment with chloroquine during pregnancy (SEDA-14, 239) (SEDA-17, 326).

An observational comparison in a rural Ghanaian hospital of 2083 pregnant women and 3084 historical controls showed no serious adverse events with chloroquine chemoprophylaxis (300 mg/week), but a high rate of pruritus (34). There was a decrease in anemia in pregnancy but no increase in perinatal mortality or birth weight in the chloroquine-treated mothers, although this was only in comparison with historical controls.

Susceptibility Factors

Genetic factors

Mutations in the ABCR gene (a photoreceptor-specific ATP-binding cassette transporter gene) have been associated with Stargardt disease, which has some features similar to chloroquine-induced retinopathy. In a case-control study of eight cases of chloroquine-induced retinopathy, five of the eight cases had mis-sense mutations in the ABCR gene, two of which have been associated with Stargardt disease (35). It may be that polymorphisms in the ABCR gene predispose to chloroquine-induced retinopathy.

Age

Small children have usually been considered as being relatively more sensitive to the effects of overdosage, but it has been calculated that on a mg/kg body weight basis, adults are in fact equally sensitive. Young children seem to be truly more susceptible to gastric irritation. Patients with a history of mania or epilepsy should be careful in taking chloroquine (9). The hypoxemic effects of chloroquine, reflecting cardiac and respiratory toxicity, pose a particular problem in the newborn, in whom existing malarial infection may not become clinically manifest until some months after birth (SEDA-16, 302).

Compared with adults, mortality in children after acute chloroquine poisoning is extremely high. Although the clinical presentation is mostly similar to that in adults (apnea, seizures, cardiac dysrhythmias), a single 300 mg chloroquine tablet was enough to kill a 12-month-old female infant (SEDA-16, 302).

Other features of the patient

Skin reactions to hydroxychloroquine occur more often in patients with dermatomyositis than in patients with systemic lupus erythematosus, as has been shown in a retrospective, age-, sex-, and race-matched case-control study in 78 patients (36). Twelve of 39 patients with dermatomyositis developed a skin reaction to hydroxychloroquine, compared with only one of 39 patients with lupus erythematosus.

Drug Administration

Drug formulations

Chloroquine has a bitter taste, which can deter children from taking it, so a sweet effervescent formulation of chloroquine phosphate has been compared with chloroquine tablets in a pharmacodynamic study (37). However,

© 2006 Elsevier B.V. All rights reserved.

sweet-tasting medications carry a risk of accidental overdose in children.

Drug administration route

If given intravenously, chloroquine should be diluted and infused slowly, since rapid injection causes toxic concentrations. Toxicity and even death have been reported after intramuscular administration of larger doses; this is probably connected with rapid absorption in such cases (SEDA-17, 327).

Drug overdose

Acute intoxication, either accidental or in attempted suicide, can cause headache, drowsiness, vision disturbance, vomiting and diarrhea, cardiovascular collapse, and respiratory failure. Deaths have been recorded at blood concentrations of 1 μg/ml (SEDA-11, 586) (38,39). Compared with adults, mortality in children after acute chloroquine poisoning is extremely high. Although the clinical presentation is mostly similar to that in adults (apnea, seizures, cardiac dysrhythmias), a single 300 mg chloroquine tablet was enough to kill a 12-month-old female infant (SEDA-16, 302).

Deaths from chloroquine overdose have been reported with doses as low as 2–3 g in adults, and the death rate is as high as 25%. The effects of chloroquine overdose include cardiac effects (such as dysrhythmias, reduced myocardial contractility, and hypotension) and central nervous system complications (such as confusion, coma, and seizures).

There have been three reports of chloroquine overdose, two from Oman (40) and one from the Netherlands (41). The two reports from Oman were similar to previously published reports of chloroquine overdose associated with cardiac dysfunction, confusion, and coma; both patients had standard treatment with activated charcoal, diazepam infusions, and positive inotropic drugs, and both survived. The single case report from the Netherlands gave pharmacokinetic measurements performed before, during, and after hemoperfusion. This showed that hemoperfusion extracted very little chloroquine and was unlikely to be of any use in chloroquine overdose, as would be expected from the high protein binding and large volume of distribution of chloroquine.

In Zimbabwe, 544 cases of poisoning by a single agent were identified in a retrospective hospital record review (42). Antimalarial drugs accounted for the largest proportion of admissions (53%), and chloroquine accounted for 96% of these (279 cases). The median length of hospital stay in those who took chloroquine was significantly shorter (1 versus 2 days) and more patients took chloroquine deliberately (80% versus 69%). The mortality rate from chloroquine poisoning was significantly higher than from poisoning with other drugs (5.7% versus 0.7%).

Overdose with hydroxychloroquine is far less common than with chloroquine. Three of eight patients died (43). Life-threatening symptoms, such as hypotension, conduction disturbances, and hypokalemia can occur within 30 minutes of ingestion and are similar to those seen in chloroquine overdose. The lethal plasma concentration of hydroxychloroquine is not well established. Therapeutic drug concentrations are usually less than 1 μmol/l. Serious toxicity has been reported at plasma concentrations of 2.1–29 μmol/l.

Management of hydroxychloroquine overdose is similar to that of chloroquine overdose, including the use of charcoal for drug adsorption, diazepam for seizures and sedation, early intubation and mechanical ventilation, and potassium replacement for severe hypokalemia.

Drug–Drug Interactions

Amlodipine

Syncope occurred in a hypertensive 48-year-old man who took oral chloroquine sulfate (total 600 mg base) while also taking amlodipine 5 mg/day (44). Chloroquine and amlodipine both cause vasodilatation, perhaps by release of nitric oxide, and the syncope in this case was probably due to a synergistic mechanism. Malaria itself can also provoke orthostatic reactions, which may be why syncope is not a reported adverse effect of chloroquine. However, in this patient malaria had been excluded.

Antibiotics

Studies of chloroquine used in combination with antibiotics showed an antagonistic effect with penicillin but a synergistic effect with chlortetracycline. Urinary tests after single doses of ampicillin 1 g and chloroquine 1 g showed a significant reduction in the systemic availability of the ampicillin.

Chlorphenamine

Chlorphenamine enhances the efficacy of chloroquine in acute uncomplicated falciparum malaria, but the disposition of chloroquine in these circumstances is unpredictable. Chloroquine (25 mg/kg) was given orally over 3 days in combination with chlorphenamine to Nigerian children with parasitemia (45). The peak whole blood chloroquine concentration was increased and the time to peak concentration shortened. In small trials there seemed to be an increase in QT interval with this combination, but less than with halofantrine (46). However, in other studies, the addition of chlorphenamine to chloroquine did not amplify the cardiac effects of chloroquine (46).

Ciclosporin

Chloroquine can increase ciclosporin blood concentrations (47).

Cimetidine

Cimetidine enhanced the susceptibility of *P. falciparum* to chloroquine in vitro in 60% of isolates (48).

Digoxin

The pharmacokinetic interaction of quinidine with digoxin also occurs with quinine and hydroxychloroquine (49).

© 2006 Elsevier B.V. All rights reserved.

Fansidar (sulfadoxine + pyrimethamine)

The combined use of Fansidar (sulfadoxine + pyrimethamine) with chloroquine has been reported to result in more severe adverse reactions (50). However, an increased risk has not been reported in recent studies (51).

Halofantrine

There is an increased risk of dysrhythmias, including torsade de pointes, when halofantrine is combined with quinine/quinidine or chloroquine and any other drug that prolongs the QT interval (52).

Insulin

There may be an interaction of chloroquine with insulin. An oral glucose load given to healthy subjects and to patients with non-insulin-dependent diabetes mellitus, before and during a short course of chloroquine, showed a small but significant reduction in fasting blood glucose concentration in the control group and improvement in glucose tolerance in the patients (SEDA-12, 240). The response seems to reflect reduced degradation of insulin rather than increased pancreatic output.

Quinine

Chloroquine antagonizes the action of quinine against *P. falciparum* in vivo. However, no such evidence of antagonism was found in a study in which Malawian children with cerebral malaria were treated with quinine. There was no difference in survival and rate of recovery in patients who had also been given chloroquine compared with those who had not (SEDA-13, 816).

Thyroxine

A marked increase in serum TSH occurred in the same patient on two occasions after several weeks of antimalarial prophylaxis with chloroquine and proguanil, the likely mechanism being enzyme induction and increased thyroxine catabolism (SEDA-22, 469).

Vaccines

Chloroquine 300 mg/week adversely affected the antibody response to human diploid-cell rabies vaccine administered concurrently. The mean rabies-neutralizing antibody titer was significantly reduced on each day of testing (SEDA-13, 806) (8). In contrast, retrospective studies of the response to pneumococcal polysaccharide in patients with systemic lupus erythematosus taking chloroquine or hydroxychloroquine, and of the response to tetanus–measles–meningococcal vaccine in a region of Nigeria where malaria is endemic, did not show an effect on antibody production. However, it was pointed out that the altered immune status of patients with systemic lupus erythematosus makes it difficult to compare their response to that of young healthy adults receiving rabies vaccine. Illness and nutritional state could have influenced the findings in the Nigerian study (SEDA-13, 807) (53).

Verapamil

Verapamil completely reversed pre-existing in vitro resistance to chloroquine to below the cut-off point of 70 nmol/l (48).

Smoking

Antimalarial drugs (chloroquine, hydroxychloroquine, or quinacrine) were given to 36 patients with cutaneous lupus, of whom 17 were smokers and 19 non-smokers (8). The median number of cigarettes smoked was one pack/day, with a median duration of 12.5 years. There was a reduction in the efficacy of antimalarial therapy in the smokers. Patients with cutaneous lupus should therefore be encouraged to stop smoking and consideration may be given to increasing the doses of antimalarial drugs in smokers with refractory cutaneous lupus before starting a cytotoxic agent.

Chlorotrianisene

General Information

Chlorotrianisene is a non-steroidal triphenylethylene with estrogen and antiestrogen activity. Diethylstilbestrol and other non-steroidal estrogens came into vogue at a time when the cost of producing steroidal estrogens, whether synthetic or of natural origin, was still prohibitive. They have fallen out of favor, in view of the association between diethylstilbestrol in pregnancy and second-generation injury. There is no reason for believing that the short-term acute adverse reactions to these non-steroidal compounds differ from those of estrogenic steroids.

Chlorotrianisene does not bind in vitro to the uterine estrogen receptor but has potent estrogenic and antiestrogenic actions in vivo, suggesting that it is a prodrug. Its antiestrogenic activity has been proposed to be due to a reactive intermediate (1).

Organs and Systems

Hematologic

In 50 postpartum women who took chlorotrianisene for lactation suppression in a double-blind, randomized, placebo-controlled study, antithrombin III concentrations were significantly lower on the third day postpartum compared with placebo (2).

References

Chloroxylenol

See also Disinfectants and antiseptics

General Information

Since the withdrawal of hexachlorophene from the nonprescription drug market in the USA, the antiseptic chloroxylenol, which is less antigenic, has been a substitute in a large number of products.

Organs and Systems

Skin

Topical exposure can cause rashes.

- A 10-day-old baby who was given a bath in a 25% solution of Dettol containing 1.2% chloroxylenol became dehydrated and developed diffuse erythema and vesicles, and afterwards exfoliative dermatitis (1). There was a good response to therapy with systemic glucocorticoids and supportive measures.

Immunologic

Allergic contact dermatitis can occur after sensitization to chloroxylenol, for example in medicated Vaseline or in electrocardiographic paste (2).

In a retrospective analysis of patch tests in 951 patients 1.8% had positive reactions to chloroxylenol (3). Most of the patients had been sensitized by popular proprietary formulations containing chloroxylenol (SEDA-11, 221).

Drug Administration

Drug overdose

There have been many cases of intoxication with oral Dettol liquid, a widespread household disinfectant that contains chloroxylenol 4.8%, pine oil, and isopropyl alcohol (4–8). Dettol was involved in 10% of hospital admissions related to self-poisoning in Hong Kong. In a retrospective study of 67 cases, serious complications were relatively common (8%) and these included aspiration of Dettol with gastric contents, resulting in pneumonia, cardiopulmonary arrest, bronchospasm, adult respiratory distress syndrome, and severe laryngeal edema with upper airway obstruction. Of 89 patients, five developed minor hematemesis, in the form of coffee-colored or blood-stained vomitus (6). One patient had a gastroscopy performed on the day after admission, which showed signs of chemical burns in the esophagus and stomach. Gastroscopy in another patient on day 11, done to rule out an esophageal stricture, showed no abnormality. All patients with hematemesis recovered completely. The authors suggest that upper gastrointestinal hemorrhage after Dettol ingestion tends to be mild and self-limiting. Gastroscopy, which may increase the risk of aspiration in patients with impaired consciousness, is not required unless other causes of gastrointestinal bleeding are suspected. Furthermore, Dettol poisoning can be associated with an increased risk of aspiration, possibly caused by the use of gastrointestinal lavage in 88% of the patients and vomiting in 62% (6,7).

Of 121 patients who ingested Dettol 200–500 ml, three developed renal impairment, as evidenced by raised plasma urea and creatinine (7). Two of these patients also had serious complications, including aspiration leading to pneumonia and adult respiratory distress syndrome; one died. Renal impairment only appears to be observed when relatively large amounts of Dettol are ingested (7).

Chlorphenamine maleate

See also Antihistamines

General Information

Chlorphenamine (chlorpheniramine) is a first-generation antihistamine, an alkylamine derivative, with sedative and antimuscarinic activity.

Organs and Systems

Psychological, psychiatric

Functional neuroimaging of cognition was impaired by chlorphenamine (1).

Skin

Lichen-planus-like contact dermatitis after topical use of chlorphenamine has been described in one case report, with positive patch-testing (2).

Drug–Drug Interactions

Chloroquine

Chlorphenamine enhances the efficacy of chloroquine in acute uncomplicated falciparum malaria, but the disposition of chloroquine in these circumstances is unpredictable. Chloroquine (25 mg/kg) was given orally over 3 days in combination with chlorphenamine to Nigerian children with parasitemia (3). The peak whole blood chloroquine concentration was increased and the time to peak concentration shortened. However, in further studies the addition of chlorphenamine to chloroquine did not amplify the cardiac effects of chloroquine (4).

Ranitidine

In the same way that pharmacokinetic studies have been used to ascertain whether co-administration of an inhibitor of CYP3A4 can lead to cardiotoxicity, similar studies have been carried out to indicate whether the co-administration of an inhibitor can enhance a limited sedative effect. Healthy subjects took a single dose of racemic chlorphenamine 4 mg on two separate occasions; the second occasion coincided with the sixth day of dosing with ranitidine 75 mg bd for 8 days. Serum concentrations and urinary excretion of chlorphenamine were not altered, and so it was considered unlikely that co-administration with ranitidine would enhance the potential of chlorphenamine to cause drowsiness (5).

Chlorphenoxamine

General Information

Chlorphenoxamine is an antihistamine closely related to diphenhydramine with a similar metabolic pathway (1). It appears to have been developed in the hope of producing a greater effect in Parkinson's disease by combining both anticholinergic and antihistaminic effects in a single molecule (2).

In the doses commonly used well-recognized anticholinergic effects can occur (3). Some patients become drowsy, whilst others are stimulated; with increasing dosages, some patients go into coma; others have agitation, convulsions, and marked euphoria, perhaps with hallucinations and disorientation.

Chlorphentermine

See also Anorectic drugs

General Information

Chlorphentermine is an anorectic sympathomimetic amine, with actions and adverse effects similar to those of amfepramone (diethylpropion).

Organs and Systems

Respiratory

Pathological changes in the lungs were produced with chlorphentermine in laboratory animals (SED-9, 14). Pulmonary complications might therefore occur in humans, which puts in doubt the wisdom of continuing to recommend chlorphentermine as an anorectic drug until more definitive information is available.

Nervous system

Much less stimulation of the central nervous system has been reported in patients taking chlorphentermine than in those taking dexamphetamine; less frequent too were complaints of light-headedness, tremors, restlessness, nervousness, and insomnia; patients taking chlorphentermine can paradoxically become drowsy (1).

Gastrointestinal

In 25 patients who had taken chlorphentermine, constipation and dryness of the mouth were more frequent than with other appetite depressants. In another comparative study with phenmetrazine in volunteers, constipation and dry mouth were again among the more frequent adverse reactions, along with sleepiness and increases in motor activity and urinary urgency (SED-8, 16).

Chlorpromazine

See also Neuroleptic drugs

General Information

Chlorpromazine is a phenothiazine with a large range of pharmacological actions; it is a dopamine receptor antagonist, an alpha-adrenoceptor antagonist, a muscarinic antagonist, and an antihistamine.

Organs and Systems

Cardiovascular

The possibility that some of the cardiac effects of chlorpromazine may be related to metabolites as well as the parent compound has been explored (1,2).

Some cases of sudden death in apparently young healthy individuals may be directly attributable to cardiac dysrhythmias after treatment with thioridazine or chlorpromazine (3).

Nervous system

In 15 schizophrenic inpatients aged 16–55 years, there was a 50% probability that a patient would have a tremor when the plasma concentration of chlorpromazine was 46 ng/ml or more, corresponding to the minimum plasma concentration that has been associated with a good clinical response (4).

Skin

Chlorpromazine most often causes photosensitivity reactions (incidence around 3%), which may result from formation of a cytotoxic by-product after exposure to ultraviolet light. Patients should be advised to avoid prolonged exposure to strong indoor light, to wear protective clothing, and to use a combined para-aminobenzoic acid plus benzophenone sunscreen when exposure to strong sunlight is unavoidable.

Toxic epidermal necrolysis has been reported in association with chlorpromazine (5).

Chlorpromazine is thought to have caused an immunologically mediated contact urticaria (6–10).

Sexual function

Two cases of priapism have been attributed to chlorpromazine: a 65-year-old man who took a single dose of chlorpromazine 25 mg and a 27-year-old man who took chlorpromazine 200 mg for agitation after a suicide attempt (11).

Drug–Drug Interactions

Amfetamine

Chlorpromazine has sometimes been used to treat amfetamine psychosis, for example due to acute poisoning in children who did not respond to barbiturates (12).

Beta-adrenoceptor antagonists

Lipophilic beta-adrenoceptor antagonists are metabolized to varying degrees by oxidation by liver microsomal cytochrome P450 (for example propranolol by CYP1A2 and CYP2D6 and metoprolol by CYP2D6). They can therefore reduce the clearance and increase the steady-state plasma concentrations of other drugs that undergo similar metabolism, potentiating their effects. Drugs that interact in this way include chlorpromazine (13).

- A schizophrenic patient experienced delirium, tonic-clonic seizures, and photosensitivity after the addition of propranolol to chlorpromazine, suggesting that chlorpromazine concentrations are increased by propranolol (14).

Although high dosages of propranolol (up to 2 g) have been used in combination with chlorpromazine to treat schizophrenia, the combination of propranolol or pindolol with chlorpromazine should be avoided if possible (15).

Haloperidol

- A 40-year-old man with schizophrenia developed a raised plasma concentration of haloperidol in combination with chlorpromazine and during overlap treatment with clozapine (16).

Like haloperidol, chlorpromazine is a competitive inhibitor of CYP2D6; however, clozapine appears to be largely metabolized by CYP1A2.

Monoamine oxidase inhibitors

Hyperthermia and labile blood pressure occurred in a patient taking chlorpromazine, phenelzine, and clomipramine (17).

Smoking

Chlorpromazine concentrations were reduced by 36% in smokers (18). Of factors that can affect chlorpromazine concentrations, smoking may be second in importance only to dosage (19).

Interference with Diagnostic Tests

Cholesterol

Chlorpromazine can cause overestimation of cholesterol (Zlatkis–Zak reaction) (20).

CSF protein

Chlorpromazine can cause falsely increased CSF protein (Folin–Ciocalteau method) (20).

Haptoglobin

Chlorpromazine can cause falsely reduced serum haptoglobin concentrations (20).

Chlorprothixene

See also Neuroleptic drugs

General Information

Chlorprothixene is a thioxanthene neuroleptic drug.

Organs and Systems

Immunologic

Rare disorders of connective tissue resembling systemic lupus erythematosus have been reported with chlorpromazine, perphenazine, and chlorprothixene (1).

Reference

1. McNevin S, MacKay M. Chlorprothixene-induced systemic lupus erythematosus. J Clin Psychopharmacol 1982;2(6):411–12.

Chlortalidone

See also Diuretics

General Information

Chlortalidone (chlorthalidone) is chemically unrelated to the thiazide diuretics but shares many of their actions and adverse effects.

It is so closely similar to the thiazide diuretics in most respects that data have generally been regarded as interchangeable.

Comparative studies

In the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT), over 40 000 participants aged 55 years or older with hypertension and at least one other risk factor for coronary heart disease were randomized to chlortalidone, amlodipine, doxazosin, or lisinopril (1,2). Doxazosin was discontinued prematurely because chlortalidone was clearly superior in preventing cardiovascular events, particularly heart failure (2). Otherwise, mean follow-up was 4.9 years. There were no differences between chlortalidone, amlodipine, and lisinopril in the primary combined outcome or all-cause mortality. Compared with chlortalidone, heart failure was more common with amlodipine and lisinopril, and chlortalidone was better than lisinopril at preventing stroke.

Organs and Systems

Electrolyte balance

In the past chlortalidone was thought to carry a greater risk of hypokalemia and hyponatremia (SED-8, 488), but this probably reflected relative overdosage with accumulation, because of its long half-life. With the much lower dosages now in use there appears to be no clear difference from the thiazides.

Skin

Pseudoporphyria has been attributed to chlortalidone (3).

Body temperature

Drug fever has been attributed to chlortalidone (4).

- A 58-year-old woman presented with intermittent nocturnal fever (up to 39.5°C) for 4 weeks beginning 2 weeks after the introduction of chlortalidone for hypertension. Otherwise, physical examination was normal. Investigations showed a normochromic normocytic anemia and a raised erythrocyte sedimentation rate and C-reactive protein. Other biochemical tests, blood cultures, and serological and immunological tests were negative. Chest radiography, lung scintigraphy, and abdominal ultrasound were unremarkable. There was no further fever after chlortalidone was withdrawn, and all biochemical tests became normal. The lymphocyte transformation test showed stimulation by chlortalidone.

Chlorzoxazone

General Information

Chlorzoxazone is a centrally acting benzoxazole derivative with a weak muscle relaxing effect (1). It is usually used in combination with paracetamol for the treatment of painful muscle spasms. The usual dose is 500 mg tds. Drowsiness, weakness, dizziness, and gastrointestinal complaints are the most frequent unwanted effects.

© 2006 Elsevier B.V. All rights reserved.

Organs and Systems

Nervous system

A spasmodic torticollis-like syndrome, repeatedly evoked after the ingestion of chlorzoxazone, is an unusual adverse effect of the drug. Benzatropine mesilate 1 mg intravenously led to resolution of the symptoms within 10 minutes (2).

Liver

The most serious adverse effect of chlorzoxazone, which fortunately occurs only rarely, is hepatotoxicity.

In one case jaundice occurred and rechallenge with a single tablet of Parafon Forte (chlorzoxazone plus paracetamol) resulted in a dramatic reaction after 5 hours, with fever, chills, nausea, vomiting, and recurrence of icterus. Paracetamol on its own had no adverse effect in this case.

The authors reviewed some 23 other cases (SEDA-12, 119) (3).

Cholera vaccine

See also Vaccines

General Information

Cholera vaccines consist of live attenuated or heat-killed *Vibrio cholerae* organisms. They can be given orally or parenterally.

Following the administration of live oral cholera vaccine (containing the attenuated strain *V. cholerae* CVD 103-HgR, prepared from *V. cholerae* 01 strain 569B), there were significant rises in serum antitoxin concentrations and only few mild adverse effects (SED-13, 925). There was protective efficacy in 82–100% of healthy adult volunteers and no difference in adverse effects between 25 recipients of the vaccine and 26 controls (1).

A randomized, double-blind, placebo-controlled trial using a live oral cholera vaccine (strain CVD 103, derived from the *V. cholerae* 01 classical Inaba strain 569B by deletion of the genes encoding the A subunit of cholera toxin) was conducted in 50 healthy Swiss adults. There was a significant rise in serum antitoxin titers in 76% of the volunteers. Two vaccinees reported watery stools after immunization (2).

When an oral single-dose cholera vaccine against *V. cholerae* 0139 was given to ten volunteers there was 83% protective efficacy and the only adverse effect, in one volunteer, was mild diarrhea (3).

The results with an oral cholera vaccine consisting of the immunogenic but completely non-toxic B subunit of cholera toxin in combination with heat- and formalin-killed *V. cholerae* represent an improvement compared with previous parenteral vaccines (4). The frequency of adverse effects (pain at the injection site, nausea, diarrhea) was low (5).

Severe complications connected with cholera (or combined) immunization are extremely rare and the causal relation is always doubtful. However, when they do occur they constitute a contraindication to further administration. There are occasional reports of neurological and psychiatric reactions (SED-8, 706) (SEDA-1, 246), Guillain–Barré syndrome (SEDA-1, 246), myocarditis (6,7), myocardial infarction (SEDA-3, 261), a syndrome similar to immune complex disease (8), acute renal insufficiency accompanied by hepatitis (9), and pancreatitis (10).

Drug Administration

Drug formulations

A parenteral cholera vaccine consisting of a heat-killed, phenol-preserved, mixed suspension of the Inaba and Ogawa subtypes of *V. cholerae*, Serovar 01, has been used subcutaneously or intramuscularly, or for booster doses intradermally. About 1% of vaccinees develop mild local skin lesions comprising transitory soreness at the injection site within 5-7 days after injection, characterized by erythema, swelling, pain, and induration, and rarely resulting in ulceration. More general reactions are allergic: as a rule, these amount at most to slight pyrexia, headache, and malaise. However, considering the low protective efficacy and high reactogenicity of this vaccine, the World Health Organization and many national health authorities do not recommend it anymore and most manufacturers have stopped producing it.

Choline

General Information

Choline has been given in the past as an acetylcholine precursor to raise acetylcholine concentrations in the brain and thus enhance cholinergic neurotransmission. There is evidence that the symptoms of tardive dyskinesia can be reduced by choline or lecithin (1).

Organs and Systems

Psychological, psychiatric

Occasionally, doses of choline up to 9 g/day have been found to produce severe depression, presumably by altering the adrenaline/acetylcholine balance (2).

Choline alfoscerate

General Information

Choline alfoscerate increases cerebral acetylcholine synthesis and release (1). In the light of animal studies it has been investigated as a possible treatment for vascular dementia (2). Adverse effects have been few, notably headache and flushing.

References

Chromium

General Information

Chromium is a metallic element (symbol Cr; atomic no. 24) that occurs naturally in minerals such as fuchsite and picotite.

Certain salts of radioactive chromium (1) are used as radiopharmaceutical tracers in various hematological procedures. Chromium compounds are also used in oral and parenteral nutrition and in artificial hip and knee joints. Chromium picolinate has been promoted as a nutritional supplement and has received a great deal of interest because of its possible beneficial effects on muscle strength and body composition.

Trivalent chromium is supposedly an essential trace element, but its essentiality continues to be discussed (2). The biochemistry of chromium has been reviewed (3), as have the mechanisms of its toxicity, carcinogenicity, and allergenicity (4) and its general toxicology (5).

Trivalent chromium compounds (chromium chloride, chromium nicotinate, and chromium picolinate) are used by patients to enhance weight loss, to increase lean body mass, or to improve glycemic control. Drug histories should include attention to the use of over-the-counter nutritional supplements often regarded as harmless by the public and lay media. The recommended daily allowance of chromium picolinate is 50–200 micrograms, but information about its toxicity is limited.

The quest for the molecular mechanisms of chromium in relation to diabetes continues (6,7). Chromium picolinate may aid muscle insulin sensitivity, and initial reports suggest that it is an effective therapy for type 2 diabetes (8). Chromium picolinate supplementation alone does not improve insulin sensitivity (9).

- In a 28-year-old woman with an 18-year history of type 1 diabetes mellitus the glycosylated hemoglobin fell from 11.3 to 7.9% and her blood glucose concentration was 1.7–3.3 mmol/l lower after she had taken chromium picolinate (200 micrograms tds for 3 months) (10). There were no adverse effects.

Chromium in metal implants and prostheses

Complications from the use of metal implants and prostheses can arise because of biochemical and histological reactions to some of the materials used (SEDA-22, 250). These include titanium, stainless steel (10–14% nickel, 17–20% chromium), and cobalt chrome alloys (27–30% chromium, 57–68% cobalt, and up to 2.5% nickel). All of these metals can produce sensitization or elicit toxic reactions when they are solubilized and come into contact with tissues; it can be difficult or even impossible to differentiate between hypersensitivity and toxic reactions.

© 2006 Elsevier B.V. All rights reserved.

Metals from prostheses can continue to be released into the system for many years. The development of hypersensitivity takes time, and allergic reactions are usually delayed for weeks, months, or 1–2 years. The symptoms can assume a variety of forms. Local reactions can cause loosening of the device or local pain. Dermatological reactions include eczema, bullous pemphigoid, urticaria, and "muscle tumors."

Attempts continue to predict metal sensitivity in the individual patient so that the choice of material can be made accordingly. In vitro tests for metal allergies have been developed on the basis of lymphokine (MIF) release from sensitized T lymphocytes exposed to metal-protein complexes (11). About 6% of patients without a previous metal implant had positive reactions to nickel, chromium, or cobalt. However, it is still not clear whether such a positive reaction is a reliable predictor of clinical problems. In practice few patients have either local or systemic reactions; when symptoms occur and other causes are ruled out, the implant should be removed. Some workers recommend removal of an implant whenever there is both a positive MIF test and a positive skin test, even in the current absence of a serious reaction. Allergic dermatitis will clear up as soon as the metal has begun to be cleared from the tissue. The type of metal and the amount released into the tissue will affect the time taken for the disappearance of toxic dermatological phenomena.

Organs and Systems

Psychological, psychiatric

There have been three reports of the efficacy of chromium in depression, with adverse effects that included dizzy spells and vivid dreams (12).

- A 50-year-old man developed bipolar II disorder with the onset of a major depressive episode in his late twenties. His mood stabilized with lithium, but he continued to have periods of irritability and breakthrough depression. He started to take chromium picolinate 400 micrograms/day and within 2 days felt more relaxed and stable than he had since the onset of his disorder. He stopped taking lithium. Several months later he forgot to take his chromium, and within a few days his symptoms returned. In order to catch up he took 800 micrograms/day and developed sweating each morning and a mild hand tremor. After reducing the dosage to 600 micrograms/day he again went into complete remission. After more than 1 year of chromium treatment he developed uric acid kidney stones. One year after switching to a different chromium salt (the polynicotinate), there was no recurrence of kidney stones.
- A 38-year-old man with bipolar II disorder took chromium polynicotinate 400 micrograms/day. Shortly after the first dose his mood started to improve, but he had unusually vivid intense dreams. The dose of chromium was increased to 600 micrograms/day. He then developed intermittent brief dizzy spells due to orthostatic hypotension. After switching to chromium picolinate his dizzy spells did not recur.
- A 47-year-old man with a dysthymic disorder and intermittent panic attacks and rage outbursts took chromium 400 micrograms/day, and after 1 day had strikingly vivid dreams. Over the next several days there was a dramatic improvement in his mood and behavior. The efficacy of chromium was later confirmed by a double-blind, placebo-controlled, *n*-of-1 trial.

Liver

Hepatic injury is a risk that is associated primarily with occupational exposure to chromium, in this case among chromium platers (13), an occupation that has an increased incidence of chronic hepatitis or liver cirrhosis. There also appears to be a trend toward a significantly increased risk of lung cancer.

- A 35-year-old woman complained of nausea, fatigue, pruritus, dark urine, pale stools, and jaundice after taking a supplement containing chromium picolinate for weight loss (14). Infectious hepatitis was excluded and a liver biopsy was consistent with toxic liver damage. Hepatic chromium concentrations were more than 10 times normal. The chromium supplement was withdrawn and she received supportive treatment with a suspension containing "natural products," colestyramine 1 g qds, and hydroxyzine 25 mg tds. She fully recovered in 3 months.

Skin

Allergic contact dermatitis has apparently been most commonly due to occupational exposure of building workers to a form of cement containing a water-soluble form of chromium (SEDA-20, 208) (15). Such reactions to medical exposure have not been described but could in principle occur.

Chromium has been reported to cause dermatitis when ingested (16).

- A 35-year-old man developed a subacute dermatitis with scattered patches of erythema and scaling on the lower legs, ankles, hands, and wrists. He had no history of atopy but a prior history of allergy to a leather watchstrap. He had taken various oral vitamin and mineral formulations for several weeks. Patch-testing showed reactions to potassium dichromate at 48 and 96 hours.

Chromium picolinate has caused acute generalized exanthematous pustulosis (17).

- A 32-year-old previously healthy man developed an extensive rash of sudden onset associated with a low-grade fever (37.4°C), a sore throat, and malaise after taking chromium picolinate 1 mg/day for 4 days. He had a confluent symmetrical erythematous eruption with numerous non-follicular 1–2 mm pustules on the trunk and proximal limbs. The eruption was most prominent in the antecubital and popliteal fossae bilaterally. There was mild pharyngeal erythema and bilateral tender cervical adenopathy, but no tonsillar enlargement or exudate. Chromium picolinate was withdrawn and he was treated with oral prednisone 60 mg/day tapered over 15 days. The acute eruption resolved within 1 week, followed by post-inflammatory desquamation. It did not recur during follow-up for 15 months.

© 2006 Elsevier B.V. All rights reserved.

Musculoskeletal

- Rhabdomyolysis has been attributed to chromium picolinate in a 24-year-old body builder who took 1200 micrograms over 48 hours (18).

Long-Term Effects

Tumorigenicity

Hexavalent chromium compounds have no medical uses and are known as mutagens and carcinogens (19). In an in vitro study the coordination of chromium by picolinate ligands made chromium picolinate more toxic to cultured cells, leading to enhanced apoptosis (20). These observations support the hypothesis that chromium picolinate is a human carcinogen.

A mortality study among workers engaged in producing chromium compounds from chromite, performed using retrospective data (21), showed a significantly increased risk of lung cancer, despite cessation of exposure. The risk of nasal cavity/sinus cancer was also significantly increased.

Drug Administration

Drug overdose

Toxicity secondary to chronic ingestion of 6–12 times the recommended daily allowance of over-the-counter chromium picolinate has been reported (22).

- A 33-year-old white woman presented with weight loss, anemia, thrombocytopenia, hemolysis, liver dysfunction (transaminase activities 15–20 times normal, total bilirubin three times normal), and renal insufficiency. She had taken chromium picolinate 1200–2400 micrograms/day for the previous 4–5 months to enhance weight loss. Her plasma chromium concentrations were 2–3 times normal. After withdrawal of chromium picolinate, she was managed with supportive measures, blood transfusions, and hemodialysis. The hemolysis stabilized and her liver and renal function eventually recovered.

Drug–Drug Interactions

Sertraline

Chromium can potentiate antidepressant pharmacotherapy for manic-depressive disorder. In five patients taking sertraline, supplementation with chromium picolinate and chromium polynicotinate led to enhanced remission of dysthymic symptoms (23).

Cianidanol

General Information

Cianidanol is an antioxidant flavonoid that occurs especially in woody plants. It is one constituent of green tea. It has immunomodulatory properties, including effects on T lymphocytes and killer cells (1).

Of 40 patients with chronic active hepatitis, 22 took cianidanol 3 g/day and 18 took placebo (2). Adverse effects of cianidanol were fever ($n = 4$), hemolysis ($n = 1$), and urticaria ($n = 1$).

Serious adverse effects were not observed when cianidanol was used to treat HBe-antigen-positive chronic hepatitis in 338 patients (3). The only adverse effect of note that appeared to be drug-related was transient pyrexia in 13, necessitating withdrawal of therapy in eight. Four patients also had a skin eruption.

Organs and Systems

Hematologic

Nine cases of acute intravascular hemolysis, severe enough to cause death in one and to necessitate hemodialysis in two others, were attributed to cianidanol on the basis of a close temporal relation and serological tests (4).

Cibenzoline

See also Antidysrhythmic drugs

General Information

Cibenzoline is an antidysrhythmic drug of Class Ia, with some additional properties of drugs of Class III and Class IV. Its pharmacology, electrophysiological effects, therapeutic effects and indications, pharmacokinetics, and adverse effects have been reviewed (1,2). Prolongation of the QT interval, leading to cardiac dysrhythmias, is the major adverse effect. Other effects include gastrointestinal disturbances, effects on the central nervous system, and hypoglycemia, perhaps related to inhibition of ATP-dependent potassium channels in the pancreas.

Comparative studies

Cibenzoline and flecainide have been compared in the prevention of recurrence of atrial tachydysrhythmias in 139 patients (3). During the study, 27 patients withdrew, in 13 cases with adverse effects, seven of which were due to cibenzoline. Overall there were 26 adverse effects in 23% of the patients taking cibenzoline; these included one case of ventricular dysrhythmia, four minor cardiac events, four cases of nausea or epigastric pain, eight cases of weakness, four cases of depression or insomnia, one skin rash, and one case of hypoglycemia. The QRS complex was prolonged by more than 13% in 14 patients, but the QT interval was not prolonged. Although this was not a placebo-controlled study, the incidence of adverse effects with cibenzoline was probably as one would expect in such a population.

Organs and Systems

Cardiovascular

Cibenzoline prolongs the PR interval, the QRS interval, and the QT_c interval (4–7). It also prolongs the AH and HV intervals (5,8) and shortens the sinus cycle length (5–8). Because of these effects it can cause dysrhythmias (4,6,7,9).

- Cardiac dysrhythmias have been attributed to cibenzoline in a 60-year-old man with hypertrophic cardiomyopathy (10).
- In a 72-year-old woman cibenzoline was associated with left bundle branch block and heart failure (11). Excess cibenzoline accumulation was suspected, because of reduced renal function, but plasma cibenzoline concentrations were not reported.

Right bundle branch block has also been reported (6).

In three patients in whom cibenzoline had caused sinus node dysfunction, normal sinus node recovery time was restored by cilostazol (12).

Cibenzoline has a negative inotropic effect and can therefore cause hypotension (6,7,13,14) and worsening heart failure (4).

Nervous system

Various nervous system complaints have been reported in occasional patients, including headache (15), disturbances of visual accommodation (15), and tremulousness (16). Dizziness and light-headedness have more commonly been reported, sometimes in association with hypertension (7,17).

There have been frequent reports of anticholinergic adverse effects, including dry mouth (7,9,13), blurred vision (4,9), and difficulty in micturition (18).

- Choreiform movements associated with persistent orofacial dystonia have been attributed to cibenzoline in a 77-year-old woman who took 260 mg/day for 1 week (19). When cibenzoline was eventually withdrawn the effects resolved within 1 month.

The authors proposed that the effect was due to inhibition of potassium channels.

A myasthenia-like syndrome has occasionally been attributed to cibenzoline (SEDA-21, 199) (20).

- A 57-year-old man with chronic renal insufficiency treated by continuous and ambulatory peritoneal dialysis took cibenzoline 150 mg/day for a ventricular dysrhythmia. Four days later he developed proximal muscle weakness, progressing to generalized muscle weakness, with dysphagia and dysarthria. Hemodiafiltration on six occasions caused complete improvement and cibenzoline was withdrawn. There was no further recurrence, even when other drugs that he had been taking were restarted.

The authors suggested that cibenzoline may have inhibited ATP-dependent potassium channels in skeletal muscle. The plasma cibenzoline concentration at the height of this patient's symptoms was very high at 1890 μg/ml (usual target range 300–600) and the authors counselled caution in patients with renal insufficiency (SEDA-15, 174).

Metabolism

Several cases of hypoglycemia have been attributed to cibenzoline (21–23) (SEDA-18, 204). In a case-control study of 14 156 outpatients, 91 had hypoglycemia, and each was matched with five controls (24). Eight of those with hypoglycemia were taking cibenzoline and three were taking disopyramide. In contrast, only seven of the controls were taking cibenzoline, a significant difference. However, 20 of the controls were taking disopyramide, which was not significant from the patients with hypoglycemia, although disopyramide is known to cause hypoglycemia. Insulin was also associated with hypoglycemia, but sulfonylureas were not. Furthermore, there was a positive association with what were termed "thyroid agents." All of these features cast some doubt on the validity of these results in relation to cibenzoline.

- A 65-year-old woman developed hypoglycemia while taking cibenzoline and alacepril (25).

It is possible that hypoglycemia due to cibenzoline can be enhanced by ACE inhibitors, which can increase insulin sensitivity (SED-14, 640).

Gastrointestinal

Various gastrointestinal adverse effects have been reported not infrequently, including nausea (15), sometimes in association with abdominal pain (7,9,13), vomiting, and diarrhea (7,8,14,16).

Liver

Hepatotoxicity with cibenzoline has been rarely reported. There has been a report of slight rises in the activities of serum transaminases (16), and one of ischemic hepatitis (26).

- A 67-year-old woman, who also had mild thrombocytopenia developed markedly abnormal liver function tests, which normalized within 3 months of withdrawal (27).

Susceptibility Factors

Renal disease

Cibenzoline is 60% eliminated by the kidneys (14,28,29). Its renal clearance falls with age (28); this is attributable to renal impairment.

- Three patients with severe renal insufficiency (creatinine clearance 10–16 ml/minute) had increased plasma cibenzoline concentrations during treatment with 300 mg/day (30). They developed prolonged QTc intervals, widened QRS complexes, dysrhythmias, hypotension, and hypoglycemia. Their plasma cibenzoline concentrations were 1944–2580 μg/l, 5–10 times higher than the usual target range. The half-lives of cibenzoline immediately after withdrawal were 69, 116, and 198 hours, 3–10 times longer than reported in patients with end-stage renal insufficiency (about 20 hours).

Drug Administration

Drug overdose

Overdose of cibenzoline has been reported.

- An 80-year-old woman who took an unknown number of 300 mg tablets had impaired consciousness, a low blood pressure (58/30 mmHg), coarse crackles in the lung, and a prolonged QT_c interval (0.64 seconds) (31). There was mild left ventricular global hypokinesia with a 50% left ventricular ejection fraction, severe mitral regurgitation, and left atrial dilatation. There was a mild partially compensated metabolic acidosis and hypoglycemia (2.9 mmol/l). The plasma concentration of cibenzoline was 2580 ng/ml. She was treated with sodium bicarbonate, dopamine, and noradrenaline. A pre-existing right ventricular pacemaker was not functioning, and the amplitude was increased from 2.5 to 7.5 volts at a rate of 90 per minute. Charcoal perfusion for 5 hours caused a dramatic fall in the plasma cibenzoline concentration in association with a reduction in the QT_c interval to 0.48 seconds and improvement in the pacing threshold.
- Fatal intoxication with cibenzoline has been reported in an 83-year-old man (32).

Diagnosis of Adverse Drug Reactions

It has been suggested that plasma concentrations of 100–200 mg/ml are necessary for efficacy and that at concentrations over 400 mg/ml there is an increased risk of adverse reactions (7). In most studies plasma cibenzoline concentrations have been around 200–400 mg/ml (4,6,8,17). Plasma concentrations correlate well with electrophysiological effects (6), its hemodynamic effects (33), and reduction in ventricular extra beats (34). In one study, patients who had adverse effects had a mean concentration of 913 mg/ml compared with 312 mg/ml in those who did not (8).

Ciclosporin

General Information

Ciclosporin is an immunosuppressant drug that primarily inhibits T cell activation, therefore down-regulating the T cell responses that mediate graft rejection. Myelotoxic effects are therefore not expected. Ciclosporin has also been used in a wide range of chronic inflammatory or autoimmune diseases.

Considerable efforts have been devoted to defining the optimal dose to ensure minimal toxicity while retaining efficacy. In transplant patients, the daily maintenance dose is 2–6 mg/kg/day. In non-transplant patients, daily doses of 2.5 mg/kg up to a maximum of 4 mg/kg are usually recommended.

In renal transplantation, ciclosporin maintenance monotherapy can be effectively achieved in a subset of patients with the aim of reducing adverse effects associated with glucocorticoids or azathioprine, but this should be carefully balanced against the risks of acute or chronic allograft rejection. This approach was again emphasized, based on data from 100 adults and a review of the most recent literature (1). According to the authors, clinical predictors of successful ciclosporin maintenance therapy included compliant patients over 25 years old with a donor age younger than 40 years, patients with later azathioprine withdrawal, patients with serum creatinine concentrations of 125 μmol/l or less, patients without a history of rejection (or one rejection episode responding favorably to glucocorticoids), and patients who have successfully discontinued glucocorticoids 6 months before.

Comparative studies

Although the pattern of long-term toxicity of ciclosporin and tacrolimus is remarkably similar for most serious adverse effects (particularly nephrotoxicity), a higher incidence of several minor adverse effects with ciclosporin, namely hirsutism, gingivitis or gum hyperplasia, has been thought to underlie a moderate but significant decrease in the quality of life with ciclosporin compared with tacrolimus (2).

General adverse effects

As regards long-term toxicity, particularly nephrotoxicity, and frequent drug interactions, the benefit-to-harm balance of ciclosporin is still debatable. Whereas the adverse effects have generally been deemed acceptable, although occasionally treatment-limiting in patients with rheumatoid arthritis given low-dose ciclosporin rather than conventional antirheumatic drugs, conflicting opinions have been expressed on the acceptability of the risks in patients with psoriasis (SEDA-20, 343).

Of 20 patients with chronic idiopathic thrombocytopenic purpura refractory to glucocorticoids or splenectomy treated with ciclosporin, six withdrew owing to toxicity (3). The target blood concentration range was identical to that aimed at in the first 3 months after kidney transplantation. The most common adverse effects were hypertension, headache, and severe myalgia.

The antileukemic effect of ciclosporin has been harnessed in the treatment of cytopenias associated with chronic lymphatic leukemia. In 31 patients the most common adverse effect was a raised serum creatinine concentration of grade 2 or worse in six patients (19%); three patients developed opportunistic infections (4).

Drug interactions with ciclosporin have been comprehensively reviewed (5).

Organs and Systems

Cardiovascular

Compared with azathioprine, hypertension has been considered one of the main long-term risks in patients taking ciclosporin, with major concerns about the post-transplantion increase in cardiovascular morbidity and mortality. However, there are many susceptibility factors for cardiovascular disease in transplant patients (6), and it is difficult to take into account their complex interplay. Ciclosporin-associated hypertension appears to be dose-related, and higher whole-blood ciclosporin concentrations were found during the preceding months in patients who had thromboembolic complications compared with patients who did not (7).

De novo or aggravated hypertension is very common in patients taking ciclosporin, with the highest incidence in cases of heart transplant (71–100%) and the lowest incidence in bone marrow transplant recipients (33–60%) (8). In addition, 30–45% of patients with psoriasis, rheumatoid arthritis, or uveitis had hypertension, suggesting that ciclosporin is a significant cause of hypertension in organ transplantation. Ciclosporin-associated hypertension can cause acute vascular injury, with microangiopathic hemolysis, encephalopathy, seizures, and intracranial hemorrhage.

The incidence, clinical features, consequences, and management of ciclosporin-induced hypertension have been reviewed (9). The prevalence was 29–54% in non-transplant patients and 65–100% in heart and liver transplant patients also taking glucocorticoids. Disturbed circadian rhythm with a loss of nocturnal blood pressure fall was the main characteristic, and patients therefore had higher risks of left ventricular hypertrophy,

© 2006 Elsevier B.V. All rights reserved.

cerebrovascular damage, microalbuminuria, and other target organ damage.

The pathophysiology of ciclosporin-induced hypertension is complex and not yet fully elucidated. Increased systemic vascular resistance subsequent to altered vascular endothelium function, renal vasoconstriction with reduced glomerular filtration and sodium-water retention, and/or increased activity of the sympathetic nervous system were suggested, while only a minor role or none was attributed to the renin–angiotensin system (10). However, hypertension often occurs before changes in renal function or sodium balance can be demonstrated, and ciclosporin nephrotoxicity alone does not explain ciclosporin-associated hypertension (8,11).

The effects of antihypertensive agents have been evaluated in patients taking ciclosporin. Collectively, dihydropyridine calcium channel blockers that do not affect ciclosporin blood concentrations substantially or at all (felodipine, isradipine, and nifedipine) are usually considered to be the drugs of choice. However, the risk of gingival hyperplasia with nifedipine, which ciclosporin also causes, should be borne in mind. Combination therapy with angiotensin-converting enzyme inhibitors or beta-blockers, or the use of other calcium channel blockers (verapamil or diltiazem) should also be considered, but careful monitoring of ciclosporin blood concentrations is recommended with the latter because they inhibit ciclosporin metabolism.

A possible role of ciclosporin in the exacerbation or development of Raynaud's disease has been suggested on one occasion; such an effect could be linked to endothelial damage or changes in platelet function (12).

A capillary leak syndrome with subsequent pulmonary edema has also been reported after intravenous ciclosporin (SEDA-21, 383).

Infusion phlebitis has been attributed to intravenous ciclosporin (13).

Respiratory

Adult respiratory distress syndrome has been described after intravenous ciclosporin. It was thought that a high concentration of the drug in the pulmonary vasculature due to administration through a central vein was responsible for capillary leakage, but in one patient the pulmonary capillary leak resolved rapidly when the intravenous ciclosporin was changed to oral (14). This suggested that Cremophor (polyoxyethylated castor oil), the solvent for parenteral ciclosporin, was responsible. However, there has been a report of an adult who developed respiratory distress syndrome in association with oral ciclosporin given after renal transplantation (15).

Hypersensitivity pneumonitis has been attributed to ciclosporin (16).

- A 35-year-old woman taking glibenclamide and mesalazine for Crohn's colitis was given ciclosporin for severe disease exacerbation. Within 6 weeks, she developed arthralgia and moderate thrombocytopenia, and ciclosporin was discontinued. Acute fever (41°C) and dyspnea were noted several days later, and a chest X-ray showed diffuse bilateral infiltrates. Bronchoalveolar lavage showed neutrophil preponderance and plasma cells, and a lung biopsy strongly suggested an acute hypersensitivity pneumonitis. All her symptoms subsided after a short course of prednisolone and oxygen.

Both the absence of an infectious cause and the rapid improvement without withdrawal of other drugs suggested that ciclosporin was the likely cause.

Nervous system

Neurological adverse effects of ciclosporin have been reported in up to 39% of all transplant patients. Most are mild. The most frequent is a fine tremor, the mechanism of which is not known. From many case reports or studies in transplant patients, the pattern of ciclosporin neurotoxicity ranges from common and mild to moderate symptoms, such as headaches, tremors, paresthesia, restlessness, mood changes, sleep disturbances, confusion, agitation, and visual hallucinations, to rare but severe or life-threatening disorders, including acute psychotic episodes, cerebellar disorders, cortical blindness (permanent in one report), spasticity or paralysis of the limbs, catatonia, speech disorders or mutism, chorea, seizures, leukoencephalopathy, and coma (SED-13, 1124) (SEDA-16, 516) (SEDA-17, 520) (SEDA-20, 343) (SEDA-21, 383) (17–19).

A 19% incidence of central nervous system toxicity with ciclosporin has been reported in pediatric renal transplantation patients; the symptoms included seizures, drowsiness, confusion, hallucinations, visual disturbances, and mental changes (20).

Neurological symptoms were observed in 12–25% of liver-transplant patients and in 29% of bone marrow transplant patients, but severe neurotoxicity occurred only in about 1% (18,19,21). They usually appeared within the first month of treatment, but were sometimes delayed (19). Particular attention should be paid to prompt recognition of severe neurotoxicity, because abnormalities of the white matter can occur. Patients usually improved rapidly after temporary ciclosporin withdrawal or dosage reduction, and tacrolimus has sometimes been used successfully instead (SEDA-21, 383) (18). However, recurrence of seizures and persistent electroencephalographic abnormalities were found in 46 and 70% of pediatric transplant patients respectively who had had ciclosporin acute encephalopathy and seizure syndrome and who were followed-up for 49 months (22).

Although the role of many other factors should be considered when neurological symptoms occur in transplant recipients, isolated reports of neurotoxicity in non-transplanted patients are in keeping with a causal role of ciclosporin. There are many susceptibility factors in ciclosporin neurotoxicity. Blood ciclosporin concentrations are sometimes raised, but severe neurological symptoms have been observed in some patients with concentrations in the usual target range (18). Other possible susceptibility factors for ciclosporin neurotoxicity include hypocholesterolemia, hypomagnesemia, aluminium overload, concomitant high-dose glucocorticoid therapy, hypertension, and concomitant microangiopathic hemolytic anemia (SED-13, 1124) (SEDA-21, 383). Acute graft-versus-host disease or HLA-mismatched and unrelated donor transplants were also potential susceptibility factors in recipients of bone marrow transplants (SEDA-22, 383) (19).

© 2006 Elsevier B.V. All rights reserved.

Ciclosporin-induced vasculopathy, with endothelial injury and derangement of the blood–brain barrier, is the postulated mechanism of neurological damage. Transient cerebral perfusion abnormalities, demonstrable in SPECT scans of the brain, have been suggested as a reliable indicator of ciclosporin neurotoxicity (SEDA-20, 344). Clinical symptoms as well as CT and/or MRI scans were very similar to those observed in hypertensive encephalopathy, with predominant and reversible white-matter occipital lesions (23). There was complete neurological recovery in most patients after blood pressure was normalized, and deaths due to intracranial hemorrhage are reported only exceptionally.

A retrospective study identified a significantly higher incidence of central nervous system symptoms in patients with Behçet's disease (24). Headache, fever, paralysis, ataxia, dysarthria, or disturbed consciousness occurred in 12 of 47 ciclosporin-treated patients compared with nine of 270 patients not treated or taking other drugs. CT and/or MRI scans were abnormal in all 12. As the clinical findings were very similar to the neurological effects of Behçet's disease, it was suggested that ciclosporin can promote the development of neurological complications in this population.

Ciclosporin neurotoxicity is particularly frequent in liver and bone marrow transplant patients, who usually recover after temporary dosage reduction or withdrawal. However, a fatal outcome has been reported (25).

- A 54-year-old man was given ciclosporin and methotrexate after allogeneic bone marrow transplantation. He noted blurred vision during several days and became confused 11 weeks after transplantation. Generalized tonic-clonic seizures occurred the day after and he was given phenytoin and antibiotics. His neurological condition deteriorated during the next 5 days, despite ciclosporin withdrawal, and he died from respiratory failure. Postmortem examination showed white matter edema and astrocyte injury without demyelination.

Most studies have focused on the central nervous system adverse effects of ciclosporin, and there have been few reports of peripheral neuropathy.

- In two patients, ciclosporin was suggested as a possible cause of an entrapment neuropathy, and surgery was required in both (26).

However, the report did not provide sufficient evidence to assess the causal relation fully.

- Another patient developed a symmetric polyneuropathy with flaccid paraplegia while her ciclosporin serum concentrations were about twice normal (27). Electromyography showed features of axonal degeneration in the peripheral nerves and neurological symptoms improved on ciclosporin dosage reduction.

Migraine associated with ciclosporin is sometimes resistant to classical treatment and the consequences can be even more severe.

- Three young adult renal transplant patients, including two with a previous history of moderate migraine, had severe attacks of unilateral throbbing migraine associated with vomiting during ciclosporin treatment (28). In two patients, vomiting was severe enough to reduce compliance with the immunosuppressive regimen, and both subsequently lost their grafts. The same sequence of events was again observed after retransplantation.

Substitution by tacrolimus may be beneficial in such cases.

Severe ciclosporin neurotoxicity has mostly been reported in transplant patients, but should also be considered in non-transplanted patients.

- An 87-year-old patient with resistant nodular prurigo was successfully treated with ciclosporin (3 mg/kg/day) and prednisone (10 mg/day) (29). Bilateral numbness and distal limb weakness developed after 18 months. Clinical examination, electromyography, and nerve conduction studies confirmed a diffuse axonal neuropathy which rapidly progressed over the next 2 months. Ciclosporin alone was withdrawn and complete remission was observed within 3 months.

Unfortunately, ciclosporin blood concentrations and renal function at the time of diagnosis were not reported.

Very severe or fatal neurotoxicity has been reported in isolated patients only.

- Based on postmortem findings in a 32-year-old woman who died with an acute encephalopathy (30) and another report of two patients investigated with transcranial Doppler ultrasound and MRI for symptoms of ciclosporin neurotoxicity (31), vascular changes with vasospasm and dissection of the vascular intima strongly suggest that vasculopathy is a possible mechanism of ciclosporin-induced encephalopathy.

Prolonged confusion is a recognized complication of ciclosporin, and can be due to non-convulsive status epilepticus (32). Three patients who developed neurotoxicity following treatment with ciclosporin manifested with generalized tonic-clonic seizures and dysarthria. The plasma ciclosporin concentration in these patients increased as the neurological signs appeared, and the signs resolved quickly after dosage reduction (33). Tonic-clonic seizures have been reported in a child taking ciclosporin (34).

- A 13-year-old boy with severe Crohn's disease developed hematochezia and required blood transfusion. He was given ciclosporin on day 22 because of persistent rectal bleeding and diarrhea, despite high-dose intravenous glucocorticoids. After 6 days he developed multiple episodes of generalized tonic-clonic seizures, with MRI findings typical but not pathognomonic of ciclosporin: prominent meningeal enhancement, bifrontal, bitemporal, biparietal, and bioccipital cortical and subcortical white matter high-signal changes, and swelling of the gyri, which obliterated the sulci.

This case illustrates that severe ciclosporin neurotoxicity can develop in patients with predisposing factors, such as hypomagnesemia, hypocholesterolemia, hypertension, and glucocorticoid therapy.

There is still debate about whether ciclosporin crosses the blood–brain barrier and enters the cerebrospinal fluid. Ciclosporin could not be identified in cerebrospinal fluid

© 2006 Elsevier B.V. All rights reserved.

from 14 patients with liver transplants who had various neurological complications (35). Ciclosporin metabolites were measurable in the cerebrospinal fluid in only four patients, who had evidence of acute renal insufficiency, cholestasis, and raised blood concentrations of ciclosporin metabolites but identical ciclosporin parent drug blood concentrations compared with 10 patients with undetectable concentrations of ciclosporin metabolites in the cerebrospinal fluid. Ciclosporin metabolites enter the cerebrospinal fluid, and direct neurotoxicity is therefore possible in at least some patients with renal or hepatic dysfunction.

Endogenous ligands for ciclosporin and tacrolimus, known as immunophilins, are found in very high concentrations in the basal ganglia, and ciclosporin can alter dopamine phosphorylation in the medium-sized neurons in the striatum. Changes in basal ganglia glucose metabolism have been studied in a patient with severe ciclosporin-related tremor (36).

- A 37-year-old man received ciclosporin after bone marrow transplantation for chronic myelogenous leukemia. Soon afterwards he developed a severe tremor, which persisted despite dosage reduction. A brain MRI scan was normal. After 22 months he developed a personality change. A high resolution PET scan showed symmetrical increases in ^{18}F-deoxyglucose uptake in both caudate and putamen.

These results confirm that ciclosporin can modulate dopaminergic transmission in the striatum, presumably by inhibition of calcineurin.

- A 16-year-old girl with end-stage renal insufficiency underwent successful renal transplantation and was given ciclosporin on day 1 (37). On day 10 she complained of tinnitus and tremor and had a right facial nerve palsy. An MRI scan showed areas of increased signal in the white matter of the periventricular region. The dose of ciclosporin was reduced, since no other cause could be determined. Her tremor and tinnitus resolved, but the facial nerve palsy persisted. She was given tacrolimus, but the tremor and tinnitus recurred. She was then given mycophenolate mofetil and prednisone, and the tremor and tinnitus disappeared, although the facial nerve palsy persisted. The MRI scan 3 months later was normal.

The serum magnesium concentration was below the reference range in this case, which may have favored the development of neurotoxicity.

Sensory systems

Controversial reports of ocular symptoms have been published in patients taking oral ciclosporin, with ptosis and diplopia attributed to unilateral or bilateral sixth nerve palsies in four patients (who had also taken ganciclovir), and nystagmus in one patient (SEDA-21, 383). Peripheral optic neuropathy, with visual loss, nystagmus, and ophthalmoplegia, has also been reported (38). Acute cerebral cortical blindness complicating ciclosporin therapy in a 5-year-old girl (39) and transient cortical blindness and occipital seizures with visual impairment (40,41) have also been reported in association with ciclosporin.

Bilateral optic disc edema is sometimes associated with ciclosporin given for bone marrow transplantation, but unilateral papilledema with otherwise asymptomatic raised intracranial pressure can occur (42). Eight cases of optic disc edema have been reported in bone marrow transplant patients taking ciclosporin. In two of the patients there were other possible explanations, but in all cases withdrawal of ciclosporin resulted in resolution of the papilledema (43).

Ciclosporin eye-drops have been used after keratoplasty, in high-risk cases, to prevent graft rejection and to treat severe vernal conjunctivitis, keratoconjunctivitis sicca, and various immune-related corneal disorders. Despite its severe adverse effects after systemic use, topical ciclosporin can generally be used without serious adverse reactions (44,45).

Ciclosporin oil-in-water emulsion has been used in the local treatment of moderate to severe dry eye disease. Chronic dry eye disease results from inflammation mediated by cytokines and receptors for autoimmune antibodies in the lacrimal glands. It affects the lacrimal gland acini and ducts, leading to abnormalities in the tear film, and ultimately disrupting the homeostasis of the ocular surface. Topical ciclosporin reduces the cell-mediated inflammatory response associated with inflammatory ocular surface diseases.

In two large, randomized controlled trials in 977 patients, the adverse effects associated with ciclosporin ophthalmic emulsion for the treatment of dry eye disease were minimal and consisted mostly of mild ocular burning and stinging (46). However, topical application of ciclosporin eye-drops was the suspected cause of severe visual loss with bilateral white corneal deposits in a 45-year-old patient with dry eye syndrome caused by graft-versus-host disease (47). Infrared spectroscopy and X-ray analysis suggested that the deposits contained ciclosporin. A reduction in tear clearance and compromised epithelial barrier function caused by the concomitant use of oxybuprocaine may have precipitated this adverse effect.

The efficacy, safety, tolerability, and optimal dose of ciclosporin eye-drops have been studied in a randomized, double-masked, vehicle-controlled multicenter trial in 162 patients with keratoconjunctivitis sicca with or without Sjögren's disease and refractory to conventional treatment (48). Ciclosporin ophthalmic emulsion 0.05, 0.1, 0.2, or 0.4%, or the vehicle alone was instilled twice daily into both eyes for 12 weeks, followed by a 4-week observation period. There was no clear dose–response relation; ciclosporin 0.1% emulsion produced the most consistent improvement in objective and subjective endpoints and ciclosporin 0.05% gave the most consistent improvement in symptoms. The vehicle also performed well, perhaps because of its long residence time on the ocular surface. There were no significant adverse effects, no microbial overgrowth, and no residence time of the vehicle emulsion on the ocular surface. All treatments were well tolerated and the highest ciclosporin blood concentration detected was 0.16 ng/ml.

To study the efficacy and safety of ciclosporin 0.05 and 0.1% ophthalmic emulsions and their vehicle in patients with moderate to severe dry eye disease, two identical multicenter, randomized, double-masked, vehicle-controlled trials have been performed in 877 patients for

© 2006 Elsevier B.V. All rights reserved.

6 months (46). More than 76% completed the course. Ciclosporin 0.05 or 0.1% eye-drops gave significantly greater improvement than the vehicle in two objective signs of dry eye disease (corneal staining and Schirmer values). Ciclosporin 0.05% also gave significantly greater improvement in three subjective measures (blurred vision, need for concomitant artificial tears, and the physician's evaluation of global response to treatment). There was no dose–response effect and there were no topical or systemic adverse findings.

Corneal deposition of ciclosporin can occur (47).

- A 45-year-old woman with dry eye syndrome caused by graft-versus-host disease after bone marrow transplantation for acute leukemia was given systemic ciclosporin and topical 0.1% sodium hyaluronate, 0.3% ofloxacin, 0.1% fluorometholone, and isotonic saline. She was also given 0.4% oxybuprocaine for the relief of severe ocular pain. The bilateral corneal epithelial defects persisted even after the application of punctal plugs, and 2% ciclosporin in olive oil was added as eye-drops three times a day bilaterally. Five days later she complained of severe visual loss in association with bilateral corneal opacities, which covered the pupil and the punctal plugs bilaterally. As she did not agree to keratectomy, infrared spectroscopy and X-ray analysis were conducted on the deposits on the plugs. The spectroscopic pattern and X-ray analysis showed that the deposits had the properties of ciclosporin.

As the corneal deposits did not abate after withdrawal of the ciclosporin eye-drops, the systemic ciclosporin as well as its topical use may have contributed to the deposits. One should be aware that precipitation of ciclosporin on a compromised cornea can lead to severe visual impairment.

Metabolism

Diabetes mellitus

Diabetes mellitus after transplantation is recognized as an important adverse effect of immunosuppressants, and has been extensively reviewed (49). However, the use of ciclosporin in immunosuppressive regimens is not associated with diabetes mellitus after transplantation (10–20%) (50).

Hyperlipidemia

Ciclosporin is potentially more toxic in patients with altered LDL concentrations or a low total serum cholesterol (51). Ciclosporin therapy itself significantly raises plasma lipoprotein concentrations by increasing the total serum cholesterol; this is due to an increase in LDL cholesterol, demonstrated in a prospective, double-blind, randomized, placebo-controlled trial in 36 men with amyotrophic lateral sclerosis (52). In 22 patients there were significant increases in mean serum triglycerides and cholesterol 2 weeks after they started to take low-dose ciclosporin (53). Hypertriglyceridemia developed in seven patients taking ciclosporin 2.0–7.5 mg/kg/day for psoriasis during the first month of therapy; the values were greater than the upper limit in age- and sex-matched controls (54).

The pathology of hyperlipidemia after transplantation is multifactorial, but it is clearly dose-dependently related to immunosuppressive therapy (55). This results in cardiovascular disease, which is one of the most common causes of morbidity and mortality in long-term survivors of organ transplantation (56). Hyperlipidemia can also cause renal atheroma, resulting in graft rejection. The possible impact of ciclosporin on lipids includes an increase in total cholesterol, LDL cholesterol, and apolipoprotein B concentrations, and a reduction in HDL cholesterol (SED-13, 1124). The influence of ciclosporin on lipoprotein(a) concentrations has been debated (SEDA-21, 383) (57). Post-transplant hyperlipidemia is multifactorial and can be affected by impaired renal function, diuretics and beta-blockers, increased age, and female sex. A combination of lipid-lowering drugs and optimization of immunosuppressive regimens compatible with long-term allograft survival is probably required to reduce post-transplantation hyperlipidemia.

Whereas azathioprine is considered to play no role, glucocorticoid use correlates positively with increased serum cholesterol concentrations. It is uncertain whether these lipid changes reflect primarily an effect of ciclosporin alone or an additive/synergistic effect of the drug plus glucocorticoids. Ciclosporin has been considered as a possible independent susceptibility factor by several investigators, but others were unable to find an association between hyperlipidemia and ciclosporin (SEDA-20, 344). There was indirect evidence for a causal role of ciclosporin in several studies; hyperlipidemia developed in non-transplant patients taking ciclosporin alone; there was a transient reduction in hyperlipidemia after ciclosporin withdrawal; there was a significant correlation between ciclosporin blood concentrations and lipid abnormalities; and there was a higher incidence of lipid abnormalities in patients taking ciclosporin alone compared with patients taking azathioprine and prednisolone (SED-8, 1131) (SEDA-17, 524) (SEDA-21, 383) (55,58). Other studies have provided striking evidence that hyperlipidemia is more frequent in patients taking ciclosporin than in those taking tacrolimus, with more patients classified as having high cholesterol concentrations in the ciclosporin group or a significant fall in total cholesterol or LDL cholesterol in patients switched from ciclosporin to tacrolimus (59,60). Although the glucocorticoid-sparing effect of tacrolimus may account for these differences, the concept that the glucocorticoid dose is a confounding factor has been disputed (SEDA-22, 412). Whether these differences translate to a higher risk of cardiovascular complications in patients taking ciclosporin has not been carefully assessed. The treatment of hyperlipidemia in transplant patients may represent a major dilemma, because of several drug interactions, with an increased risk of myopathy and rhabdomyolysis after the combined use of ciclosporin and several lipid-lowering drugs.

Hyperuricemia

Significant hyperuricemia has been observed in as many as 80% of patients taking ciclosporin (61). In one series, hyperuricemia occurred in 72% of male and 82% of

© 2006 Elsevier B.V. All rights reserved.

female patients taking ciclosporin after cardiac transplantation; there was also an increased incidence of gouty arthritis in these patients (62). Episodes of gout developed mostly in men taking diuretics, but the incidence was lower than in the hyperuricemic population. In renal transplant patients, the incidence of gout was 5–24% and tophi sometimes developed rapidly after the onset of gout (63). The potential mechanisms of hyperuricemia include reduced renal function and impaired tubular secretion of acid uric, with hypertension and diuretics as confounding factors (SEDA-21, 383).

Nutrition

Higher plasma homocysteine concentrations, which may contribute to atherosclerosis, have been found in patients taking ciclosporin, compared with both transplant patients not taking ciclosporin and non-transplant patients with renal insufficiency (SEDA-20, 344).

Electrolyte balance

Mild and uncomplicated hyperkalemia is commonly observed in patients taking ciclosporin and is generally prevented by a low potassium diet. A reduction in distal nephron potassium secretion and tubular flow rate, with insensitivity to exogenous mineralocorticoids, and leakage of cellular potassium into the extracellular fluid are possible mechanisms (SED-13, 1124) (64).

Mineral balance

Hypomagnesemia and hypercalcemia occur infrequently during ciclosporin treatment (SED-13, 1124).

- In a 43-year-old renal transplant patient, hypomagnesemia was associated with muscle weakness and a near four-fold increase in serum creatine kinase activity (65). Both disorders resolved after magnesium supplementation, and ciclosporin was continued.

Renal magnesium wasting occurred in 24% of a series of renal transplant patients taking ciclosporin; other indicators of renal function were normal (66,67).

Hypomagnesemia in the early post-transplant period has been cited as a possible risk factor for acute ciclosporin neurotoxicity. Ciclosporin-induced sustained magnesium depletion has been investigated in 109 ciclosporin-treated patients with renal transplants who had been stable for more than 6 months (68). Total and ionized plasma magnesium concentrations were significantly lower than in 21 healthy volunteers and in 15 patients with renal transplants who were not taking ciclosporin. Ciclosporin-treated patients who were also taking hypoglycemic drugs had lower plasma magnesium concentrations, but patients taking diuretics did not.

Hematologic

A very few cases of ciclosporin-induced immune hemolytic anemia have been reported (SED-13, 1125) (69,70), but a direct causal relation with ciclosporin is difficult to establish. Ciclosporin-induced hypercoagulability was suggested in patients with aplastic anemia (SEDA-20, 344). Higher whole-blood ciclosporin concentrations were found during the preceding months in patients who experienced thromboembolic complications compared with patients who had not.

Ciclosporin-associated thrombotic microangiopathy occurs in 3–14% of patients with a renal transplant and can cause allograft loss. Renal impairment, reflected by an increase in serum creatinine concentration, is often the only change found, and hemolysis is not always present. Plasmapheresis has been used to treat this complication (71).

- A 47-year-old multiparous Hispanic woman received a living-unrelated kidney transplant for end-stage renal disease secondary to polycystic kidney disease. On the day of transplantation she received intravenous daclizumab 1 mg/kg plus methylprednisolone 300 mg and mycophenolate mofetil 3 g/day, and on day 3 ciclosporin emulsion 4 mg/kg/day. On day 8 she developed thrombotic microangiopathy without evidence of rejection. Ciclosporin was withdrawn. Plasmapheresis with fresh frozen plasma was started. Daclizumab on day 14 was postponed for 24 hours and plasmapheresis was stopped to avoid clearance of daclizumab. Thereafter she was given tacrolimus, without recurrence of hemolysis.

Mouth and teeth

Ciclosporin-induced gingival hyperplasia was noted in the early 1980s, and subsequent studies investigated the prevalence and pathophysiology of this adverse effect (SED-13, 1127). The reported incidence was 7–70%, and clinically significant gingival overgrowth, that is to say requiring treatment or surgical excision, affected about 30% of patients within the first 6 months of treatment (72). Clinical and histological features are similar to those associated with phenytoin or nifedipine. Compared with control specimens, ultrastructural gingival examinations in patients taking ciclosporin showed many fibroblasts, abundant amorphous substance, and marked plasma cell infiltration (73). Although an imbalance between the production and removal of collagen is supposed to account for gingival hyperplasia, the mechanism of ciclosporin-induced gingival overgrowth has not yet been clearly established. Possible local lymphocyte resistance to ciclosporin resulting in an increasing number of several inflammatory cells in the gingival lamina propria and ciclosporin-induced inhibition of prostaglandin I_2 synthesis have also been suggested (74,75).

There are many susceptibility factors for ciclosporin-induced gingival hyperplasia. The duration of treatment and the cumulative dose during the first 6 months play a major role. Accordingly, reduction of the ciclosporin dose can lessen the risk, and the use of lower doses is thought to reduce the overall incidence (76,77). There is also a positive correlation between the degree of gingival hyperplasia and changes in renal function (78). There are conflicting findings regarding the effects of blood concentrations on the incidence of gingival hyperplasia, and no clear relation between saliva and blood ciclosporin concentrations has been found. Lower age correlated significantly with the presence of gingival hyperplasia and children under 6 years of age are more susceptible to the complication in severe form (76,79). Male sex is a predisposing factor, a finding supported by the report of an

© 2006 Elsevier B.V. All rights reserved.

increased androgen metabolism in gingival hyperplasia induced by ciclosporin (80). There has been also speculation concerning genetic differences in the susceptibility to develop these changes (72) (SEDA-21, 384). Finally, the combination of ciclosporin and nifedipine is additive with an increased prevalence and/or severity of gingival hyperplasia (SED-13, 1127) (76,77,80–82). As several other calcium channel blockers can produce gingival overgrowth, more frequent gingival hyperplasia should be expected, at least theoretically, when these drugs are combined with ciclosporin.

It is not yet clearly established whether bacterial plaque, gingival bleeding index, or inflammation are the cause or result of gingival hyperplasia. Certainly, poor oral health with subsequent local inflammation appears to be a contributing factor. Consequently, careful dental hygiene with plaque control is often sufficient to improve or resolve hyperplasia, but surgical treatment is sometimes necessary. Preliminary case reports have suggested that azithromycin or metronidazole can improve ciclosporin-induced gingival hyperplasia (SEDA-19, 350). This has been confirmed for azithromycin, with no indication that ciclosporin blood concentrations are modified during a short course of azithromycin (SEDA-22, 414).

Gastrointestinal

Gastrointestinal symptoms due to ciclosporin are usually mild and transient. In rheumatoid arthritis, gastrointestinal intolerance has been reported in 50% of patients, being the main cause for withdrawal of ciclosporin in 8% (83). Whereas worsening colitis did not occur in patients with inflammatory bowel disease, ciclosporin was involved in the development of acute colitis in isolated reports (SED-13, 1125).

Liver

There was at least one episode of hepatotoxicity in 228 of 466 patients (49%) with renal transplants who took ciclosporin; 110 (48%) had hyperalbuminemia, 108 (47%) a raised aspartate transaminase, and 167 (59%) a raised alkaline phosphatase (84). Ciclosporin dosage reduction resulted in resolution of hepatotoxicity in 185 patients (81%), while 32 (14%) had recurrent or persistent liver function abnormalities. Eleven (2.4%) developed biliary calculous disease. The serum ciclosporin concentration was high among the patients with hepatotoxicity. Pharmacokinetic studies showed an increased AUC in the patients with hepatotoxicity, probably due to reduced drug clearance.

A causal association has been shown between the hepatotoxicity of ciclosporin and cold ischemic liver damage that can occur during preservation before liver transplantation (85). This presents a problem when ciclosporin is used after liver transplantation. In more than 1000 patients there was an incidence of mild reversible hepatotoxicity of 40% in patients taking 5-fluorouracil and levamisole as adjuvants for more than 1 year; the incidence of mild hepatotoxicity in those taking levamisole alone and amongst those receiving no treatment at all was the same, a little over 16% (86).

Experiments with isolated human hepatocytes have shown that ciclosporin competitively inhibits the uptake of cholate and glycocholate bile acids; the biological features of ciclosporin-associated hepatotoxicity are therefore mostly those of cholestasis, with reduced bile excretion (87). The presence of underlying chronic viral hepatitis can increase the severity of ciclosporin-induced cholestasis (88).

Ciclosporin can cause cholestasis and cellular necrosis by an inhibitory effect on hepatocyte membrane transport proteins at both sinusoidal and canalicular levels. It induces oxidative stress by accumulation of various free radicals. Ademetionine (*S*-adenosylmethionine) is a naturally occurring substance that is involved in liver detoxification processes. The efficacy of ademetionine in the treatment and prevention of ciclosporin-induced cholestasis has been studied in 72 men with psoriasis (89). The patients who were given ciclosporin plus ademetionine had low plasma and erythrocyte concentrations of oxidants and high concentrations of antioxidants. The authors concluded that ademetionine may protect the liver against hepatotoxic substances such as ciclosporin.

A possible consequence of bile acid abnormalities and cholestasis associated with ciclosporin is the development of cholelithiasis in liver transplant patients when the donor has pre-existing susceptibility for cholesterol gallstone formation or abnormalities of bile composition.

- A young patient who received a liver from a 78-year-old donor subsequently developed cholesterol gallstones (SEDA-21, 383).

In a retrospective study in 50 consecutive patients who received both parenteral nutrition and glucocorticoids, with or without the addition of ciclosporin, at some stage in their management, there was no evidence that ciclosporin caused more liver dysfunction than that associated with parenteral nutrition (90).

Urinary tract

The renal toxicity of ciclosporin has been described as being an adverse effect of the drug on the compensatory mechanisms of the kidney, without effects on proximal tubular function (urea and sodium reabsorption) (91). A rise in serum creatinine concentration may be adequate to identify acute-onset ciclosporin nephrotoxicity, but it is not suitable for identification of chronic, late-onset ciclosporin nephrotoxicity (92).

Presentation

Acute renal impairment

Acute ciclosporin-induced nephrotoxicity, causing reduced renal function, develops within the first month, and includes a dose-related rise in serum creatinine concentrations and hyperkalemia. Fatal acute tubular necrosis has also been noted after very high intravenous doses (SEDA-19, 345). Although it is clinically often difficult to differentiate from acute allograft rejection in renal transplant patients, the alteration in renal function promptly resolves on ciclosporin withdrawal or dosage reduction, and initial acute renal insufficiency is not clearly associated with the development of subsequent chronic renal dysfunction (93). Several conditions, such as pre-existing hypovolemia, concomitant diuretic treatment, or renal artery stenosis, are susceptibility factors.

© 2006 Elsevier B.V. All rights reserved.

Hypothyroidism was thought to be involved in one patient (94), and the transplanted kidney itself rather than interindividual differences between recipients was thought to play a role (SEDA-21, 384).

Hemolytic–uremic syndrome and thrombotic microangiopathy

Hemolytic–uremic syndrome, with histological findings of thrombotic microangiopathy and possible evolution to graft loss or death, is another instance of very severe acute nephrotoxicity (SED-13, 1125). It usually occurs at between the second and fourth weeks after transplant, with associated fever, thrombocytopenia, erythrocyte fragmentation, neurotoxicity, and renal impairment. Uncommon clinical features have been reported.

- In two women, hemolytic–uremic syndrome was apparently revealed by an episode of severe acute depression (95).
- In another patient, a single injection of ciclosporin may have induced the development of fibrin thrombi seen in the perioperative graft biopsy (96). Later on, she was confirmed to have clinical and biological features of hemolytic–uremic syndrome, which reversed after ciclosporin withdrawal.

Hemolyti–uremic syndrome has also been reported during ciclosporin treatment for Behçet's disease (SEDA-21, 384). Both early and delayed hemolytic–uremic syndrome can occur after transplantation, and its actual incidence may have been underestimated. Thrombotic microangiopathy with clinical features of hemolytic–uremic syndrome was found in 3.5–5% of renal transplant patients (97,98). Graft loss was mostly found in patients who developed hemolytic–uremic syndrome early after transplantation, and the clinical distinction from acute rejection can be very difficult. Hemolytic–uremic syndrome does not recur after initial withdrawal and further ciclosporin reintroduction, once renal function has normalized, or even despite ciclosporin maintenance with dosage reduction (SED-13, 1125) (SEDA-20, 345). In some cases, the patient was successfully switched to tacrolimus, and only one case of hemolytic–uremic syndrome with recurrence on ciclosporin rechallenge has been reported (SEDA-21, 384). In contrast, both ciclosporin and tacrolimus were significant susceptibility factors for recurrence of hemolytic–uremic syndrome in patients who had undergone renal transplantation for end-stage renal disease (99).

The factors that contribute to the development of thrombotic microangiopathy have been retrospectively investigated in 50 of 188 patients with kidney or kidney + pancreas allografts who underwent graft biopsies and in 19 control patients who had never had renal graft dysfunction or a biopsy (100). There were definite histological features of thrombotic microangiopathy 4 days to 6 years after transplantation in 26 patients, of whom 24 were taking ciclosporin and two were taking tacrolimus, showing that this complication can occur at any time after transplantation. Eight patients had graft loss, but only two had associated systemic evidence of microangiopathy, that is thrombocytopenia and intravascular hemolysis, suggesting that thrombotic microangiopathy should be considered in any patients with renal graft dysfunction, even if there are no suggestive systemic symptoms. Although the more frequent use of the microemulsion form of ciclosporin (Neoral) in patients with confirmed thrombotic microangiopathy than in controls suggested a possible role of this formulation, this issue remains to be further investigated, because the number of evaluable patients was small. None of the other investigated variables (age, sex, race, living-related or cadaveric donor status, the degree of HLA mismatch, the type of allograft, or the incidence of urinary tract infections after transplantation) was significantly associated with the occurrence of thrombotic microangiopathy compared with patients without thrombotic microangiopathy. Finally, the most successful strategy was a switch from ciclosporin to tacrolimus, which resulted in normalization of graft function in 81% of these patients.

Chronic renal insufficiency

Chronic renal impairment, as first reported in cardiac transplant patients (101), is of major concern, because of possible irreversible renal dysfunction. A considerable amount of work has subsequently accumulated on the development of progressive renal dysfunction in patients receiving long-term ciclosporin for organ transplantation or chronic inflammatory disease (SED-13, 1125) (SEDA-20, 345) (SEDA-21, 384) (SEDA-22, 413), and there have been several comprehensive reviews (102–105). About one-third of all patients have increased serum creatinine concentrations and reduced glomerular filtration rate during ciclosporin maintenance therapy. The histopathological features of chronic nephropathy consist mostly of non-specific tubular atrophy and interstitial fibrosis (106); arteriolar lesions are considered very suggestive of ciclosporin nephrotoxicity. The prevalence of renal damage due to ciclosporin has fallen considerably since the use of lower doses. Arteriolopathy sometimes improves after reducing or withdrawing ciclosporin. Morphological features in patients with autoimmune diseases are non-specific, and include a wide range of lesions, mostly characterized by tubulointerstitial changes and arteriolopathy. There is no significant correlation between histological findings and ciclosporin dose. Severe histological lesions can be identified in some patients with normal renal function (107); the severity of tubulointerstitial lesions has been deemed to be a better index than the glomerular filtration rate for predicting the occurrence of chronic nephropathy, but in one study there was no correlation between histological renal findings and various measures of renal function (108).

Because the possibility of irreversible renal dysfunction is a major problem in ciclosporin maintenance in both transplant and non-transplant patients, this issue continues to receive attention. Even though many studies have been performed, the long-term prognosis is a source of conflicting opinions, and the initial assumption that long-term use of ciclosporin will sooner or later cause irreversible chronic nephropathy is hotly debated. It is still unclear to what extent long-term ciclosporin contributes to progressive renal insufficiency and whether chronic ciclosporin nephropathy is irreversible or improves after dosage reduction. A retrospective analysis

© 2006 Elsevier B.V. All rights reserved.

of more than 12 000 renal transplant patients showed that long-term maintenance with a glucocorticoid-free ciclosporin regimen (ciclosporin alone or with azathioprine) significantly increased renal graft and patient survival, compared with patients taking other immunosuppressive regimens (109). This allowed the use of higher doses of ciclosporin without increasing the frequency of nephrotoxicity. In contrast, several investigators have considered a change to a ciclosporin-free regimen in 40% of patients, because of progressive renal deterioration with histological signs of nephrotoxicity (110). The incidence of end-stage renal insufficiency requiring dialysis or renal transplantation ranges from 1% in renal transplant patients to 3–6% in heart-transplant patients (111–114). Nevertheless, several investigators have shown that despite an initial reduction in renal function, serum creatinine concentrations stabilized with no strong evidence of progressive nephropathy after several years of surveillance in various organ transplant patients (93,112,115–117).

The potential long-term consequences of ciclosporin nephrotoxicity constitute a major disadvantage in non-transplant patients. Renal function was assessed 7 years after the end of a 1-year ciclosporin treatment period in 36 young patients from a randomized, placebo-controlled trial of ciclosporin in diabetes mellitus, 19 taking ciclosporin, and 17 taking placebo (118). Blood pressure did not differ between the groups. Compared with baseline values, urinary albumin excretion rate was significantly higher and estimated glomerular filtration rate significantly lower with ciclosporin. The results in the placebo group showed no change or increases. In addition, there was progression to micro- or macro-albuminuria in four patients taking ciclosporin, and two of five patients who underwent renal biopsy had arteriolar hyalinosis. It is not known whether these changes will translate to an increased risk of nephropathy, but they suggest that ciclosporin might enhance it. Of 91 consecutive patients with renal transplants with a minimum graft survival of 1 year who were followed for 7–8 years, 65% had stable renal function despite ciclosporin serum concentrations of 200–250 ng/ml (119). In addition, none of the 26 patients with worsening renal function had features of ciclosporin nephrotoxicity on renal biopsy.

Frequency

In a meta-analysis of 18 trials involving ciclosporin doses below 10 mg/kg/day for at least 2 months in autoimmune diseases, the weighted percentage increase in serum creatinine concentrations was 17% in ciclosporin-treated patients and 1.7% in controls (120). The corrected risk difference for an increase of more than 50% of pretreatment serum creatinine concentrations between the two groups was 21% (95% CI = 12, 30) (120). This meta-analysis did not fully consider the long-term outcome, but clinical and histological evidence of sustained or progressive ciclosporin nephropathy in this population continues to accumulate. Unfortunately, some of the findings are discordant (107,121–130).

In a retrospective study of 106 patients following renal transplantation who had been treated with ciclosporin, 85% were hypertensive compared with 54% of patients taking azathioprine (131). Renal function was significantly better in hypertensive patients treated with nifedipine than with other antihypertensive medication (beta-blockers and vasodilators), and it was similar to that of normotensive patients treated with ciclosporin.

Pathophysiology

The pathogenesis of chronic ciclosporin nephrotoxicity is not fully understood (105). Intrarenal afferent arteriolar vasoconstriction may play an important part, particularly in acute nephrotoxicity (132), in which a marked reduction in renal blood flow associated with an increase in renal vascular resistance, probably due to postglomerular vasoconstriction, has been demonstrated (133,134). The supposed mechanism is primarily an imbalance between several regulatory mechanisms of renal vasodilatation and vasoconstriction, leading to increased renal vasoconstriction, and the explanations that have been proposed include activation of the renin–angiotensin system, prostaglandin inhibition, and sympathetic nervous system activation (135). However, it is unclear whether a continuous increase in renal vascular resistance can account for chronic renal dysfunction in patients taking long-term ciclosporin. There are many possible mediators of renal vasoconstriction, for example nitric oxide, the renin–angiotensin and kallikrein–kinin systems, endothelin-1 release, and stimulation of sympathetic nervous system activity. A major effect of ciclosporin is to promote calcium accumulation in the mitochondrial matrix, which in turn reduces ATP synthesis (136). The main morphological abnormality that has been demonstrated in the kidneys of patients taking long-term ciclosporin is interstitial fibrosis. Vascular lesions, predominantly arteriolar, with arterial intimal fibrosis have been noted in renal biopsies from patients with chronic ciclosporin nephrotoxicity (137).

Renal morphology has been studied in 17 patients who received ciclosporin for sight-threatening uveitis. Most had not received other potentially nephrotoxic drugs. Variable interstitial fibrosis, frequently associated with tubular atrophy, was noted in all 17. The extent of the pathological changes did not correlate with the age, treatment duration, or average cumulative dose (138). Ciclosporin nephrotoxicity mimics the histological features of acute allograft rejection and tubular necrosis. It is important to be able to distinguish clinically between ciclosporin toxicity on the one hand (necessitating a reduction in dose) and rejection (requiring an increase in dose) on the other.

The long-term effects of ciclosporin on renal function in 11 liver transplant recipients were evaluated over a follow-up period of 6–26 months (135). Immediately postoperatively, glomerular filtration rate (GFR) and effective renal plasma flow (ERPF) fell by 60%, subsequently settling at 45–60% of normal. There were additional toxic effects on renal tubular function. Histopathological findings were mild to moderate; notably, arterial and arteriolar nephrosclerosis. Renal function improved as the dose of ciclosporin was reduced, despite continued administration of the drug. This suggests a persistent, potentially reversible, functional component to chronic ciclosporin nephrotoxicity.

© 2006 Elsevier B.V. All rights reserved.

The respective roles of organ preservation and ciclosporin in the pathogenesis of post-transplant renal damage have been studied in an in vitro model that simulates the hypothermic kidney preserved before surgery in Collins' solution and exposed after transplantation to ciclosporin (139). The results showed that preservation sensitizes the kidney to ciclosporin injury, which is consistent with clinical experience (140). If the preserved kidney cells were given a period of repair before administration of ciclosporin, further injury did not happen. In animal experiments, prolonged cold preservation causes progressive deterioration in the renal cortical microcirculation; concentration of ciclosporin in the renal cortex of hypoperfused kidneys markedly potentiates the vascular damage caused by cold preservation (131).

Large-scale studies with long periods of follow-up have emphasized the major role of graft arteriopathy (chronic graft rejection) rather than chronic ciclosporin nephrotoxicity as the primary cause of graft failure (111,116,141). Severe ciclosporin nephropathy was the cause of renal transplant failure in less than 1% of patients.

Susceptibility factors and prediction

Many factors have been postulated as being relevant to ciclosporin nephrotoxicity. Whereas in several studies initial high doses of ciclosporin increased the risk of chronic nephrotoxicity (115,121), others suggested that patients maintained on relatively high ciclosporin concentrations had no more chance than others of developing toxic nephropathy (116). Neither the daily dose nor the duration of ciclosporin treatment reasonably predicts the risk of chronic renal insufficiency. Chronic renal dysfunction can be observed, despite the maintenance of ciclosporin blood concentrations below 400 ng/ml. However, age, sustained hypertension, hypertriglyceridemia, low HDL cholesterol concentrations, and recurrent episodes of severe acute nephrotoxicity increase susceptibility to chronic ciclosporin nephrotoxicity (122,142).

From a prospective study in 36 heart transplant patients with stable renal function for at least 6 months after transplantation, it was suggested that high urinary retinol-binding protein concentrations may indicate tubulointerstitial damage and therefore detect patients who are at risk of ciclosporin nephrotoxicity (143). At the start of the study, 13 patients had high urinary retinol-binding protein concentrations and 23 had normal concentrations. After 5 years of follow-up, five of the 13 patients developed end-stage renal insufficiency requiring dialysis, whereas none of the 23 other patients had terminal renal insufficiency. Although these data await confirmation, the authors suggested that ciclosporin dosage reduction should be considered in patients with high urinary retinol-binding protein concentrations, in order to limit renal damage.

Ciclosporin can cause tubulointerstitial lesions, the pathogenesis of which is unclear. In 37 patients, the duration of ciclosporin treatment and of heavy proteinuria were independent risk factors for ciclosporin-induced tubulointerstitial disease (144).

Management

The possible risk of precipitating end-stage renal insufficiency should not be regarded as a major limitation to ciclosporin treatment in organ-transplant patients, and no matter how defective our knowledge of the susceptibility factors is, attempts must be made to prevent or manage ciclosporin nephrotoxicity. Delaying the introduction of ciclosporin until post-transplant renal function has returned to normal and reducing the dose of ciclosporin when increases in serum creatinine concentrations are more than 30% above baseline values are measures that may well reduce the risk of acute nephrotoxicity. In the long term, switching patients from ciclosporin to azathioprine, reducing ciclosporin doses, or even electively withdrawing ciclosporin have been suggested as helpful measures, but they should be regarded cautiously and set against the risk of rejection (145–149). Once-daily dosing of ciclosporin in the morning improves glomerular filtration rate and renal blood flow compared with half the dose taken twice daily (150). Despite evidence for a very similar profile of nephrotoxicity, conversion from ciclosporin to tacrolimus has been used successfully (SEDA-20, 347).

Finally, several drugs have been investigated in experimental and clinical studies to prevent ciclosporin nephrotoxicity. Calcium channel blockers, such as nifedipine, diltiazem, or verapamil, have repeatedly been proposed as reliable adjunctive drugs to minimize the long-term nephrotoxic effects of ciclosporin in renal transplant patients. Among anti-ischemic drugs, trimetazidine might be a good choice, because it prevents the loss of ATP synthesis caused by ciclosporin in rat kidney cells. S-15176 and S-16950 are trimetazidine derivatives that antagonize the mitochondrial toxicity of ciclosporin without changing its immunosuppressive effects.

Viewing the evidence as a whole, it appears that the use of lower doses of ciclosporin is probably the most important factor accounting for the fact that the majority of patients on long-term ciclosporin do not today have evidence of progressive nephrotoxicity.

Skin

Mild flushing often occurs during ciclosporin treatment, but more severe extensive erythema is uncommon.

- Recurrent episodes of diffuse flushing of the arms, the face, and the trunk reportedly occurred about 2 hours after each dose of ciclosporin in a 24-year-old man who had received a renal transplant 6 years before (151). These episodes were noted from the beginning of treatment, but worsened after he changed to Neoral, the microemulsion form of ciclosporin, and completely resolved after ciclosporin was replaced by tacrolimus.

Ciclosporin sometimes causes chronic inflammatory dermatitis, and there have been two reports of four male transplant recipients who developed clinical and histopathological features of keloid acne of the posterior scalp or neck (152,153). *Staphylococcus aureus* infection was identified in three. Ciclosporin-induced hypertrichosis was suggested as a possible cause, with local bacterial infection and immunosuppression as trigger factors.

- Multiple, large epidermoid cysts have been described in a 23-year-old man taking ciclosporin (154).

Acute generalized pustular psoriasis occurred 1 week after ciclosporin withdrawal in a 32-year-old woman

© 2006 Elsevier B.V. All rights reserved.

who had taken ciclosporin for 12 weeks for chronic plaque psoriasis (155). This is in keeping with a similar phenomenon sometimes observed after glucocorticoid withdrawal.

Coarsening of facial features and a possibly more frequent occurrence of acne vulgaris and keratosis pilaris have been described in children taking ciclosporin (SED-8, 1125) (156). In 19 children who took ciclosporin and prednisone after renal transplantion, there was coarsening of facial features with thickening of the nares, lips, and ears, puffiness of the cheeks, prominence of the supraorbital ridges, and mandibular prognathism; this was found in all the children who had been treated for 6 months (157). Although the concurrent use of glucocorticoids may play a role in the development of acne, resolution of severe acne was in one reported case attained only after ciclosporin withdrawal (SEDA-20, 345). Convincing but anecdotal evidence of the worsening of subcutaneous sarcoidosis has been reported (SEDA-22, 384).

Sebaceous glands

Juxtaclavicular beaded lines are unique malformation of sebaceous glands or a variant of sebaceous hyperplasia.

- A 63-year-old man developed small, asymptomatic, linear papules over the neck and clavicles. He had taken prednisone and ciclosporin for 30 months after kidney transplantation (158). A skin biopsy showed sebaceous hyperplasia.

The pathogenesis of juxtaclavicular beaded lines is unclear. Some authors have reported a prevalence of 16% in heart transplant patients, but only in men. Because ciclosporin is highly lipophilic, it has many adverse effects associated with alterations of pilosebaceous follicles, such as hypertrichosis and acne. In this case the authors postulated that the combined effect of prednisone and ciclosporin may have induced sebaceous gland hyperplasia.

Hair

Widespread hypertrichosis is one of the most common complications of ciclosporin, and distichiasis (accessory eyelashes) has been reported in one patient (SEDA-20, 345). Ciclosporin-associated soft tissue proliferation with an abnormal hyperplastic reaction has been suggested to account for the development of hyperplastic pseudofolliculitis barbae (159).

Alopecia areata or alopecia totalis has been noted in isolated cases (SEDA-21, 384).

A white-headed man noted progressive darkening of the hair while taking ciclosporin (160).

Nails

Several nail changes (excess granulation tissue or ingrowing toenails) have been attributed to ciclosporin (SED-13, 1127).

- Marked pitting with Mees' lines (homogeneous transverse white lines in the nail plates) in the fingernails, a disorder that has not been previously reported, was attributed to ciclosporin-associated kidney dysfunction in a 41-year-old man who inadvertently took ciclosporin 300 mg/day for psoriasis (161).

Musculoskeletal

Muscle disorders attributed to ciclosporin have been mostly described in anecdotal case reports (SED-14, 1291). In an analysis of published or spontaneous case reports, the manufacturers found 29 cases of muscle disorders in patients taking ciclosporin; the complications fell into two categories (162). Myopathic symptoms, that is myalgia and muscle weakness without rhabdomyolysis, were reported in 0.17% of patients and abated after dose reduction or treatment withdrawal. Rhabdomyolysis occurred in under 0.05% of patients and was mostly observed in patients taking other drugs, such as lovastatin or colchicine.

This topic has been re-analysed in a systematic review of published papers, in which relevant information from a total of 34 patients was identified (163). All but two patients were also taking concomitant drugs known to affect the muscles, among which glucocorticoids, simvastatin, lovastatin, colchicine, and pyrazinamide were the most frequently cited. Ciclosporin is therefore difficult to implicate in most patients, but at least one case with positive ciclosporin re-administration supported a causative role. The clinical picture was non-specific, with myalgia, cramps, and muscle weakness, sometimes associated with raised serum creatine kinase activity, and heterogeneous histopathology. Finally, skeletal muscle abnormalities have rarely been described in patients without muscle symptoms.

Ciclosporin is increasingly cited as a possible cause of severe bone and joint pain (164). Acute bilateral deep bone pain, mostly involving the legs, has been retrospectively identified in 19% of patients taking ciclosporin, with the highest prevalence in renal transplant recipients (165). In addition, about half of the patients with osteonecrosis had a history of episodic bone pains. Another study showed features of acute bone marrow edema on MRI in six patients who had bone pain, including one patient who further developed avascular necrosis (SEDA-21, 385). Calcium channel blockers dramatically improved bone pain in prospectively evaluated transplant patients, suggesting a possible vascular etiology (165).

Osteopenia is another potential adverse effect after renal transplantation, but the possible contribution of ciclosporin to bone loss and subsequent osteoporosis is controversial (SEDA-19, 350) (SEDA-20, 345). Moreover, ciclosporin did not appear to have a negative influence on post-transplantation growth in prepubertal children (166).

Both ciclosporin and tacrolimus cause increased bone turnover and significant reductions in bone mass, more marked with tacrolimus (FK506). As most transplantation regimens include glucocorticoids, the individual effects of ciclosporin and tacrolimus are uncertain. As tacrolimus is the more potent immunosuppressant, theoretically, its use after transplantation should allow reduction in glucocorticoid doses, which would be associated with higher bone mineral density. Preliminary data suggest that there is a lower rate of vertebral fractures in patients taking tacrolimus compared with those taking ciclosporin. In 18 men who underwent liver transplantation and took ciclosporin and seven patients who took tacrolimus, bone mineral density in the lumbar spine and proximal femur was

© 2006 Elsevier B.V. All rights reserved.

prospectively measured before and at 6, 12, and 24 months after transplantation (167). Serum concentrations of parathyroid hormone and 25-hydroxycolecalciferol were determined at the same time. Although the two groups had the same pattern of rapid early bone loss, tacrolimus was associated with lower doses of glucocorticoids and a trend to faster lumbar bone mass recovery. This may have a favorable effect on long-term bone mass evolution, especially in the femoral neck.

Reproductive system

Benign mammary hyperplasia occurs in 0.7% of women taking ciclosporin (168). The mechanism is poorly understood, but it may be related to trophic effects in the breast through ciclosporin receptors on fibroblasts (169), to an effect of ciclosporin on the hypothalamic-pituitary axis (170), or to antagonism at prolactin receptor sites on B and T (171,172).

Immunologic

Anaphylactoid reactions can occur with intravenous ciclosporin, sometimes after the first dose. Reported symptoms included pruritic rash, respiratory symptoms, chest pain, and, rarely, cardiopulmonary arrest. The presence of Cremophor EL, polyoxyethylated castor oil used as a solvent, is likely to account for this life-threatening reaction. The mechanism is still unclear, and results of skin tests were available in only three of 22 previously published patients.

In a report of an anaphylactic reaction, positive intradermal tests suggested a possible IgE-mediated reaction, most probably directed against Cremophor EL, as the patient subsequently tolerated the corn-oil-based soft gelatin formulation (173).

During a Phase I/II trial of high-dose intravenous ciclosporin, there was a high incidence of anaphylactoid reactions associated with improper mixing during preparation of the infusions, perhaps due to large initial bolus infusions of the vehicle, Cremophor EL (174).

Infection risk

Infections, in particular bacterial and viral (cytomegalovirus, *Herpes simplex* virus, Epstein–Barr virus), and also protozoal and fungal infections, are major causes of morbidity and mortality after transplantation, whatever the immunosuppressive regimen used (175–177). Based on an analysis of medical and autopsy records, infections were found to be the cause of death in 70% of transplant patients, with bacteria (50%) or fungi (29%) the most common pathogens (178).

Body temperature

Recurrent episodes of fever, which disappeared after ciclosporin withdrawal, have only been reported in one patient (SEDA-22, 414).

Long-Term Effects

Mutagenicity

An increase in chromosomal abnormalities correlated with serum ciclosporin concentrations in one study (179).

Tumorigenicity

Because of the varied indications for azathioprine and mercaptopurine, it is difficult to determine whether there is an increased incidence of cancer specifically related to prolonged drug exposure. Data from the Cincinnati Transplant Tumor Registry, published in 1993, helped to define comprehensively the characteristics of neoplasms observed in organ transplant recipients (180). Skin and lip cancers were the most common, and non-Hodgkin's lymphomas represent the majority of lymphoproliferative disorders, with an incidence some 30- to 50-fold higher than in controls. There is also an excess of Kaposi's sarcomas (181), carcinomas of the vulva and perineum, hepatobiliary tumors, various sarcomas, and renal cell carcinomas (182–184). In one case, complete regression of Kaposi's sarcoma followed withdrawal of ciclosporin (185). In contrast, the incidence of common neoplasms encountered in the general population is not increased. In renal transplant patients, the actuarial cumulative risk of cancer was 14–18% at 10 years and 40–50% at 20 years (186,187). Skin cancers accounted for about half of the cases. Very similar figures were found in later studies (SEDA-20, 341).

In patients with transplanted organs ciclosporin is associated with a small but significant risk of Epstein–Barr virus-associated lymphoproliferative disorders.

- A 39-year-old man with atopic eczema was given ciclosporin for an exacerbation, which responded well (188). After 2 years he developed a large ulcerated erythematous nodule, a CD30+ lymphoma of the skin. Ciclosporin was withdrawn and the lesion resolved within 2 months.

Of all transplant-related lymphomas 15% are of T cell origin and are unrelated to Epstein–Barr virus infection. Cutaneous T cell lymphomas are rare and carry a good prognosis, with a 90%, 4-year survival rate. Regression is often observed when immunosuppression is withdrawn or reduced.

While there is no doubt that the incidence of malignancies is increased in the transplant population, there has been controversy as to which factors (namely duration of treatment, total dosage, the degree of immunosuppression, or the type of immunosuppressive regimens) are the most relevant in determining risk. Partial or complete regression of lymphoproliferative disorders and Kaposi's sarcomas after reduction of immunosuppressive therapy argues strongly for the role of the degree of immunosuppression (180). The incidence of cancer was also significantly higher in renal transplant patients taking triple therapy regimens compared with dual therapy (189). Similarly, aggressive immunosuppressive therapy may account for the higher incidence of lymphomas in patients with cardiac versus renal allografts.

In a large, multicenter study in more than 52 000 kidney or heart transplant patients between 1983 and 1991, the rate of non-Hodgkin's lymphomas in the first post-transplantation year was 0.2% in kidney and 1.2% in heart recipients, and fell substantially thereafter

© 2006 Elsevier B.V. All rights reserved.

(190). Initial immunosuppression with azathioprine and ciclosporin, and prophylactic treatment with antilymphocyte antibodies or muromonab was associated with a significantly increased incidence of non-Hodgkin's lymphomas compared with other immunosuppressive regimens, which confirmed the major role of the level of immunosuppression. Later studies confirmed that immunosuppression per se rather than a single agent is responsible for the increased risk of cancer (SEDA-20, 340). Finally, the most striking difference between conventional and modern immunosuppressive regimens, including ciclosporin, was the average time to the appearance of tumors, in particular skin cancers and lymphomas, which was shorter in ciclosporin-treated patients (191,192).

Multiple factors with complex interactions are involved in the observed pattern and increased incidence of neoplasms. They include severely depressed immunity with an impaired immune surveillance against various carcinogens, the activation of several oncogenic viruses, and a possible mutagenic effect of the drugs. Viruses, such as papillomavirus, cytomegalovirus, and Epstein–Barr virus, are believed to play an important role in the development of several post-transplant cancers. From a theoretical point of view, the use of antiviral drugs active against herpes viruses which are commonly implicated as co-factors can be expected to produce a reduction in the incidence of post-transplant lymphoproliferative disorders.

In an in vitro and in vivo experiment, ciclosporin promoted tumor growth by a direct cellular effect (193). This was suggested to be due to increased synthesis of transforming growth factor beta (TGF beta); anti-TGF beta antibodies blocked the increased spread of cancer cells. The clinical relevance of these data awaits further careful clinical confirmation. Continuing analysis of clinical experience has not provided clear evidence for a ciclosporin-specific effect and has instead supported an immunosuppressive effect (194).

Fibroadenomata are the most common solid breast masses in young women. Between 1997 and 2000, five women who had had transplant surgery and who were taking ciclosporin developed new breast masses, which were histologically confirmed to be fibroadenomata (195).

Ciclosporin-associated soft tissue proliferation with an abnormal hyperplastic reaction has been suggested to account for the development of eruptive angiomatosis (196).

Second-Generation Effects

Pregnancy

Pregnancies in women who took ciclosporin resulted in live neonates in 68%; half were premature while the other half were of low birth weights (197). Reduced renal graft function during pregnancy was associated with greater risks of neonates of lower birth weights and graft loss. In another study, a ciclosporin-based regimen was associated with more frequent miscarriage, preterm birth and intrauterine growth retardation, compared with previous experience (198).

It has been suggested that ciclosporin is more likely to induce maternal renal dysfunction or pre-eclampsia than tacrolimus, but this view was based on a comparison involving only a small number of patients (SEDA-22, 414).

Teratogenicity

Maternal azathioprine treatment during pregnancy is clearly teratogenic in animals, but the mechanisms are not known. A large number of reports have described the outcome of pregnancies following the use of immunosuppressant drugs, in particular in renal transplant patients, and hundreds of pregnancies have been analysed (199). The largest experience is that derived from the National Transplantation Pregnancy Registry which has been built up in the USA since 1991 (200). This registry has accumulated data on more than 900 pregnancies, of which 83% followed kidney transplantation and in this and other studies there was no difference in the rate of malformations when comparing ciclosporin with other immunosuppressive regimens (197,198,201). Ectopic pregnancies and miscarriages seemed to occur at a similar rate as in the general population. The most common complications were frequent prematurity and more frequent intrauterine growth retardation with low birthweight. Risk factors associated with adverse pregnancy outcomes included a short time interval between transplantation and pregnancy (that is less than 1–2 years), graft dysfunction before or during pregnancy, and hypertension (202).

There have been no reports that physical and mental development or renal function are altered. In one study, there were changes in T lymphocyte development in seven children born to mothers who had taken azathioprine or ciclosporin, but immune function assays were normal (203). Thus, development of the fetal immune system is not affected by ciclosporin (204).

Renal function in 14 children born to women with transplants treated throughout pregnancy with a ciclosporin-based regimen has been extensively investigated at a mean of 2.6 years after delivery (205). No renal function abnormalities were found. In particular, glomerular filtration rate was within the reference range. Renal function was found to be normal in 22 children evaluated after a mean of 39 months after birth (206), and no adverse effects on the immune function were identified in the few infants examined in this respect (203).

In a meta-analysis of the effects of exposure to ciclosporin during pregnancy, 15 studies (total 410 patients; 6 studies with control groups who were not given ciclosporin) met inclusion criteria for malformations, 10 for preterm delivery, and five for low birth weight (207). Ciclosporin did not appear to be a major human teratogen, but was associated with increased rates of prematurity.

Lactation

Ciclosporin is excreted into human breast milk and because of potential immunosuppression, breastfeeding is usually regarded as contraindicated. Reassuring reports are now however available (SEDA-21, 385). After follow-up for 12–36 months in seven breast-fed infants (duration 4–12 months) whose mothers were treated with ciclosporin, none of them experienced renal or other long-term adverse

© 2006 Elsevier B.V. All rights reserved.

consequences (208). Although ciclosporin concentrations measured in breast milk from six mothers were close to those measured in blood samples, it was calculated that the infants ingested less than 300 μg/day, and ciclosporin was not detectable in random blood samples.

Drug Administration

Drug formulations

In an attempt to overcome the poor and unpredictable absorption of the standard oral formulation, a microemulsion-based formulation (Neoral) has been developed. The benefit-to-harm balance of conversion from the standard to the microemulsion formulation have been discussed at length and guidelines for conversion have been proposed (209).

From the results of a retrospective study of 227 liver transplant patients who took Neoral as the primary immunosuppressant, it was suggested that this formulation may reduce the risk of severe neurotoxicity (210). Mild-to-moderate symptoms, that is headache ($n = 24$), mild hand tremor ($n = 13$), and paresthesia ($n = 5$), were the most frequent, whereas generalized seizures were reported in only two patients.

In one large study in 1097 patients, there was a significantly higher incidence of neurological complications, gastrointestinal disturbances, and increased serum creatinine concentrations during the first month of treatment with Neoral, compared with conventional ciclosporin (211). However, a meta-analysis showed that the adverse events profile was similar with the two formulations, while primary immunosuppression with Neoral produced significant benefit in terms of a lower incidence of rejection (212). In particular, in liver transplant patients treated with Neoral from the start, the incidence of adverse events was halved. All the same, because dosage adjustments were often required and often hazardous, owing to the risk of adverse effects and transplant rejection, other investigators concluded that switching to Neoral may be of little benefit, at least in previously stable liver transplant patients (213).

As the data from this meta-analysis were subject to many potential biases, the same authors reanalysed their results, taking into account only randomized, prospective studies (214). The incidence of adverse effects was higher with Sandimmune in open-label studies (840 patients) and higher with Neoral in blinded studies (3006 patients). In accordance with other investigators, these authors concluded that de novo immunosuppression with Neoral is beneficial, without significant differences in the incidence of adverse effects, whereas conversion from Sandimmune to Neoral in previously stable patients is associated with significantly more adverse effects with Neoral.

Drug dosage regimens

Several authors were unable to find convincing evidence that ciclosporin specifically increases the risk of tumors in transplant patients compared with previously used immunosuppressive regimens, and some even suggested a possibly lower incidence in ciclosporin-treated patients (191,192,215). However, in analyses from Japan and France (3454 patients), the average time that elapsed until the occurrence of cancer was significantly shorter in patients treated with ciclosporin compared with those taking conventional immunosuppressive treatment, that is 43–452 months versus 92–96 months (216,217). In addition, French authors found a higher cumulative risk of cancer after 10 years in ciclosporin-treated patients (14 versus 8.4%), and this was mostly due to an increased incidence of skin carcinomas (216). Other significant risk factors included age, a shorter duration of pretransplant dialysis and the combination with azathioprine treatment. The occurrence of cancer in ciclosporin-treated patients is thought to be dose-related, and one study found a significantly higher frequency of cancer in the normal than in the low-dose group (218). These positive findings were limited by the more frequent occurrence of acute rejection in the low-dose group.

Long-term ciclosporin also carries the risk of malignancies in non-transplant patients, and the overall incidence of lymphoma was estimated to be 0.14% among 3700 patients treated for autoimmune disease (219). However, the available studies are again conflicting. They are mostly based on a limited number of patients or a short duration of follow-up. Patients with rheumatoid arthritis receiving ciclosporin had an increased relative risk of malignancies compared with those given glucocorticoids, but it was similar to the risk in patients treated with disease-modifying antirheumatic drugs (220). Another study showed no increased risk of malignancies in ciclosporin-treated patients compared with controls who had never received ciclosporin (221). The spontaneous occurrence of cancers unrelated to the treatment cannot be excluded, and an increased risk of lymphomas has been repeatedly found in patients with rheumatoid arthritis. In patients with psoriasis and as compared to the expected incidence rate of cancer in this population, the relative risk of malignancies was 5.6 (95% CI = 3.9, 8.0) in a cohort of 1223 ciclosporin-treated patients (222). This was comparable to the increased risk of cancer in patients treated with other immunosuppressants.

Drug overdose

Experience with ciclosporin overdose has been reviewed by the manufacturers using published data or cases spontaneously reported (223). Accidental overdose was the most common, with doses of 20–400 mg/kg. In adults, no serious clinical consequences were observed with doses up to 100 mg/kg, and there were only minor clinical or biological effects (transient hypertension, tachycardia, headache, gastrointestinal symptoms, or slight increases in serum creatinine concentrations). However, life-threatening reactions occurred in three neonates, of whom one died after severe metabolic acidosis and renal insufficiency. Subchronic ciclosporin overdose over 8 days did not appear to cause any additional risk (224).

Taken together, the available data suggest that the acute toxicity of ciclosporin is low in adults, but that more severe intoxication could be expected in neonates. However, two reports, including one fatal case, have shown that accidental intoxication sometimes produces severe complications in adults (225,226).

© 2006 Elsevier B.V. All rights reserved.

- A 29-year-old man received a double lung transplantation for end-stage cystic fibrosis. After uneventful surgery, he was accidentally given ten times the intended dose of ciclosporin (30 instead of 3 mg/kg) and 18 hours later became anuric. His blood ciclosporin concentration was 4100 ng/ml. Hemodialysis was required for 6 weeks. A renal biopsy 7 weeks later showed typical features of acute tubular necrosis and lesions that resembled chronic nephrotoxicity. Renal function was still abnormal when he died from another cause 14 weeks after the accidental overdose.
- A 51-year-old man underwent double lung transplantation for pulmonary fibrosis, accidentally received an infusion of ciclosporin 30 mg/hour instead of 3 mg/hour, and 3 hours later had bilateral reactive mydriasis and absence of tendon reflexes. A CT brain scan showed diffuse cerebral edema, and massive intracranial hypertension rapidly developed. He died 5 hours later from brainstem compression, and pathological examination showed diffuse cerebral edema with neuronal necrosis.

The first of these cases suggested that acute renal dysfunction secondary to acute overdose can lead to renal sequelae. In the second patient, an isolated neurotoxic effect of ciclosporin was suggested because no predisposing factor except overdose was identified.

Drug–Drug Interactions

Acetazolamide

The interaction of ciclosporin with acetazolamide was previously supported by a single case report only. In three further patients, the addition of acetazolamide produced a near seven-fold increase in ciclosporin blood concentrations within 3 days (227).

Aciclovir

In an analysis of changes in ciclosporin clearance and systemic availability obtained from the medical records of 100 transplant patients, aciclovir altered ciclosporin pharmacokinetics (228).

The coadministration of ciclosporin with drugs with nephrotoxic effects carries a risk of increased renal dysfunction. Although a possible enhancement of nephrotoxicity has been suggested in patients also taking aciclovir (229), there were no such findings in a retrospective analysis of a double-blind study (230).

Aminoglycoside antibiotics

Severe nephrotoxicity has been reported in three renal transplant patients who received ciclosporin and gentamicin, and in others receiving both drugs before surgical procedures, even though toxic serum concentrations of either drug were not reached (231).

Angiotensin receptor blockers

In an analysis of changes in ciclosporin clearance and systemic availability obtained from the medical records of 100 transplant patients, losartan and valsartan altered ciclosporin pharmacokinetics (228).

Bisphosphonates

In an analysis of changes in ciclosporin clearance and systemic availability obtained from the medical records of 100 transplant patients, alendronic acid altered ciclosporin pharmacokinetics (228).

Calcium channel blockers

A large amount of data has accumulated on the effects of various calcium channel blockers on ciclosporin metabolism or a possible renal protective effect. Diltiazem, nicardipine, or verapamil inhibit ciclosporin metabolism, and this has been investigated as a potential beneficial combination for ciclosporin-sparing effects, particularly for diltiazem or verapamil (232,233). Any change in the formulation of calcium channel blockers in patients previously stabilized should be undertaken cautiously because unpredictable changes in ciclosporin concentrations can occur (234). In contrast, nifedipine, isradipine, or felodipine do not significantly affect ciclosporin pharmacokinetics (SED-13, 1129). Results obtained with amlodipine are conflicting; some studies have shown no effect, while others indicate an increase of up to 40% in ciclosporin blood concentrations (SEDA-19, 351) (SEDA-20, 345). Co-administration of calcium channel blockers is also regarded as a valuable option in the treatment of ciclosporin-induced hypertension, or to prevent ciclosporin nephrotoxicity.

There are conflicting results from studies on the protective role of calcium channel blockers in patients taking ciclosporin in regard to blood pressure and preservation of renal graft function. In a multicenter, randomized, placebo-controlled study in 131 de novo recipients of cadaveric renal allografts, lacidipine improved graft function from 1 year onwards, but had no effect on acute rejection rate, trough blood ciclosporin concentrations, blood pressure, number of antihypertensive drugs, hospitalization rate, or rate of adverse events (235).

The combination of ciclosporin with nifedipine produces an additive on gingival hyperplasia, with an increased prevalence and/or severity (SED-13, 1127) in both children (77,81) and adults (76,80,82). In contrast, verapamil had no significant additional effects on the prevalence or severity of ciclosporin-induced gingival overgrowth (SEDA-21, 385).

Chloramphenicol

Chloramphenicol was suspected of causing a dramatic increase in ciclosporin blood concentrations in a single patient (236). However, multiple concomitant confounding factors made this interaction purely speculative.

Clindamycin

In two lung-transplant patients aged 39 and 48 years, blood ciclosporin concentrations fell after the addition of oral clindamycin (1.8 g/day), and both patients required temporary increases in daily ciclosporin dose until clindamycin withdrawal (237).

© 2006 Elsevier B.V. All rights reserved.

Colchicine

The combination of colchicine with ciclosporin increased the risk of myopathy. In a retrospective study of 221 renal transplant patients, five of 10 patients who took both drugs developed acute or chronic proximal myopathy, whereas none of the 30 controls matched for age, sex, transplant duration, ciclosporin use, and cumulative dose of glucocorticoids had similar symptoms (238).

Cytotoxic drugs

High-dose chemotherapy with cyclophosphamide, vincristine, prednisolone, and intrathecal methotrexate given for post-transplant lymphoproliferative disease was suggested to have favored the occurrence of acute ciclosporin neurotoxicity (headache, fever, seizures, and visual agnosia) in a 9-year-old cardiac transplant patient (239). Ciclosporin serum concentrations were normal and a further similar episode occurred on ciclosporin readministration.

In 27 patients, ciclosporin caused a marked increase in the AUC of idarubicin and its main metabolite idarubicinol, perhaps due to inhibition of the multidrug transporter P-glycoprotein (240).

There was a dramatic increase in the systemic availability of paclitaxel when ciclosporin was administered concomitantly (241) and in a phase I study of the pharmacokinetics of twice-daily oral paclitaxel 60–160 mg/m^2 in 15 patients in combination with ciclosporin (15 mg/kg) there was a seven-fold increase in the systemic exposure to paclitaxel; the plasma concentration increased from negligible to therapeutic concentrations (242). The inhibitory effect of ciclosporin on the gastrointestinal multidrug transporter P-glycoprotein was suggested to account for these interactions.

Several studies have shown that ciclosporin reduces the clearance or increases the AUC of dactinomycin, etoposide, mitoxantrone, and vincristine (5,243).

Digoxin

In an analysis of changes in ciclosporin clearance and systemic availability obtained from the medical records of 100 transplant patients, digoxin increased ciclosporin systemic availability (228).

Doxorubicin

High-dose ciclosporin increased the AUC of doxorubicin and doxorubicinol and produced greater doxorubicin-related myelotoxicity (244).

Fibrates

A possible synergistic risk of muscle disorders should be considered in patients taking ciclosporin with fibric acid derivatives (SEDA-19, 351).

Fluoroquinolones

Although ciprofloxacin was initially thought to increase ciclosporin blood concentrations and enhance ciclosporin nephrotoxicity, no definite evidence to support this interaction has been found (245). A norfloxacin-induced increase in ciclosporin blood concentrations has been reported in children (5,246), while ofloxacin did not appear to alter ciclosporin metabolism (247).

Foscarnet

Foscarnet (248), but not ganciclovir (249), has also been involved in reversible renal insufficiency after concomitant use with ciclosporin.

Grapefruit juice

Following the observation that grapefruit juice ingestion can increase the systemic bioavailability of ciclosporin, there was considerable interest in its possible use to reduce ciclosporin doses (SEDA-19, 351). However, this has been strongly criticized and considered hazardous because of large interindividual variability and the commercial availability of different formulations of grapefruit juice with potentially different effects on ciclosporin pharmacokinetics (250).

Histamine H_2 receptor antagonists

The available data on a possible interaction between histamine H_2 receptor antagonists and ciclosporin are inconclusive. Whereas neither cimetidine nor ranitidine significantly altered ciclosporin pharmacokinetics, there was an increase in serum creatinine concentration in patients taking both ciclosporin and cimetidine, but not ranitidine. The clinical significance of this interaction is probably limited, and it has been attributed to competition of cimetidine with creatinine for tubular secretion (251).

HMG-CoA reductase inhibitors

Dosages of statins should be reduced in patients taking ciclosporin, because of pharmacodynamic and pharmacokinetic interactions.

Pharmacodynamic interactions

Patients taking ciclosporin with conventional dosages of lovastatin or simvastatin can develop acute muscle toxicity (SED-14, 1296) (SEDA-19, 351). Among 110 ciclosporin-treated patients with heart transplants, four of 18 patients taking simvastatin 20 mg/day developed rhabdomyolysis, whereas none of the patients taking simvastatin 10 mg/day (26 patients) or pravastatin 20 mg/day (66 patients) had similar symptoms (252). Inhibition of CYP3A by ciclosporin was the most likely mechanism. In another study, there was a five-fold higher AUC of lovastatin (10 mg/day for 10 days) in 16 patients taking ciclosporin compared with 13 patients not taking ciclosporin (253).

- The addition of atorvastatin (10 mg/day) to a multidrug regimen including ciclosporin in a 40-year-old patient with a renal transplant resulted in rhabdomyolysis within 2 months (254).

Similar interactions are expected with other HMG-CoA reductase inhibitors such as cerivastatin and rosuvastatin.

Pharmacokinetic interactions

Plasma concentrations of lovastatin- or simvastatin-active metabolites were increased in several patients and in a

© 2006 Elsevier B.V. All rights reserved.

pharmacokinetic study, suggesting that ciclosporin can inhibit their metabolism (255–257). Lower doses of lovastatin and simvastatin can be safely administered (258). Fluvastatin or pravastatin may offer some advantages, as no significant drug interactions have been documented with ciclosporin, at least for pravastatin (259).

From an analysis of changes in ciclosporin clearance and systemic availability obtained from the medical records of 100 transplant patients, atorvastatin, fluvastatin, pravastatin, and simvastatin were found to affect ciclosporin pharmacokinetics (228).

In a study of the safety and efficacy of simvastatin in hyperlipidemia after renal transplantation in 15 patients, the C_{max} and AUC of simvastatin were increased seven-fold by ciclosporin (260). In contrast, in 17 patients, tacrolimus had no effect. Although there were no complications, such as myopathy or rhabdomyolysis, creatine kinase activity must be monitored during co-administration of simvastatin and ciclosporin.

Ciclosporin produced a three- to five-fold increase in the plasma concentrations of cerivastatin and its metabolites in 12 patients with renal transplants who took cerivastatin 0.2 mg/day for 7 days compared with a single dose in 12 healthy controls (261).

Hypericum perforatum (St. John's wort)

Hypericum perforatum (St. John's wort), which is used for mild depression, is an inducer of cytochrome P-450. It caused a rapid dramatic fall in ciclosporin blood concentrations, resulting in acute heart transplant rejection in two patients aged 61 and 63 years (262). It produces an average 50% reduction in ciclosporin blood concentrations (263). At least three other case reports have clearly confirmed that St. John's wort is dangerous in transplant patients, because it produced a rapid and dramatic reduction in blood ciclosporin concentration and resulted in acute organ rejection in two patients (264–266). Induction of CYP3A4 and/or P-glycoprotein was the most likely mechanism.

- A 44-year-old black woman with a living-related renal transplant had an acute rejection within 3 months and was given muromonab but was from then on stable. She was later given oral ciclosporin (Neoral 2 mg/kg bd), mycophenolate mofetil 1000 mg bd, and prednisolone 7.5 mg/day. Over 6 months her ciclosporin blood concentrations were consistently below the target concentration of 200 ng/ml. It was then discovered that she had also been taking 2–3 tablets/day of St. John's wort (Your Life, Leiner Health Products, Carson CA, 300 mg standardized to 0.3% hypericin). The St. John's wort was withdrawn and her blood ciclosporin concentrations reached the target within 2 weeks.
- A 29-year-old white woman with cadaveric kidney and pancreas transplants had two early rejection episodes but then stabilized on ciclosporin 100 mg bd and prednisolone 5 mg/day. Her blood ciclosporin concentration was consistently 200–350 ng/ml. She then started to take St. John's wort and over the next 30 days her blood ciclosporin concentration fell to 155 ng/ml and 3 weeks later to 97 ng/ml. Her serum creatinine rose to 1.3 mg/dl (115 μmol/l) and her serum amylase rose from a baseline of 60–90 to 314 U/l; this was associated with abdominal pain. Renal biopsy confirmed acute rejection, which was treated. She subsequently developed chronic rejection, confirmed by renal biopsy.

Imidazoles

Among the imidazole derivatives, numerous case reports or studies have shown that ketoconazole, fluconazole, and itraconazole can inhibit ciclosporin metabolism and increase blood ciclosporin concentrations (267). Ketoconazole, which is undoubtedly the most potent inhibitor, has been used to reduce the dose, and therefore the cost or adverse effects, of ciclosporin (268–270). There was also a beneficial effect on the rate of rejection or infection. In contrast, interactions with metronidazole and miconazole have only been described in isolated case histories (SEDA-19, 351) (5).

In a double-blind, randomized, placebo-controlled study in renal transplant patients taking ciclosporin, voriconazole increased the mean ciclosporin AUC 1.7-fold (271). The authors therefore recommend halving the dose of ciclosporin in these patients and carefully monitoring ciclosporin blood concentrations.

Imipenem/cilastatin

In contrast to what has previously been stated, there was no significant increase in the frequency of seizures among 77 patients with bone marrow transplants who were taking ciclosporin alone (three seizures), 45 patients taking ciclosporin plus imipenem/cilastatin (two seizures), and 44 patients taking imipenem/cilastatin alone (no seizures) (272).

Inducers, inhibitors, or substrates of 3A

Ciclosporin is absorbed to a variable extent from the gastrointestinal tract and almost completely metabolized in both the liver and small intestine by CYP3A, which metabolizes a large number of drugs. Inducers, inhibitors, or substrates of CYP3A therefore have the potential to interact with ciclosporin. In addition, ciclosporin has wide pharmacokinetic variability and a narrow therapeutic index. Conversely, ciclosporin can inhibit the hepatic metabolism of other drugs that share the same CYP3A metabolic pathway.

Drugs that increase the systemic availability of ciclosporin do not always have negative effects, and several ciclosporin-sparing agents have indeed been used for the purpose of improving efficacy while reducing the cost of treatment. However, use of such combinations should be balanced against their potential risks (273).

Table 1 lists drugs that have proven or possible clinically relevant drug interactions with ciclosporin.

Macrolide antibiotics

Erythromycin increases ciclosporin blood concentrations, and increased serum creatinine concentrations have been consistently demonstrated; isolated reports have also suggested possible interactions with clarithromycin, josamycin, midecamycin, or pristinamycin (SEDA-21, 385) (274). A two-fold increase in ciclosporin concentrations has been

Table 1 A summary of major interactions with ciclosporin

Pharmacokinetic	Pharmacodynamic
Anticonvulsants	**Increased risk of nephrotoxicity**
Carbamazepine*	ACE inhibitors
Phenobarbital*	Aciclovir (see text)
Phenytoin*	Aminoglycosides
Primidone*	Amphotericin
Antidepressants	Co-trimoxazole
Fluoxetine (unproven; see text)	Diuretics
Fluvoxamine	Foscarnet (see text)
Nefazodone	Melphalan
St. John's wort	Nafcillin (see text)
Antimicrobial drugs	NSAIDs (unproven, see text)
Antifungal drugs	**Increased risk of muscle toxicity (see text)**
Ketoconazole, fluconazole, itraconazole, metronidazole	Colchicine
Chloramphenicol (unproven)	Fibric acid derivatives
Clindamycin*	HMG CoA reductase inhibitors (statins)
Fluoroquinolones	Pyrazinamide (SEDA-20, 346)
Griseofulvin*	**Increased risk of gingival hyperplasia**
Macrolides or related drugs (see text)	Nifedipine
Clarithromycin, erythromycin, josamycin, midecamycin, miocamycin, pristinamycin	**Increased risk of neurotoxicity**
Protease inhibitors	Imipenem/cilastatin
Ritonavir, saquinavir	**Increased risk of hepatotoxicity**
Pyrazinamide*	Androgens
Quinupristin/dalfopristin (SEDA-21, 386)	Norethandrolone, oxymetholone
Rifamycins*	Parenteral nutrition (see text)
Sulfadiazine*	**Increased risk of hyperkalemia**
Terbinafine* (SEDA-21, 386)	Potassium salts
Cardiovascular drugs	Potassium-sparing diuretics
Amiodarone	
Calcium channel blockers	
Amlodipine, diltiazem, nicardipine, verapamil	
Carvedilol (SEDA-22, 415)	
Clonidine	
Propafenone	
Hypoglycemic drugs	
Glibenclamide	
Glipizide	
Troglitazone*	
Miscellaneous drugs	
Acetazolamide	
Allopurinol	
Bezafibrate	
Bile acid resin*	
Chloroquine	
Danazol	
Glucocorticoids	
Grapefruit juice	
Modafinil*	
Muromonab (SEDA-21, 386)	
Octreotide*	
Oral contraceptives (unproven)	
Orlistat*	
Probucol*	
Sulfasalazine*	
Sulfinpyrazone*	
Tacrolimus	
Ticlopidine*	
Vitamin E (water-soluble) (SEDA-20, 346)	

*These drugs reportedly reduce ciclosporin blood concentrations; the rest increase them

reported in patients receiving miocamycin. In contrast, spiramycin or roxithromycin did not significantly affect ciclosporin concentrations, and a single report involving azithromycin (SEDA-19, 351) was not substantiated by several prospective studies.

Mycophenolate mofetil

The interaction of ciclosporin with mycophenolate mofetil was investigated in 52 renal transplant patients taking triple therapy (ciclosporin, mycophenolate mofetil, and prednisone), who continued taking the same treatment ($n = 19$) or underwent elective ciclosporin withdrawal ($n = 19$) or prednisolone withdrawal ($n = 14$) 6 months after transplantation (275). Median mycophenolate mofetil trough concentrations 3 months later were about two-fold higher in patients who had discontinued ciclosporin compared with patients who continued to take triple therapy and patients who had discontinued prednisone. No clear mechanism readily explains these changes.

Nefazodone

Nefazodone can alter blood ciclosporin concentrations (276,277). In one case there was nearly a 10-fold increase in whole-blood ciclosporin concentrations in a cardiac transplant patient shortly after the addition of nefazodone (278).

NSAIDs

Based on the theoretical possibility of additive nephrotoxic effects, the combined use of NSAIDs with ciclosporin is expected to reduce renal function and therefore to increase ciclosporin-induced nephrotoxicity.

- In an 8-year-old girl with rheumatoid arthritis, the combination of ciclosporin with NSAIDs (indometacin and diclofenac) was suggested to have caused biopsy-proven, non-specific colitis, because her symptoms occurred only when the combination was used (279).

From several studies performed in healthy volunteers, repeated doses of diclofenac, aspirin, indometacin, or piroxicam did not significantly alter ciclosporin single-dose pharmacokinetics, but the AUC of diclofenac was increased by ciclosporin (280). In a further study of 20 patients with rheumatoid arthritis who took ciclosporin for 4 weeks, there was a two-fold increase in diclofenac AUC, and a small but significant increase in serum creatinine concentrations (281). Changes in renal function were easily managed by dosage titration of both drugs. In another study of 32 patients who received a 4-week course of paracetamol, indometacin, ketoprofen, or sulindac, changes in the calculated creatinine clearance were minimal (282). There were no striking differences among different NSAIDs. Taken together, the results of these studies and previous findings suggested that the clinical relevance of this interaction is limited.

Orlistat

Orlistat reduces plasma ciclosporin concentrations.

- A 29-year-old woman with increased body weight after renal transplantation was unable to adhere to a low-fat

© 2006 Elsevier B.V. All rights reserved.

diet and took orlistat, which gave her severe diarrhea (283). Her plasma ciclosporin concentrations fell to subtherapeutic, even though she took the orlistat 2 hours before the ciclosporin and even though the daily dose of orlistat was reduced to 240 mg/day.
- There was a two-fold reduction in blood ciclosporin concentrations 2 weeks after orlistat was given to a 61-year-old patient with a heart transplant (284).

The FDA has received six reports of subtherapeutic blood ciclosporin concentrations soon after transplant recipients started to take orlistat (285). Reduced absorption of ciclosporin is the most likely mechanism (286,287) by reduction in fat absorption rather than by a direct drug–drug interaction.

Oxycodone

In an analysis of changes in ciclosporin clearance and systemic availability obtained from the medical records of 100 transplant patients, oxycodone reduced ciclosporin systemic availability (228).

Parenteral nutrition

Cholestasis from other causes can increase the accumulation of ciclosporin or its metabolites, which in turn worsens hepatic cholestasis. This mechanism has been suggested in patients with bowel diseases who experienced an aggravation of hyperbilirubinemia or an increased incidence of hepatotoxicity from the combination of total parenteral nutrition and ciclosporin (SEDA-19, 348) (288).

Protease inhibitors

Interactions of ciclosporin with protease inhibitors should be expected, particularly with ritonavir, a potent inhibitor of CYP3A.

- Despite a prophylactic reduction in the dose of ciclosporin (100 mg/day) before antiretroviral treatment, a 40-year-old woman had an acute increase in ciclosporin trough concentrations (over 1000 ng/ml) and serum creatinine concentration (from 84 to 228 μmol/l) after taking zidovudine (600 mg/day), saquinavir (800 mg/day), and ritonavir (800 mg/day) for 11 days (289). Despite ciclosporin withdrawal, ciclosporin and creatinine blood concentrations remained high for over 10 days until triple drug therapy was withdrawn. Ritonavir was the most likely suspect.

Proton pump inhibitors

Conflicting data have emerged on the interaction of omeprazole with ciclosporin, with isolated case reports suggesting that omeprazole can increase or reduce ciclosporin concentrations, whereas no effect of omeprazole was demonstrated in a controlled trial (290–292).

Quinidine

In an analysis of changes in ciclosporin clearance and systemic availability obtained from the medical records of 100 transplant patients, digoxin increased ciclosporin systemic availability (228).

Saquinavir

A reciprocal interaction between ciclosporin and saquinavir has been reported in an HIV-positive kidney transplant patient (293). Whereas ciclosporin concentrations were previously acceptable, there was a three-fold increase in ciclosporin trough concentrations after 3 days of saquinavir (3600 mg/day). In addition, the saquinavir AUC was four times higher than that usually observed in patients taking similar dosages.

Selective serotonin reuptake inhibitors

Fluvoxamine and fluoxetine have been involved in isolated cases of increased blood ciclosporin concentrations, but fluoxetine was not confirmed to affect ciclosporin concentrations significantly in 13 patients (SEDA-20, 345) (SEDA-22, 385–386). In an analysis of changes in ciclosporin clearance and systemic availability obtained from the medical records of 100 transplant patients, sertraline altered ciclosporin pharmacokinetics (228).

Sulfasalazine

In a 51-year-old woman with a renal transplant who had been stable for the past 13.5 months with ciclosporin (9.6 mg/kg) and sulfasalazine (1.5 g/day) for ulcerative colitis, sulfasalazine withdrawal resulted in an almost two-fold increase in ciclosporin blood concentrations over the next 10 days (294).

Sulfinpyrazone

In 120 heart transplant patients, sulfinpyrazone (200 mg/day) for ciclosporin-associated hyperuricemia was associated with lowered blood ciclosporin concentrations despite an increase in the daily dose (295). The authors cited evidence (296) that sulfinpyrazone induces ciclosporin metabolism.

Sulfonylureas

Both glipizide and glibenclamide increase ciclosporin concentrations significantly (297).

Ticlopidine

Although there was no interaction between ciclosporin and ticlopidine in a pharmacokinetic study, a 64-year-old patient with a renal transplant had a reduction in the concentration:dose ratio of ciclosporin after each of two successive courses of ticlopidine (298).

Troglitazone

Case reports and a retrospective evaluation of seven renal transplant patients showed that troglitazone can increase ciclosporin metabolism with a subsequent reduction of 15–45% in ciclosporin trough concentrations (299). The interaction of ciclosporin with troglitazone has been confirmed in four heart transplant patients with a 30–60% fall in ciclosporin concentrations within days of taking troglitazone 200 mg/day (300).

© 2006 Elsevier B.V. All rights reserved.

Monitoring Therapy

Ciclosporin pharmacokinetics vary considerably between patients, and even in an individual patient from time to time, with changes in the clinical condition and treatment, particularly with administration of other drugs (301). Inadequate exposure to ciclosporin is a key factor in acute rejection and contributes to the development of chronic rejection and graft failure. Monitoring of ciclosporin concentrations is widely adopted as an accurate and practical measure of drug exposure (302).

In an open, randomized, parallel-group study in 307 patients, ciclosporin blood concentrations measured 2 hours after a dose were compared with conventional trough ciclosporin blood concentrations (303). The traditional predose blood concentration did not correlate well with drug exposure, and the 2-hour concentration was superior in preventing acute rejection. This is important, because data derived from the database of the United Network for Organ Sharing Scientific Liver Transplant Registry has shown that moderate and more severe grades of rejection are associated with poor graft function and outcome in liver transplant recipients.

Of 53 bone marrow transplant recipients in whom ciclosporin was used to suppress graft-versus-host disease, 63% developed acute nephrotoxicity (304). These patients had significantly higher plasma ciclosporin concentrations during the first month after transplantation than those who did not develop acute nephrotoxicity, even though they received the same cumulative dose. Children received a higher cumulative dose, but their plasma concentrations did not differ significantly from the adults, and they suffered less nephrotoxicity.

Although a correlation between early post-transplantation whole-blood concentrations of ciclosporin and the occurrence of ciclosporin-induced toxicity has been suggested, blood concentrations in most patients are in the target range, and the identification of patients susceptible to adverse effects has yet to be achieved (305).

Cidofovir

General Information

Cidofovir (*S*-1-3-hydroxy-2-phosphonylmethoxypropylcytosine), also known as HPMPC, is a nucleotide analogue with potent activity against cytomegalovirus (CMV) in vitro and in vivo.

Observational studies

Cidofovir has been used to treat 14 patients with cytomegalovirus infection after stem-cell transplantation; no adverse effects were reported in this small study (1).

In an open study of the use of intralesional cidofovir in treating laryngeal papilloma, 14 adults received monthly injections of cidofovir (maximum dose 37.5 mg per injection in 6 ml of saline; mean 22.5 mg) (2). Remission was achieved in all cases with an average of six injections and without additional laryngeal scarring, vocal cord damage, or systemic adverse effects.

Organs and Systems

Sensory systems

In a placebo-controlled study of the efficacy of cidofovir 1% eye-drops with and without ciclosporin 1% eye-drops four or ten times a day for acute adenovirus keratoconjunctivitis in 34 patients, the frequency of severe corneal opacities was lower with cidofovir (3). However, cidofovir caused conjunctival pseudomembranes, conjunctivitis, and erythematous inflammation of the skin of the eyelids, and the trial was stopped as a result.

Two cases of iritis shortly after intravenous administration of cidofovir have been reported (4). Intravitreal administration of cidofovir delays the progression of CMV retinitis, but can be associated with reduced intraocular pressure or vitreitis (5). In two cases the drug association with the iritis was demonstrated by withdrawal and rechallenge (6). These patients had also taken probenecid, but it is not clear whether or not that was involved. The evidence is that in such cases the cidofovir should be withdrawn; treatment should be with a mydriatic and glucocorticoids.

In a study of compassionate use of intravenous cidofovir in AIDS patients with CMV retinitis, iritis developed in 21 of 51 individuals (7). The appearance of this inflammatory process did not fit the characteristics of the vitritis associated with immune reconstitution, or with HIV-induced vitritis. The high rate in this cohort (compared with a 5–7% incidence in randomized trials) was associated with severe CMV retinitis, and the authors suggested that breakdown of the blood–ocular barrier in these patients may promote higher intraocular concentrations of cidofovir and thus enhance local toxicity. Previous correlations of prior use of HIV protease inhibitors with iritis were not confirmed in this study, although patients with iritis had better immunological and virological status than those without the disease.

Uveitis (8) and cystoid macular edema (9) are recognized risks associated with cidofovir treatment for cytomegalovirus retinitis. The latter is almost certainly an immune recovery phenomenon, since it is apparently encountered only in eyes with inactive CMV retinitis; the unaffected contralateral side never develops cystoid macular edema. The time range of appearance (3–48 weeks after administration) also makes a direct toxic effect of cidofovir unlikely.

In a retrospective record review of 18 HIV-infected patients (30 eyes) who were being treated with intravenous cidofovir for complicated cytomegalovirus retinitis, eight patients developed anterior uveitis after a median of four (range 2–8) doses of cidofovir or a median of 55 (20–131) days after the start of therapy (10). While they were receiving treatment with cidofovir, none of the patients showed any evidence of progression of CMV retinitis. Five of the eight had symptoms of photophobia and blurred vision at the onset of uveitis, and the other three were asymptomatic. There was no difference in the use of HIV-1 protease inhibitors between the patients who did or did not develop anterior uveitis. Baseline intraocular pressure measurements were available for 11/18 patients. With the introduction of cidofovir there was a fall in mean intraocular pressure, and a trend for this fall to be more pronounced in those who developed anterior uveitis. Withdrawal of cidofovir was necessary in only one patient, after which all symptoms and signs disappeared and vision returned to baseline within 1 month. In two of the seven other patients, cidofovir had to be withdrawn because of nephrotoxicity. In the other five patients, cidofovir was continued and the uveitis was controlled with topical therapy, consisting of corticosteroids with or without a cycloplegic agent.

During long-term follow-up of patients with AIDS treated with parenteral cidofovir for CMV retinitis, the median time to discontinuation for intolerance was 6.6 months (11). Cidofovir-associated uveitis occurred in 10 of 58 patients and ocular hypotony (a 50% fall in intraocular pressure from baseline to below 5 mmHg) occurred at a rate of 0.16 per person-year. There were 51 episodes of proteinuria in 30 of the 58 patients and 82% of these episodes resolved on withdrawal (median time to resolution 20 days). No nephrotoxic events required dialysis.

Urinary tract

The main adverse effect associated with intravenous cidofovir is renal tubular damage (12), although it is usually mild. However, cases of acute renal insufficiency leading to end-stage disease have been reported (13,14). Acute renal insufficiency has also been attributed to topical cidofovir (15).

- A 28-year-old bone marrow transplant recipient with chronic renal insufficiency developed genital condylomata resistant to standard therapy. After application of topical cidofovir (1% daily for 5 days, then 4% for 12 days) the lesions improved but local erosions appeared. He developed acute renal insufficiency with features of tubular acidosis on day 19. He recovered after cidofovir withdrawal.

It was not clear whether this effect was due to the cidofovir or to its vehicle, propylene glycol. The authors suggested that topical cidofovir should be avoided on abraded skin and should be carefully monitored.

© 2006 Elsevier B.V. All rights reserved.

The risk of renal toxicity was higher in patients with established CMV infections than in those who were taking it prophylactically, and there was no relation between dosage and nephrotoxicity; toxicity occurred early in therapy, usually within the first 3 weeks (16). Proteinuria seems to be an early indicator of this adverse effect. Other laboratory abnormalities associated with nephrotoxicity are glycosuria, reduced serum phosphate, uric acid, and bicarbonate, and an increased serum creatinine. Serious and potentially irreversible nephrotoxicity can generally be prevented by the concomitant administration of intravenous saline and oral probenecid, monitoring the blood and urine immediately before each infusion of cidofovir, and withdrawing the drug for low-threshold increases in either urinary protein or serum creatinine concentrations (17). Concomitant use of other nephrotoxic drugs should be avoided.

In a rare cytomegalovirus comparison trial, a ganciclovir insert (an intraocular implant) plus oral ganciclovir was compared with intravenous cidofovir (18). Based on data from 61 patients (the trial was stopped early owing to low recruitment), cidofovir was associated with a raised serum creatinine concentration of 142 μmol/l (1.6 mg/dl) or greater (0.48 per person-year), 3+ or greater proteinuria (0.29 per person-year), uveitis (0.35 per person-year), and neutropenia (0.11 per person-year).

Prophylactic cidofovir treatment for CMV antigenemia has been investigated in a prospective study in patients with transplants (19). Renal toxicity, occasionally with proteinuria, was reported, as was nausea. The renal toxicity was mild and reversible.

Susceptibility Factors

Renal disease

The pharmacokinetics of cidofovir were studied in 24 subjects with varying degrees of renal insufficiency, who were given a single intravenous dose of cidofovir 0.5 mg/kg over 1 hour (20). Those who were not receiving dialysis were given intravenous hydration and concomitant oral probenecid. Mean cidofovir clearance in control subjects (normal renal function; $n = 5$) was 1.7 ml/minute/kg, and this fell markedly with falling renal function. The mean steady-state volume of distribution did not change significantly in those with kidney disease, but the half-life of cidofovir was significantly prolonged in those with severe renal insufficiency. Cidofovir was not significantly cleared during continuous ambulatory peritoneal dialysis, but high-flux hemodialysis resulted in the removal of 52% of the dose. The authors concluded that very considerable aggressive dosage reduction of cidofovir would be necessary in subjects with kidney disease to ensure comparable drug exposure in terms of serum concentrations.

Cilazapril

See also Angiotensin converting enzyme inhibitors

General Information

Cilazapril is a non-sulfhydryl ACE inhibitor (1). Like enalapril and ramipril it is a prodrug and is hydrolysed after absorption to cilazaprilat, which has a long half-life allowing once-daily administration (2).

Organs and Systems

Skin

Many cases of pemphigus have been reported with ACE inhibitors, related to the amide group they contain. This is the case for cilazapril.

- A 69-year-old white woman developed skin lesions of pemphigus foliaceus after she had taken cilazapril for 3 months; they resolved on withdrawal and the addition of prednisone and azathioprine (3).
- Pemphigus vulgaris possibly triggered by cilazapril has been reported (4).

Cilostazol

General Information

Cilostazol is a phosphodiesterase inhibitor that suppresses platelet aggregation and also acts as a direct arterial vasodilator. Small studies in Japan suggested that it might be useful for treating chronic arterial disease and symptoms of intermittent claudication. A trial in 81 patients with claudication substantiated this claim: claudication distance was improved by 35% for initial and 41% for absolute claudication distance.

Placebo-controlled studies

The efficacy and safety data of cilostazol in placebo-controlled clinical trials have been repeatedly subjected to meta-analysis, with the same conclusion (1,2). Cilostazol is well tolerated; headache, bowel complaints, and palpitation are the most common but mild adverse effects.

Six multicenter placebo-controlled trials have been conducted in the USA (3,4). They involved more than 2000 patients with intermittent claudication and established the efficacy of cilostazol in improving walking distance in these patients.

Cilostazol was approved by the FDA in January 1999 for the treatment of symptoms of intermittent claudication; from 1984 to 1999 pentoxifylline was the only drug approved in the USA for this indication. The two drugs have been compared with placebo in a large, randomized, double-blind, placebo-controlled trial (5). After 24 weeks of treatment the mean increase in maximal walking distance was 54% with cilostazol and only 30% with pentoxifylline and 34% with placebo. Headache, diarrhea, abnormal stools, and bouts of palpitation were significantly more common with cilostazol. They were reported as generally mild to moderate and self-limiting and have been previously recognized as being related to cilostazol.

The efficacy of antithrombotic prophylaxis with cilostazol for the secondary prevention of cerebral infarction has been studied in a Japanese, placebo-controlled trial in 1095 patients (6). There was a 42% relative risk reduction compared with placebo. As in the trials in patients with peripheral arterial disease, mild to moderate headache and palpitation were the most commonly observed symptomatic adverse events attributed to cilostazol; they respectively occurred in 13 and 5.3%. Headache with cilostazol is attributed to cerebral vasodilatation induced by relaxation of vascular smooth muscle.

In another placebo-controlled trial, there were gastrointestinal complaints in 44% of the cilostazol-treated patients and in 15% of the placebo group. The most commonly reported adverse effects included diarrhea, loose stools, flatulence, and nausea; they were usually mild and transient but persisted in some patients. Headache occurred in 20% of cilostazol-treated patients but also in 15% of those given placebo (7).

Safety data relating to the use of cilostazol in 2702 patients who participated in eight USA–UK placebo-controlled trials have been re-analysed (8). The most frequently recorded adverse events were headache (32%), diarrhea (17%), and abnormal stools (14%).

© 2006 Elsevier B.V. All rights reserved.

Palpitation, tachycardia, and dizziness were additional events that occurred more often in cilostazol-treated patients and were considered to be probably related to treatment. Headache led to withdrawal of cilostazol in 3.5% of patients, and palpitation and diarrhea led to withdrawal in another 1%. All adverse events quickly resolved after withdrawal. Cardiovascular and all-cause mortality were similar with cilostazol and placebo.

Organs and Systems

Cardiovascular

Ventricular tachycardia has been reported during cilostazol therapy (9).

- A 92-year-old woman developed sudden runs of ventricular tachycardia, a few days after she started to take cilostazol because of subacute leg ischemia. She was known to have atrial fibrillation and intraventricular conduction delay. The runs did not respond to empirical magnesium therapy but subsided shortly after withdrawal of cilostazol.

The phosphodiesterase III inhibitors have no known direct dysrhythmogenic effects. However, the authors speculated that raised concentrations of cAMP may have contributed to the ventricular tachycardia, mainly because ventricular dysrhythmias have been mentioned with other agents of the same family in patients with heart failure. Whether some populations are particularly vulnerable is unknown.

Cimetidine

See also Histamine H_2 receptor antagonists

General Information

Cimetidine is a histamine H_2 receptor antagonist.

General adverse effects

The main varieties of adverse effects attributed to cimetidine relate to its antiandrogenic properties and its actions in sufficient concentrations on the central nervous system. There is also a spectrum of drug interactions, mainly attributable to inhibition of hepatic CYP isoforms, but they only have clinical consequences under special circumstances. Occasional adverse effects, which are generally minor, include bradycardia and conduction defects, thrombocytopenia, neutropenia, interstitial nephritis, mild hepatic dysfunction, and headache. Intestinal infection due to loss of the gastric acid barrier also occurs, and myalgia, fever, monoamine oxidase-like interactions, and neuropathies have been well documented occasionally. Allergic reactions, such as bronchospasm, have rarely been described. Anaphylaxis with recurrence on rechallenge is on record, as are asthma and skin effects.

Organs and Systems

Cardiovascular

Rapid infusion of cimetidine causes an increase in plasma histamine concentration, and this could be one reason for its cardiac effects. A marked degree of bradycardia (for example a 30% reduction in heart rate) is uncommon although well recognized (SEDA-17, 417); sinoatrial and atrioventricular conduction effects and dysrhythmias of every possible type have occasionally been noted, particularly after infusion but also with oral therapy. It has been suggested that if a patient is particularly at risk (for example because of poor renal function) the electrocardiogram should be monitored (SEDA-15, 394).

Symptoms of vasodilatation have been attributed to cimetidine (1).

- A 31-year-old white man taking maintenance hemodialysis had frequent episodes of hot flushes, sweating, palpitation, and dizziness, which started after about 1 month of treatment with cimetidine 400 mg/day. When the drug was temporarily discontinued and later when it was totally withdrawn, he noted marked improvement in 2–5 days.

Respiratory

Bronchospasm is occasionally reported, reflecting the possibility of allergy to cimetidine, and the need for some caution with its initial use in any patient with

© 2006 Elsevier B.V. All rights reserved.

asthma (SEDA-15, 394). In pre-existing atopic asthma, H_2 receptor antagonists can enhance bronchial reactivity (SEDA-16, 421). Central nervous system effects can lead to respiratory depression, although this is rare.

Loss of the gastric acid barrier can predispose to intestinal infection, and pulmonary aspiration of infected gastrointestinal secretions can very occasionally cause pneumonia after anesthesia or during intensive care (2). Interstitial lung disease can occur under these conditions.

Nervous system

Cimetidine crosses the blood–brain barrier and its adverse events include central respiratory depression and extrapyramidal and cerebellar disturbances. There have been convincing isolated reports of choreiform movements (3,4).

Severe central neurological problems are not common with cimetidine. In one intensive survey of nearly 10 000 patients followed for 3 months there were only five cases of confusion, though there were 34 with sensations of dizziness, 23 with headache, and 74 with other milder central nervous effects (5). The overall incidence of adverse neurological effects reported to the US public health authorities (which naturally represent only a small proportion of those that actually occur) was 8.6 per million prescriptions for cimetidine and virtually the same for ranitidine. Healthy elderly people are probably not at particular risk.

Occasionally, neuropathies have been documented (6). The fear that cimetidine or ranitidine might increase the incidence of motor neuron disease was raised in the light of case-control work, but seems to have been allayed by data from the Oxford Record Linkage Study published in 1993 (7).

A dystonic reaction has been attributed to cimetidine (8).

- A 39-year-old woman developed a dystonic reaction (masseter spasm, lip smacking, oculogyric crisis, and mild neck spasm) within 5 minutes of intravenous administration of cimetidine 300 mg for epigastric pain. She had epilepsy and had not taken her antiepileptic medication regularly. She had developed a similar dystonic reaction to prochlorperazine 1 week before. She recovered within 5 minutes of treatment with intravenous diphenhydramine and lorazepam.

Psychological, psychiatric

Cimetidine crosses the blood–brain barrier and can cause confusion, particularly in elderly or sick individuals with compromised hepatic or renal function, and especially after intravenous treatment. Very rarely an acute confusional psychosis has been seen in a younger person (9). Delirium has been thought to be a particular problem with intravenous use, but this is more likely to be a reflection of patient selection. Depression has occasionally been attributed to cimetidine (10,11).

Metabolism

In the earlier years of cimetidine use there were scattered (although well-documented) reports of the drug having destabilized severe diabetes, resulting in impaired control (12); however, most people with diabetes are unlikely to be affected.

Modest increases in serum high-density lipoproteins have occasionally been noted in patients taking cimetidine (SED-12, 942) (13).

Hematologic

There was concern during the first years of cimetidine therapy that it might produce severe blood dyscrasias, but most of those that have been described have occurred in patients who were already severely ill or exposed to other toxic influences (SED-12, 942) (SEDA-15, 394).

Thrombocytopenia has been attributed to cimetidine, with recurrence on rechallenge, and neutropenia has also been documented as an occasional adverse effect, possibly related to inhibition of granulocyte colony growth (SEDA-10, 325). These effects appear to occur with all H_2 receptor antagonists in an incidence roughly proportional to their sales. Exceptionally, thrombocytopenia and leukopenia have occurred together (SEDA-17, 417). In one case of pancytopenia there was cimetidine dose-related inhibition of normal human CFU-GM colon formation (SEDA-16, 422).

Mouth and teeth

Parotitis with positive rechallenge has been documented in one case (14).

Gastrointestinal

An early concern was the possibility that H_2 receptor antagonists could predispose to gastric carcinogenesis, but this seems to have been allayed, as was the fear once expressed that ulcers might be more liable to perforate after cimetidine had been given and withdrawn.

Liver

The rate of acute liver injury due to cimetidine 800 mg/day in the UK has been estimated at over 10 per 100 000 users. The increased risk was seen mainly in the first 2 months of use. The risks of liver injury due to ranitidine and omeprazole were much lower (SEDA-22, 391) (15).

Cimetidine has rarely been reported to cause hepatic encephalopathy.

- Cimetidine-induced hyperammoniacal encephalopathy has been reported in a previously healthy 44-year-old man who had taken cimetidine 400 mg/day for 4 days; he recovered completely after drug withdrawal (16).

Pancreas

Pancreatitis has several times been suggested as a complication of treatment (17), but this is unconfirmed.

Urinary tract

Minor rises in serum creatinine concentrations reflect interference with tubular function; this seems to be clinically unimportant and fully reversible. There were two early reports of reversible acute renal insufficiency, one of them with positive rechallenge and a biopsy finding of interstitial infiltrates of inflammatory cells (18).

© 2006 Elsevier B.V. All rights reserved.

Skin

Allergic skin reactions to cimetidine include urticaria (19), exfoliative dermatitis (20), and the various forms of erythema multiforme (21–23).

Several cases of psoriasis have been precipitated or aggravated by cimetidine, and ranitidine has the same rare effect (24).

Xerosis and asteatotic dermatitis are among the rare cutaneous effects that can occur with cimetidine; they may be of antiandrogenic origin (25).

Hair

A possibly unique case of alopecia affecting the entire body was described in 1981; in that case the temporal association was convincing and there was a correlation with an antiandrogenic effect on hormone concentrations (26).

Musculoskeletal

A small proportion of patients develop troublesome myalgia when taking cimetidine (27). There have been incidental reports of polymyositis and a form of myopathy probably of motor neuron origin. Myalgia can also be associated with arthritis and joint effusion, but this is extremely unusual (SED-12, 942) (28).

Sexual function

Mild antiandrogenic properties, which are dose-related, are associated with binding of cimetidine to androgen receptors. Reduced sperm counts have been reported, as have modestly raised serum prolactin levels after intravenous treatment (SEDA-9, 313). Some slight degree of male breast enlargement is not uncommon (for example in one series of 25 men, five had it) (29), but it can regress with continued treatment; it is very rarely massive and unilateral; there is no strict parallel between the effects on the breasts and the blood prolactin concentration. In 81 535 men aged 25–84 years, the relative risk of gynecomastia among users of cimetidine compared with non-users was 7.2. The period of maximum risk lay between the 7th and the 12th months of treatment (SEDA-19, 313).

Erectile impotence has been suggested in the light of some case experiences; this type of effect is always difficult to prove but it has been described repeatedly with various H_2 receptor antagonists.

One well-documented case suggested that in an infant girl reversible premature puberty was induced, but it must be noted that domperidone was also being given (SEDA-15, 394); in another instance an 18-month-old infant had marked enlargement of one breast (SEDA-16, 421–422), but this is probably similar to the effect sometimes seen in adult men rather than a true endocrine effect.

Body temperature

Fever is occasionally noted with cimetidine (30).

Long-Term Effects

Drug withdrawal

A complex neurobehavioral and gastroenteric withdrawal syndrome has been seen with both cimetidine and ranitidine. The characteristics included anxiety, sleeplessness, anorexia with weight loss, irritability, tachycardia, diarrhea, nausea and vomiting, abdominal pain, headache, and vertigo. The syndrome virtually disappeared when the drugs were given again, but reappeared when they were withdrawn once more. The syndrome may be related to a fall in prolactin concentrations; it responded well to domperidone (31).

Susceptibility Factors

Age

Neurological adverse effects are more likely to occur in elderly patients with impaired hepatic or renal function.

Sex

It has been suggested that women with spinal cord injuries may be at increased risk of galactorrhea due to H_2 receptor antagonists, since such injuries can themselves cause galactorrhea (SEDA-17, 417).

Drug–Drug Interactions

General

The many drug interactions described with cimetidine are largely attributable to inhibition of CYP isozymes or renal clearance of other drugs. Cimetidine also reduces hepatic blood flow and so can, for example, reduce the clearance of lidocaine. In the kidneys cimetidine interferes with the tubular excretion of procainamide and quinidine. Both effects are small, and the long list of drugs for which interference is demonstrable (Table 1) is out of all proportion to the number for which interference is of clinical significance.

Table 1 Groups of drugs interacting with cimetidine

Drug	Effect	References
Analgesics		
Methadone	Potentiation	(32)
Anticoagulants		
Acenocoumarol	Potentiation	(33,34)
Phenindione	Potentiation	(33)
Warfarin	Potentiation	(35,36)
Antiepileptic drugs		
Carbamazepine	Transient rise in concentrations	(37,38)
Phenytoin	Increased steady-state concentrations Small reduction in to clearance	(39)
Valproate		(40)
Antidepressants		
Tricyclics		
Amitriptyline	Reduced metabolism	(41)

© 2006 Elsevier B.V. All rights reserved.

Drug	Effect	References
Desipramine	Reduced metabolism in extensive hydroxylators	(42)
Doxepin	Reduced metabolism	(43)
Imipramine	Reduced metabolism	(44,45)
Nortriptyline	Reduced metabolism	(45)
SSRIs		
Fluoxetine	Parkinsonism	(46)
Paroxetine	Reduced metabolism	(47)
Antidysrhythmic drugs		
Cifenline	Increased serum concentrations	(48)
Encainide	Increased serum concentrations	(49)
Flecainide	Increased serum concentrations	(50)
Lidocaine	Toxic concentrations	(51)
Moracizine	Reduced metabolism	(52)
Procainamide	Increased plasma concentrations	(53)
Quinidine	Increased plasma concentrations	(54,55)
Tocainide	Reduced oral systemic availability	(56)
Anti-inflammatory to drugs		
Indometacin	Reduced serum concentrations	(57)
Benzodiazepines		
Adinazolam	Increased plasma concentrations	(58)
Alprazolam	Increased plasma concentrations	(59,60)
Chlordiazepoxide	Increased plasma concentrations	(61)
Clobazam	Increased plasma concentrations	(62)
Clorazepate	Prolonged elimination	(63)
Diazepam	Increased plasma concentrations	(64,65)
Flurazepam	Increased plasma concentrations	(66)
Nitrazepam	Increased plasma concentrations	(67)
Triazolam	Increased plasma concentrations	(59,60)
Beta-blockers		
Atenolol	Slightly prolonged half-life	(68)
Labetalol	Increased systemic availability; toxicity	(69,70)
	Increased plasma concentrations	
Metoprolol	Increased plasma concentrations	(71)
Propranolol		(72)
Bronchodilators		
Theophylline	Increased plasma concentrations; toxicity	(73,74)
Calcium channel blockers		
Diltiazem	Increased plasma concentrations	(75)
Felodipine	Increased plasma concentrations	(76)
Nifedipine	Increased plasma concentrations	(77)
Nimodipine	Increased systemic availability	(78)
Nisoldipine	Increased systemic availability	(79)
Nitrendipine	Increased systemic availability	(80)
Verapamil	Increased systemic availability	(81)
	Reduced clearance	(82)
Cytotoxic drugs		
Fluorouracil	Increased plasma concentrations	(83)
	Increased antiproliferative effect	(84)
Diuretics		
Furosemide	Increased AUC	(85)
Hypoglycemic drugs		
Gliclazide	Hypoglycemia	(86)
Immunosuppressants		
Ciclosporin	Increased plasma concentrations; toxicity	(87)
Neuromuscular blockers		
Suxamethonium	Delayed recovery (not confirmed)	(88,89)
Vecuronium	Delayed recovery	(90,91)

In most cases the slowing of the metabolism of other drugs, by a third at most, is only likely to be troublesome for drugs with a narrow margin between the therapeutic and toxic dose, such as theophylline, phenytoin, and warfarin; the clearance of theophylline may be reduced by up to 22% and the half-life increased by 50% (SEDA-16, 421).

Alcohol

Cimetidine slightly reduces the rate of metabolism of alcohol and alters its absorption (92–94), but it is doubtful if these effects are clinically significant.

Cimetropium bromide

See also Anticholinergic drugs

General Information

Cimetropium bromide is an anticholinergic drug that belongs to a series of scopolamine quaternary salts with strong antimuscarinic effects (1).

Reference

1. Scarpignato C, Bianchi Porro G. Cimetropium bromide, a new antispasmodic compound: pharmacology and therapeutic perspectives. Int J Clin Pharmacol Res 1985;5(6): 467–77.

Cinchocaine

See also Local anesthetics

General Information

Cinchocaine (dibucaine) is an aminoamide local anesthetic. It is ten times more potent than lidocaine and potentially very toxic. It is available in a number of over-the-counter topical formulations, such as antihemorrhoidal drugs.

Organs and Systems

Nervous system

Low concentrations of cinchocaine (0.003 and 0.03% respectively) caused irreversible neurotoxicity in A_β and C rabbit vagus nerve preparations (1). Cinchocaine had the greatest neurotoxic effect and the lowest safety margin compared with tetracaine and bupivacaine.

Cauda equina syndrome has been reported after a spinal anesthetic using cinchocaine (2).

- A 64-year-old man with a history of borderline diabetes who had undergone two previous operations uneventfully under spinal anesthetic received a spinal anesthetic with hyperbaric 0.24% dibucaine 2.2 ml and then a general anesthetic because of unilateral block. The next day he complained of difficulty in defecation and urination, with abnormal anal sensation. A diagnosis of cauda equina syndrome was made. He made a gradual recovery, but mild hypesthesia remained after 4 months.

A possible cause for this adverse event may have been maldistribution in the intrathecal space of the high concentration of cinchocaine, affecting the cauda equina and resulting in nerve damage; the incomplete block achieved in this case is suggestive of this. Elderly patients undergoing urological surgery often have risk factors for cauda equina syndrome, such as intraoperative lithotomy position, frequent spinal anesthetics, old age, and diabetes mellitus. The authors suggested that cinchocaine should be avoided for spinal anesthesia in these patients, because of its high neurotoxicity compared with other local anesthetics.

Hematologic

Cinchocaine inhibits ADP-mediated platelet aggregation (3); it is not known whether this has any clinical significance.

Skin

Two cases of contact dermatitis have been reported after the use of Proctosedyl and Ruscens Llorens, both of which contain cinchocaine. After patch testing, the first case was found to be allergic in origin and the second was due to photosensitivity. Neither showed cross-sensitivity to other local anesthetics (4).

Two cases of allergic contact dermatitis have been described after the use of cinchocaine formulations.

- A 71-year-old Japanese man, who was using an over-the-counter formulation, Makiron, for minor wounds, developed an itchy rash with seropapules and erosions on his right leg at the site of application (5). Makiron contains 0.1% cinchocaine hydrochloride and chlorphenamine maleate as well as naphazoline hydrochloride and benzethonium chloride. On patch testing, he was positive to both chlorphenamine and cinchocaine.
- A 79-year-old man presented with a 10-day history of weeping dermatitis affecting the perianal skin, buttocks, and proximal thighs (6). He had used Proctosedyl ointment topically for the preceding 3 weeks. Proctosedyl is an over-the-counter topical formulation for use as an antihemorrhoidal agent. It contains cinchocaine 5%, hydrocortisone, and lanolin. Patch testing was strongly positive to cinchocaine.

© 2006 Elsevier B.V. All rights reserved.

The authors highlighted the potential limitations of the International Contact Dermatitis Research Group (ICDRG) standard series for topical anesthetics. Benzocaine is the only topical anesthetic in the series and it will not detect contact allergy to amide agents; cross-sensitivity can also exist. They suggested that patch testing should include agents from both groups.

DoloPosterine N is an ointment for topical application in the treatment of hemorrhoids. Its active ingredient is cinchocaine. Although cinchocaine is a known contact sensitizer, as described above, systemic contact dermatitis is rare.

- A 62-year-old woman, who had applied DoloPosterine N ointment topically to the perianal skin and rectal mucosa for several days, developed erythematous vesicular lesions in the perianal area and an erythematous edematous rash of the face, axillae, elbow flexures, and inner thighs (7). This abated on withdrawal of the drug and the administration of oral prednisolone for 10 days. Patch testing was positive with cinchocaine.

Immunologic

An anaphylactic reaction to cinchocaine has been described.

- A 71-year-old man received intrathecal anesthesia using 0.3% cinchocaine 2 ml for a transurethral prostatectomy (8). He had a history of allergic rhinitis, and 2 months before had had an uneventful prostate biopsy and cystoscopy, also under spinal anesthesia with isobaric bupivacaine. Within 45 minutes of the spinal injection he complained of periorbital itching, started to shake, and developed muscle rigidity. He rapidly became unconscious, with a systolic blood pressure of 40 mmHg and widespread erythema. He was treated with hydrocortisone and antihistamines and required an infusion of adrenaline. Intradermal testing after full recovery was positive with cinchocaine.

Death

Three deaths after seizures and cardiac arrest have been reported in toddlers who accidentally ingested small amounts of cinchocaine (SEDA-21, 135).

Cinchophen

General Information

Cinchophen is a uricosuric drug that was formerly used in the treatment of gout (1). In 1991 the Spanish authorities withdrew cinchophen. It had been known for some time that it can cause severe hepatitis (SEDA-17, 114).

Reference

Cinmetacin

See also Non-steroidal anti-inflammatory drugs

General Information

Cinmetacin is an NSAID related to indometacin. There has been little experience with its use. In one study, gastrointestinal adverse effects developed in 13 of 30 patients (1).

Reference

1. Lucietti MV, Banchieri G. Studio clinico sulla efficacia e tollerabilita di un nuovo antiflogistico non-steroideo, la cinmetacina. [Clinical study of the efficacy of and tolerance for a new nonsteroidal anti-inflammatory agent, cinmetacin.] G Clin Med 1980;61(7):545–52.

Cinnarizine and flunarizine

See also Antihistamines

General Information

Cinnarizine and flunarizine are piperazine derivatives with antihistaminic properties and calcium channel blocking activity (SEDA-13, 131) (SEDA-14, 136) (SEDA-22, 178). Flunarizine is the difluoro derivative of cinnarizine. Cinnarizine is used to treat motion sickness.

© 2006 Elsevier B.V. All rights reserved.

A few controlled clinical trials of flunarizine in patients with intermittent claudication have suggested significant improvements in subjective signs and some objective measurements. Its effectiveness in patients with cerebrovascular insufficiency has not been clearly shown, but its use in the prevention of migraine and other forms of common headache has been studied extensively. Several double-blind controlled studies have suggested that flunarizine in a dosage not over 10 mg/day reduces the frequency of headaches (SEDA-11, 179). Clinical studies of the antiepileptic efficacy of flunarizine have been equivocal (SEDA-20, 191).

With a maintenance dosage of 10 mg/day, the main adverse effects of flunarizine are somnolence, sedation, fatigue, and drowsiness during the first few days in up to 10% of patients. During prolonged treatment some patients note difficulty in sleeping, lethargy, and reduced motivation. A dosage of 20 mg/day or more can cause drowsiness, increased sweating, peripheral edema, and fatigue (SEDA-7, 229).

Organs and Systems

Nervous system

A study in young volunteers has established the effects of cinnarizine 15–45 mg on daytime sleepiness and performance (1). Doses of 30 mg or more caused impaired performance and increased sleepiness. The authors therefore advised that cinnarizine should not be used in aircrew involved in tasks that demand attention.

Insomnia has been described with cinnarizine (SEDA-22, 178).

Blepharospasm has been attributed to flunarizine in an elderly woman (SEDA-22, 178).

Extrapyramidal adverse effects

Several reports have described extrapyramidal reactions and depression associated with the use of cinnarizine and flunarizine (SEDA-14, 136) and worsening of motility in parkinsonian patients (SEDA-13, 391).

In a Spanish study there were 70 reports of tremor and parkinsonism in patients taking cinnarizine and 11 reports of tremor and parkinsonism in patients taking flunarizine (2).

In a Brazilian study carried out to establish whether there are geographic differences in the cause of parkinsonism, the diagnosis of drug-induced parkinsonism was made in 45 of 338 patients (3). Cinnarizine and flunarizine were two of the three most commonly prescribed drugs.

In a retrospective study in 74 patients with cinnarizine-induced parkinsonism over 15 years, cinnarizine-induced parkinsonism was more frequent in women; most of the patients (66/74) recovered completely within 16 months after withdrawal (4). This suggests that cinnarizine-induced parkinsonism is reversible in most cases, but there is still a question of whether cinnarizine predisposes to permanent Parkinson's disease in a few patients. Cinnarizine-induced parkinsonism is a warning against prolonged use of an apparently harmless drug, especially in elderly people.

Parkinsonism, tardive dyskinesia, and depression have been described in some mostly elderly patients taking flunarizine (SEDA-12, 170) (SEDA-13, 169) (SEDA-14, 167) (SEDA-15, 198). These symptoms are resistant to anticholinergic drugs, levodopa, and bromocriptine, but regress within a few weeks to months after withdrawal of flunarizine; however, mild rigidity and bradykinesia persist in some patients. The recommended dosage of 10 mg/day should never be exceeded, and in elderly patients dosages higher than 5 mg/day can lead to an increased risk of extrapyramidal symptoms. Patients who take flunarizine to prevent migraine are usually some 25–30 years younger than those with cerebrovascular and peripheral vascular disease and appear to be at less risk of developing extrapyramidal symptoms with flunarizine (5).

Liver

Drug-induced cholestasis has rarely been reported in patients taking cinnarizine.

- An 87-year-old man took cinnarizine 75 mg/day for tinnitus and developed jaundice 7 weeks later, with dark urine and pale stools (6). He had taken no other drugs. Bile duct obstruction was ruled out and serological tests for viral hepatitis were negative. A liver biopsy 6 weeks later showed distinct centrilobular cholestasis and a slight lymphocytic infiltrate. He recovered completely and the liver tests were normal after another 3 months without cinnarizine. Rechallenge was not performed.

Skin

Various skin lesions have been attributed to cinnarizine and flunarizine.

- A 32-year-old woman developed subacute cutaneous lupus erythematosus after exposure to the sun while taking cinnarizine and thiethylperazine for vertigo (7). A similar eruption had occurred 10 years before, after exposure to the sun, while she was taking cinnarizine only. The problem did not occur when she was not taking the drug.
- A 78-year-old woman developed generalized lichen pemphigoides while taking cinnarizine (225 mg/day) and recovered after withdrawal of the drug and anti-inflammatory drug treatment (8).
- A lichen planus pemphigoides-like eruption following the use of cinnarizine has been reported in a Japanese woman (SEDA-11, 146).

Immunologic

Subacute cutaneous lupus erythematosus has been attributed to cinnarizine.

- A 32-year-old woman developed an erythematous, papulosquamous, annular, polycyclic skin eruption on her neck, trunk, and lateral parts of the limbs after sunbathing while taking cinnarizine and thiethylperazine (a phenothiazine) for vertigo. She had positive antinuclear antibodies (nucleolar pattern, anti-Ro/SSA). The lesions cleared without residual scars within a few weeks after stopping both drugs and starting steroids and chloroquine.

© 2006 Elsevier B.V. All rights reserved.

Phenothiazines can induce photosensitivity, but cinnarizine does not. The authors' arguments that cinnarizine was to blame in this case were its structural resemblance to piperazine and a similar episode of skin eruption in the same patient after sunbathing many years before while she was taking cinnarizine only but for which she did not seek medical advice (7).

Ciprofloxacin

See also Fluoroquinolones

General Information

Ciprofloxacin is a fluoroquinolone antibacterial drug with a wider spectrum of activity than nalidixic acid.

Observational studies

Antimicrobial prophylaxis to prevent inhalational anthrax has been recommended for people potentially exposed to *Bacillus anthracis* as a result of recent bioterrorist attacks. Of 3428 people taking ciprofloxacin, 666 (19%) reported severe nausea, vomiting, diarrhea, or abdominal pain; 484 (14%) reported fainting, lightheadedness, or dizziness; 250 (7%) reported heartburn or acid reflux; and 216 (6%) reported rashes, hives, or an itchy skin. Of those taking ciprofloxacin, 287 (8%) stopped taking it, 116 (3%) because of adverse events, 27 (1%) because of fear of possible adverse events, and 28 (1%) because they "did not think it was needed" (1–4).

The imaging of inflammation/infection with ^{99m}Tm-labeled ciprofloxacin in 96 patients had a sensitivity of 81% and specificity of 87%. The positive and negative predictive values were 90 and 75% respectively. No adverse effects were reported (5).

Comparative studies

In a multicenter, double-blind study of 234 patients with acute bacterial exacerbations of chronic bronchitis, ciprofloxacin (500 mg bd) was associated with a trend toward a longer infection-free interval and a significantly higher bacteriological eradication rate compared with clarithromycin (500 mg bd) after 14 days (6).

In a double-blind study, ciprofloxacin (500 mg bd) was associated with an infection-free interval and clinical response that were similar to those achieved with cefuroxime axetil (500 mg bd), but the bacteriological eradication rate associated with ciprofloxacin was significantly higher (7).

Organs and Systems

Cardiovascular

Ciprofloxacin causes prolongation of the QT interval (8,9).

Nervous system

Headache was recorded in 8% of patients taking ciprofloxacin (10)

Ciprofloxacin can cause confusion and general seizures (11,12).

Ciprofloxacin can cause facial dyskinesia (13,14).

Two cases of generalized painful dysesthesia associated with ciprofloxacin have been reported (15).

Sensory systems

Eyes

Bilateral acute visual loss, possibly due to toxic optic neuropathy, was observed after 4 weeks of treatment with ciprofloxacin 1.5 g/day and improved after withdrawal (16).

Ciprofloxacin 0.3% ophthalmic drops can cause microprecipitates of pure ciprofloxacin in the corneal epithelium (17). In four corneal transplantation patients treated preoperatively with ciprofloxacin 0.3% ophthalmic drops, there were microprecipitates associated with damaged corneal epithelium in two patients; another developed a macroprecipitate in a corneal ulcer (18). The crystalline precipitates were pure ciprofloxacin.

Ears

Topical 0.2% ciprofloxacin (0.2 ml od for 7 days) did not significantly affect the auditory brainstem response thresholds of guinea pigs, whereas 4% gentamicin (0.2 ml od for 7 days) resulted in total hearing loss (19).

Topical 0.2% ciprofloxacin solution was effective and well tolerated in 232 patients with chronic suppurative otitis media; the most frequently reported adverse events were pruritus, stinging, and earache. Audiometric tests did not show changes attributable to ciprofloxacin (20).

In children with tympanic membrane perforation, topical ciprofloxacin caused no signs of local intolerance or

© 2006 Elsevier B.V. All rights reserved.

ototoxicity and did not result in significant serum concentrations (21).

Psychological, psychiatric

The administration of ciprofloxacin has been associated with psychosis (22,23) and hypoactive delirium (24,25).

- A 27-year-old woman developed an acute psychotic reaction following the use of ciprofloxacin eye-drops (1 drop hourly to each eye) (26).

Hematologic

Ciprofloxacin has been associated with hemolysis in combination with a severe skin reaction in a young adult (27).

Fatal ciprofloxacin-associated thrombotic thrombocytopenic purpura (28) and thrombocytopenia (29) have been reported.

Gastrointestinal

In a randomized, double-blind comparison of prulifloxacin 600 mg/day and ciprofloxacin 500 mg bd in 235 patients with acute exacerbations of chronic bronchitis, the most common treatment-related adverse event was gastric pain of mild or moderate intensity, reported in 8.5% of the patients taking prulifloxacin and 6.8% of those taking ciprofloxacin (30).

Ciprofloxacin has been associated with diarrhea due to *Clostridium difficile* (31–33). In 27 patients the only significant risk factor for nosocomial *C. difficile*-associated diarrhea was the use of ciprofloxacin (34).

Liver

Ciprofloxacin causes a mild reversible rise in liver enzymes in 2–3% of patients. Acute hepatitis is rare, but has been reported in a 32-year-old man (35).

Pancreas

A report has suggested that ciprofloxacin can cause pancreatitis (36).

Urinary tract

Two cases of acute renal insufficiency due to necrotizing vasculitis associated with ciprofloxacin were reported in elderly patients (37). In two patients who underwent high-dose chemotherapy with autologous stem cell rescue, acute renal insufficiency developed while they were taking prophylactic ciprofloxacin; withdrawal resulted in prompt reversal of renal insufficiency (38). Ciprofloxacin-induced acute renal insufficiency has been reported in cancer patients undergoing high-dose chemotherapy and autologous stem cell rescue (38). A case report has suggested that ciprofloxacin overdose can lead to acute renal insufficiency characterized by acute tubular necrosis with distal nephron apoptosis (39).

- An 18-year-old woman with cystic fibrosis had pronounced impairment of renal function after taking oral ciprofloxacin 750 mg tds (30 mg/kg/day) for 3 weeks; withdrawal led to normalization of renal function within 10 days (40).

Hemolytic-uremic syndrome has been attributed to ciprofloxacin (41).

- A 53-year-old white man was given chemotherapy for acute lymphoblastic leukemia and after 4 weeks recovered his blood cell count but developed a fever and was given oral ciprofloxacin 500 mg bd. After four doses he developed the typical features of hemolytic–uremic syndrome with microangiopathic hemolytic anemia. The ciprofloxacin was withdrawn, and he received five sessions of plasma exchange. He recovered completely.

Bilateral hydronephrosis and acute renal insufficiency due to urinary tract stones predominantly composed of ciprofloxacin has been reported (42).

Skin

Ciprofloxacin can cause a fixed drug eruption (43,44), purpuric skin lesions (44,45), bullous pemphigoid (46), cutaneous vasculitis (45–47), and ultraviolet recall-like phenomenon (48).

Musculoskeletal

Tendinopathy

Ciprofloxacin can be associated with partial or complete tendinitis. Of 72 lung transplant recipients who received ciprofloxacin, 20 had Achilles tendon involvement (tendinitis 15, rupture 5) (49). Tendon rupture occurred at a lower dosage of ciprofloxacin than tendinitis and the mean recovery duration was significantly longer.

- Achilles tendon rupture without any sudden pain occurred in a 45-year-old female runner who developed bilateral tendinopathy of the Achilles tendon after repeated treatment with ciprofloxacin; histological analysis showed cystic changes with focal necrosis (50).

Arthropathy

The available data suggest that the incidence of arthrotoxicity in children taking ciprofloxacin is the same as in adults; the use of other fluoroquinolones is too rare to obtain clear information about the risks in children (51). In 12 children with sickle cell disease treated successfully for acute osteomyelitis with oral ciprofloxacin, transient bilateral Achilles tendon tendinitis occurred in one 5-year old (52). Another case was reported in a hemodialysis patient with a ciprofloxacin-associated Achilles tendon rupture (53).

In 75 children with typhoid fever, aged under 6 years (mean age 32 months), ciprofloxacin had no adverse effects on growth or joints (54). In another study only 2 of 219 children treated with ciprofloxacin developed arthropathy, in one case transiently (55). In a necropsy study on children treated with ciprofloxacin 20–40 mg/kg/day for an average of 148 days, there were no chondrotoxic effects; however, synovial membranes showed signs of subacute synovitis, which had not been noted in life (56).

Data on more than 1500 children treated with ciprofloxacin suggest that the safety profile of ciprofloxacin in children and adolescents is similar to the profile in adults (57). Adverse events, mostly involving the gastrointestinal tract, were noted in 5–15% of patients. Reversible

© 2006 Elsevier B.V. All rights reserved.

arthralgia occurred in 36 of 1113 patients, but there was no radiographic evidence of cartilage damage.

An acute reversible arthropathy has been described in a child with cancer treated with a short course of ciprofloxacin for febrile neutropenia (58).

Immunologic

Anaphylactoid reactions occurred in 3 of about 3200 students who took ciprofloxacin 500 mg for chemoprophylaxis of meningococcal meningitis; two had no history of atopic illness (59). Additional adverse reactions were mild skin rashes in three students and nausea and vomiting in two.

Angioimmunoblastic lymphadenopathy is a rare disorder characterized by generalized lymphadenopathy, fever, hepatosplenomegaly, immune hemolytic anemia, and polyclonal hypergammaglobulinemia. Biopsy-proven angioimmunoblastic lymphadenopathy has been reported in a 79-year-old man who had received ciprofloxacin (60).

A Jarisch–Herxheimer reaction to ciprofloxacin has been reported (61).

- A 14-year-old girl developed tachycardia, hypotension, and disseminated intravascular coagulation after her first dose of oral ciprofloxacin 500 mg for presumed pyelonephritis. A peripheral blood smear showed spirochetes consistent with *Borrelia* species.

Susceptibility Factors

Age

Children

In 36 premature infants, delivered at 25–35 weeks and with birth weights of 750–2050 g, ciprofloxacin (13.8 mg/kg/day in two or three divided doses for 3–20 days) had good efficacy in 66% of cases (62). Thrombocytopenia (five cases), raised transaminases (three cases), hyperbilirubinemia (three cases), and raised creatinine concentration (two patients) were reported as adverse events; one child developed femoral osteitis.

In a Russian study of children with cystic fibrosis, the adverse effects of ciprofloxacin were chiefly gastrointestinal (nausea, stomach pain, diarrhea) and increased transaminase activity (63). One episode of arthrotoxicity was transient. There were no negative effects on growth and no chondrotoxicity.

Oral ciprofloxacin (10 mg/kg bd) was as safe and effective as intramuscular ceftriaxone (50 mg/kg/day) in the treatment of acute invasive diarrhea in 201 children (aged 6 months to 10 years) (64). Possible drug-related adverse events occurred in 8% and were mild and transient. Joints were normal during and after the completion of therapy in all patients.

Elderly people

In a retrospective analysis there were no clinically important differences in the safety profile of ciprofloxacin in patients aged under or over 65 years (65). The incidence of drug-related adverse events was higher in those under 65 years (25%) than in those aged 65 years or more (17%); the most common adverse events affected the gastrointestinal and central nervous systems.

Other features of the patient

Ten patients with peripheral arterial occlusive disease were scheduled to undergo elective percutaneous transluminal angioplasty after a single dose of ciprofloxacin 400 mg (66). Antibiotic concentrations were significantly reduced in ischemic lesions compared with healthy adipose tissue. However, improvement of arterial blood flow in the affected limb was associated with increased cure rates of soft tissue infections.

The pharmacokinetics of intravenous ciprofloxacin have been studied in intensive care unit patients during continuous venovenous hemofiltration ($n = 5$) or hemodiafiltration ($n = 5$) (67). Ciprofloxacin clearance was not altered. A dosage of 400 mg/day was sufficient to maintain effective drug plasma concentrations in patients undergoing continuous renal replacement therapy.

Drug Administration

Drug administration route

In a comparison of intravenous and oral ciprofloxacin in children, treatment associated adverse events were reported in 11% of children taking oral ciprofloxacin, compared with 19% of the children who were treated intravenously (68). In 31 children (1.5%) arthralgia occurred, but it was generally mild to moderate and resolved spontaneously.

Drug overdose

A patient developed acute renal insufficiency after ciprofloxacin overdose. This was mediated by tubulointerstitial nephritis with distal nephron apoptosis, as evidenced by renal biopsy (39).

Drug–Drug Interactions

Ciclosporin

In 42 patients who had received a kidney transplant, cases were treated with ciprofloxacin in the first 1–6 months after transplantation, and matched controls (two per case) were not. The proportion of cases with at least one episode of biopsy-proven rejection 1–3 months after transplantation (45%) was significantly higher than in the controls (19%). The authors speculated that ciprofloxacin increases rejection rates in renal transplant recipients by antagonizing ciclosporin-dependent inhibition of interleukin-2 production (69).

Clozapine

Ciprofloxacin can alter plasma clozapine concentrations, perhaps by inhibition of cytochrome P450 enzymes (70).

Didanosine

Didanosine one enteric-coated capsule/day (400 mg/day) did not affect the absorption of ciprofloxacin in 16 patients (71).

© 2006 Elsevier B.V. All rights reserved.

Glibenclamide

Hypoglycemia and raised serum concentrations of glibenclamide, which is metabolized by CYP2C9, occurred after treatment with ciprofloxacin for 1 week in a patient taking long-term glibenclamide (72).

Insulin

Hypoglycemia occurred in a patient treated with insulin and ciprofloxacin 500 mg bd (29).

Methadone

Ciprofloxacin, given to a patient who had been successfully treated with methadone for more than 6 years, caused profound sedation, confusion, and respiratory depression (73). This may have been due to inhibition of CYP1A2 and CYP3A4, two of the isozymes involved in the metabolism of methadone.

Methotrexate

Methotrexate elimination can be delayed by ciprofloxacin. Two adolescents with malignant diseases had reduced elimination of methotrexate (12 g/m^2 4-hourly) when they took ciprofloxacin 500 mg bd (74).

Oral contraceptives

Some antibiotics can reduce the efficacy of oral contraceptives. However, there is pharmacokinetic evidence that plasma concentrations of oral contraceptive steroids are unchanged by co-administration of ciprofloxacin (75). Furthermore, ciprofloxacin (500 mg bd) did not interfere with the ovarian suppression produced by the oral contraceptive Marvelon (30 micrograms of ethinylestradiol plus 150 micrograms of desogestrel) in 24 healthy women in a randomized, double-blind, placebo-controlled, crossover trial (76).

Phenytoin

Ciprofloxacin may interact with phenytoin reducing phenytoin concentrations (77).

- A lower than expected phenytoin serum concentration has been measured in a 78-year-old white woman with a grade III astrocytoma of the right parieto-occipital region treated with ciprofloxacin (500 mg bd) (78).

Increased renal excretion has been suggested to be at least partly responsible for the increased clearance.

Besides this kinetic interaction, the possible epileptogenic potential of ciprofloxacin itself may contribute to the development of seizure activity.

Probenecid

The renal excretion of ciprofloxacin was reduced and plasma concentrations increased by probenecid (79).

Quinidine

Serum quinidine concentrations rose during concomitant administration of ciprofloxacin (80). The authors speculated that the mechanism was inhibition of cytochrome P450 by ciprofloxacin.

Rifamycins

Rifampicin-induced lupus-like syndrome is associated with combination therapy with ciprofloxacin, since rifampicin is metabolized by (among others) CYP3A4, which is inhibited by ciprofloxacin, and combined usage may lead to higher rifampicin blood concentrations (81).

Ropinirole

During co-administration of ciprofloxacin with ropinirole in 12 patients there was an increase in the plasma ropinirole concentration, which is metabolized by CYP1A2 (82).

Warfarin

Ciprofloxacin can occasionally cause an exaggerated hypoprothombinemic response and bleeding in patients taking warfarin. In 66 patients (median age 72 years, range 36–94), the mean time to detection of the coagulopathy after ciprofloxacin challenge was 5.5 days (83). Hospitalization was reported in 15 cases, bleeding in 25, and death in one. The median INR was 10.0. Patients in their seventh decade and those requiring polypharmacy were most at risk.

Food–Drug Interactions

The systemic availability of ciprofloxacin is reduced by 30–36% when it is taken with dairy products (84).

Ciramadol

General Information

Data on the incidence of adverse effects after usual doses of oral ciramadol are conflicting. In one study there was a low incidence of mild adverse effects (1), but in another, in which ciramadol 60 mg was more effective than codeine 60 mg or placebo, there was a high incidence of opioid adverse effects (2); some other workers have had the same experience.

Cisapride

General Information

Cisapride is structurally similar to metoclopramide, but has no dopamine receptor antagonist activity and hence no central antiemetic effect. However, because it stimulates the release of acetylcholine in the gastrointestinal tract it is effective in conditions such as reflux esophagitis and gastroparesis. During clinical trials, the most frequent unwanted effects were diarrhea (5–11%) and abdominal pain (16% with 20 mg bd).

Observational studies

The effect of cisapride 20 mg bd for 7 days in preventing symptoms of gastro-esophageal reflux disease induced by a provocative meal has been assessed in 122 patients who had had symptoms suggestive of gastro-esophageal reflux for at least 3 months (1). Cisapride prevented or reduced the symptoms of heartburn and related symptoms, such as belching and regurgitation. Mild to moderate diarrhea was the main adverse effect.

Comparative studies

In a randomized, double-blind study in 106 patients with non-ulcer dyspepsia, cinitapride 1 mg tds was as effective as cisapride 5 mg tds in relieving symptoms (2). Adverse events, mainly gastrointestinal, were transient and did not require drug withdrawal. In another randomized study in 28 children (aged 5–17 years) with diabetic gastroparesis, domperidone 0.9 mg/kg/day for 8 weeks was superior to cisapride 0.8 mg/kg/day in reversing gastric emptying delay and gastric electrical abnormalities, as well as in improving dyspeptic symptoms and diabetic control (3). No potentially drug-related adverse effects were reported.

Placebo-controlled studies

The effect of cisapride 10 mg qds for 5 days on the frequency of nocturnal transient lower esophageal sphincter relaxation and esophageal acid exposure has been studied in a double-blind, placebo-controlled, crossover study in 10 patients with gastro-esophageal reflux disease (4). Cisapride significantly reduced the frequency of transient lower esophageal sphincter relaxation during sleep and increased lower esophageal sphincter pressure without changing gastric emptying. However, in a larger double-blind, placebo-controlled, crossover study in 30 patients with gastro-esophageal reflux disease, cisapride 20 mg bd for 4 weeks (despite adequate plasma concentrations) had no significant effects on swallow-induced esophageal peristaltic activity, the basal tone of the lower esophageal sphincter, or the number of transient lower esophageal sphincter relaxations induced by gas distension of the stomach (5). Adverse effects were similar in the two treatment sequences, although there were a few more episodes of abdominal cramps, nausea, and headache with cisapride.

General adverse effects

A comparison of data from prescription event monitoring in over 13 000 recipients of cisapride and from a further 9726 recipients involved in a controlled study showed that diarrhea, in about 2–4% of patients, was the commonest adverse effect reported. Other relatively common adverse effects are headache, abdominal pain, nausea and vomiting, and constipation, all in about 1–1.5% of patients.

A thorough review of the effects of cisapride in patients in intensive care suggested that adverse reactions are not likely to be severe or problematical (6). However, cisapride has been withdrawn because of the risk of prolongation of the QT interval and consequent ventricular dysrhythmias.

Organs and Systems

Cardiovascular

The FDA reported that between September 1993 and April 1996 it received reports of prolonged QT intervals in 23 patients and torsade de pointes or ventricular fibrillation in 34. Some proved fatal (SEDA-21, 361).

Several later studies confirmed the finding of QT interval prolongation during cisapride therapy in children (7).

© 2006 Elsevier B.V. All rights reserved.

The effects of cisapride on the QT_c interval, heart rate, and cardiac rhythm were reported in a controlled study of 83 infants aged 2–54 months who received cisapride for a minimum of 4 days for gastro-esophageal reflux and 77 controls, using continuous bipolar limb lead electrocardiography for 8 hours (8). The QT_c interval was significantly prolonged by cisapride in infants under 3 months old. There was no significant difference in heart rates and there were no dysrhythmias. None of the infants was receiving drugs that inhibit the hepatic metabolism of cisapride via CYP3A4.

The effect of cisapride 0.8 mg/kg/day for 14 days on the QT_c interval has been studied prospectively in 50 infants with feeding intolerance, apnea, and bradycardia episodes secondary to gastro-esophageal reflux and gastrointestinal dysmotility (9). In 15 infants there was prolongation of the QT_c interval at some time during the 14 days. Infants with a QT_c interval on day 3 at least two standard deviations above the mean baseline QT_c interval were more likely to develop a prolonged QT_c interval.

Over 30 drugs (for example clarithromycin, erythromycin, and troleandomycin; nefazodone; fluconazole, itraconazole, and ketoconazole; indinavir and ritonavir) and other substances (for example grapefruit juice) can interact with cisapride and enhance its dysrhythmogenic effect. Despite regulatory action, including strengthened warnings in the product information, reports of dysrhythmias have repeatedly appeared. For example, in the UK the Medicines Control Agency received 60 reports of serious cardiac adverse events between 1988 and 2000; five were fatal (10). The corresponding worldwide figures were 386 serious ventricular dysrhythmias with 125 deaths and 50 unexplained deaths.

- An 81-year-old woman, who had a permanent pacemaker for complete heart block with symptomatic bradycardia-dependent torsade de pointes, had breakthrough torsade de pointes during therapy with cisapride 10 mg tds for 22 days and paroxetine for 9 days (11). She made a good recovery on withdrawal of the drugs.

In some countries therefore the product licence was suspended (10) and cisapride was subsequently withdrawn from the market by Janssen Cilag in 2003 (12).

Before its withdrawal in the UK cisapride was specifically contraindicated in premature babies for up to 3 months after birth, because of the risk of QT interval prolongation (10). Between 1988 and 2000 the Medicines Control Agency received 64 reports of suspected adverse effects of cisapride in children under 13 years, of which two were cases of QT prolongation and two were sudden unexplained deaths. Another 106 cardiovascular events were reported from other countries, including 30 cases of QT prolongation, six cases of ventricular fibrillation or tachycardia, and four sudden unexplained deaths.

Electrocardiographic changes and predisposition to cardiac dysrhythmias were investigated in 63 children (mean age 29 months) with gastro-esophageal reflux who had taken cisapride 0.2 mg/kg tds for at least 15 days and 57 control children (mean age 27 months) who were hospitalized for other reasons and were not given cisapride or other oral treatment (13). All the children had an electrocardiogram performed at inclusion, and 24-hour Holter recording was performed in all children with prolonged QT intervals. When a prolonged QT interval was detected cisapride was withdrawn and a new electrocardiogram was recorded. Five children in the treatment group and six controls had prolonged QT intervals, which normalized in three of the five children after cisapride was withdrawn. Holter recording was normal in all children.

The effect of cisapride 0.2 mg/kg tds for 8 weeks on cardiac rhythm was studied in a placebo-controlled, double-blind trial in 49 children aged 0.5–4 years with gastro-esophageal reflux resistant to other medical therapy (14). None had underlying cardiac disease or electrolyte imbalance. Cisapride had no effect on cardiac electrical function. However, in a prospective study cisapride 2 mg/kg qds given for 72 hours to 10 premature infants caused a significant increase in the QT_c interval compared with pretreatment values (15).

The relation between cisapride plasma concentrations, QT_c interval, and cardiac rhythm was evaluated in a controlled study in 211 infants undergoing routine 8-hour polysomnography (16). Cisapride was given for at least 4 days. At comparable doses of cisapride and comparable plasma concentrations, the QT_c was significantly higher in infants below 3 months of age.

In a postmarketing study of the safety of cisapride during 1993–9, 341 patients had cardiac effects, of whom 80 (23%) died, the deaths being directly or indirectly associated with a dysrhythmic event (17). The cardiac effects included QT interval prolongation, torsade de pointes, polymorphous ventricular tachycardia, ventricular fibrillation, ventricular tachycardia, cardiac arrest, unspecified "serious" dysrhythmias, and sudden death. In most instances the dysrhythmia occurred in the presence of risk factors such as other drugs or medical conditions.

Nervous system

Despite the fact that cisapride is not a dopamine receptor antagonist, tardive dyskinesia has been reported.

- Tardive dyskinesia with involuntary movement of muscles of mastication and the tongue has been reported in a 76-year-old man who took cisapride 10 mg tds, with complete resolution on withdrawal (18).

Psychological, psychiatric

In 16% of children given cisapride for intestinal pseudo-obstruction, treatment was followed by mild irritability and hyperactivity (SEDA-18, 370). In one adult, aggressive behavior seemed to be a direct complication of treatment (19).

Gastrointestinal

The effect of cisapride 10 mg bd on gastroduodenal reflux and gall bladder motility has been assessed in 77 patients with gallstones in a double-blind, placebo-controlled study (20). Cisapride increased gallbladder motility but did not have any effect on gastroduodenal reflux. Diarrhea, abdominal cramps, and increased bladder frequency were common adverse effects.

© 2006 Elsevier B.V. All rights reserved.

A multicenter trial in 353 patients assessed the efficacy and tolerance of sodium alginate (four 10 ml sachets a day) compared with cisapride (5 mg qds) in the symptomatic treatment of uncomplicated gastro-esophageal reflux without severe esophagitis (21). Sodium alginate, which costs less than cisapride, was more effective in relieving symptoms. Adverse effects were rare and not serious. Constipation was the most common adverse effect of alginate while diarrhea was the commonest adverse effect of cisapride.

Liver

In one elderly man receiving cisapride, hepatitis occurred and resolved rapidly on drug withdrawal; there was no detectable cause other than the use of cisapride (22).

Urinary tract

Cisapride can cause functional changes in the urinary tract because of increased pressure in the bladder, which may be a problem in individuals with hyperactive bladders. In individuals who had complete traumatic spinal cord injury, the increase in reflex bladder contractions was sufficient to reduce compliance markedly (23).

Six cases of pollakiuria have been published (24), reversible when treatment was withdrawn (SEDA-19, 325).

Susceptibility Factors

Age

Children

The use of cisapride and its benefit to harm balance in children has been reviewed (25). Overall it is well tolerated. The most common adverse effects are diarrhea, abdominal cramps, borborygmi, and colic. Serious adverse events are rare and include isolated cases of extrapyramidal reactions, seizures in epileptic patients, cholestasis, QT interval prolongation and ventricular dysrhythmias, anorexia, and enuresis. Interactions of cisapride with other drugs are similar to those reported in adults. Co-administration of drugs that inhibit CYP3A4, such as imidazoles, macrolide antibiotics, the antidepressant nefazodone, and protease inhibitors such as ritonavir, are contraindicated. Furthermore, co-administration of anticholinergic drugs can compromise the beneficial effects of cisapride.

A systematic review of randomized, controlled trials of cisapride for gastro-esophageal reflux in children has been reported (26). Seven comparisons of cisapride with placebo (286 children in all) were included. The reflux index was significantly reduced by cisapride. However, there was no clear evidence that cisapride reduced symptoms of gastro-esophageal reflux. Adverse events (mainly diarrhea) were not significantly more common with cisapride.

The effects of cisapride 0.2 mg/kg tds on acid gastro-esophageal reflux in 32 formerly preterm infants receiving respiratory stimulation with caffeine have been studied using 24-hour esophageal pH monitoring (27). Cisapride significantly reduced the reflux index and the frequency of reflux without impairing the systemic availability or therapeutic effects of caffeine.

The effects of cisapride 0.2–0.3 mg/kg tds on chronic constipation were studied in a double-blind, placebo-controlled trial in 36 children (28). Cisapride was effective in the treatment of chronic constipation without major adverse effects.

The effects of low-dose cisapride (0.1 mg/kg tds) on gastric emptying and the QT interval were studied in a double-blind, placebo-controlled, crossover trial in 20 infants of low birth weights (29). Low-dose cisapride significantly improved gastric emptying without prolonging the QT interval.

Elderly patients

The pharmacokinetics of cisapride have been studied in eight elderly patients (mean age 85 years) (27). There were no adverse effects, apart from a slight increase in stool frequency. There were no changes in the corrected QT interval. However, plasma cisapride concentrations were higher than expected. Thus, in extremely elderly patients cisapride should be given once or twice a day rather than three times.

Other features of the patient

Cisapride should not be prescribed for patients with a history of disturbances of cardiac rhythm or who are at risk of developing frank dysrhythmias, especially individuals with hypokalemia or hypomagnesemia (SEDA-22, 389).

Cisapride should not be used in cases of intestinal obstruction, perforation, or hemorrhage (SEDA-22, 389).

Drug–Drug Interactions

Cimetidine

In eight healthy volunteers oral cimetidine 400 mg tds increased the steady-state C_{max} and AUC of oral cisapride 10 mg tds. Cisapride shortened the t_{max} and reduced the AUC of cimetidine (30). The authors concluded that cimetidine inhibits the metabolism of cisapride, and cisapride enhances the gastrointestinal absorption of cimetidine.

Digoxin

A possible interaction between cisapride and digoxin has been reported (31).

- A 90-year-old woman took cisapride, first in a dose of 5 mg bd and then 5 mg tds. She had been taking digoxin for a long time, but the serum digoxin concentration began to fall gradually after cisapride was given, from 1.1 nmol/l in January to 0.7 nmol/l in March and 0.5 nmol/l in August. The digoxin tablets were of reportedly high dissolution rate, with an onset of action at 30–60 minutes and a peak effect at 4–6 hours after a single dose. The onset of action of cisapride is 30–60 minutes, but the duration of its promotility effect during multiple dose therapy is not clear. The drugs were then separated by 4 hours, with the aim of reducing the promotility effect of cisapride on digoxin absorption, and there was an improvement in both clinical response and digoxin concentration.

© 2006 Elsevier B.V. All rights reserved.

The authors speculated that cisapride reduced digoxin absorption by accelerating bowel transit time.

Diltiazem

A possible interaction of cisapride 20 mg/day with diltiazem has been reported in a 45-year-old woman who developed near syncope and had QT interval prolongation (32). The QT interval returned to normal after withdrawal of cisapride. Rechallenge was not attempted. Diltiazem inhibits CYP3A4, and should therefore probably be avoided in combination with cisapride.

Oral anticoagulants

The absorption of the anticoagulants warfarin and phenprocoumon is unaffected by cisapride (SEDA-21, 361).

Propranolol

The absorption of propranolol is unaffected by cisapride (SEDA-21, 361).

Cisatracurium besilate

See also Neuromuscular blocking drugs

General Information

Cisatracurium is one of the ten isomers of atracurium. With an ED_{95} of 0.05 mg/kg it is about three times more potent than atracurium (1–3). The duration of action of cisatracurium tends to be slightly longer than that of atracurium. Less cisatracurium is required to achieve a given degree of neuromuscular blockade and so less laudanosine is produced.

Cisatracurium and atracurium share the same metabolic pathways, but Hofmann elimination may have a greater role in the elimination of cisatracurium than in atracurium (2,4–7). Spontaneous in vivo degradation accounts for 77% of total body clearance of cisatracurium (6). Organ clearance is 23% of total body clearance. Major metabolites of cisatracurium are laudanosine and a monoquaternary acrylate.

Clinical problems due to histamine release after bolus administration of cisatracurium have not been observed, even with very large doses up to 0.4 mg/kg (3,8), but in some patients there were considerable increases in plasma histamine concentrations (8–10).

Organs and Systems

Cardiovascular

With doses up to eight times the ED_{95} no cardiovascular adverse effects were observed (8) and in other studies cisatracurium had only minor cardiovascular adverse effects (9,11,12). Patients with coronary artery disease undergoing myocardial revascularization tolerated cisatracurium doses up to several fold the ED_{95} well; hemodynamic changes from pre- to postinjection were minimal (13,14).

Immunologic

Anaphylactic reactions have been reported (15–17).

Susceptibility Factors

Age

In line with its non-organ-dependent elimination pathways, neither the plasma clearance nor the duration of action of cisatracurium differed between young and elderly patients (18).

Renal disease

In patients with or without renal failure, there was no difference in the duration of action of cisatracurium (19).

Hepatic disease

In patients with hepatic failure neither the half-life nor the duration of action of cisatracurium was prolonged when compared with controls (20). In another study, however, the volume of distribution was increased and the plasma clearance reduced in patients with end-stage liver disease (21). Recovery times were not statistically different but the variability was greater in patients with liver disease (21).

Drug–Drug Interactions

General anesthetics

The action of cisatracurium is potentiated by isoflurane, sevoflurane, and enflurane (22).

Citalopram and escitalopram

See also Selective serotonin re-uptake inhibitors (SSRIs)

General Information

Citalopram is a racemic bicyclic phthalane derivative and is a highly selective serotonin re-uptake inhibitor with minimal effects on noradrenaline and dopamine neuronal reuptake. Inhibition of 5-HT re-uptake by citalopram is primarily due to the *S*-enantiomer (escitalopram). Its most frequent adverse events (nausea, somnolence, dry mouth, increased sweating) are mainly transient and mostly mild to moderate (1).

The single and multiple-dose pharmacokinetics of citalopram are linear and dose-proportional in the range 10–60 mg/day. Citalopram is metabolized to demethylcitalopram, didemethylcitalopram, citalopram-N-oxide, and a deaminated propionic acid derivative. Citalopram has a mean half-life of about 35 hours (2). Racemic citalopram is several times more potent than its metabolites in inhibiting serotonin reuptake (3).

In a systematic review of clinical trials the therapeutic efficacy of citalopram was significantly greater than that of placebo and comparable with that of other antidepressants (4).

Escitalopram oxalate is the *S*-enantiomer of citalopram (5). The therapeutic activity of citalopram resides in the *S*-isomer and escitalopram binds with high affinity to the human serotonin transporter; *R*-citalopram is about 30-fold less potent. The half-life of escitalopram is 27–32 hours. Citalopram and escitalopram have negligible effects on CYP isozymes.

Escitalopram was efficacious in patients with major depressive disorder in short-term, placebo-controlled trials, three of which included citalopram as an active control, and in a 36-week study in the prevention of relapse in depression (5). It has also been used to treat generalized anxiety disorder, panic disorder, and social anxiety disorder. Results also suggest that, at comparable doses, escitalopram demonstrates clinically relevant and statistically significant superiority to placebo treatment earlier than citalopram. The most common adverse events associated with escitalopram include nausea, insomnia, disorders of ejaculation, diarrhea, dry mouth, and somnolence. Only nausea occurred in more than 10% of patients taking escitalopram.

A meta-analysis of 20 short-term studies of five SSRIs (citalopram, fluoxetine, fluvoxamine, paroxetine, and sertraline) has been published (6). There were no overall differences in efficacy, but fluoxetine had a slower onset of action. Citalopram and sertraline were least likely to cause drug interactions, but citalopram was implicated more often in fatal overdoses.

Organs and Systems

Cardiovascular

There has been some concern about the cardiovascular safety of citalopram, mainly because of animal studies showing effects on cardiac conduction. These most commonly occur in large overdoses, in which a variety of cardiac abnormalities, including QT_c prolongation, have been noted. However, this can occur with therapeutic doses too.

- Bradycardia (34/minute) with a prolonged QT_c interval of 463 ms occurred in a patient taking citalopram 40 mg/day (7). The bradycardia resolved when citalopram was withdrawn. The patient also had alcohol dependence and evidence of cardiomyopathy; presumably this may have potentiated the effect of citalopram on cardiac conduction.
- A 21-year-old woman developed QT_c prolongation (457 ms) after taking a fairly modest overdose (400 mg) of citalopram (usual daily dose 20–60 mg) (8). The QT_c prolongation resolved uneventfully over the next 30 hours.

© 2006 Elsevier B.V. All rights reserved.

This suggests that even modest overdoses of citalopram can cause QT_c prolongation and that cardiac monitoring should be considered. Based on the pharmacokinetic profile of citalopram and the temporal pattern of QT_c change, the authors suggested that the effect of citalopram on the QT_c interval was mediated by one of its metabolites, dimethylcitalopram.

Prolongation of the QT_c interval has been reported in five patients who made non-fatal suicide attempts by taking large amounts of citalopram. Their electrocardiograms showed other conduction disorders, including sinus tachycardia and inferolateral repolarization disturbances (SEDA-21, 12).

Nervous system

SSRIs can infrequently cause extrapyramidal movement disorders and can also worsen established Parkinson's disease (SEDA-22, 23) and another case has been reported (9).

- A 68-year-old woman developed major depression. A neurological assessment excluded neurological diseases, including Parkinson's disease. After treatment with citalopram, 20 mg/day for 7 days, she developed severe parkinsonism, with rigidity, tremor, and bradykinesia, and became unable to walk. The citalopram was withdrawn after a further week and nortriptyline was substituted; however, 10 days later parkinsonism was still present. Her symptoms eventually responded to cobeneldopa.

The authors concluded that the citalopram had probably precipitated latent Parkinson's disease. Citalopram is the most highly selective SSRI and, in anecdotal accounts, has been implicated somewhat less often than other SSRIs in extrapyramidal movement disorders. However, this case, together with another report of citalopram-induced worsening of pre-existing Parkinson's disease (10), suggests that it should be used with caution in patients with this disorder.

Psychological, psychiatric

Mania has been reported in six patients, five of whom were taking citalopram and one paroxetine (SEDA-22, 12).

Electrolyte balance

Hyponatremia can sometimes cause severe disturbances of consciousness.

- A 47-year-old woman with multiple sclerosis took citalopram 20 mg/day for 4 weeks and was found unconscious in her apartment (11). The main finding was a low plasma sodium (108 mmol/l). As a result of prolonged coma, she had rhabdomyolysis and required intubation for 3 days as well as sodium replacement therapy. She eventually made a full recovery.

It is possible in this case that the underlying demyelinating disease may have made the patient more susceptible to the sodium-lowering effects of the SSRI.

- A 45-year-old woman developed hyponatremia complicated by rhabdomyolysis while taking citalopram and the antipsychotic drug chlorprothixene for depressive psychosis (12). The hyponatremia became apparent 2 weeks after the dose of citalopram was increased to 40 mg/day, when she complained of weakness and lethargy.

SSRI-induced hyponatremia is unusual in non-geriatric populations, but the chlorprothixene may have played a role in this case.

Gastrointestinal

Gastrointestinal adverse effects are one of the major disadvantages of SSRIs. The most common is nausea, and the incidence is said to be 20% or more for citalopram (13,14).

Sexual function

Citalopram has a relatively modest effect in delaying ejaculation (15).

Sexual disinhibition has been reported in five patients, four of whom were taking citalopram; they had an unusual increase in sexual interest, with preoccupation with sexual thoughts, promiscuity, and excessive interest in pornography (16). In some of the cases symptoms such as diminished need for sleep suggested the possibility of a manic syndrome.

Long-Term Effects

Drug withdrawal

Reports of withdrawal symptoms after citalopram withdrawal are rare, but it is uncertain whether this reflects a truly lower propensity to cause withdrawal symptoms.

- A 30-year-old man with a history of major depression and panic disorder had been in remission for a year with citalopram 20 mg/day, valproate 600 mg/day, and alprazolam 3 mg/day (17). The citalopram was tapered over 3 weeks to 5 mg/day and then withdrawn. The day after the last dose he experienced anxiety and irritability together with frequent short-lasting bursts of dizziness, not having had the latter previously panic and depression did not recur and after a week the symptoms resolved spontaneously.
- A 45-year-old woman achieved remission from an episode of major depression within 2 weeks of taking citalopram (40 mg/day). After about 3 months of treatment she missed her daily dose of citalopram, and 3 hours later had a sudden episode of dizziness while driving. A similar episode occurred 2 weeks later again after a missed dose of citalopram. The dizziness remitted about 1 hour after the citalopram was taken.

These symptoms, particularly dizziness, are characteristic of SSRI withdrawal, and suggest that citalopram, like other SSRIs, can cause a withdrawal syndrome in some patients, despite slow tapering of the dose.

Withdrawal symptoms in the 2 weeks after sudden discontinuation of citalopram have been examined in a double-blind, placebo-controlled study (18). Withdrawal symptoms were overall mild, but neurological and psychiatric disturbances were 2–3 times as common in patients randomized to placebo than in those randomized to continue with citalopram. The authors pointed out that withdrawal symptoms were particularly common in

© 2006 Elsevier B.V. All rights reserved.

patients who were randomized to placebo who also had depressive relapses. This shows the difficulty of disentangling the effects of depressive relapse from those of pure treatment withdrawal. However, it is also possible that acute withdrawal of medication induces an abnormal neurobiological state, in which both depression and abstinence symptoms are more likely to occur. It would be wise to warn patients about the possible effects of missing doses of the shorter-acting SSRIs.

Second-Generation Effects

Lactation

Citalopram has been reported to cause sleep disturbance in a breast-fed infant (19).

- A 29-year-old woman took citalopram (40 mg/day) while breast feeding her 5-week-old daughter. The maternal citalopram concentrations were 99 ng/ml in the serum and 205 ng/ml in the breast milk. The serum concentration in the infant was 13 ng/ml, and the child's sleep was fitful and disturbed. The dosage of citalopram was reduced to 20 mg/day and the two feeds after each daily dose were replaced by artificial nutrition. One week later the infant was sleeping normally, and the serum citalopram concentrations in mother and infant had fallen to 35 ng/ml and 2 ng/ml, respectively.

These data suggest that although breast feeding during citalopram treatment is possible, careful dosing and close observation of mother and infant are necessary.

Drug Administration

Drug overdose

Six deaths have been reported after overdosage of citalopram. Although five of the six had also taken other substances, these were not thought to have contributed significantly (SEDA-20, 8). Of five patients who made non-fatal suicide attempts by taking large amounts of citalopram (up to 5200 mg), four developed generalized seizures and all had prolonged QT_c intervals. Other conduction disorders included sinus tachycardia and inferolateral repolarization disturbances. Two patients developed rhabdomyolysis and one hypokalemia. These data suggest that citalopram overdose can cause seizures and disturbances of cardiac conduction that might predispose to fatal dysrhythmias (SEDA-21, 12) (20,21).

In another case prolonged sinus bradycardia occurred (22).

- A 32-year-old woman took 800 mg of citalopram, 20 times her usual daily dose, in a suicide attempt. On admission to hospital she had a sinus bradycardia (41/minute) but the electrocardiogram was otherwise normal, with a QT interval of 430 ms. Treatment with atropine failed to increase her heart rate and she had hypotension and syncope. A temporary pacemaker was inserted and was required for the next 6 days before it could be safely removed.

There are concerns that citalopram may be less safe in acute overdose than other SSRIs (SEDA-21, 12). Among all fatal poisonings in one forensic district of Sweden, citalopram was the fourth most commonly used drug (22 of 358 cases) (23). However, when correction was made for prescription rate, citalopram was less toxic than amitriptyline, dextropropoxyphene, or nitrazepam. This study has confirmed that citalopram is less toxic than tricyclic antidepressants such as amitriptyline. However, whether it is more toxic than other SSRIs is still uncertain.

Drug–Drug Interactions

General

Of all the SSRIs citalopram has the least inhibitory effect on cytochrome P450 enzymes and has not been associated with clinically significant interactions with other CNS drugs.

It has been used successfully in combination with the tricyclic antidepressant desipramine in a 45-year-old woman who had previously suffered tricyclic toxicity when desipramine had been combined with paroxetine (24).

Acenocoumarol

When a drug has a relatively narrow therapeutic index, such as acenocoumarol, pharmacokinetic interactions can have serious clinical consequences.

- A 63-year-old woman taking acenocoumarol 18 mg/week (INR 1.8) started to take citalopram 20 mg/day and 10 days later noted spontaneous bleeding from her gums; the INR had risen to more than 15 (25). She was treated with two units of whole blood and the citalopram was withdrawn. Five days later the INR had returned to the target range.

Citalopram is said to be less likely than other SSRIs to cause drug interactions, because it is a relatively weak inhibitor of CYP isozymes. However, even slight inhibition may have produced serious consequences in this case.

Clozapine

The effect of citalopram on plasma concentrations of clozapine have been prospectively studied in 15 patients with schizophrenia taking clozapine 200–400 mg/day (26). The addition of citalopram 40 mg/day did not alter plasma clozapine concentrations.

However, in a 39-year-old man with a schizoaffective disorder, citalopram 40 mg/day appeared to increase plasma clozapine concentrations and increased adverse effects (27). The adverse effects settled within 2 weeks of a reduction in citalopram dosage to 20 mg/day, with a corresponding 25% fall in clozapine concentrations. It is possible that at higher doses, citalopram can increase clozapine concentrations, perhaps through inhibition of CYP1A2 or CYP3A4.

Digoxin

Citalopram 40 mg/day for 4 weeks did not alter the pharmacokinetics of digoxin 1 mg orally (28). Digoxin is not a CYP substrate, so an interaction with SSRIs is unlikely, but the authors cited a report that fluoxetine increased plasma digoxin concentrations (29).

© 2006 Elsevier B.V. All rights reserved.

Risperidone

The effect of citalopram on plasma concentrations of risperidone has been prospectively studied in 15 patients with schizophrenia (26). The addition of citalopram did not alter plasma risperidone concentrations.

Citric acid and citrates

General Information

Citric acid is used in effervescing mixtures and granules. Formulations that contain citric acid are used in the management of dry mouth and to dissolve renal calculi, alkalinize the urine, and prevent encrustation of urinary catheters. Citric acid is also an ingredient of citrated anticoagulant solutions.

Uses

Urinary calculi

Treatment of complex and large urinary calculi secondary to infection can be difficult, and complete removal of the stone may not always be possible. Residual stone fragment rates are 37% (range 10–57%) after percutaneous nephrolithotomy and 20% after anatrophic nephrolithotomy (1). Technical advances in the management of urinary calculi have resulted in improved stone clearance rates in these cases. Owing to a combination of factors, such as large stone mass, associated infection, abnormal renal anatomy, and poor general health of the patient, infection stones can still pose a difficult treatment problem. This has resulted in the use of alternative (and minimally invasive) treatment options. Dissolution treatment, either alone or as adjuvant therapy, has been used. Citric acid, in various concentrations, has been used in dissolution treatment (2). Citric

© 2006 Elsevier B.V. All rights reserved.

acid, being a urinary acidifier, inhibits the formation of precipitates of calcium phosphate, calcium carbonate, and magnesium ammonium phosphate, and allows dissolution of stones. It may also help to reduce the size of calculi, allowing spontaneous elimination.

Citric acid has been used to treat 22 patients (10 men and 12 women, mean age 45, range 15–60 years; 23 affected kidneys) with kidney stones (14 staghorn calculi, four partial staghorn calculi, and five large-burden calculi) (3). They underwent irrigation with solution R (citric acid monohydrate 6 g, magnesium carbonate 2.8 g, glucolactone 0.6 g, and water 100 ml) following debulking of the stone with percutaneous nephrolithotomy ($n = 20$), ureteroscopy, and shock wave lithotripsy ($n = 2$) combined with open procedures ($n = 4$). Irrigation was performed through a nephrostomy tube ($n = 20$) or in a retrograde fashion ($n = 3$) using a closed infusion pump system (40 ml/hour). The response to treatment was checked using a nephrostogram and/or plain X-ray. In six kidneys irrigation had to be abandoned because of loin pain, leak, or sepsis after an average duration of 2 (1–5) days. The average duration of irrigation was 6 (1–20) days. At the end of irrigation, four kidneys had complete radiographic clearance, and the stone was reduced to calyceal dust in three. There was a partial response in 11 and no response in five. Following alternative interventions in six cases (four with a partial response and two with no response), further clearance was achieved in three and calyceal dust in three. The response was better if the stone was reduced to less than 10 mm before irrigation. At the mean follow-up of 2.4 (1–4) years, of 13 kidneys with stone clearance or calyceal dust, nine suffered recurrence or re-growth, five of which required further interventions. Only four of the 23 kidneys remained stone-free.

In patients with complex stone disease, adjuvant solution R irrigation can reduce the stone burden, although the overall success rate is limited. However, there is a considerable potential for adverse effects, necessitating close monitoring for sepsis and electrolyte abnormalities.

Anticoagulation

In 2000 the FDA issued an urgent warning to all hospital pharmacies and hemodialysis units that triCitrasol, an unapproved formulation of sodium citrate that has been used as an anticoagulant to keep intravascular lines open, can cause death after intravenous infusion. triCitrasol is marketed in individual sterile 30 ml glass vials, distributed both individually and in hemodialysis kits (4). A patient died of cardiac arrest shortly after the injection of triCitrasol 46.7% into a permanent hemodialysis blood access catheter that had just been implanted. Rapid or excessive infusion of citrate solutions can cause fatal cardiac dysrhythmias, seizures, or bleeding due to sequestration of blood calcium.

triCitrasol is manufactured by Cytosol Laboratories, and is distributed by Medcomp (previously by Citra Anticoagulants, Inc). Both Cytosol Labs and Medcomp have voluntarily recalled triCitrasol for use with blood access catheters. On 9 April 2000, Medcomp announced in a letter to its customers that it was recalling its kits (or trays) containing triCitrasol and the Medcomp Ash Split Catheter II for hemodialysis or apheresis, a blood separation and re-transfusion process. About 3000 Medcomp catheter kits with triCitrasol were distributed nationwide. They were also distributed in Puerto Rico and Canada.

The FDA urged hospital pharmacies and hemodialysis units across the USA to stop using the product. Alternative 4% solutions of citrate are available for use in these and most other medical settings.

Organs and Systems

Cardiovascular

Citric acid toxicity has been reported previously, but only after intravenous administration. It was originally seen with massive transfusion of blood products with citrate as the anticoagulant. Two case reports have described accidental intravenous administration of citrate or citric acid; at a maximum serum concentration of citrate (4.1 mmol/l) there were profound alterations in blood pressure and QT interval; these were reversed by calcium infusion (5).

Metabolism

Although there is a long list of causes of metabolic acidosis with an increased anion gap (6,7), clinical clues can help diagnosis. A case report has illustrated the acute metabolic and hemodynamic effects of ingestion of a massive load of oral citric acid. The principal findings included a metabolic acidosis accompanied by an increase in the plasma anion gap, not due to lactic acidosis, hyperkalemia, and the abrupt onset of hypotension (8).

- A 42-year-old previously healthy male prisoner drank a large volume of a commercial solution of unknown composition. His medical history was non-contributory, except for severe epigastric pain. Within an hour, his condition deteriorated; he was ashen, his blood pressure was 80/40 mmHg, and his pulse rate was 102/minute. His neck vessels were flat and his breath sounds were equal bilaterally, with occasional expiratory wheezes at both bases. There were no cardiac murmurs. The abdomen was soft and the bowel sounds were active. His extremities were warm with no cyanosis or edema. There were no neurological abnormalities. Fortuitously, because of therapy to avoid cardiac complications of hyperkalemia, he was given 1 g of calcium chloride, 50 mmol of sodium bicarbonate, 25 g of glucose, and 10 units of regular insulin intravenously. His blood pressure immediately increased to 116/76 mmHg and his pulse rate fell to 90/minute. By the next morning his plasma acid–base balance was normal, as was his ionized calcium concentration (1.1 mmol/l).

Because of the short duration and severity of the metabolic acidosis, together with a near-normal lactate concentration, acid ingestion was the most likely cause for his acid–base disorder. This diagnosis was confirmed once the composition of the ingested fluid was known.

Clarithromycin

See also Macrolide antibiotics

General Information

Clarithromycin is a commonly used macrolide antibiotic and is a regular part of regimens for the eradication of *Helicobacter pylori*, often in combination with a nitroimidazole antibiotic as well, in addition to a proton pump inhibitor. Variable rates of adverse events (4–30%) have been reported with clarithromycin.

Comparative studies

In a double-blind, multicenter trial in 328 patients with *H. pylori* infection and non-ulcer dyspepsia, omeprazole 20 mg bd, amoxicillin 1 g bd, and clarithromycin 500 mg bd were compared with omeprazole alone. The rate of success and quality of life were similar in both groups. There were no serious adverse events. However, there were 12 withdrawals in the group given omeprazole and antibiotics and two in the group given omeprazole alone. Diarrhea occurred in 63 patients in those given omeprazole and antibiotics and in ten patients given omeprazole alone (1). In another double-blind, placebo-controlled trial eradication of *H. pylori* (omeprazole 20 mg, amoxicillin 1 g, and clarithromycin 500 mg bd) in long-term users of NSAIDs with past or current peptic ulcer or troublesome dyspepsia led to impaired healing of gastric ulcers and did not affect the rate of peptic ulcers or dyspepsia over 6 months (2).

Beta-lactam antibiotics

In a multicenter, double-blind, randomized comparison of cefprozil, 500 mg bd for 5 days and clarithromycin 500 mg bd for 10 days in 295 subjects with an acute exacerbation of chronic bronchitis, the most common adverse effects of clarithromycin were nausea (8%), diarrhea (12%), taste disturbance (8%), and dry mouth (5%) (3).

Clarithromycin (250 mg bd for 10 days) was as effective as cefuroxime axetil (250 mg bd for 10 days) in the treatment of acute maxillary sinusitis in a randomized, double-blind, multicenter study in 370 patients; 10% of patients in each group had adverse events (4).

Other macrolides

The incidence of disseminated *Mycobacterium avium* complex (MAC) infection has increased dramatically with the AIDS epidemic. Treatment regimens for patients with a positive culture for MAC from a sterile site should include two or more drugs, including clarithromycin. Prophylaxis against disseminated MAC should be considered for patients with a CD4 cell count of less than 50 x 10^6/l (5). In a randomized, open trial in 37 patients with HIV-associated disseminated MAC infection, treatment with clarithromycin + ethambutol produced more rapid resolution of bacteremia, and was more effective at sterilization of blood cultures after 16 weeks than azithromycin + ethambutol (6).

In a direct comparison of clarithromycin with erythromycin stearate, the rate of adverse events was 19% in 96 patients taking clarithromycin and 35% in 112 patients taking erythromycin (7). Most of the adverse events associated with clarithromycin affect the gastrointestinal tract (7%).

In a prospective, single-blind, randomized study of a 7-day course of clarithromycin (7.5 mg/kg bd) and a 14-day course of erythromycin (13.3 mg/kg tds) in 153 children with pertussis, the incidence of treatment-emergent drug-related adverse events was significantly higher with erythromycin than with clarithromycin (62 versus 45%) (8). Three subjects given erythromycin withdrew prematurely because of adverse events: one because of a rash; one with vomiting and diarrhea; and one with vomiting, abdominal pain, and rash.

Quinolones

In a multicenter, double-blind, randomized comparison of trovafloxacin 200 mg and clarithromycin 500 mg bd in 176 subjects with acute exacerbations of chronic bronchitis, the most common adverse effects of clarithromycin were nausea (3%), diarrhea (4%), and taste disturbances (4%) (9).

Tetracyclines

Clarithromycin (0.75–2 g/day), minocycline (200 mg/day), and clofazimine (100 mg/day) for 15 months were investigated as treatment of MAC lung disease in 30 HIV-negative patients. Eight patients did not complete the study owing to deviations from protocol or adverse effects. Persistently negative cultures were found in 14 of the other patients. There were three cases of hepatic disturbances and three of ototoxicity, which required a reduction in clarithromycin dosage after a short interruption of treatment (10).

Organs and Systems

Cardiovascular

- QT interval prolongation and a ventricular dysrhythmia occurred in an HIV-positive 30-year-old man at the start of intravenous clarithromycin therapy 500 mg 12-hourly (11).

© 2006 Elsevier B.V. All rights reserved.

Intravenous clarithromycin caused thrombophlebitis in four patients when it was given inappropriately as a rapid bolus injection instead of a short infusion; the manufacturers have received other reports of similar reactions, even with infusions, but the incidence seems to be considerably lower than with erythromycin (12). In a prospective, non-randomized study, phlebitis occurred in 15 of 19 patients treated with intravenous erythromycin (incidence rate of 0.40 episodes/patient-day) and in 19 of 25 patients treated with intravenous clarithromycin (0.35 episodes/patient-day) (13).

Respiratory

Bronchospasm with clarithromycin occurred in a 44-year-old woman who had no history of respiratory allergies but had had adverse drug reactions to general and regional anesthetics and to ceftriaxone (14). After the administration of a quarter of the therapeutic dose the patient had dyspnea, cough, and bronchospasm throughout the lung.

Nervous system

Adverse events on the nervous system due to clarithromycin have been observed in 3% of patients.

- Progressive loss of strength and difficulty in swallowing and eye opening after the first dose of clarithromycin (2 g/day) occurred in a patient with cerebral toxoplasmosis and AIDS (15). This myasthenic syndrome resolved within 6 hours of withdrawal of clarithromycin and administration of pyridostigmine.

The authors postulated that this adverse effect may have been the consequence of neuromuscular blockade, through inhibition of the presynaptic release of acetylcholine.

Sensory systems

Eyes

Topical clarithromycin can cause self-resolving corneal deposits (16).

Ears

- Ototoxicity was attributed to clarithromycin in a 76-year-old man 4 days after he started to take clarithromycin for atypical pulmonary tuberculosis (17). When the clarithromycin was withdrawn his hearing improved subjectively, but it worsened again on re-exposure.

Taste

Abnormal taste developed in 17 of 175 patients treated with clarithromycin 250 mg bd for 10 days for community-acquired pneumonia, compared with 3 of 167 patients treated with sparfloxacin (18). Mild to moderate gastrointestinal disturbances were the most common adverse events and were reported in 13 and 11% respectively.

Psychological, psychiatric

Two patients, a man aged 74 and a woman aged 56 years, developed delirium after taking clarithromycin (19).

Two patients (aged 21 and 33 years) with late-stage AIDS had acute psychoses shortly after taking clarithromycin (2 g/day) for MAC bacteremia (20). In both cases the psychosis resolved on withdrawal but recurred on rechallenge. In one case treatment with azithromycin was well tolerated.

Of cases of mania attributed to antibiotics and reported to the WHO, 28% were due to clarithromycin (21).

- A 77-year-old man who was HIV-negative developed mania after 6 days treatment with clarithromycin 1 g/day for a soft tissue infection; his mental state resolved on withdrawal (22).
- A 53-year-old Canadian lawyer taking long-term fluoxetine and nitrazepam developed a frank psychosis 1–3 days after starting to take clarithromycin 500 mg/day for a chest infection (23). His symptoms resolved on withdrawal of all three drugs, and did not recur with erythromycin or when fluoxetine and nitrazepam were restarted in the absence of antibiotics.

The symptoms may have been due to a direct effect of clarithromycin or else inhibition of hepatic cytochrome P450 metabolism, leading to fluoxetine toxicity.

Clarithromycin occasionally causes hallucinations.

- Visual hallucinations with marked anxiety and nervousness occurred after the second dose of oral clarithromycin 500 mg in a 32-year-old woman (24). Clarithromycin was withdrawn and the symptoms disappeared a few hours later.
- Visual hallucinations developed in a 56-year-old man with chronic renal insufficiency and underlying aluminium intoxication maintained on peritoneal dialysis 24 hours after he started to take clarithromycin 500 mg bd for a chest infection, and resolved completely 3 days after withdrawal (25).

Hematologic

- Thrombotic thrombocytopenic purpura was reported in a 42-year-old man with no past medical history after he had just completed a 30-day course of clarithromycin 250 mg bd (26).

Gastrointestinal

Erythromycin acts as a motilin receptor agonist (27–29). This mechanism may be at least partly responsible for the gastrointestinal adverse effects of macrolides. Clarithromycin may act on gastrointestinal motility in a similar way. In dogs, clarithromycin caused contractions and discomfort, as did erythromycin (30). In healthy volunteers, oral clarithromycin 250 mg bd caused a statistically significant increase in the number of postprandial antral contractions and antral motility (31). A single oral dose of clarithromycin 3000 mg resulted in severe abdominal pain within 1 hour of administration in two patients (32).

Based on observations made in dogs and rabbits, clarithromycin is significantly less potent than azithromycin and erythromycin as an agonist for stimulation of smooth muscle contraction (33). Therefore, a lower rate of gastrointestinal adverse events would be expected with clarithromycin.

Pseudomembranous colitis is relatively rarely seen with macrolides, but has been reported with clarithromycin (SED-12, 597) (34,35).

© 2006 Elsevier B.V. All rights reserved.

Liver

Abnormal liver function tests and hepatomegaly have been described with clarithromycin; in 4291 patients, the frequency of increased alanine transaminase activity was 5% (36). Clarithromycin was also associated with cholestatic hepatitis (30). To date, at least nine cases of hepatotoxicity have been described in HIV-negative patients taking clarithromycin 1–2 g/day for chronic lung disease due to *M. avium* or *Mycobacterium abscessus* (37). The pattern of liver enzyme abnormality was primarily cholestatic, and the patients were typically elderly (all but one aged over 60 years), or of low weight. Only three patients were symptomatic, and the liver function abnormalities resolved on withdrawal. Subsequent rechallenge was successful in four patients, unsuccessful in one, and not performed in four. There was some dispute as to whether toxicity was dose-related or not, but it is wise to recommend that elderly patients should receive an initial daily dose of 1 g in this disease setting.

Although cholestatic hepatitis has been typically described in association with erythromycin, newer macrolides are not totally free of this risk. A gradual increase in bilirubin and transaminases has been reported during treatment of a *Mycobacterium chelonae* infection with clarithromycin. These alterations were quickly reversible after withdrawal, but re-appeared on re-exposure to clarithromycin 1 g (38).

- Fatal drug-induced cholestasis associated with clarithromycin 500 mg bd for 3 days has been reported in a 59-year-old woman with diabetes mellitus and chronic renal insufficiency (39).
- Idiosyncratic drug-induced fatal fulminant hepatic failure has been reported in a 40-year-old woman with end-stage renal insufficiency taking clarithromycin 500 mg bd (40).

Skin

Clarithromycin has been associated with fixed drug eruptions and hypersensitivity reactions (41,42). In one case a clarithromycin-induced fixed drug eruption was reproduced by oral provocation, whereas patch tests on both unaffected and residual pigmented skin were negative (43).

- A 31-year-old woman developed Stevens–Johnson syndrome after she had taken oral erythromycin 333 mg tds for otitis media (44). After two doses she developed oral ulcers, tongue swelling, and a generalized erythematous rash. The diagnosis was confirmed histologically. She recovered slowly after withdrawal of erythromycin.
- Roxithromycin-induced generalized urticaria and tachycardia with a positive prick test and a cross-reaction to erythromycin and clarithromycin has been reported in a 31-year-old woman (45).

Clarithromycin can cause phototoxicity (46).

Drug–Drug Interactions

Antifungal imidazoles

In three patients with pulmonary MAC and aspergillosis infections, itraconazole was suggested to increase the plasma concentration of clarithromycin as well as the clarithromycin:14-hydroxyclarithromycin ratio (47). This effect may have been due to inhibition of CYP3A4 by itraconazole.

Antihistamines

Toxic effects of terfenadine and astemizole have been reported in patients taking concomitant macrolides, especially clarithromycin (48–51), typically resulting in prolongation of the QT interval and cardiac dysrhythmias (torsade de pointes) (52).

Cisapride

Cisapride can prolong the QT interval, with a risk of ventricular dysrhythmias (53,54). Clarithromycin increases serum concentrations of cisapride (55). This potentially dangerous interaction can result in QT interval prolongation and dysrhythmias such as torsade de pointes.

- Torsade de pointes occurred in a 77-year-old woman taking cisapride and clarithromycin (56).

Warnings have been issued by the manufacturers to avoid concomitant administration.

Colchicine

- Fatal colchicine intoxication occurred in a 67-year-old man who had taken clarithromycin 500 mg bd for 4 days (57).

Clarithromycin may have inhibited colchicine metabolism and caused a rise in colchicine concentration.

Digoxin

Clarithromycin has been reported to cause digoxin toxicity (58). Two different mechanisms are involved, inhibition of the renal excretion of digoxin and alteration of intestinal flora, which reduces the presystemic hydrolysis of digoxin.

- A 70-year-old woman taking digoxin for atrial fibrillation developed nausea, vomiting, and dizziness 2 days after starting to take clarithromycin (59). Her serum digoxin concentration was 3.9 ng/ml (target range 0.5–2.0).

Disulfiram

Fatal toxic epidermal necrolysis and fulminant hepatitis occurred shortly after the start of treatment with clarithromycin in a 47-year-old man who was taking disulfiram (60).

- A 47-year-old man with a history of chronic alcoholism took disulfiram 250 mg/day for 1 month. He then took clarithromycin 500 mg bd and paracetamol 500 mg tds and 1 week later noticed non-pruritic cutaneous maculopapular lesions on his legs, extending to the rest of his body, excluding the palms and soles. Previous drug therapy was withdrawn. A skin biopsy showed toxic epidermal necrolysis. During the next several days the skin lesions worsened. Cutaneous blisters became evident, initially covering less than 10% of the body surface, but then extending all over the body. The serum

© 2006 Elsevier B.V. All rights reserved.

bilirubin concentration was 359 μmol/l (direct bilirubin 213 μmol/l), the partial thromboplastin time longer than 200 seconds, and the prothrombin time 26 seconds. He developed septic shock and, despite supportive measures, died.

Ergot alkaloids

In patients with ergotamine toxicity, vasoconstriction can lead to frank ischemia. Clarithromycin interferes with ergotamine metabolism.

- A 41-year-old woman developed worsening lower leg pain, pallor, and a sensation of coolness aggravated by exertion; there was severe vasospasm in the legs (61). She had taken a caffeine + ergotamine formulation for migraine for many years and had recently been given clarithromycin 500 mg bd for flu-like symptoms.

HIV nucleoside reverse transcriptase inhibitors

Clarithromycin reduced the peak concentration and AUC of zidovudine at steady state by about 12% (32), possibly as a result of reduced zidovudine absorption (62). However, if the two drugs were taken at least 2 hours apart, the pharmacokinetics of zidovudine were unaffected.

In 12 HIV-positive patients there was no statistically significant difference in concentrations of didanosine when clarithromycin was added (63).

Midazolam

In an open, randomized, crossover, pharmacokinetic and pharmacodynamic study in 12 healthy volunteers who took clarithromycin 250 mg bd for 5 days, azithromycin 500 mg/day for 3 days, or no pretreatment, followed by a single dose of midazolam (15 mg), clarithromycin increased the AUC of midazolam by over 3.5 times and the mean duration of sleep from 135 to 281 minutes (64). In contrast, there was no change with azithromycin, suggesting that it is much safer for co-administration with midazolam.

Omeprazole

In 21 healthy volunteers, clarithromycin (400 mg bd) for 3 days before omeprazole (20 mg/day) significantly inhibited the metabolism of omeprazole (65).

Pimozide

Clarithromycin inhibits the metabolism of pimozide, pimozide plasma concentrations increase, and there is an increased risk of cardiotoxicity through prolongation of the QT interval and fatal ventricular dysrhythmias (66).

Rifamycins

Clarithromycin is one of the core drugs for MAC infections in both HIV-infected and non-infected patients. For this indication, doses of up to 2000 mg/day are used, typically in combination with other drugs.

The interaction of clarithromycin with the rifamycins is complex. Clarithromycin inhibits CYP3A4, while both rifampicin and rifabutin induce P450 cytochromes, including CYP3A4, resulting in enhanced metabolism of drugs. The changes in serum concentrations of clarithromycin and its metabolite in the presence of the enzyme inducers rifampicin and rifabutin suggest that metabolism of clarithromycin by CYP3A4 is increased (67).

After the addition of rifampicin, peak serum concentrations of clarithromycin fell markedly, from a mean of 5.8–2.5 μg/ml (67). At the same time the ratio of the serum concentrations of clarithromycin and its 14-OH metabolite was reversed from 3.3:1 to 1:2.7. There were similar, although less marked, changes after the addition of rifabutin 600 mg/day to a regimen that included clarithromycin 1000 mg/day.

Whether these changes in serum clarithromycin concentrations are relevant to its antimicrobial activity is unknown, since prediction of clinical efficacy based on serum concentrations of clarithromycin is probably not justified, given that the macrolides accumulate to a large degree in tissues and macrophages.

In patients with MAC infections taking rifabutin or rifampicin the addition of clarithromycin resulted in rifamycin-related adverse events in 77% of patients (68). These included uveitis (69–72), especially at rifabutin doses of 600 mg/day or more, neutropenia, nausea, vomiting, diarrhea, and abnormal liver enzyme activities. In addition, diffuse polyarthralgia (19%) was observed. Since inhibition of cytochrome P450 by clarithromycin can interfere with rifabutin metabolism, as illustrated by a report of a significant increase in the AUC of rifabutin during treatment with clarithromycin (68), the authors recommended using rifabutin in a dosage of 300 mg/day in regimens that include a macrolide.

The effects of fluconazole and clarithromycin on the pharmacokinetics of rifabutin and 25-*O*-desacetylrifabutin have been studied in ten HIV-infected patients who were given rifabutin 300 mg qds in addition to fluconazole 200 mg qds and clarithromycin 500 mg qds (73). There was a 76% increase in the plasma AUC of rifabutin when either fluconazole or clarithromycin was given alone and a 152% increase when both drugs were given together. The authors concluded that patients should be monitored for adverse effects of rifabutin when it is co-administered with fluconazole or clarithromycin.

Sulfonylureas

- Severe hypoglycemia occurred in two elderly men with type 2 diabetes mellitus and mild to moderate impaired renal function, who took clarithromycin 1000 mg/day for respiratory infections, in addition to a sulfonylurea (glibenclamide 5 mg/day in one case and glipizide 15 mg/day in the other) (74). Both developed severe hypoglycemia within 48 hours of starting clarithromycin.

Tacrolimus

Clarithromycin can increase the steady-state concentrations of drugs that depend primarily on CYP3A metabolism.

© 2006 Elsevier B.V. All rights reserved.

- Steady-state tacrolimus concentrations rose in a 32-year-old African-American man who took clarithromycin 500 mg bd for 4 days (75).
- In two women aged 37 and 69, acute and reversible tacrolimus nephrotoxicity developed after the addition of clarithromycin for an upper respiratory tract infection (76).

Theophylline and other xanthines

Inhibition of cytochrome P450 activity by clarithromycin affects the metabolism of theophylline. However, the results of several studies of the effect of clarithromycin on theophylline concentrations are conflicting. While the total body clearance of theophylline fell (77) and plasma theophylline concentrations increased by 18% (78), mean theophylline concentrations remained within the target range (78). Based on these data it is wise to monitor serum theophylline concentrations in patients taking high dosages of theophylline or in patients with theophylline concentrations in the upper target range who start to take clarithromycin (36).

Warfarin

Increases in International Normalized Ratio (INR) have been detected in patients who have previously been stabilized on warfarin when they were simultaneously given clarithromycin. In one case this caused a suprachoroidal hemorrhage (79).

Clebopride

General Information

Like alizapride, clebopride is a prokinetic dopamine receptor antagonist that has extrapyramidal effects. These effects were initially overlooked, but a warning was eventually issued in 1988 (1). The problem has continued to be reported, the incidence at effective doses probably being as high as 25%.

In a 1991 report on a crossover trial, a third of the participants had to withdraw because of adverse effects, among which drowsiness, dizziness, tremors, and anxiety were prominent (2).

Organs and Systems

Nervous system

Clebopride can cause extrapyramidal syndromes (3,4). They range from transient dyskinesia to persistent parkinsonism, tardive dyskinesia (5,6), and tardive dystonia (7).

Extrapyramidal symptoms associated with clebopride have been reported in two 17-year-old patients within 10–16 hours of taking clebopride 0.5 mg tds (3).

In one case respiratory dyskinesia, which can easily be mistaken for psychogenic hyperventilation, was described (SEDA-17, 414).

Progressive supranuclear palsy has also been described (8).

Clemastine

See also Antihistamines

General Information

Clemastine (SEDA-7, 172) (SEDA-21, 173) belongs to the benzhydryl ether group and was developed in the hope of lessening sedative effects. There was no significant difference compared with other first-generation antihistamines.

Organs and Systems

Nervous system

Clemastine caused sedation in 9–50% of patients (1).

© 2006 Elsevier B.V. All rights reserved.

Clenbuterol

See also Beta$_2$-adrenoceptor agonists

General Information

Clenbuterol may cause somewhat more adverse effects than some other beta$_2$-adrenoceptor agonists and its long half-life could perhaps explain this.

Organs and Systems

Cardiovascular

Induction of physiological cardiac hypertrophy has important implications in various clinical settings, particularly in training of the left ventricle in operations for certain types of congenital heart disease. Positive effects of beta$_2$-adrenoceptor overexpression on cardiac function have been shown in experiments in mice (1).

The hypothesis that clenbuterol improves right ventricular systolic function in large mammalian species when given at the time of induction of pressure-overload cardiac hypertrophy has been tested in 15 open-chest operated sheep before and after 6 weeks of pulmonary artery banding (2). The animals were randomly assigned to either saline solution or clenbuterol. There was a highly significant improvement in the slope of the end-systolic pressure–volume loops in the clenbuterol-treated animals, without detrimental hemodynamic effects. No predictions can be made as to the lasting effects of clenbuterol's ability to augment systolic function in a chronically pressure-overloaded, thin-walled ventricle beyond 6 weeks, or the potential for tachyphylaxis.

Nervous system

Dyskinetic movements have been reported in one elderly patient taking clenbuterol (SEDA-17, 164).

Drug Administration

Drug overdose

The effects of overdose with clenbuterol have been described (3).

- A 28-year-old woman developed a sustained sinus tachycardia (140/minute), hypokalemia (2.4 mmol/l), hypophosphatemia (0.29 mmol/l), and hypomagnesemia (0.76 mmol/l) after accidentally ingesting a reportedly small quantity of clenbuterol. She was treated with metoprolol and potassium. Her serum clenbuterol concentration was 2.93 ng/ml 3 hours after ingestion, well above the maximal peak serum concentration of 0.087 ng/ml 2.4 hours after administration of a therapeutic dose of 20 μg of clenbuterol (4).

Clidinium bromide

See also Anticholinergic drugs

General Information

The anticholinergic drug clidinium is best known as a component of Librax (chlordiazepoxide 5 mg plus clidinium bromide 2.5 mg); the dose used is sufficient to produce typical anticholinergic adverse effects. Since here it is combined with a benzodiazepine, it is most unwise to allow patients taking Librax to drive motor vehicles or to ingest alcohol.

Clobazam

See also Benzodiazepines

General Information

Clobazam, a 1,5-benzodiazepine, differs in its chemical structure from most other benzodiazepines. It has been claimed to have less sedative effects for its effective anticonvulsant and anti-anxiety effects (SED-12, 98). Whether because of tolerance or not, clobazam tends to be less sedative than clonazepam. Both the therapeutic and adverse effects of clobazam have been related to its major metabolite *N*-desmethylclobazam, the formation of which depends on CYP2C19 activity. Mutant alleles that confer high CYP2C19 activity, and are therefore associated with high concentrations of the metabolite, are particularly common (30–40%) in Asian populations (1).

© 2006 Elsevier B.V. All rights reserved.

Comparative studies

In a randomized double-blind comparison of clobazam, carbamazepine, and phenytoin monotherapy in children with epilepsy, there were no differences in tests of intelligence, memory, attention, psychomotor speed, and impulsivity between clobazam and the other drugs after 6 and 12 months of therapy, suggesting that the adverse effects of clobazam on cognition and behavior may be less common than generally thought (2). However, the authors did not discuss a trend for some scores, particularly items in the Wechsler Intelligence Scale for Children–Revised, to improve significantly only in children taking non-benzodiazepine anticonvulsants. Moreover, many children withdrew from the study before completion of the follow-up, resulting in potential bias.

In a prospective multicenter double-blind comparison of clobazam with phenytoin or carbamazepine monotherapy in children with partial or generalized tonic-clonic seizures, the retention rate after one year did not differ, but exit due to inefficacy tended to be more common with clobazam (19 versus 11% for the other drugs combined), while exit due to adverse effects tended to be more common with carbamazepine or phenytoin (15 versus 4% for clobazam) (3). Although all treatments were claimed to have similar efficacy, detailed descriptions of the changes in seizure frequency and the proportion of patients who gradually achieved seizure control in each treatment group were not given. Behavioral and mood problems tended to be more common with clobazam than with the other drugs (38/119 versus 29/116). Drooling was more common with clobazam (7/119 versus 2/116), whereas rash or vomiting were more common with the other treatments (9/116 versus 4/119 and 10/116 versus 4/119 respectively). Tolerance was reported in 7.5% of patients taking clobazam, in 4.2% of those taking carbamazepine, and in 6.7% of those taking phenytoin; however, the definition of tolerance (no seizures for 3–6 months, followed by seizures sufficiently numerous to require a switch to another drug) was questionable, and no information was given about patients with seizure relapses who required an increase in dosage. Although these results suggest that clobazam is a valuable alternative to phenytoin and carbamazepine in childhood epilepsy, more precise characterization of responses would have been desirable.

Organs and Systems

Respiratory

Patients receiving intravenous benzodiazepines must be monitored for respiratory depression, and may need artificial ventilation during intensive treatment.

Nervous system

Clobazam is better tolerated than other benzodiazepines used in epilepsy (4). Its most common adverse effects are mild and transient drowsiness, dizziness, or fatigue; rather less common are muscle weakness, restlessness, aggressiveness, weight increase, ataxia, mood disorders, psychotic and behavioral disturbances, vertigo, hypotonia, hypersalivation, and edema (SED-13, 152). There may be a loss of therapeutic response over time.

Akathisia has been rarely seen with benzodiazepines (SED-13, 152).

Psychological, psychiatric

Of 63 children with refractory epilepsy given add-on clobazam (mean dosage 0.8 mg/kg/day) and followed for 15–64 months, 15 (24%) had to discontinue treatment owing to adverse effects, which included severe aggressive outbursts, hyperactivity, insomnia, and depression with suicidal ideation (5). Likewise, there were behavioral or mood problems in 38 of 119 children taking clobazam monotherapy over one year of follow-up, while drooling was reported in seven children (3). In another study, 7 of 63 children treated with clobazam developed aggressive agitation, self-injurious behavior, insomnia, and incessant motor activity. All the affected children were relatively young (mean age 6 years) and mentally disabled (6).

In controlled trials with clonazepam, adverse events were recorded in 60–90% of cases, and led to withdrawal rates as high as 36% (7). The most common effects were drowsiness, ataxia, and behavioral and personality changes. Other problems were hypersalivation, tolerance, and sometimes a paradoxical increase in seizure frequency.

Skin

Toxic epidermal necrolysis has been associated with clobazam (SEDA-21, 48). Bullae with sweat gland necrosis rarely complicate coma, but have recently been reported in association with clobazam, used as adjunctive therapy for resistant epilepsy in a 4-year-old girl (8).

Long-Term Effects

Drug tolerance

Clobazam has similar effects on anxiety to other benzodiazepines, but may be better tolerated (SEDA-20, 31). Used as an anticonvulsant, clobazam is generally well tolerated in epileptic patients, many showing little evidence of tolerance (4). On the other hand, children with epilepsy appear unusually prone to adverse behavioral reactions when taking clobazam (SEDA-19, 34).

Drug withdrawal

Withdrawal effects can be troublesome. Of 13 patients taken off clonazepam 0.01–0.5 mg/day because of adverse effects, 8 had withdrawal seizures and 5 had other withdrawal symptoms (SEDA-19, 63). Choreoathetosis was described in one patient completing withdrawal of clonazepam (SED-13, 152).

Epileptic-negative myoclonus status (almost continuous lapses in muscle tone associated with epileptiform discharges and interfering with postural control and motor coordination) rarely occur after rapid withdrawal of clobazam or valproate (9).

© 2006 Elsevier B.V. All rights reserved.

Drug–Drug Interactions

Antiepileptic drugs

Several metabolic interactions between clobazam and other antiepileptic drugs have been reported, in particular phenytoin intoxication after the addition of clobazam (SED-12, 98).

Carbamazepine

Negative myoclonus and more typical signs of carbamazepine intoxication (fatigue, ataxia, clumsiness) occurred in a 66-year-old man after he took add-on clobazam (10 mg/day) for 4 weeks (10). Plasma concentrations of carbamazepine (58 μmol/l) and carbamazepine-10,11-epoxide (19 μmol/l) were higher than before clobazam therapy, and his symptoms resolved quickly when carbamazepine dosage was reduced and clobazam was withdrawn. The interaction was confirmed on rechallenge.

This interaction does not occur in most patients.

Stiripentol

After the addition of stiripentol (50 mg/kg) in 20 children treated with clobazam, mean serum clobazam concentrations increased about twofold and norclobazam concentrations increased about threefold; a mean 25% reduction in clobazam dose was required because of adverse effects (11). Serum concentrations of concomitantly administered valproic acid rose by about 20%. These findings are in agreement with evidence that stiripentol is a potent metabolic inhibitor.

Clobuzarit

See also Non-steroidal anti-inflammatory drugs

General Information

Clobuzarit, a methylpropionic acid derivative, thought to have a penicillamine-like effect, was withdrawn from the market in the 1980s because of several reports of Stevens–Johnson syndrome (1).

Reference

1. Bird HA. Rheumatology and the pharmaceutical industry. J Rheumatol 1983;10(4):663–4.

Clofazimine

See also Antituberculosis drugs

General Information

Clofazimine is weakly bactericidal against *Mycobacterium leprae*. It is active in chronic skin ulcers (Buruli ulcer) and partly against *Mycobacterium avium* intracellulare. The usual adult dosage is 50–100 mg/day. At higher doses, its anti-inflammatory effect seems to prevent the development of acute reactions, such as erythema nodosum leprosum.

Clofazimine is a strongly lipophilic dye and accumulates in tissues, especially fat, bile, macrophages, the reticuloendothelial system, and skin. This is the basis of adverse reactions, including skin discoloration (1). Lymphedema (2), diminished sweating, and reduced tearing have been observed (3).

Observational studies

In 84 patients with leprosy who took clofazimine, the most common adverse effect was a dark red skin pigmentation of varying intensity, which appeared within 10 weeks of the start of therapy (4). The intensity of the colour was proportional to the density of the infiltration. There was ichthyosis in 56 patients. Adverse effects such as anorexia, diarrhea, lymph gland enlargement, liver enlargement, corneal drying, and loss of weight were self-correcting, but nine patients had severe gastrointestinal effects (severe abdominal pain, vomiting, and diarrhea).

© 2006 Elsevier B.V. All rights reserved.

Organs and Systems

Respiratory

Clofazimine crystals were observed in macrophages in the respiratory alveoli of a patient with AIDS; this is considered harmless (5).

Nervous system

Intraneural deposition of a ceroid-like pigment has been seen after treatment of lepromatous leprosy with clofazimine (6). This pigment does not affect the healing process. Treatment can be continued, provided that the dose is not too high.

Sensory systems

In 76 patients taking multidrug therapy, including clofazimine, for at least 6 months, 46% had conjunctival deposition, 53% had deposition in the cornea, and crystals were found in the tears of 32% (7). Conjunctival pigmentation has been reported, as well as reversible linear brownish corneal streaks. Two cases of macular pigmentation have also been described (SEDA-5, 294).

Gastrointestinal

Nausea, vomiting, diarrhea, abdominal pain, and anorexia have been reported with clofazimine (8).

Clofazimine can accumulate and precipitate in tissues, such as the wall of the small bowel, after prolonged administration. Enteropathy can develop if crystals are stored in the lamina propria of the jejunal mucosa and the mesenteric lymph nodes. These effects depend on the dosage and duration of therapy. When this complication is suspected jejunal biopsy is indicated. At laparotomy, all organs can have an orange–yellow color (SEDA-9, 272) (1,9). On drug withdrawal, the enteropathy progressively improves. Recognized for the first time in 1967, only 14 cases of this complication have so far appeared in the English-language literature (10). Acute or chronic abdominal pain was the main symptom. In most patients, the diagnosis was made after exploratory laparotomy. Barium meal follow-through or CT scanning of the abdomen showed mucosal thickening in the small intestine. Mesenteric lymph node enlargement was present in the index case. Characteristic eosinophilic clofazimine crystals were demonstrated in the histiocytes of all patients except three. The authors proposed the term "clofazimine-induced crystal-storage histiocytosis" to emphasize causes other than B cell neoplasms for crystal-storage histiocytosis. Awareness of this complication of clofazimine can avoid unnecessary surgical exploration.

Liver

Clofazimine can inhibit the liver damage that is associated with lepromatous leprosy and the leprosy reaction; it has only minimal or no deleterious effects on liver function (11).

Skin

Pigmentation and purple skin discoloration are the most frequent adverse effects of clofazimine. It is therefore unacceptable to most light-skinned patients (12).

Ichthyosis is very frequent at dosages of clofazimine over 100 mg/day (SEDA-8, 290).

Nails

Nail changes, such as brown discoloration of the nail plate and onycholysis, have been described in patients taking high doses (300 mg/day) of clofazimine (13). Clofazimine crystals were demonstrated in the nails and nail beds.

Clofedanol

General Information

Clofedanol is a centrally acting cough suppressant with mild local anesthetic properties. In an open study 30 patients were treated with clofedanol for 14 days. Two were withdrawn from the study because of tiredness and vomiting. These adverse effects disappeared immediately after treatment was withdrawn (1).

© 2006 Elsevier B.V. All rights reserved.

Cloforex

See also Anorectic drugs

General Information

Cloforex is similar in structure to chlorphentermine. It produces adverse effects similar to those of other appetite suppressants. Outstanding among them are sleeplessness or tiredness, headache, diarrhea, increased sweating, and dryness of the mouth; there may also be tolerance to its effects (1).

Clometacin

See also Non-steroidal anti-inflammatory drugs

General Information

The NSAID clometacin is an indometacin derivative.

Because of the risk of long-term or repeated use of clometacin, the French authorities restricted its use to prescriptions for no more than 8 days. It seems wise to recommend that it be no longer used.

Organs and Systems

Hematologic

Thrombocytopenia has been attributed to clometacin (SEDA-6, 94).

Liver

The hepatotoxic potential of clometacin was first reported in France in 1978. Since then many cases of hepatotoxic effects have been described (SEDA-7, 109). In two retrospective studies the clinical, biochemical, immunological, and histopathological features were outlined in detail (1,2). The patients had jaundice and/or hepatomegaly (90%), weakness (60%), fever (30%), and abdominal pain (20%), with or without diarrhea, nausea, and vomiting, usually presenting after long-term use or shortly after a rechallenge. The biochemical disorders were hepatocellular hepatitis and cholestatic hepatitis. High titers of antitissue antibodies and hypergammaglobulinemia were also present in most patients. Histological findings were characteristic of acute hepatitis or chronic active hepatitis. There was a high prevalence of HLA-antigen B8. These immunological features suggest an autoimmune pathogenesis.

Urinary tract

A retrospective analysis of acute renal insufficiency related to NSAID therapy in France showed that clometacin was most frequently implicated. Cases of functional renal insufficiency and interstitial nephritis with nephrotic syndrome were reported (SEDA-12, 84).

Skin

Skin eruptions, generalized pruritus, and weight loss have been reported (1).

Clomethiazole

General Information

Clomethiazole is a sedative-hypnotic that has been used extensively in the treatment of alcohol withdrawal, as well as for inducing sedation and sleep in the elderly. In addition to GABA enhancement, which it shares with the benzodiazepines, clomethiazole also enhances the activity of another inhibitory amino acid, glycine. Whether this property is clinically important is uncertain. As well as the expected effects of sedation and memory impairment, it produces nasal irritation, especially in younger patients, in whom it has a shorter half-life. Its use in alcohol withdrawal is becoming less common, possibly owing to the demonstrated safety and efficacy of longer-acting benzodiazepines, such as chlordiazepoxide, and alternatives such as carbamazepine.

Hypotension, phlebitis, and respiratory depression can occur after intravenous use. While effects in the elderly may be increased, the incidence of adverse effects is similar to that seen in younger subjects (1).

Clomethiazole, like the benzodiazepines, has an additive effect with other CNS depressants, and can cause profound bradycardia when combined with beta-adrenoceptor antagonists.

© 2006 Elsevier B.V. All rights reserved.

Organs and Systems

Nervous system

In a double-blind, double-dummy, placebo-controlled comparison of clomethiazole and gammahydroxybutyrate in ameliorating the symptoms of alcohol withdrawal, alcohol-dependent patients were randomized to receive either clomethiazole 1000 mg or gammahydroxybutyrate 50 mg/kg (2). There was no difference between the three treatments in ratings of alcohol withdrawal symptoms or requests for additional medication. After tapering the active medication, there was no increase in withdrawal symptoms, suggesting that physical tolerance did not develop to either clomethiazole or gammahydroxybutyrate during the 5-day treatment period. The most frequently reported adverse effect of gammahydroxybutyrate was transient vertigo, particularly after the evening double dose.

The effect of clomethiazole on cerebral outcome in patients undergoing coronary artery bypass surgery has been investigated in 245 patients, who were randomized double-blind to placebo or clomethiazole (1800 mg over 45 minutes followed by 800 mg/hour until the end of surgery) (3). A battery of eight neuropsychological tests was administered preoperatively and repeated 4–7 weeks after surgery. There were no differences between the clomethiazole and placebo groups in postoperative neuropsychological tests scores. Thus, clomethiazole did not improve or worsen cerebral outcome after coronary artery bypass surgery.

The efficacy and safety of clomethiazole (75 mg/kg by intravenous infusion over 24 hours), as a neuroprotective drug, were studied in a double-blind, placebo-controlled trial (CLASS, the Clomethiazole Acute Stroke Study) in 1360 patients with acute hemispheric stroke (4). Clomethiazole was generally well tolerated and safe. Sedation was the most common adverse event, leading to treatment withdrawal in 16% of patients compared with 4.2% of placebo-treated patients.

In a small subset of CLASS (95 patients) mortality at 90 days was 19% in the clomethiazole group and 23% in the placebo group (5). Sedation was the most common adverse event (clomethiazole 53%, placebo 17%), followed by rhinitis and coughing. The incidence and pattern of serious adverse events was similar between the groups.

A report has illustrated the dangers of driving a motor vehicle whilst taking clomethiazole (6).

- A 53-year-old male car driver was followed by the police for about 2 km, while he drove in an unsafe manner, until the car crashed into the owner's garage. Analysis of his blood showed a clomethiazole concentration of 3.3 μg/ml. Neither alcohol nor any other drug could be detected. One day later he committed suicide by swallowing at least 60 capsules of clomethiazole.

Liver

Reversible cholestatic jaundice has been attributed to clomethiazole (SEDA-21, 39).

Long-Term Effects

Drug abuse

As with other GABA enhancers, clomethiazole is highly abusable in susceptible individuals and should not be used for outpatient detoxification (7).

Drug dependence

Clomethiazole maintains its efficacy with apparently less dependence than temazepam during prolonged use (7).

Drug–Drug Interactions

Alteplase

The safety of the thrombolytic drug alteplase (tPA) plus clomethiazole in patients with acute ischemic stroke has been assessed in a randomized, double-blind study (8). All received alteplase 0.9 mg/kg, beginning within 3 hours of stroke onset, and then either intravenous clomethiazole 68 mg/kg ($n = 97$) over 24 hours, or placebo ($n = 93$) beginning within 12 hours of stroke onset. During follow-up for 90 days the number of serious adverse event reports was 47 in the clomethiazole group and 48 in the placebo group. There were 15 deaths in those given clomethiazole and nine in those given placebo, but this was not significantly different. Sedation was also greater with clomethiazole (42%) than with placebo (13%).

Cimetidine

Cimetidine can reduce clomethiazole clearance by 60–70% (9).

Clomiphene

General Information

Clomiphene is a very weak non-steroidal estrogen; it blocks the feedback effect of endogenous estrogens on the pituitary, promoting the further secretion of gonadotropins. The primary use of clomiphene in women is in the induction of ovulation. In men, it has been used to treat infertility in view of its ability to increase endogenous production of testosterone (1).

General adverse effects

In one large study, some adverse reactions in treated women were due to its ovulatory effects and others were direct reactions to the substance itself (2). The most common problem was ovarian enlargement (14%), followed by hot flushes (11%), abdominal and pelvic discomfort (7.0%), and nausea and vomiting (2.1%). Incidental symptoms were breast discomfort, vaginal changes, psychological symptoms, headache, heavier menses, and increased urinary frequency. Sporadic case-reports on clomiphene in the literature relate to fetal ovarian dysplasia or maternal psychosis (SEDA-7, 391), either of which may have been coincidental. However, it must be borne in mind that the substance is related structurally to triparanol, an obsolete drug that produced a series of disastrous adverse effects some 40 years ago.

In another study, the adverse effects of the antiestrogenic effects of clomiphene citrate were hot flushes (10%), mood swings, depression, headaches (1%), pelvic pain (5.5%), nausea (2%), breast tenderness (2–5%), dryness and loss of hair (0.3%), visual symptoms, halos and streaks around lights (particularly at night), blurring, and scotoma (1.5%) (3).

Organs and Systems

Nervous system

In a multicenter WHO study, two men withdrew because of visual disturbances, dizziness, and headaches (4).

Reproductive system

In some men taking clomiphene in the hope of improving subfertility, a non-bacterial pyospermia developed and could well have had an adverse effect on the outcome; it appeared more commonly in clomiphene users than controls (5).

Long-Term Effects

Tumorigenicity

Mammary cancer in the mother has been suspected as a risk of clomiphene, but specific investigations into the matter have not supported this suspicion (SED-12, 1034) (6).

A case of testicular seminoma in a man receiving both clomiphene and mesterolone for 15 months for oligospermia has been described (7), but it is unlikely that the drug was responsible.

Malignant melanoma

Concern that the drug treatment of female infertility might predispose the user to malignant melanoma was first engendered by a US study published in 1995 (8). Among women who had used clomiphene citrate for infertility, the incidence of melanoma was higher (RR = 1.8; 95% CI = 0.8, 3.5) than among American women in general. However, in a case-cohort study of nearly 4000 infertile women there was a similar increase in the incidence of melanoma among those who had been treated with human chorionic gonadotropin compared with the rest; there was no association with the use of clomiphene.

Quite apart from the inherent discrepancy in these findings, several pieces of evidence have confused the debate. In the first place, the cohort of melanoma cases was small—barely a handful. In the second place, some earlier papers had suggested that infertility in women might of itself have an association with melanoma. The same impression came from various studies, in which the incidences of cancers in infertile women were examined (9–11). If that were true, it could affect the initial findings in either direction: a high spontaneous incidence might mask a real drug effect, or it might provide a predisposition to melanoma, which the drugs might then more readily trigger.

In the meantime, data from Australia have shown no greater incidence of melanoma among women who had used fertility drugs and undergone in vitro fertilization than in the country's general female population (12). Since then there has been one more significant paper, again from Australia, using data from a specialized fertility clinic in Queensland, relating to all women who attended the center over a decade (13). Whenever possible, the women were traced and their subsequent history noted. Originally intended as a retrospective case-cohort study using a subcohort, the approach had to be amended because no cases of melanoma were found in the subcohort. The work therefore proceeded as a matched case-control study; all the data were taken and set against publicly available figures on melanoma in Queensland. After some necessary exclusions, 3186 women were included; care was taken to minimize recall bias. Fourteen women developed melanoma after fertility treatment, eight cases being invasive. The expected incidence in the general population would have been 15.8

© 2006 Elsevier B.V. All rights reserved.

cases in the same period. The incidence actually observed was therefore only 0.89 of that anticipated (95% CI = 0.54, 1.48). The numbers of women who had used clomiphene or human menopausal gonadotropin were too small to make more differentiated calculations, but the incidence of melanoma seemed to correspond to that in the general population.

On current evidence there seems no reason to discourage fertility-promoting drug treatments because of any risk of melanoma; they may even reduce it to some extent. However, this does not alter the fact that the data are deficient in various ways. Quite apart from the small numbers of melanoma cases that have been recorded, all the work to date has been performed in relatively sunny parts of the world; it is not known what would happen in other climates. Within countries there are sharp differences in melanoma figures; in the USA, where about 32 000 new cases of skin melanoma were projected for 1994 (14), the highest melanoma rates occur among light-skinned populations in areas of intense sunlight, for example Arizona; the same applies to Queensland, Australia. In the USA as a whole there is a melanoma incidence among whites of 12.4 per 100 000 (15), while mortality rates vary inversely with latitude (16). Furthermore, in whites, there has been a recent increase in the incidence of melanoma, during the precise period that this type of treatment has become popular, but probably for entirely different reasons, which may be associated with lifestyles and holiday habits; the reported incidence in whites rose by no less than 102% from 1973 to 1991 (16). Finally, as the Australian authors themselves stressed, the fact that the Queensland clinic was a private institution specializing in IVF/GIFT therapy means that women with endocrine-associated or ovulation-associated infertility may not have been referred to it so readily.

All this makes it very difficult to find a baseline incidence for melanoma with which cases treated for infertility can be compared. It is to be hoped that data of this type will continue to arrive from other centers, so that a definitive judgement will become possible.

Second-Generation Effects

Teratogenicity

Suspicions that clomiphene might adversely affect a fetus that has developed as a result of successful ovulation induction are difficult to confirm or allay, since the condition for which clomiphene is being used, that is subfertility, might itself be associated with a risk of malformation. The fear originally arose after 18 cases of trisomy had been reported in the USA; later data on a large series of clomiphene-induced pregnancies (17) indicated that if there was indeed such risk it must be very small; a study of 200 instances of Down's syndrome showed that none of them had been exposed to the drug (SEDA-6, 357). Another report concerned a case of congenital retinopathy (SEDA-7, 391).

Cornel and colleagues concluded in 1989 that there was a relative risk of at least two of an association between disturbed fertility and neural tube defects (18), but others found no evidence for an association between maternal clomiphene use and such defects. The authors of a pooled analysis of all published work concluded that any increase in neural tube defects is likely to be less than two-fold and that there may in fact be no increase at all (1).

One unusual possibility is a change in the sex ratio; in one study the ratio of boys to girls among infants conceived after induction of ovulation with clomiphene was 0.85, significantly different from the normal human sex ratio at birth, which is about 1.06 (19).

An unusual condition that has been tentatively ascribed to clomiphene is persistence of the hyperplastic primary vitreous, that is fetal ophthalmic tissue that normally resolves before birth. If more than a trace of the material persists, ocular complications, including cataract and retinal detachment, can result. In a case reported from Canada, there had been an estimated 3 weeks of exposure to high doses of clomiphene (100 mg/day) after gestation, and the child's vision was severely impaired (20). This is probably not a mere chance association, since several cases of visual defects of various types after exposure to clomiphene have been described before, and in some animal studies the drug does adversely affect ocular development.

Clomipramine

See also Tricyclic antidepressants

General Information

Clomipramine is the imipramine analogue of chlorpromazine. However, while the difference between chlorpromazine and promazine is large, adding a chloride atom to imipramine hardly affects its actions. Most trials have failed to show any superiority of the chlorinated compound over imipramine. The adverse effects profile is similar (1), but drowsiness, confusion, and "feeling awful" are commonly reported (2).

In a controlled comparison between clomipramine and amitriptyline, the former caused adverse effects more often, especially drowsiness (3). Overdose toxicity is the same as with other tricyclic antidepressants (4); fatal interactions with monoamine oxidase (MAO) inhibitors have been reported (SEDA-18, 16) (5). Altogether, toxic effects are not substantially different.

Besides depression, clomipramine is also widely used in the treatment of phobic and obsessive-compulsive disorders (6–8) and in panic disorders (9).

Organs and Systems

Cardiovascular

Venous thrombosis is a recognized complication of tricyclic antidepressants. Thrombosis of the cerebral veins occurred in a 61-year-old woman after intravenous clomipramine, and the authors suggested that the risk may be greater when the intravenous route is used (10).

Intravenous administration invariably produced electrocardiographic changes, sometimes slow to reverse, in elderly patients (11).

At therapeutic doses, tricyclic antidepressants can cause postural hypotension, but they are regarded as being safe in patients who require general anesthesia. However, hypotension during surgery has been associated with clomipramine (12).

- A 57-year-old man due to undergo mitral valve surgery took clomipramine (150 mg at night) up to the night before surgery. His blood pressure before induction with thiopental (250 mg) and fentanyl (250 μg) was 105/65 mmHg, with a heart rate of 70 beats/minute. Anesthesia was maintained with isofluorothane, and 45 minutes after induction, his systolic blood pressure fell to 90 mmHg. Ephedrine (30 mg total), phenylephrine (500 μg total), or dopamine (10 μg/kg/minute) did not increase the blood pressure. After sternotomy, his systolic blood pressure fell to 55 mmHg and his pulse rate to 60 beats/minute, and he had third-degree atrioventricular block. Further ephedrine, phenylephrine, and adrenaline were without effect. During cardiopulmonary bypass, a noradrenaline infusion was started (0.2 μg/kg/minute) and isofluorothane was withdrawn. After he had been weaned from bypass the noradrenaline infusion was continued at a dose of 0.2–0.8 μg/kg/minute, sufficient to maintain the systolic blood pressure at 90–100 mmHg. After the operation, clomipramine was withheld and the noradrenaline infusion tapered off, and 3 days later the hypotension had resolved.

The hypotension in this case was severe and refractory to noradrenergic stimulation, perhaps because of the alpha$_1$-adrenoceptor antagonist properties of clomipramine. The fall in systolic blood pressure was accompanied by a paradoxical fall in heart rate, perhaps because the anticholinergic effect of clomipramine removed the effect of vagal tone on the resting heart rate. It seems likely that the hypotensive effect of clomipramine was potentiated by general anesthesia; however, such a reaction is rare and the underlying cardiac problem may have contributed to this severe adverse reaction. This case reinforces current advice that tricyclic antidepressants are best avoided in patients with significant cardiac disease.

Nervous system

Use of the intravenous route is fraught with danger and without any demonstrable advantages.

- A 31-year-old woman who received clomipramine intravenously 300 mg/day developed seizures and cardiac arrest on the 15th day; she was successfully resuscitated (13).

Seizures occurred in four of 50 patients receiving intravenous treatment. Those vulnerable to this complication were not identified in advance by prescreening electroencephalography (14).

Endocrine

Clomipramine has also aroused interest because of an action on prolactin release, which occurs with major tranquillizers but not with other tricyclic antidepressants (15). This action of clomipramine is related to its chemical structure and reflects a greater effect on dopamine

© 2006 Elsevier B.V. All rights reserved.

metabolism and serotonin uptake compared with other antidepressants.

Sexual function

Delayed or complete abolition of ejaculation is attributed to strong 5-HT re-uptake blockade but perhaps with additional alpha-adrenoceptor-blocking activity (16). Impotence may be due to a ganglionic blocking action.

Four patients taking up to 100 mg/day developed uncontrollable yawning, in three cases (two men and one woman) associated with sexual arousal, in two instances with spontaneous orgasm (17). In all four patients the symptoms disappeared after withdrawal.

Clonazepam

See also Benzodiazepines

General Information

Clonazepam is a benzodiazepine that is used predominantly in epilepsy, panic disorder, and mania, and also appears to be effective in relieving antipsychotic drug-induced akathisia (1). The use of clonazepam in psychiatric disorders is complicated by significant drowsiness in a majority of patients, and additional behavioral problems in children (SEDA-19, 34).

Although they are commonly used in the adjunctive management of chronic pain, benzodiazepines are generally not analgesic per se. One exception may be the stabbing/lancinating neuropathic pain that often responds to anticonvulsants, including clonazepam. Nevertheless, the use of benzodiazepines in pain syndromes is generally contraindicated, and clonazepam, although often effective, should be used with caution (SEDA-17, 42). This is because of the availability of other agents with comparable or superior efficacy and the significant incidence of adverse effects of clonazepam, including depression, self-poisoning, cognitive impairment, and dependence (2), as well as the potential for diversion.

Organs and Systems

Nervous system

In controlled trials with clonazepam, adverse events were recorded in 60–90% of cases and led to withdrawal rates as high as 36% (3). The most common effects were drowsiness, ataxia, and behavioral and personality changes. Other problems were hypersalivation, tolerance, and sometimes a paradoxical increase in seizure frequency.

Psychological, psychiatric

The addition of clonazepam to clomipramine has been reported to have caused acute mania (4).

- A 48-year-old Japanese man with a history of bipolar affective disorder became depressed again. He was already taking lithium carbonate 800 mg/day and carbamazepine 800 mg/day. Clomipramine was added, and the dose was increased to 225 mg/day over 2 months and then maintained for 2 months. Because clomipramine had little effect, clonazepam 3 mg/day was added. On the first day after he took clonazepam, symptoms of hyperthymia, haughtiness, talkativeness, and flight of ideas suddenly appeared once more. Drug-induced delirium was excluded, because orientation was not disrupted and the symptoms did not fluctuate over time. Clomipramine and clonazepam were withdrawn. Because the symptoms were similar to the previous manic episode, the same prescription was reinstated, with the addition of sodium valproate 800 mg/day. After 3 months, he was discharged in remission and

had no recurrence. He had not taken other benzodiazepines throughout the treatment.

This report suggests that clonazepam induced a switch to mania, possibly in combination with an effect of clomipramine.

Mouth and teeth

A sensation of a burning mouth has been attributed to clonazepam (5).

- A 52-year-old white woman developed a burning mouth. She had previously taken alprazolam for anxiety, but this was changed to clonazepam because of increased anxiety and panic. Clonazepam relieved her symptoms, but after 4 weeks of therapy she continued to have a constant, mild, oral burning sensation. Examination of the mouth was normal and laboratory tests were unremarkable. The dose of clonazepam was reduced and her symptoms abated but remained intolerable. Clonazepam was withdrawn and her symptoms completely resolved. Since no other medications relieved her anxiety and panic she took clonazepam again, but again developed an intolerable burning mouth. Clonazepam was again withdrawn and her symptoms resolved.

Long-Term Effects

Drug withdrawal

Withdrawal effects can be troublesome. Of 13 patients taken off clonazepam at a rate of 0.016–0.5 mg/day because of adverse effects, 8 had withdrawal seizures and five had other withdrawal symptoms (SEDA-19, 63). Choreoathetosis was described in one patient completing withdrawal of clonazepam (SED-13, 152).

- A 43-year-old man underwent an incomplete transcranial removal of a pituitary growth-hormone-secreting macroadenoma (6). His daily insulin dose was reduced from more than 300–104 U/day and he was given hydrocortisone and levothyroxine replacement therapy, together with lanreotide injections. A month after discharge, he was given high-dose clonazepam. Three months later, the clonazepam was withdrawn abruptly and he developed hypoglycemic coma.

The author concluded that interruption of benzodiazepine treatment had caused reduced growth hormone secretion and insulin requirements.

Drug–Drug Interactions

Carbamazepine

The mutual interaction of clonazepam and carbamazepine has been investigated in 183 children and adults with epilepsy during routine clinical care (7). Carbamazepine increased the clearance of clonazepam by 22% and clonazepam reduced the clearance of carbamazepine by 21%.

The effects of concomitant carbamazepine, phenytoin, sodium valproate, and zonisamide on the steady-state serum concentrations of clonazepam have been investigated in 51 epileptic in-patients under 20 years of age (8). Serum concentrations of clonazepam correlated positively with the dose of clonazepam and negatively with the doses of carbamazepine and valproic acid, but not with phenytoin or zonisamide. These results confirm that as the oral doses of carbamazepine and sodium valproate increase, the serum concentration of clonazepam falls, but there is no interaction with either phenytoin or zonisamide. In the case of carbamazepine the mechanism of action is thought to be enzyme induction, increasing the metabolism of clonazepam. It is not known what the mechanism is with sodium valproate. In patients with epilepsy, the co-administration of either sodium valproate or carbamazepine will reduce the serum concentration of clonazepam and increase the risk of a seizure. When clonazepam is used in the treatment of epilepsy, sodium valproate and carbamazepine should be avoided; phenytoin and zonisamide would be safer alternatives.

Phenelzine

A flushing reaction has been associated with an interaction of phenelzine with clonazepam (SEDA-17, 17).

Sertraline

In a randomized, double-blind, placebo-controlled, crossover study in 13 subjects, sertraline did not affect the pharmacokinetics or pharmacodynamics of clonazepam (9).

Valproate

The effects of concomitant carbamazepine, phenytoin, sodium valproate, and zonisamide on the steady-state serum concentrations of clonazepam have been investigated in 51 epileptic in-patients under 20 years of age (8). Serum concentrations of clonazepam correlated positively with the dose of clonazepam and negatively with the doses of carbamazepine and valproic acid, but not with phenytoin or zonisamide. These results confirm that as the oral doses of carbamazepine and sodium valproate increase, the serum concentration of clonazepam falls, but there is no interaction with either phenytoin or zonisamide. In the case of carbamazepine the mechanism of action is thought to be enzyme induction, increasing the metabolism of clonazepam. It is not known what the mechanism is with sodium valproate. In patients with epilepsy, the co-administration of either sodium valproate or carbamazepine will reduce the serum concentration of clonazepam and increase the risk of a seizure. When clonazepam is used in the treatment of epilepsy, sodium valproate and carbamazepine should be avoided; phenytoin and zonisamide would be safer alternatives.

Clonidine and apraclonidine

General Information

The presynaptic alpha-adrenoceptor agonists, particularly methyldopa and clonidine, are agonists at presynaptic alpha$_2$-adrenoceptors. Guanabenz, guanfacine, and tiamenidine appear to be qualitatively similar to clonidine; clear evidence of quantitative differences remains to be confirmed.

The mechanism of action of these drugs depends on reducing sympathetic nervous outflow from the nervous system by interference with regulatory neurotransmitter systems in the brainstem. Because none of the drugs was selective or specific for circulatory control systems, the hypotensive effects were invariably accompanied by other nervous system effects. However, the identification of imidazoline receptors has suggested that it may be possible to develop drugs, such as moxonidine and relminidine, with greater selectivity for circulatory control mechanisms and a reduced likelihood of unwanted nervous system depressant effects (1).

Clonidine has been used to treat hypertension and migraine. It ameliorates the opioid withdrawal syndrome by reducing central noradrenergic activity. Its role in the treatment of psychiatric disorders has been the subject of an extensive review, but without new information on its safety (2). Clonidine is also used epidurally, in combination with opioids, neostigmine, and anesthetic and analgesic agents, to produce segmental analgesia, particularly for postoperative relief of pain after obstetrical and surgical procedures.

The use of clonidine in children has been comprehensively reviewed (3,4).

Apraclonidine (*para*-aminoclonidine) is a relatively nonspecific alpha$_1$- and alpha$_2$-adrenoceptor agonist, which is less likely to cross the blood–brain barrier than clonidine. Apraclonidine suppresses aqueous humor flow by 39–44% and lowers intraocular pressure by 20–23% (5).

Organs and Systems

Cardiovascular

Clonidine causes sinus bradycardia and atrioventricular block, as illustrated by two cases, one a 10-year-old boy (6) and the other a 71-year-old woman (7), who developed Wenckebach's phenomenon. Clonidine was also studied in seven patients subjected to electrophysiological studies after 5 weeks of therapy (8). It slowed the sinus rate and increased the atrial pacing rate, producing Wenckebach's phenomenon, indicating depressed function of the sinus and AV nodes.

In three patients with chronic schizophrenia and primary polydipsia given clonidine in doses of up to 800 micrograms/day for 2–5 months, blood pressure and pulse fell significantly in a dose-dependent manner, but fluid intake, as assessed by measurements of weight and 24-hour urine volume, was not affected (9). Hypotension and bradycardia limited the extent to which the dose of clonidine could be increased. The lack of effect of clonidine on polydipsia in this small sample and the inconsistent results of two other recent studies have provided little overall support for using clonidine to treat primary polydipsia associated with schizophrenia.

Clonidine-induced hypertension has been reported in a patient with autonomic dysfunction (10).

- A 39-year-old quadriplegic man with poorly controlled pain had many features consistent with autonomic dysfunction (for example a C4 spinal lesion, orthostatic hypotension, hypertension). He routinely used transdermal clonidine and transdermal glyceryl trinitrate as needed for control of acute hypertensive episodes. The clonidine was discontinued, after which his blood pressure fell (maximum systolic and diastolic pressures by about 50 and 25 mmHg respectively).

Because clonidine relies on central alpha$_2$-adrenoceptor agonist activity for its hypotensive effects, it can cause hypertension in patients with autonomic dysfunction. It should therefore be used with great caution when autonomic dysfunction is suspected.

The effect of intrathecal clonidine has been evaluated in a prospective randomized study in 45 children aged 6–15 years, who were randomized to receive either 0.5% hyperbaric bupivacaine or 0.5% hyperbaric bupivacaine plus clonidine 2 micrograms/kg (11). Clonidine was associated with non-significant prolongation of motor block, from an average of 150–190 minutes. Postoperative analgesia was significantly longer with clonidine (490 versus 200 minutes). Clonidine was associated with higher incidences of hypotension (54 versus 36%) and bradycardia (30 versus 0%).

Respiratory

The effects of clonidine and other alpha$_2$-adrenoceptor agonists on respiratory function in asthmatics have been

© 2006 Elsevier B.V. All rights reserved.

reviewed (12). Inhaled alpha$_2$-adrenoceptor agonists reduce the bronchial response to allergens, and if ingested they can aggravate the bronchial response to histamine.

Nervous system

Treatment with centrally acting agents is characterized by a relatively high incidence (up to 60% in some studies) of nervous system depressant effects (dizziness, drowsiness, tiredness, dry mouth, headache, depression), particularly during the initial period of treatment or after dosage increments. Sedation, lethargy, and tiredness are common with clonidine, particularly at the start of treatment (13).

In a placebo-controlled study of a single oral dose of clonidine 0.25–3 mg in 18 healthy men aged 18–21 years, clonidine caused more sleepiness than placebo; it significantly reduced stage 1 and rapid-eye-movement (REM) sleep and increased stage 2 sleep (14).

Clonidine 300 micrograms was given orally to 30 patients 60 minutes before intrathecal anesthesia with lidocaine 40 mg or 80 mg, and 60 other patients received either plain lidocaine 100 mg or lidocaine 40 mg or 80 mg with clonidine 100 micrograms intrathecally (15). Clonidine, both intrathecally and orally, prolonged the duration of spinal block and allowed a reduction in the dose of lidocaine needed for a given duration of block, but prolongation of motor block, exceeding the duration of sensory block, was a drawback with both routes and doses of clonidine. The smallest hemodynamic changes were seen with lidocaine 40 mg + clonidine 100 micrograms intrathecally, which provided adequate anesthesia for operations lasting up to 140 minutes. All doses of clonidine caused sedation.

Endocrine

Clonidine stimulates the release of growth hormone and has been used as a provocation test of growth hormone reserve (16).

Clonidine reduces plasma renin activity and urinary aldosterone and catecholamine concentrations (17).

Mouth

Dry mouth is common with clonidine, and investigation of the mechanism has come from an experimental study in which the direct effect of clonidine on salivary amylase excretion from rat parotid dispersed cells was measured in vitro (18). Clonidine stimulated calcium influx into the cells and inhibited postsynaptic alpha$_1$-adrenoceptor responses.

Gastrointestinal

Constipation is frequent with clonidine, and one case of pseudo-obstruction of the bowel has been reported (19).

Urinary tract

Epidural clonidine is less likely to produce urinary retention than epidural opioids (20,21).

Skin

Rashes occur in about 4% of patients taking clonidine (22).

Transdermal clonidine formulated in adhesive skin patches has been used for long-term treatment with once-weekly application. When transdermal clonidine is used to lower blood pressure systemic adverse effects seem to be fewer than with oral clonidine (23). However, localized skin reactions are common, and the incidence increases with the dose and duration of use. Common signs include erythema, scaling, vesiculation, excoriation, and induration. Allergic contact dermatitis is less frequent but still common. Hyperpigmentation and depigmentation also occur. Pretreatment with 0.5% hydrocortisone is associated with less skin irritation and higher blood concentrations.

Immunologic

During long-term treatment of glaucoma with apraclonidine allergic reactions can occur. In a retrospective analysis of 64 patients who used apraclonidine 1% for more than 2 weeks, 31 (48%) developed an allergic reaction that led to withdrawal of treatment, with a mean latency of 4.7 months (24). Those who had allergic reactions tended to be older and female.

- A 46-year-old woman, who took clonidine 25 mg bd for menopausal flushing, developed depigmentation and swelling of her forearms (25). A skin biopsy showed a pattern consistent with immune complex disease, with IgG, IgM, Clq, C2c, and C4 complement between muscle fibers and at the dermo-epidermal junctions. All of these abnormalities disappeared after withdrawal.

Long-Term Effects

Drug tolerance

During long-term treatment of glaucoma, apraclonidine 0.5% is effective in reducing intraocular pressure, both in the short term and for up to 24 months. However, efficacy is lost in some patients. Of 174 patients followed for up to 24 months apraclonidine was ineffective in 38 patients (21%), at some point during the study (26).

Drug withdrawal

A withdrawal syndrome with marked rebound hypertension (attributed to increased sympathetic nervous activity as a result of drug-modified receptor responses) is an occasional but well-recognized complication of the abrupt withdrawal of alpha$_2$-adrenoceptor agonists, particularly with clonidine. In its most florid form, the clonidine withdrawal syndrome is characterized by a pronounced increase in blood pressure, tachycardia, tremulousness, and sweating (27). There is an associated marked increase in catecholamine output and the features are reminiscent of pheochromocytoma or accelerated hypertension. Milder cases can pass unnoticed, unless the patient is being carefully monitored. The syndrome begins within 48 hours of withdrawal, and although the exact incidence is unknown it is more likely if the patient has been taking a high dosage. There has even been a case report of rebound hypertension in association with transdermal clonidine (28). Treatment is by combined alpha- and beta-blockade, and it is important to avoid monotherapy with a beta-blocker, since this may exacerbate the syndrome by promoting unopposed alpha-adrenergic effects.

© 2006 Elsevier B.V. All rights reserved.

There have been two case reports of other serious complications arising from the acute withdrawal of clonidine. Neuropsychiatric disturbance with self-injury occurred in a child (29) and myocardial infarction developed in a patient with no history of ischemic heart disease (30).

Drug Administration

Drug formulations

Transdermal clonidine (clonidine TTS) has been used with some success for the treatment of mild hypertension. Systemic adverse effects are similar to those seen after oral administration, but are less frequent and milder. They include dry mouth, drowsiness, headache, sexual disturbance, cold extremities, obstipation, and fatigue (31–33). These adverse effects rarely necessitate withdrawal of clonidine TTS.

A high percentage of patients who take clonidine (up to 38%) (34) develop contact allergic reactions, usually due to the active ingredient, at the patch application site (35). This has been reported with a frequency of 15% in 357 African–American hypertensive patients. It can lead to drug discontinuation in 4.2% of patients.

Recurrent maculopapular rash due to both topical and systemic administration of clonidine has been reported (36).

- A 47-year-old woman was given transdermal, oral, and intravenous clonidine at different times, separated by several months. The patches were withdrawn after 2 months because of pruritic erythematous vesiculation at the site of application. Oral clonidine (0.3 mg/day) had to be withdrawn when a generalized maculopapular rash appeared on the third day, and was promptly exacerbated by each dose. Intravenous clonidine 0.150 mg was followed within 30 minutes by a severe, generalized, maculopapular reaction requiring systemic steroids and antihistamines.

The authors interpreted these reactions as being allergic. A patch test was very positive to the commercial formulation. Clonidine is a weak sensitizer, but occlusion and prolonged skin contact during transdermal application can cause delayed hypersensitivity.

Drug administration route

The most common ocular adverse effects of topical apraclonidine are conjunctival hyperemia, itching, foreign body sensation, and lacrimation. The most frequent systemic adverse effects are dry mouth and unusual taste perception (37–39). With *para*-aminoclonidine, headaches, attributable to ocular vasoconstriction, as well as anxiety, vomiting, dry mouth, tremor, and pallor, have been reported (40).

Drug overdose

The effects of exposure to clonidine hydrochloride in children, as reported to US poison centers from 1993 to 1999, have been retrospectively reviewed (41). There were 10 060 reported exposures, of which 57% were in children under 6 years, 34% in children aged 6–12 years, and 9% in adolescents aged 13–18 years. In 1999 there were 2.5 times as many exposures as in 1993. Clonidine was the child's medication in 10% of those under 6 years, 35% of those aged 6–12 years, and 26% of the adolescents. Unintentional overdose was most common in those under 6 years, while therapeutic errors and suicide attempts predominated in those aged 6–12-years and the adolescents. In 6042 symptomatic children (60%), the most common symptoms were lethargy (80%), bradycardia (17%), hypotension (15%), and respiratory depression (5%). Most of the exposures resulted in no effect (40%) or minor effects (39%). There were moderate effects in 1907 children (19%), major effects in 230 (2%), and one death in a 23-month-old child.

- A hypertensive crisis and myocardial infarction occurred in a 62-year-old woman after a combined injection of hydromorphone 48 mg and clonidine 12 mg subcutaneously in an attempt to refill an implanted epidural infusion pump (42). She was immediately treated with naloxone, but she subsequently had accelerated hypertension, a brief tonic-clonic seizure, and an anteroseptal myocardial infarction. Cardiac catheterization showed no coronary narrowing or blockage, but an anterior infarct was confirmed.

It is believed that the reaction was secondary to the vasoconstricting effects of high-dose clonidine through stimulation of peripheral alpha-adrenoceptors.

Drug–Drug Interactions

Mianserin

Mianserin has alpha-adrenoceptor activity and so might interact with clonidine (43). In healthy volunteers, pretreatment with mianserin 60 mg/day for 3 days did not modify the hypotensive effects of a single 300 mg dose of clonidine. In 11 patients with essential hypertension, the addition of mianserin 60 mg/day (in divided doses) for 2 weeks did not reduce the hypotensive effect of clonidine. The results of this study appear to have justified the authors' conclusion that adding mianserin to treatment with clonidine will not result in loss of blood pressure control.

Mirtazapine

Hypertension has been reported with mirtazapine plus clonidine (44).

- A 20-year-old man had had Goodpasture's syndrome for 2.5 years, end-stage renal disease on chronic hemodialysis for 15 months, and hypertension controlled with metoprolol, losartan, and clonidine. He developed dyspnea and hypertension (blood pressure 178/115 mmHg) 2 weeks after his psychiatrist first gave him mirtazapine 15 mg at bedtime to treat depression. His blood pressure did not fall significantly, despite the addition of losartan and minoxidil and the use of intravenous glyceryl trinitrate and labetalol. Only after emergency dialysis and intravenous nitroprusside did his blood pressure fall to 150–180/80–100 mmHg. When mirtazapine was withdrawn, his blood pressure was controlled with minoxidil 5 mg, clonidine 0.1 mg, and metoprolol 10 mg, all bd.

© 2006 Elsevier B.V. All rights reserved.

The authors recognized that mirtazapine alone could have caused the hypertensive event. In postmarketing surveillance of mirtazapine, hypertension occurred in at least 1% of patients. However, it is likely that the patient lost antihypertensive control because mirtazapine antagonized the antihypertensive effect of clonidine. Mirtazapine, a tetracyclic antidepressant, stimulates the noradrenergic system through antagonism at central alpha$_2$ inhibitory receptors, which is precisely opposite to the effect of clonidine.

Neostigmine

Clonidine increases the analgesic effect of intrathecal neostigmine without enhancing its adverse effects (45).

Clopidogrel

General Information

Clopidogrel is a thienopyridine compound, structurally related to ticlopidine, which inhibits ADP-induced platelet aggregation (1). Its efficacy in stroke, myocardial infarction, and other vascular causes of death has been demonstrated in the CAPRIE Study (2), a large trial in which 9599 patients were treated with clopidogrel. The most frequent adverse effects were gastrointestinal symptoms, although they were not significantly more frequent than with aspirin. Bleeding disorders were as common with clopidogrel as with aspirin (9.3% with each). More patients withdrew from treatment because of rashes from clopidogrel (0.9%) than from aspirin (0.4%). Neutropenia and thrombocytopenia occurred very rarely and with similar rates in the two groups.

The adverse effects of clopidogrel have been reviewed (3).

Organs and Systems

Hematologic

During active surveillance by medical directors of blood banks, hematologists, and the manufacturers of clopidogrel, 11 patients were identified in whom thrombotic thrombocytopenic purpura developed during or soon after treatment with clopidogrel (4). Of these 11 patients, 10 had taken clopidogrel for 14 days or less before the onset. From this study it is not possible to calculate the frequency of thrombotic thrombocytopenic purpura, since the size of the population from which the 11 cases were drawn is unknown.

- Fatal aplastic anemia has been reported in two patients taking clopidogrel (5,6). Aplastic anemia was diagnosed 5 months after starting clopidogrel in the first patient and after 3 months in the second. Both died from infection (sepsis and pneumonia). Except for allopurinol in the first case, these patients did not take any medications associated with aplastic anemia.

Major bleeding is uncommon with clopidogrel. In a randomized, double-blind, placebo-controlled, 18-month study of the effects of aspirin 75 mg/day in 7599 high-risk patients with recent ischemic stroke or transient ischemic attacks and at least one additional vascular risk factor who were already taking clopidogrel 75 mg/day, life-threatening bleeding was more common in the group who took aspirin and clopidogrel compared with clopidogrel alone: 96 (2.6%) versus 49 (1.3%); absolute risk increase 1.3% (95% CI 0.6, 1.9) (7). Episodes of major bleeding were also more common in those taking aspirin plus clopidogrel, but there was no difference in mortality.

Acquired autoimmune hemophilia has been attributed to clopidogrel (8).

Skin

Clopidogrel can cause pruritus and urticaria (9).

Immunologic

A severe allergic reaction has been associated with clopidogrel (10).

- A 57-year-old man took clopidogrel after a myocardial infarction and after 5 days developed a fever, rash, pruritus, and abdominal pain. Three days later he developed shock. He had thrombocytopenia, lymphopenia, aseptic leukocyturia, and raised serum activities of transaminases, amylase, and gamma-glutamyl transpeptidase. Blood cultures were negative. Clopidogrel was withdrawn and within 1 week he had completely recovered and all blood tests had returned to normal. One month later, he took clopidogrel again; 4 hours later the same symptoms

© 2006 Elsevier B.V. All rights reserved.

reappeared, with aseptic leukocyturia and raised transaminases and gamma-glutamyl transpeptidase. Drug allergy was suspected and clopidogrel was withdrawn. All the symptoms disappeared within a few days and did not recur during the following year.

It is highly probable that this reaction was provoked by clopidogrel because of the positive rechallenge and because the patient did not take any other drug.

Clortermine hydrochloride

See also Anorectic drugs

General Information

Clortermine, an alpha-dimethylphenethylamine chlorine derivative, suppresses food-reinforced behavior without concomitant stimulation or depression of the central nervous system. Headache was the main characteristic complaint in 49 obese people taking clortermine 50 mg/day; in four subjects it was severe enough to stop treatment. In all cases, the complaints were drug-related and not placebo-related (SED-9, 17) (1).

Clotiapine

See also Neuroleptic drugs

General Information

Clotiapine is a dibenzothiazepine neuroleptic drug.

Organs and Systems

Pancreas

Pancreatitis has been attributed to clotiapine (1).

- A 49-year-old woman started to take clotiapine 200 mg/day for a severe psychotic episode. On the second day, she complained of abdominal pain and nausea, followed by vomiting. Increased activities of serum amylase (1490 U/ml), serum lipase (3855 U/ml), and urinary amylase (3417 U/ml) suggested pancreatitis. There was no evidence of gallstones or tumor. She was given perphenazine instead, and her amylase and lipase activities fell to normal. Six months later, when she had a psychotic relapse, she was again treated with clotiapine and 2 days later had a rapid rise in amylase activity (887 U/ml). When switched to perphenazine, she had new peaks in amylase and lipase. A year later, her amylase and lipase were normal and her psychiatric disorder was stabilized with pimozide.

Cloximate

General Information

Cloximate is approved in only a few countries, so experience with its use is limited. The usual adverse effects of NSAIDs (headache, insomnia, drowsiness, anorexia, gastrointestinal symptoms, a transient increase in blood urea, leukopenia, thrombocytopenia, and rashes) have been reported (1).

Clozapine

See also Neuroleptic drugs

General Information

Clozapine is a dibenzodiazepine, an atypical neuroleptic drug with a high affinity for dopamine D_4 receptors and a low affinity for other subtypes (1). It is also an antagonist at alpha-adrenoceptors, 5-HT_{2A} receptors, muscarinic receptors, and histamine H_1 receptors.

Observational studies

Rates of hospitalization with clozapine have been analysed by Novartis, the manufacturers, based on two retrospective studies of hospitalization among patients with treatment-resistant schizophrenia (2). All the patients who began clozapine treatment in Texas State psychiatric facilities during the early 1990s ($n = 299$) were compared with controls who received traditional neuroleptic drugs ($n = 223$), matched for severity, age, and sex. More patients in the latter group required continuous hospitalization: at 4 years, four times as many patients taking a traditional medication had a 6-month period of continuous hospitalization.

In a study in Ohio, patients with chronic borderline personality disorder who were in hospital for an average of 110 days/year were given clozapine (mean daily dosage at time of discharge 334 mg; range 175–550 mg) (3). None stopped taking clozapine and few adverse effects were reported. Among the seven patients who were taking clozapine when they were discharged, hospitalization fell to a mean of 6.3 days per patient per year. There was no control group in this study.

- Of 10 adolescent inpatients (aged 12–17 years) with severe acute manic or mixed episodes, who did not improve after treatment with conventional drugs and who were given clozapine (mean dose 143 mg/day), all responded positively after 15–28 days and adverse effects (increased appetite, sedation, enuresis, sialorrhea) were frequent but not severe enough to require reduced dosages (4). Mean weight gain after 6 months was 7 kg (11%), and neither reduced white cell counts nor epileptic seizures were reported during follow-up for 12–24 months.

In a case series in which clozapine was used as add-on medication, two patients with bipolar disorder and one with schizoaffective disorder had marked reductions in affective symptoms after clozapine had been added to pretreatment with a mood stabilizer; transient and moderate weight gain and fatigue were the only adverse effects (5).

In a retrospective open study of 46 patients taking clozapine for 4 years, clozapine had to be discontinued in 10 patients (21%) and serious adverse effects were rare; no patient had agranulocytosis (6). The most troublesome adverse effects were drooling, sedation, and weight gain, and three patients had seizures.

Experiences in uncontrolled open studies in Chinese patients have been summarized (7). The most common adverse effect of clozapine was hypersalivation, followed by sedation. Mandatory blood monitoring is considered an obstacle in persuading some patients to undergo a trial of clozapine, mainly for cultural reasons, summed up by the Chinese proverb that "a hundred grains of rice make a drop of blood."

Clozapine has been used in some special groups of patients, including patients with severe borderline personality disorder (8), patients with aggressive schizophrenia (9), and mentally retarded adults (10).

Of 12 in-patients with borderline personality disorder treated with clozapine for 16 weeks, 10 developed sedation, which disappeared during the first month of treatment; 9 had hypersialorrhea, and 6 had falls in white blood cell counts, which never reached unsafe values.

Patients with aggressive schizophrenia ($n = 29$) improved when treated with clozapine; one was withdrawn after the development of leukopenia. In 10 mentally retarded patients taking clozapine for 15 days to 46 months improvement was observed. Half of the patients developed sedation and hypersalivation, and one discontinued the drug after 2 weeks because of neutropenia. The putative neurotoxicity of clozapine in moderately to profoundly retarded patients (that is, those with an accentuation of cognitive deficits due to the drug's anticholinergic and sedating properties) was not observed. Fifty special hospitalized patients with schizophrenia associated with serious violence were treated with clozapine (mean dose at 2 years 465 mg) (11). The most frequent adverse effects were hypersalivation ($n = 14$), sedation ($n = 10$), and weight gain ($n = 6$); two patients had tonic-clonic seizures, two others developed mild neutropenia, and in one case treatment was stopped owing to agranulocytosis.

In a retrospective review, 33 mentally retarded patients were evaluated; adverse effects were mild and transient, constipation being the most common ($n = 10$) (12). There were no significant cardiovascular adverse effects and no seizures; no patient discontinued treatment because of agranulocytosis. Small sample sizes, short durations of treatment, and lack of controls in these studies preclude definite conclusions.

A 37-item survey covering a variety of somatopsychic domains has been administered to 130 patients with schizophrenia taking a stable clozapine regimen (mean dose 464 mg/day; mean duration 34 months) (13). Most of them reported an improvement in their level of satisfaction, quality of life, compliance with treatment, thinking, mood, and alertness. Most reported worse nocturnal salivation (88%); weight gain (35%) came second; fewer patients reported a worsening of various gastrointestinal and urinary symptoms.

Clinical predictors of response have been examined in 37 partially treatment-refractory outpatients who

© 2006 Elsevier B.V. All rights reserved.

had been assigned to clozapine in a double-blind, haloperidol-controlled, long-term (29-week) study (14). Clozapine responders were rated as less severely ill, had fewer negative symptoms, and had fewer extrapyramidal adverse effects at baseline compared with non-responders.

Combination therapy

Of 656 Danish patients who were taking clozapine, 35% were taking concomitant neuroleptic drugs, 28% benzodiazepines, 19% anticholinergic drugs, 11% antidepressants, 8% antiepileptic drugs, and 2% lithium (15). The rationale for supplementing clozapine treatment in refractory schizophrenia in this way has been thoroughly reviewed following a bibliographic search covering 1978–1998 (16). In all, 70 articles were retrieved but only a few were controlled studies, most being case reports/series. Among the many possible drug combinations, the evidence suggests that clozapine plus sulpiride is the most efficacious combination. The combined use of benzodiazepines and clozapine can cause cardiorespiratory collapse; valproate can cause hepatic dysfunction and more so with clozapine; lithium can cause neurotoxicity and seizures and more so with clozapine; and at least some serotonin reuptake inhibitors (SSRIs) appear to raise plasma clozapine concentrations to above the usual target range.

Organs and Systems

Cardiovascular

Clozapine has been associated with cardiomyopathy (SED-14, 142) (SEDA-21, 52) (17), changes in blood pressure (SEDA-21, 52) (SEDA-21, 52) (SEDA-22, 57) (18,19), electrocardiographic changes (SEDA-22, 57) (20–22), and venous thromboembolism (SEDA-20, 47).

Hypertension

Several cases of hypertension have been associated with clozapine (SEDA-22, 57), and alpha$_2$-adrenoceptor blockade has been proposed as a possible mechanism (18). Four patients developed pseudopheochromocytoma syndrome associated with clozapine (23); all had hypertension, profuse sweating, and obesity. The authors suggested that clozapine could increase plasma noradrenaline concentrations by inhibiting presynaptic reuptake mediated by alpha$_2$-adrenoceptors.

Hypotension

Hypotension is the most commonly observed cardiovascular adverse effect of neuroleptic drugs, particularly after administration of those that are also potent alpha-adrenoceptor antagonists, such as chlorpromazine, thioridazine, and clozapine (24). A central mechanism involving the vasomotor regulatory center may also contribute to the lowering of blood pressure.

- A 51-year-old man taking maintenance clozapine developed profound hypotension after cardiopulmonary bypass (19).

Cardiac dysrhythmias

A substantial portion of patients taking clozapine develop electrocardiographic abnormalities; the prevalence was originally estimated at 10% (SEDA-20, 47) (SEDA-22, 57). However, although the prevalence may be higher, most of the effects are benign and do not need treatment. In 61 patients with schizophrenia taking clozapine, in whom a retrospective chart review was conducted to identify electrocardiographic abnormalities, the prevalence of electrocardiographic abnormalities in those who used neuroleptic drugs other than clozapine was 14% (6/44), while in the neuroleptic drug-free patients it was 12% (2/17); when treatment was switched to clozapine, the prevalence of electrocardiographic abnormalities rose to 31% (19/61) (25).

The correlation between plasma clozapine concentration and heart rate variability has been studied in 40 patients with schizophrenia treated with clozapine 50–600 mg/day (21). The patients had reduced heart rate variability parameters, which correlated negatively with plasma clozapine concentration.

Clozapine can cause prolongation of the QT interval (26).

- In a 30-year-old man taking clozapine there were minor electrocardiographic abnormalities, including a prolonged QT interval. A power spectrum analysis of heart rate variability showed marked abnormalities in autonomic nervous system activity. When olanzapine was substituted, power spectrum analysis studies showed that his heart rate had improved significantly and that his cardiovascular parameters had returned to normal. Serial electrocardiograms showed minimal prolongation of the QT interval.

Tachycardia is the most common cardiovascular adverse effect of clozapine, and atrial fibrillation has also been reported (SEDA-22, 57) (20).

The reports of sudden death associated with clozapine and the possibility that it may have direct prodysrhythmic properties have been reviewed (27).

A patient developed ventricular fibrillation and atrial fibrillation after taking clozapine for 2 weeks (22).

- A 44-year-old man with no significant cardiac history was given clozapine and 12 days later had bibasal crackles in the chest and ST segment elevation in leads V2 and V3 of the electrocardiogram. He then developed ventricular tachycardia and needed resuscitation. He also developed atrial fibrillation for 24 hours, which subsequently resolved.

Cardiomyopathy

Cardiomyopathy has been associated with neuroleptic drugs, including clozapine (28–30), and partial data initially suggested an incidence of 1 in 500 in the first month.

A thorough study of the risk of myocarditis or cardiomyopathy in Australia detected 23 cases (mean age 36 years; 20 men) out of 8000 patients treated with clozapine from January 1993 to March 1999 (absolute risk 0.29%; relative risk about 1000–2000) (17). All the accumulated data on previous reports of sudden death, myocarditis, or cardiac disease noted in connection with clozapine treatment were requested from the Adverse Drug Reactions

© 2006 Elsevier B.V. All rights reserved.

Advisory Committee (ADRAC); there were 15 cases of myocarditis (five fatal) and 8 of cardiomyopathy (one fatal) associated with clozapine. All cases of myocarditis occurred within 3 weeks of starting clozapine. Cardiomyopathy was diagnosed up to 36 months after clozapine had been started. There were no confounding factors to account for cardiac illness. Necropsy results showed mainly eosinophilic infiltrates with myocytolysis, consistent with an acute drug reaction.

The manufacturers analysed 125 reports of myocarditis with clozapine and found 35 cases with fatal outcomes (31). A total of 53% occurred in the first month of therapy, and a small number (4.8%) occurred more than 2 years after the start of treatment. In this series, 70% of the patients were men.

Taking into account the results from an epidemiological study of deaths in users and former users of clozapine (32), the cardiovascular mortality risk related to clozapine may be outweighed by the overall lower mortality risk associated with its beneficial effects, since the death rate was lower among current users (322 per 100 000 person years) than among past users (696 per 100 000 person years). The reduction in death rate during current use was largely accounted for by a reduction in the suicide rate compared with past use (RR = 0.25; CI = 0.10, 0.30).

Since cardiomyopathy is potentially fatal, some precautions must be taken. If patients taking clozapine present with flu-like symptoms, fever, myalgia, dizziness or faintness, chest pain, dyspnea, tachycardia or palpitation, and other signs or symptoms of heart failure, consideration should always be given to a diagnosis of myocarditis. Suspicion should be heightened if the symptoms develop during the first 6–8 weeks of therapy. It should be noted, however, that flu-like symptoms can also occur during the titration period, supposedly as a result of alpha-adrenoceptor antagonism by clozapine. Patients in whom myocarditis is suspected should be referred immediately to a cardiac unit for evaluation.

Clozapine rechallenge after myocarditis has been described (33).

- A 23-year-old man with no history of cardiac disease was given clozapine 12.5 mg/day, increasing to 200 mg/day over 3 weeks; 5 weeks later he complained of shortness of breath and non-specific aches and pains in his legs and body. There was marked ST-segment depression and T wave inversion in the lateral and inferior leads of the electrocardiogram. There was no eosinophilia, and creatine kinase activity was not raised. An echocardiogram showed a hyperdynamic heart and left ventricular size was at the upper limit of normal. The heart valves were normal. Clozapine was withdrawn, but his mental state and quality of life deteriorated, and 2 years later clozapine was restarted because other drugs had not produced improvement. The dose of clozapine was built up to 225 mg at night and he remained well and free from cardiac adverse effects.

In this case a consultant cardiologist diagnosed myocarditis secondary to clozapine, as no other confounding co-morbidity was identified. However, the negative rechallenge suggests either that the clozapine was not responsible or that there was tolerance to the effect.

Pericarditis

Serositis (pericarditis and pericardial effusion, with or without pleural effusion) has been reported in patients taking clozapine (34–36).

- A 43-year-old man developed a pericardial effusion after taking clozapine for 7 years. The condition resolved when the drug was withdrawn.
- A 16-year-old girl developed pericarditis associated with clozapine. There were electrocardiographic changes and serial rises in serum troponin I, a highly sensitive and specific marker of myocardial injury.

The latter is said to be the first reported case of pericarditis due to clozapine demonstrating rises in troponin I, which resolved despite continuation of therapy. The authors suggested that troponin I is the preferred marker for monitoring the cardiac adverse effects of clozapine.

Venous thromboembolism

Typical neuroleptic drugs have been associated with an increased risk of venous thromboembolism (37). Data from the Swedish Reactions Advisory Committee suggested that clozapine is also associated with venous thromboembolic complications (38). Between 1 April 1989 and 1 March 2000, 12 cases of venous thromboembolism were collected; in 5 the outcome was fatal. Symptoms occurred in the first 3 months of treatment in eight patients; the mean clozapine dose was 277 mg/day (75–500). Although during the study total neuroleptic drug sales, excluding clozapine, accounted for 96% of all neuroleptic drug sales, only three cases of thromboembolism associated with those neuroleptic drugs were reported. The reported risk of thromboembolism associated with clozapine is estimated to be 1 per 2000–6000 treated patients, the true risk being higher owing to under-reporting. These conclusions were consistent with those from an observational study (32).

Between February 1990, when clozapine was first marketed in the USA, and December 1999 the FDA received 99 reports of venous thromboembolism (83 mentioned pulmonary embolism with or without deep vein thrombosis and 16 mentioned deep vein thrombosis alone) (39). In 63 cases death had resulted from pulmonary embolism; 32 were confirmed by necropsy. Of 36 non-fatal cases, only 7 had been documented objectively by such diagnostic techniques as perfusion-ventilation lung scanning and venography. Thus, in 39 of the 99 reports there was objective evidence of pulmonary embolism or deep vein thrombosis. The median age of the 39 individuals was 38 (range 17–70) years and 20 were women. The median daily dose was 400 (range 125–900) mg. The median duration of clozapine exposure before diagnosis was 3 months (range 2 days to 6 years). Information on risk factors for pulmonary embolism and deep vein thrombosis varied; however, 18 of the 39 patients were obese. The frequency of fatal pulmonary embolism in this study is consistent with that described in the labelling for clozapine in the USA.

As of 31 December 1993, there were 18 cases of fatal pulmonary embolism in association with clozapine therapy in users aged 10–54 years. Based on the extent of use recorded in the Clozapine National Registry, the mortality rate associated with pulmonary embolism was 1 death per 3450 person years of use. This rate was about 28 times

© 2006 Elsevier B.V. All rights reserved.

higher than that in the general population of a similar age and sex (95% CI = 17, 42). Whether pulmonary embolism can be attributed to clozapine or some characteristic(s) of its users is not clear (40).

Fatal pulmonary embolism occurred in a 29-year-old man who was not obese, did not smoke, and had not had recent surgery, after he had taken clozapine 300 mg/day for 6 weeks (41).

Nervous system

Clozapine has been used to treat benign essential tremor refractory to the usual drugs (propranolol, primidone, alprazolam, phenobarbital, and botulinum toxin) in a randomized, double-blind, crossover study in 15 patients with essential tremor (42). Responders with more than 50% improvement after a single dose of clozapine 12.5 mg, compared with placebo, subsequently received 39–50 mg unblinded for a mean of 16 months. Tremor was effectively reduced by a single dose of clozapine in 13 of 15 patients; sedation was the only adverse effect reported.

Sleep

In a study of the effects of clozapine on the electroencephalogram, 13% of patients developed spikes with no relation to dose or serum concentration of clozapine; 53% developed electroencephalographic slowing. Compared with plasma concentrations below 300 ng/ml, a clozapine serum concentration of 350–450 ng/ml led to more frequent and more severe electroencephalographic slowing (43). There were considerable differences in the electroencephalographic patterns between classical neuroleptic drugs and clozapine (44). Clozapine-treated patients showed significantly more stage 2 sleep, more stable non-REM sleep (stages 2, 3, and 4), and less stage 1 than patients treated with haloperidol or flupentixol. In a longitudinal study, clozapine significantly improved sleep continuity and significantly increased REM density, but did not affect the amount of REM sleep (45).

Seizures

Clozapine has a proconvulsant effect. Factors that increase the likelihood of seizures include high doses of clozapine, rapid dose titration, the concurrent use of other epileptogenic agents (such as antidepressants, neuroleptic drugs, and mood stabilizers) and a previous history of neurological abnormalities (46).

The prevalence of seizures with clozapine is higher than average (about 5%) and is dose-dependent (SED-14, 142) (47,48).

- A tonic-clonic seizure occurred in a 30-year-old man 4 weeks after he started to take clozapine 400 mg/day (49). This was followed by a large increase in liver enzymes, which had been normal the week before.

Seizure characteristics and electroencephalographic abnormalities in 12 patients taking clozapine have been identified; there was a surprisingly high incidence of focal epileptiform abnormalities (50). Seizures associated with clozapine are dose-dependent (SEDA-21, 53) (SEDA-22, 57). However, there have been reports of seizure activity in patients taking therapeutic or subtherapeutic doses of clozapine (47,48). Seizures have occasionally been reported in patients taking low doses.

- A 28-year-old woman, with no history of prior seizures and not taking concomitant medication, had seizures while taking clozapine 200 mg/day (48).
- A 75-year-old patient developed seizures while taking clozapine 12.5 mg/day.

However, in the second case the seizure was unlikely to have been due to clozapine, given the very low dose and non-recurrence with rechallenge at higher dosages (51).

Despite the risk of seizures in patients without pre-existing epilepsy, six patients with epilepsy and severe psychosis taking clozapine had no increases in seizure frequency, and three had a substantial reduction (52).

Several anticonvulsants have been shown to be helpful in the prevention and treatment of clozapine-induced seizures.

- A 15-year-old boy with refractory schizophrenia had seizures with clozapine; he was given gabapentin, and several years later was free of seizures (53).

The addition of lamotrigine to clozapine therapy has been associated with rapid improvement of psychiatric symptoms (54); this has been observed in three cases of poor response or resistance to clozapine monotherapy.

Stuttering has been associated with clozapine (SEDA-22, 58). The pathogenesis of developmental stuttering, as well as acquired or neurogenic stuttering, is unclear. However, since clozapine-induced stuttering can precede a seizure (SEDA-25, 64) it may be related to an effect on the brain rather than to a dystonic syndrome, as previously suggested.

- A 28-year-old man taking clozapine 300 mg/day developed severe stuttering and subsequently had a generalized tonic-clonic seizure while taking 425 mg/day (55). There were electroencephalographic abnormalities, especially left-sided slowing.
- A 49-year-old woman had prominent stuttering before a generalized epileptic seizure and recovered after antiepileptic treatment (56).

Extrapyramidal effects

Clozapine has a more favorable extrapyramidal effects profile than other neuroleptic drugs (57) and little or no parkinsonian effect (58).

Akathisia

The low prevalence of akathisia in patients taking clozapine has led to the proposal that clozapine should be used to treat patients with neuroleptic drug-induced chronic akathisia (59,60).

Parkinsonism

The efficacy and safety of treatment with clozapine in patients with Parkinson's disease have been discussed (SEDA-22, 57), and a multicenter retrospective review of the effects of clozapine in 172 patients with Parkinson's disease has been published (61). The mean duration of clozapine treatment was 17 (range 1–76) months. Low-dose clozapine improved the symptoms of

© 2006 Elsevier B.V. All rights reserved.

psychosis, anxiety, depression, hypersexuality, sleep disturbances, and akathisia. Of the 40 patients, 24% withdrew as a result of adverse events, mostly sedation ($n = 19$). Sedation was reported in 46%, sialorrhea in 11%, and postural hypotension in 9.9%. Neutropenia was detected in four patients (2.3%).

Six patients who met the criteria for a diagnosis of HIV-associated psychosis, and who had previously developed moderate parkinsonism as a result of typical neuroleptic drugs, were treated with clozapine (62). Parkinsonism improved by an average of 77%, but one patient did not complete the trial because of a progressive fall in leukocyte count.

Clozapine has been used to treat psychosis related to Parkinson's disease (SEDA-22, 57) (61). In a randomized, double-blind, placebo-controlled trial of low doses of clozapine (6.25–50 mg/day) in 60 patients (mean age 72 years) with idiopathic Parkinson's disease and drug-induced psychosis, the patients in the clozapine group had significantly more improvement after 14 months than those in the placebo group in all measures used to determine the severity of psychosis (63). Clozapine improved tremor and had no deleterious effect on the severity of parkinsonism, but in one patient it was withdrawn because of leukopenia.

In a randomized, double-blind, placebo-controlled, 4-week trial in 60 patients with similar drug-induced psychosis in Parkinson's disease, assigned to clozapine ($n = 32$) or placebo ($n = 28$), the initial clozapine dose of 6.25 mg/day was titrated over at least 10 days to a maximum of 50 mg/day and was rapidly effective (64). Somnolence and worsening of parkinsonism were significantly more frequent in the clozapine group, seven of whom reported worsening of Parkinson's disease, usually mild or transient, which was confirmed by aggravation of the Schwab and England score by 10–20% in three patients; however, no-one withdrew for this reason.

Tardive dyskinesia

It is said that clozapine causes less tardive dyskinesia than haloperidol and even that it can improve pre-existing tardive dyskinesia (65–69).

Patients with schizophrenia with ($n = 15$) and without ($n = 11$) tardive dyskinesia differed markedly in their dopaminergic response to haloperidol, assessed by means of plasma homovanillic acid variations, which increased, whereas this difference was not observed after clozapine (70).

Nevertheless, 46 patients taking clozapine had higher tardive dyskinesia scores compared with 127 taking typical neuroleptic drugs (71). In a multiple regression analysis, there was a significant relation between the total score on the Abnormal Involuntary Movement Scale (AIMS) as a dependent variable and current neuroleptic drug dose, duration of treatment, age, sex, diagnosis, current antiparkinsonian therapy, and illness duration. There was no beneficial effect of clozapine on the prevalence of tardive dyskinesia, and the authors' conclusion was that certain patients develop tardive dyskinesia despite long-term intensive clozapine treatment; however, since most clozapine users were past users of typical neuroleptic drugs, this conclusion must be regarded with caution.

- A 45-year-old woman developed tardive dyskinesia while taking clozapine (72). She had never had any of the symptoms before she started to take 223 mg/day and first experienced involuntary tongue movements and akathisia 5 months after the start of treatment.
- Tardive dyskinesia has been attributed to clozapine in a 44-year-old man, who had discontinued haloperidol 24 days before the event (73).

Tardive dystonia

It is generally considered that clozapine has little or no potential to cause tardive dystonia; it has even been speculated that it may be an effective therapy for this adverse effect (SEDA-21, 53). The efficacy of clozapine in severe dystonia was therefore assessed in an open trial in five patients (74). All had significant improvement; nevertheless, all had adverse effects, such as sedation and orthostatic hypotension: in one case persistent symptomatic orthostatic hypotension and tachycardia limited treatment.

However, there was no evidence of a beneficial effect of clozapine in primary dystonia, the most common form of dystonia and a difficult disorder to treat, until the report of a 56-year-old woman with severe and persistent primary cranial dystonia (Meige's syndrome), who responded to clozapine (50–100 mg) (75).

Tardive dystonia, probably associated with clozapine, has been described (76).

- A 37-year-old man, who had taken numerous neuroleptic drugs from 1975 to 1990, was switched to clozapine because of breakthrough psychosis. Clozapine was effective and was his only neuroleptic drug treatment from that time. In 1996, when his clozapine dosage was 825 mg/day, he had left torticollis of 60–70°, mild left laterocollis, and superimposed spasmodic head movements jerking his head to the left. He had difficulty rotating his head to the right past the midline.

Tardive tremor

Tardive tremor is a hyperkinetic movement disorder associated with chronic neuroleptic drug treatment. It was first described in 1991 as a symmetrical tremor, of low frequency, present at rest and during voluntary movements but most prominent during maintenance of posture, and often accompanied by tardive dyskinesia. Tetrabenazine is the current treatment. Sequential responsiveness to both tetrabenazine and clozapine has been reported (77).

- A 55-year-old man with a 15-year history of schizophrenia treated with various neuroleptic drugs developed a tremor and was given tetrabenazine 75 mg/day, with complete regression of the tremor. Three months later he developed depression, a known adverse effect of tetrabenazine, which was discontinued, with subsequent partial improvement of his depressive symptoms but reappearance of the tardive tremor. Clozapine 25 mg/day was started and increased to 75 mg/day; his tardive tremor again disappeared.

© 2006 Elsevier B.V. All rights reserved.

Neuroleptic malignant syndrome

Neuroleptic malignant syndrome has been associated with clozapine (SEDA-22, 58) (78), although some doubts were expressed about the features of earlier cases. In the light of two cases, a 35-year-old man and a 62-year-old woman, the literature was comprehensively reviewed and the characteristics of neuroleptic malignant syndrome due to clozapine and typical neuroleptic drugs were compared (79). Causation with clozapine was deemed highly probable in 14 cases, of medium probability in 5 cases, and of low probability in 8 cases. The most commonly reported clinical features were tachycardia, changes in mental status, and sweating. Fever, rigidity, and raised creatine kinase activity were less prominent than in the neuroleptic malignant syndrome associated with typical neuroleptic drugs. This suggests that the presentation of clozapine-induced neuroleptic malignant syndrome may be different from that of typical neuroleptic drugs. Two other cases have also illustrated that possibility (80,81).

Neuroleptic malignant syndrome and subsequent acute interstitial nephritis has been reported in a 44-year-old woman (82). This patient met the main criteria for neuroleptic malignant syndrome, although she did not develop rigidity or a rise in creatine kinase activity. On the other hand, abnormal creatine kinase activity and signs of myotoxicity were respectively found in 14% and 2.1% of patients who took clozapine for an average of 18 months ($n = 94$) (83).

Delirium

Toxic delirium caused by neuroleptic drugs with potent anticholinergic properties has been widely reported (SED-11, 107), and has been reported with low-dose clozapine (84).

Psychological, psychiatric

Suicide, suicidality, and suicidal ideation are very serious problems in patients with schizophrenia. Based on general observations that 1–2% of patients with schizophrenia complete suicide within 1 year after initial attempts, the authors of a retrospective study of 295 neuroleptic drug-resistant patients with schizophrenia who had taken clozapine monotherapy for at least 6 months would have expected as many as 10 or 11 successful suicides or suicide attempts, but none was observed (85).

Obsessive-compulsive symptoms during clozapine therapy have been suggested to be more common than first reported (SEDA-21, 54). In a retrospective cohort study, new or worse obsessiveness has been analysed in 121 consecutive young patients with recent-onset schizophrenia or other psychotic disorders taking clozapine and other neuroleptic drugs (86). More clozapine-treated subjects (21%) had new or worse obsessiveness than subjects treated with other neuroleptic drugs (1.3%). However, there was no information on comparability of the groups.

Panic disorder has been attributed to clozapine (87).

- A 34-year-old woman taking clozapine 400 mg/day for psychiatric symptoms had recurrent attacks of sudden chest pressure, dizziness, fear of dying, and intense anxiety; reducing the dose of clozapine to 250 mg/day led to modest improvement. Olanzapine 10 mg/day was then substituted, without recurrence, and her panic symptoms progressively improved.

Metabolism

Diabetes mellitus

Several cases of de novo diabetes mellitus or exacerbation of existing diabetes in patients taking neuroleptic drugs have been reported, including patients taking clozapine (88–91). There was no significant relation to weight gain.

- A 49-year-old man taking olanzapine developed diabetes mellitus and recovered after withdrawal (92).
- Diabetic ketoacidosis occurred in a 31-year-old man who had taken clozapine 200 mg/day for 3 months for refractory schizophrenia (93). Clozapine was withdrawn and he remained metabolically stable. Two months later, clozapine was restarted, and only 72 hours after drug re-exposure he had increased fasting glycemia and insulinemia, suggesting insulin resistance as the underlying mechanism. Apart from slight obesity, he had no predisposing factors.

Hyperglycemia occurs at 2 weeks to 3 months after the start of clozapine treatment and occurs without predisposing factors. Clozapine-induced hyperglycemia can be serious, leading to coma, but it is reversible if clozapine is withdrawn. In some cases, continuation of clozapine is possible by controlling blood glucose concentrations with hypoglycemic drugs. This approach can be useful in refractory schizophrenia responsive to clozapine. All patients should be advised to report altered consciousness, polyuria, or increased thirst.

Glucose metabolism has been studied in 17 patients taking clozapine (94). Six had impaired glucose tolerance and eight had a glycemic peak delay.

Diabetes was also more common in 63 patients taking clozapine than in 67 receiving typical depot neuroleptic drugs (95). The percentages of type 2 diabetes mellitus were 12% and 6% respectively. Nevertheless, the mechanism is not known. In six patients with schizophrenia, clozapine increased mean concentrations of blood glucose, insulin, and C peptide (96). The authors concluded that the glucose intolerance was due to increased insulin resistance.

However, opposite data have been found in a case-control study in 7227 patients with new diabetes and 6780 controls, all with psychiatric disorders (97). Clozapine was not significantly associated with diabetes (adjusted OR = 0.98; 95% CI = 0.74, 1.31) and there was no suggestion of relations between larger dosages or longer durations of clozapine use and an increased risk of diabetes. Among individual non-clozapine neuroleptic drugs, there were significantly increased risks for two phenothiazines: chlorpromazine (OR = 1.31; 95% CI = 1.09, 1.56) and perphenazine (OR = 1.34; 95% CI = 1.11, 1.62). The authors suggested that, in contrast to earlier reports, these results provided some

© 2006 Elsevier B.V. All rights reserved.

reassurance that clozapine does not increase the risk of diabetes. However, cases of diabetes were identified by the new use of antidiabetic drugs, and it is therefore possible that clozapine was associated with less pronounced glucose intolerance that did not require drug therapy.

Weight gain

Weight gain is often associated with clozapine (SEDA-21, 54). In 42 patients who took clozapine for at least 1 year, men and women gained both weight and body mass, which is more directly related to cardiovascular morbidity (98). Over 10 weeks, leptin concentrations, which correlate with body mass index, increased significantly from baseline in 12 patients taking clozapine (99).

The association between clozapine-related weight gain and increased mean arterial blood pressure has been examined in 61 patients who were randomly assigned to either clozapine or haloperidol in a 10-week parallel-group, double-blind study, and in 55 patients who chose to continue to take clozapine in a subsequent 1-year open study (100). Clozapine was associated with significant weight gain in both the double-blind trial (mean 4.2 kg) and the open trial (mean 5.8 kg). There was no significant correlation between change in weight and change in mean arterial blood pressure.

There were no significant associations between cycle length and weight change during clozapine treatment in 13 premenopausal women with psychoses (101).

Sleep apnea associated with clozapine-induced obesity has been reported (102).

- A 45-year-old woman with schizophrenia who took clozapine 300 mg/day for 16 months gained 18 kg and had hypertriglyceridemia and glucose intolerance. She had daytime sedation, difficulty in sleeping at night, loud snoring, and periods of apnea during sleep.

Nasal continuous positive airway pressure produced improvement.

Phenylpropanolamine 75 mg/day did not promote weight loss in a randomized, placebo-controlled study in 16 patients with schizophrenia who had gained at least 10% of their body weight while taking clozapine (103).

- A 29-year-old man taking clozapine 800 mg/day gained 46 kg in weight after 25 months, and had myoclonic jerks in the hands, arms, and shoulders on both sides (104). He was treated with topiramate (which causes weight loss). The myoclonic jerks disappeared completely. He lost 21 kg over 5 months, with no significant change in eating habits or food consumption, and felt more energetic, more active, and more motivated to exercise.

Hematologic

Neutropenia and agranulocytosis

DoTS classification (BMJ 2003; 327:1222–1225)
Dose-relation: hypersusceptibility effect
Time-course: intermediate or delayed
Susceptibility factors: genetic; age

Incidence

Clozapine-induced agranulocytosis was originally determined to be 0.21% in a selected Finnish population (SED-9, 83) (105), and the drug was withdrawn, only to be cautiously reintroduced in some countries a decade later, with hematological monitoring. With mandatory hematological monitoring by the Clozaril Patient Management System in the USA, the cumulative incidence of agranulocytosis was 0.8% at 1 year and 0.9% at 1.5 years of treatment; the risk was not related to dosage (SEDA-18, 54) (106). In France, the incidences of agranulocytosis and neutropenia in clozapine-treated patients from December 1991 were 0.46 and 2.1% respectively (107). Some of the available postmarketing data on clozapine-induced agranulocytosis are presented in Table 1 (108).

Mechanism

The underlying mechanisms of agranulocytosis are unknown, but hemopoietic cytokines, such as granulocyte colony-stimulating factor (G-CSF), are likely to be involved (109).

- In a 26-year-old woman who developed granulocytopenia twice, first when taking clozapine and again when taking olanzapine, G-CSF concentrations, but not those of other cytokines, closely paralleled the granulocyte count.
- In a 73-year-old patient who developed granulocytopenia while taking clozapine, G-CSF and leukocyte

Table 1 Reported incidences of clozapine-induced agranulocytosis

Country	Period	Number of patients	Incidence (mortality) (%)	Reference
Finland	1975	2260	0.70 (0.35)	(SED-9, 83) (105)
USA	1990–1991	11382	0.80 (0.02)	(SEDA-18, 54)
France	1992	2834	0.46 (ND)	(SEDA-21, 54)
USA	1990–1994	99502	0.38 (0.01)	(SEDA-22, 59)
UK and Ireland	1990–1994	6316	0.80 (0.03)	(SEDA-22, 59)
New Zealand	1988–1995	963	1.15 (0.00)	(SEDA-22, 59)
Australia	1993–1996	4061	0.90 (0.00)	(99)

counts were reliable indicators of the evolution of the condition, showing an abortive form of toxic bone-marrow damage with subsequent recovery (110).

Immune-mediated mechanisms of clozapine-induced agranulocytosis have been reviewed in the context of agranulocytosis in a 46-year-old woman (111). Immune and toxic mechanisms have also been explored in patients taking clozapine, three who developed agranulocytosis, seven who developed neutropenia, and five who were asymptomatic. There was no evidence of antineutrophil antibodies in the blood of patients shortly after an episode of clozapine-induced agranulocytosis, and an antibody mechanism seems unlikely, in view of the delay in onset of clozapine-induced agranulocytosis on re-exposure to the drug (112).

Susceptibility factors

Some of the genetic aspects of clozapine-induced agranulocytosis have been evaluated (113). Polymorphisms of specific clozapine metabolizing enzyme systems were determined in 31 patients with agranulocytosis and in 77 without. Genotyping of a recently discovered G-463 A polymorphism of the myeloperoxidase gene and CYP2D6 showed no evidence of an association.

Because of the unusually high incidence of agranulocytosis in Finnish and Jewish patients (SEDA-20, 49), an ethnic susceptibility factor for agranulocytosis has been suggested. Human leukocyte antigen (HLA) B38 phenotype was found in 83% of patients who developed agranulocytosis and in 20% of clozapine-treated patients who did not develop agranulocytosis (114). Gene products contained in the haplotype may be involved. In an open study in 31 German patients with clozapine-induced agranulocytosis and 77 controls with schizophrenia, agranulocytosis was significantly associated with HLA-Cw*7, DQB*0502, DRB1*0101, and DRB3*020 (115). No other antigens were associated with agranulocytosis, but age was another major susceptibility factor. In another study in two groups of Finnish patients (19 "clozapine responders" and 26 patients with a history of non-fatal clozapine-induced granulocytopenia or agranulocytosis), the frequency of the HLA-A1 allele in the latter was low (12%), whereas HLA-A1 was associated with a good therapeutic response at an allele frequency of 58% (the frequency of HLA-A1 being 20% in the Finnish population) (116).

Concordant clozapine-induced agranulocytosis in monozygotic twins also suggested a genetic susceptibility; in both twins there was a low leukocyte count after 9 weeks of treatment (117). Serological typing of the HLA system showed identical patterns in the twins: HLA-A: 28, 26; HLA-B: 49, 63; DR: 2 (versus 16), 12, 52; DQ: 1. The authors pointed out that these data suggest that genetic factors may participate not only in the time of onset of schizophrenia, but also in the emergence and timing of agranulocytosis in response to clozapine.

Clinical features

Careful attention should be paid to possible early warnings of agranulocytosis, such as fever, sore throat, and lymphadenopathy.

Circadian variation in white cell count, with a dip in the morning, has been misdiagnosed as clozapine-induced neutropenia (118).

- A 31-year-old man with resistant schizophrenia took clozapine 500 mg/day. Although this was effective, the granulocyte count fell to 1.2×10^9/l (total count not given) and clozapine was withdrawn. During the subsequent year, several neuroleptic drugs were used, with unsatisfactory results. Careful monitoring showed a pronounced diurnal variation in both total white cell count ($2.9–4.2 \times 10^9$/l in the morning and $3.6–7.1 \times 10^9$/l in the afternoon) and granulocytes ($0.8–1.4 \times 10^9$/l in the morning and $2.9–5.5 \times 10^9$/l in the afternoon).

Thus, an apparently low white cell count may simply reflect the nadir of the diurnal variation and may not indicate a need to withdraw clozapine.

In over 11 000 patients the risk of agranulocytosis was higher in the first 3 months of treatment and is greater among women and elderly patients (119).

Agranulocytosis after very long-term clozapine therapy has been reported (120).

- A 41-year-old man suddenly developed agranulocytosis after taking clozapine nearly continuously for 89 months. During this time, his white blood cell and granulocyte counts remained stable. The white blood cell and granulocyte counts returned to baseline shortly after withdrawal of clozapine and administration of sargramostim.

Rechallenge

Cases of negative or positive rechallenge in patients with agranulocytosis have been reported (SEDA-20, 54) (SEDA-22, 59).

- A 58-year-old man developed agranulocytosis during a second trial of clozapine, despite a successful previous trial (121).
- A 17-year-old boy with severe clozapine-induced neutropenia had a negative rechallenge; because he had had an unsatisfactory response to traditional neuroleptic drugs, clozapine was continued despite a fall in white blood cell count, since concomitant treatment with granulocyte colony-stimulating factor was followed by rapid normalization of the white blood cell count (122).
- A 29-year-old woman developed agranulocytosis after taking clozapine 300 mg/day for 5 years; 4 months after withdrawal, the clozapine was reintroduced (500 mg/day), and after 8 months the leukocyte count was still within the reference range (123).

Monitoring therapy

Over 10 000 patients have been treated with clozapine in Australia since its introduction in 1993, and the Clozaril monitoring system has ensured that since that time there have been no deaths from agranulocytosis in patients taking clozapine (124).

An increase in white blood cell count of at least 15% above previous counts is a sensitive, although not specific, predictor for the development of agranulocytosis within 75 days (119). Clozapine dosage and baseline white cell count do not appear to predict agranulocytosis.

© 2006 Elsevier B.V. All rights reserved.

Monitoring G-CSF concentrations, if available, may be useful in following patients in whom clozapine-induced marrow damage is suspected.

An example of a false sense of security gained by relying on monitoring monthly blood counts in patients taking clozapine has been published (125).

- A 61-year-old man who had taken clozapine for 3 years had normal blood counts. However, one day, his hemoglobin was 8.5 g/dl, having previously been 13 g/dl, following a steady asymptomatic fall over 6 months that had been documented but had gone unnoticed. He subsequently underwent investigation and treatment for anemia.

However, it is not clear in this case that clozapine was responsible for the anemia.

Treatment

Withdrawal of clozapine can lead to resolution of agranulocytosis, but not always. Granulocytopenia, presumably induced by clozapine, persisted in a 53-year-old woman after she switched from clozapine to quetiapine (126).

Treatment with granulocyte colony-stimulating factor and granulocyte macrophage colony stimulating factors was helpful in a case of sepsis and neutropenia induced by clozapine (127) and in a case of agranulocytosis in a 45-year-old man (128).

Lithium can be used in combination with clozapine, and in these patients the possibility of inducing leukocytosis and increasing the total leukocyte count and the granulocyte count has been considered (SEDA-20, 50). Lithium has even been used to prevent clozapine-induced neutropenia (SEDA-22, 59). It has also been used in a patient with clozapine-induced neutropenia and in another with complete agranulocytosis: in both cases lithium increased the neutrophil count to within the reference range within 6 days (129). In the patient who had neutropenia, clozapine was restarted in the presence of lithium and the neutrophil count did not fall thereafter. Five other patients who took combined clozapine and lithium had a significant improvement with this combination and there were no cases of agranulocytosis, neuroleptic malignant syndrome, or other adverse effects (130).

Eosinophilia

Clozapine-induced eosinophilia and subsequent neutropenia has been reported (131). As the patient had a high IgE concentration, an allergic cause was proposed. In a previous study in 70 patients there was no predictive value of eosinophilia for clozapine-induced neutropenia (132). Eosinophilia associated with clozapine treatment has been reported in 13% of treated patients in a study in Australia (28).

Platelet count

Thrombocytosis and thrombocytopenia have both been reported.

- Thrombocytosis (774×10^9/l) occurred in a middle-aged man taking clozapine (133).
- A 43-year-old man developed thrombocytopenia (platelet count 60×10^9/l), which persisted for 40 months after clozapine treatment (134). There was increased in vitro platelet serotonin release in the presence of clozapine (135).

In the second case, the authors suggested an immune mechanism and pointed out that the manufacturers recommend withdrawing clozapine when the platelet count falls below 100×10^9/l.

Mouth and teeth

Hypersalivation is a common adverse effect of clozapine (136), which has been estimated to occur in 10–23% of patients (SEDA-20, 49). Salivary gland swelling has been reported in patients treated with clozapine (SEDA-20, 49) (137).

There is evidence implicating alpha-adrenoceptors in hypersalivation caused by clozapine, and it has been hypothesized that a biallelic polymorphism in the promoter region of the alpha$_2$-adrenoceptor gene confers susceptibility to schizophrenia, which is associated with a clozapine-induced favorable therapeutic response and/or clozapine-induced hypersalivation (138). However, the results in 97 patients showed that the alpha$_2$-adrenoceptor gene polymorphism did not play a major role in susceptibility to hypersalivation or the therapeutic response of patients with schizophrenia.

A comprehensive review has been published on the evidence of the benefit of using antimuscarinic agents, adrenoceptor antagonists, and adrenoceptor agonists in treating clozapine-induced hypersalivation (139). There is a lack of good-quality controlled trials, most papers having reported series of uncontrolled cases dependent on subjective measures of improvement reported by patients; however, the authors suggested that the most effective treatment may be a combination of terazosin and benzhexol (140). Ten patients with sialorrhea associated with clozapine, who did not respond to anticholinergic or adrenergic drugs, received intranasal ipratropium bromide; at 6 months, six patients maintained improvement (141).

Gastrointestinal

Reflux esophagitis has been reported in patients taking clozapine (142). It has been speculated that reduced esophageal motility was the mechanism (143).

Constipation is an adverse effect that has often been associated with clozapine; it can be serious and even fatal (SEDA-22, 60).

- A 49-year-old man taking clozapine developed a perforated colon and peritonitis (144). He survived, albeit with a markedly reduced quality of life.

The authors suggested that diet modification and regular exercise should be encouraged in patients taking clozapine, in order to prevent constipation.

- A 43-year-old man took clozapine 750 mg/day for 6 years and developed vomiting and epigastric pain (145). He had ulcerative esophagitis, and a CT scan was reportedly normal "apart from constipation." He was given omeprazole 20 mg/day and twice-daily psyllium. Six months later he developed abdominal

© 2006 Elsevier B.V. All rights reserved.

pain with feculent vomiting. Emergency laparotomy revealed large-bowel obstruction secondary to severe fecal impaction. He died 3 weeks later with septic shock and progressive multisystem organ failure.

Liver

Transient asymptomatic liver enzyme rises are common with clozapine (146).

Hepatitis associated with clozapine has been reported (SEDA-20, 49) (SEDA-22, 59).

- A 49-year-old woman (147) took clozapine 300 mg/day and developed lethargy, anorexia, fever, eosinophilia, leukocytosis, and abnormal liver function tests. The serum clozapine concentration was 8595 nmol/l. Clozapine was withdrawn and after 8 days her condition stabilized and low-dose clozapine treatment was successfully restarted with serum monitoring.

Obstructive jaundice has been described (148).

- A 48-year-old man with schizophrenia started taking clozapine 12.5 mg/day, increasing over the next 18 days to 150 mg/day. By that time he was icteric, with mild distress and fever and raised bilirubin 149 μmol/l (reference range 5–26), direct bilirubin 92 μmol/l, gamma-glutamyl transpeptidase 446 IU/l (<65), alanine transaminase 100 IU/l (<40), and aspartate transaminase 56 IU/l (<40). Hepatitis serology showed positive hepatitis B surface antibodies, and HBs antigen was negative, as were hepatitis A, hepatitis C, Epstein-Barr virus, and cytomegalovirus. He also had hyperglycemia, pleural effusion, eosinophilia, hematuria, and proteinuria, which also resolved on clozapine withdrawal.

A case of fatal liver failure has been reported (149).

Pancreas

Occasional cases of pancreatitis have been related to clozapine therapy (SEDA-17, 63).

- A 73-year-old woman with a 4-year history of Parkinson's disease developed hallucinations and delusions that were interpreted as secondary effects of levodopa (150). She was given clozapine 25 mg/day and continued to take levodopa. Four days later she complained of abdominal pain. She had raised activities of serum amylase 806 IU/l (reference range <220 IU/l), lipase 2598 IU/l (<190 IU/l), and creatine kinase 464 IU/l (<190 IU/l), and normal concentrations of total and direct bilirubin. Other causes of pancreatitis were ruled out.

Two other cases have been reported in patients with no prior history of alcohol abuse or gallstones (151,152). The authors recommended monitoring serum amylase activity during slow increases in the dosage of clozapine if there is leukocytosis or eosinophilia, which may be associated with asymptomatic pancreatitis.

Urinary tract

Enuresis has been rarely associated with clozapine (0.23% of patients) (SEDA-19, 54) (153), and has been successfully treated with benzatropine in patients taking a variety of psychotropic medications (154).

In a retrospective study, 27 of 61 Chinese patients who took clozapine for more than 3 months developed urinary incontinence, persistent in 15 cases (155). The reaction could not be related to age, sex, clozapine dosage, duration of clozapine use, duration of hospitalization, duration of illness, age at onset of schizophrenia, or concurrent treatment with other psychiatric drugs.

Polymorphisms of the alpha 1a adrenoceptor gene were found to play no major role in the pathogenesis of schizophrenia or in clozapine-induced urinary incontinence (156).

Acute interstitial nephritis has been attributed to clozapine (157).

- A 38-year-old woman developed anorexia, lethargy, and vomiting, and noticed a profound reduction in urine output about 11 days after starting clozapine (125 mg bd). Severe renal insufficiency was confirmed (blood urea 33 mmol/l and creatinine 1200 μmol/l). There was no history of pre-existing renal or other systemic disease.

Musculoskeletal

Clozapine-induced myokymia (weakness and reduced muscle tone, with undulating movements of the muscle and skin, accompanied by involuntary repetitive firing of grouped motor unit action potentials) has been reported (158).

- A 33-year-old woman developed muscle twitching and spasms of the legs and back after having taken clozapine for 3 years (158). Neurological examination showed myokymia in both thighs, calves, and the lower lip. The myokymia disappeared 1 week after withdrawal of clozapine.

In an open study in 41 patients, strength control was evaluated before the start of clozapine therapy and again at the end of the titration period (on average 9 weeks later). The results suggested that the strength deficit was primarily due to clozapine and that there were two distinct effects: an initial transient stage characterized by "drowsiness" and a subsequent stage with dose-dependent myoclonic features (159).

- Rhabdomyolysis occurred in two men, aged 21 and 42 years, taking clozapine (160,161). The first had no risk factors, but calcium-dependent potassium efflux, normally responsible for membrane hyperpolarization and muscle refractoriness, was severely impaired in his erythrocytes. The second had marked hyponatremia, due to psychogenic polydipsia, and developed a marked rise in creatine kinase activity (62 730 U/l) after correction of hyponatremia with hyperosmolar fluids.

Sexual function

The frequency and course of sexual disturbances associated with clozapine have been studied in a prospective open study in 75 men and 25 women, mean age 29 years, and compared with the effects of haloperidol in 41 men and 12 women, mean age 26 years (162). There were no statistically significant differences between the patients

© 2006 Elsevier B.V. All rights reserved.

taking haloperidol and those taking clozapine. During 1–6 weeks of treatment with clozapine, the most frequent sexual disturbances among women were diminished sexual desire (28%) and amenorrhea (12%), while among men they were diminished sexual desire (57%), erectile dysfunction (24%), orgasmic dysfunction (23%), ejaculatory dysfunction (21%), and increased sexual desire (15%). The mean daily doses were haloperidol 16 mg and clozapine 261 mg.

Retrograde ejaculation has been associated with clozapine (163).

Immunologic

Allergic reactions associated with clozapine are uncommon; however, a case of rash (SEDA-21, 55) and a case of pleural effusion (SEDA-22, 60) have previously been reported. Both rash and pleural effusion have been reported in a 37-year-old woman about 1 week after starting clozapine (164).

Body temperature

Clozapine often causes a benign transient increase in body temperature early in treatment (165).

Long-Term Effects

Drug withdrawal

Rebound psychosis or delirium or both have been reported after withdrawal of clozapine (166–171). Clozapine withdrawal has also been associated with nausea, vomiting, diarrhea, headache, restlessness, agitation, and sweating (172,173), which occur as the result of cholinergic rebound and which may respond to anticholinergic drugs (174), and with dystonias and dyskinesias. Delirium and the return of dyskinetic movements can occur within days after clozapine withdrawal.

Four patients had severe dystonias and dyskinesias on abrupt withdrawal of clozapine (175), and another two had obsessive-compulsive symptoms during withdrawal; resumption of clozapine led to the complete disappearance of the obsessive-compulsive symptoms (176).

Second-Generation Effects

Pregnancy

Clozapine caused no serious complications or developmental abnormalities during pregnancy in two cases (177).

Susceptibility Factors

Age

Data from an open study ($n = 329$) have suggested that patients aged 55–64 years may have a better response to clozapine than those aged 65 and older, but there were no significant differences between the two age groups in the number of patients remaining on clozapine therapy and the number in whom therapy was discontinued ($n = 134$) (178). The mean duration of clozapine therapy was 278 days. The most common adverse effects that required withdrawal were sedation ($n = 12$), hematological adverse effects ($n = 7$), and cardiovascular adverse effects ($n = 6$).

In over 11 000 patients the risk of agranulocytosis was greater among elderly patients (119).

Sex

In over 11 000 patients the risk of agranulocytosis was greater among women (119).

Other features of the patient

Patients with Lewy body dementia may be more intolerant of neuroleptic drugs, including atypical drugs, than other patients with neurodegenerative dementia. However, because hallucinations are common in this form of dementia, it is likely that people with Lewy body dementia will be exposed to neuroleptic drugs. Two patients with Lewy body dementia taking clozapine developed confusion and behavioral symptoms (179).

Drug Administration

Drug formulations

Since clozapine is expensive, it is interesting that generic clozapine (given as 25 and 100 mg tablets) behaves like Clozaril, the branded formulation; bioequivalence has been observed in 30 patients with schizophrenia (180).

Drug dosage regimens

Since up to 17% of patients must discontinue clozapine because of adverse effects, strategies for minimizing and managing the adverse effects of clozapine have been reviewed (181,182). Treatment should begin with a low dosage, 12.5–25 mg/day.

The optimal plasma concentration of clozapine is 200–350 ng/ml, which usually corresponds to a daily dose of 200–400 mg (183,184). A nomogram to predict clozapine steady-state plasma concentrations has been generated using data from 71 patients (185). Clozapine steady-state plasma concentrations and demographic variables were obtained. The model explained 47% of the variance in clozapine concentrations. Two equations were obtained to predict steady-state plasma concentrations, one for men and one for women:

$$\text{clozapine (ng/ml)} = 0.464D + 111S + 145 \text{ (men)}$$
$$\text{clozapine (ng/ml)} = 1.590D + 111S - 149 \text{ (women)}$$

where D = dosage (mg/day), S = 1 for smokers, and S = 0 for non-smokers.

A further model for optimizing individual dosage regimens using Bayesian methods has been proposed (186).

Drug overdose

Fatal overdoses have been reported with clozapine (187).

Seven patients who took large doses of clozapine (mean 3 g, range 0.4–16 g) have been reported (188). All made a full recovery and toxicokinetic modelling suggested that

© 2006 Elsevier B.V. All rights reserved.

norclozapine was formed by a saturable process but that clozapine kinetics were linear over the estimated doses.

- Clozapine overdose (2.5 g) in a 67-year-old woman resulted in seizures, loss of consciousness, metabolic acidosis, prolonged sedation, and aspiration pneumonia (189). By 9 days after intoxication she had recovered completely.
- A 40-year-old man who took 3–4 g of clozapine became unconscious, with constricted pupils, sinus tachycardia, and twitching; peak clozapine and norclozapine concentrations were 3.5 mg/l and 0.7 mg/l respectively, with secondary peaks at about 36 hours (190). Recovery was uneventful, and he was well 2 days after admission.
- A 41-year-old woman took 12.5 g of clozapine (125 tablets of 100 mg each) in a suicide attempt (191). She developed agitation, hallucinations, diminished distrust, and lethargy; she was given physostigmine 2 mg and recovered completely within 1 week.

Drug–Drug Interactions

Benzodiazepines

Caution has been recommended when starting clozapine in patients taking benzodiazepines (SEDA-19, 55). Three cases of delirium associated with clozapine and benzodiazepines (192) have been reported. There have been several reports of synergistic reactions, resulting in increased sedation and ataxia, when lorazepam was begun in patients already taking clozapine (193).

Hypotension, collapse, and respiratory arrest occurred when low doses (12.5–25 mg) of clozapine were added to a pre-existing diazepam regimen in several patients (SEDA-22, 41).

- A 50-year-old man developed syncope and electrocardiographic changes (sinus bradycardia with deep inverted anteroseptal T waves and minor ST changes in other leads) with the concurrent administration of clozapine (after the dosage was increased to 300 mg/day) and diazepam (30 mg/day) (194).

Caffeine

Caffeine has been associated with changes in the metabolism of clozapine (SEDA-20, 50) (SEDA-22, 61). Seven schizophrenic patients taking clozapine monotherapy participated in a study of the effects of caffeine withdrawal from the diet (195). After a caffeine-free diet for 5 days, clozapine plasma concentrations fell by 50%. The authors suggested that schizophrenic patients treated with clozapine should have their caffeine intake medically supervised, and that monitoring of concentrations of clozapine and its metabolite may be warranted.

Ciprofloxacin

A possible pharmacokinetic interaction between ciprofloxacin, which inhibits CYP1A2, and clozapine, with moderately increased serum concentrations of clozapine, has been reported (196).

Cisplatin

There is a potentially dangerous interaction with cancer treatment in patients with schizophrenia taking clozapine, because of the unpredictable risk of myelotoxicity. However, a 37-year-old patient taking clozapine for schizophrenia was given full-dose cisplatin and concomitant radiotherapy for an undifferentiated nasopharyngeal carcinoma, without significant neutropenia (197).

Cocaine

An interaction between clozapine and cocaine, causing near syncope, has been reported (198).

Erythromycin

Increased clozapine serum concentrations have been reported with erythromycin (199,200) and can cause adverse effects (SEDA-21, 55). However, in 12 healthy men who took a single dose of clozapine 12.5 mg alone or in combination with a daily dose of erythromycin 1.5 g, the metabolism of clozapine was not altered (201). This confirms that CYP3A4 is a relatively minor pathway for clozapine metabolism, in contrast to CYP1A2.

In a case of neutropenia the authors suggested that an interaction of clozapine with erythromycin had been the precipitating factor (202).

Interferon alfa

Agranulocytosis was observed after patients taking clozapine were given interferon alfa (SEDA-22, 404) (203). In one case, agranulocytosis occurred after 7 weeks of combined therapy in a 29-year-old patient who had been taking clozapine for more than 5 years without developing hematological abnormalities (203). Even so, it was not clear in these cases whether the agranulocytosis was due to the combination of clozapine with interferon-alfa or the clozapine alone.

Lithium

Seizures and other neurological effects have been described in a few cases when lithium was added to clozapine (204), but in other instances the combination was beneficial in overcoming treatment resistance or attenuating clozapine-induced leukopenia.

Modafinil

Clozapine toxicity occurred in a 42-year-old man after he was given modafinil 300 mg/day, a central stimulant, to combat sedation associated with clozapine (450 mg/day) (205). He complained of dizziness, had an unsteady gait, and fell twice. His serum clozapine concentration was 1400 ng/ml, which suggested a metabolic interaction between clozapine and modafinil. The authors suspected that inhibition of CYP2C19 by modafinil had reduced clozapine clearance.

Perphenazine

Perphenazine doubled clozapine concentrations in a 46-year-old male smoker, with paradoxical myoclonus, hypersalivation, and worsening of psychosis (206). The mechanism of this effect is not known; perphenazine is a

© 2006 Elsevier B.V. All rights reserved.

substrate for CYP2D6, but that is not important in the metabolism of clozapine.

Phenobarbital

Phenobarbital can stimulate the metabolism of clozapine, probably by inducing its N-oxidation and demethylation. Seven patients taking clozapine in combination with phenobarbital had significantly lower plasma clozapine concentrations than 15 controls taking clozapine only (207).

Risperidone

Clozapine plasma concentrations increase when risperidone is introduced. The effects of risperidone 3.25 mg/day on cytochrome P450 isozymes have therefore been assessed in eight patients by determination of the metabolism of caffeine (for CYP1A2), dextromethorphan (for CYP2D6), and mephenytoin (for CYP2C19) (220). The results suggested that risperidone is a weak in vivo inhibitor of CYP2D6, CYP2C19, and CYP1A2. The authors concluded that inhibition by risperidone of those isozymes is an unlikely mechanism to explain increased clozapine concentrations.

SSRIs

Some SSRIs increase clozapine plasma concentrations (SEDA-20, 50) (SEDA-21, 55) (SEDA-22, 62) by inhibiting its metabolism.

Citalopram

Citalopram had no effect on plasma concentrations of clozapine ($n = 8$), risperidone ($n = 7$), or their active metabolites over 8 weeks (208). However, a possible interaction of clozapine with citalopram has been reported, with increased serum clozapine concentrations, perhaps dose-related (209).

Fluoxetine

In 10 patients stabilized on clozapine (200–450 mg/day) who took fluoxetine (20 mg/day) for 8 weeks, mean plasma concentrations of clozapine, norclozapine, and clozapine N-oxide increased significantly by 58%, 36%, and 38% respectively (210).

In two cases ingestion of clozapine and fluoxetine had a fatal outcome (211). The blood fluoxetine concentration was 0.7 μg/ml, which would be considered a high therapeutic concentration (usual target range 0.03–0.5 μg/ml). The blood clozapine concentration was 4900 ng/ml, which is within the lethal concentration range (1600–7100 ng/ml).

Dual effects were observed in a 44-year-old schizophrenic patient taking clozapine with both fluoxetine and sertraline for mood stabilization (212). Clinical and motor status improved with both fluoxetine and sertraline; cognitive function improved with clozapine and fluoxetine, but was not sustained with sertraline.

Fluvoxamine

Fluvoxamine increases clozapine plasma concentrations (210,213). In 16 patients taking clozapine monotherapy, fluvoxamine 50 mg was added in the hope of ameliorating the negative symptoms of schizophrenia (214). At steady state the serum concentrations of clozapine and its metabolites increased up to five-fold (average two- to three-fold). However, adverse effects were almost unchanged in frequency and severity, in spite of the pharmacokinetic interaction.

In another study there were similar increases in plasma clozapine concentrations and adverse reactions in 18 patients taking fluvoxamine 50 mg (week 5, mean dose 97 mg) (215).

In nine men who were given a single dose of clozapine 50 mg on two separate occasions with a 2-week interval, fluvoxamine increased clozapine plasma concentrations, and the total mean clozapine AUC was increased by a factor of 2.6; all the patients were sedated during combined therapy (216).

Combined therapy with clozapine and fluvoxamine ($n = 11$) and clozapine monotherapy ($n = 12$) have been monitored before and during the first 6 weeks of medication (217). The co-administration of fluvoxamine attenuated and delayed the clozapine-induced increase in plasma concentrations of tumor necrosis factor-alpha, enhanced and accelerated the clozapine-induced increase in leptin plasma concentrations without a significant effect on clozapine-induced weight gain, and reduced granulocyte counts.

In two studies of short duration (18 patients each) there were benefits of using low doses of clozapine plus fluvoxamine, and the authors suggested taking advantage of this interaction (218). Patients taking fluvoxamine required relatively low doses of clozapine and had clinically significant reductions in the symptoms of their illness while avoiding the sedative adverse effects associated with the usual doses of clozapine.

Paroxetine

The effect of paroxetine on steady-state plasma concentrations of clozapine and its metabolites has been studied in 17 patients taking clozapine (200–400 mg/day), nine of whom took additional paroxetine (20–40 mg/day) (219). Paroxetine, a potent inhibitor of CYP2D6, inhibited the metabolism of clozapine, possibly by affecting a pathway other than N-desmethylation and N-oxidation. After 3 weeks of paroxetine, mean plasma concentrations of clozapine and norclozapine increased significantly by 31% and 20% respectively, while concentrations of clozapine N-oxide were unchanged.

Sertraline

Dual effects were observed in a 44-year-old schizophrenic patient taking clozapine with both fluoxetine and sertraline for mood stabilization (212). Clinical and motor status improved with both fluoxetine and sertraline; cognitive function improved with clozapine and fluoxetine, but was not sustained with sertraline. However, sertraline did not affect steady-state plasma concentrations of clozapine and its metabolites in 17 patients taking clozapine (200–400 mg/day), 8 of whom took additional sertraline (50–100 mg/day) (219).

Tricyclic antidepressants

Nefazodone had minimal effects on clozapine metabolism when co-administered in six patients: mean clozapine concentrations rose by 4% and norclozapine concentrations by 16% (221).

Valproate

Clozapine inhibits the metabolism of valproate (222). Valproic acid has been reported to increase the sedative effects of clozapine (SEDA-20, 50) and alter serum concentrations of clozapine.

- In a 33-year-old woman taking clozapine and valproic acid, the serum concentrations of clozapine fell significantly (223).

The authors suggested that valproic acid had induced the metabolism of clozapine.

However, one study showed only small effects on plasma clozapine concentrations, which were thought to be unlikely to be clinically significant (224).

Smoking

Smoking is highly prevalent among patients with schizophrenia, of whom 70–80% smoke tobacco. In a before-and-after study, 55 smokers smoked less when treatment was switched to clozapine than when they were taking typical neuroleptic drugs (225). Nevertheless, it is probable that heavy smoking can induce CYP1A2, the main enzyme involved in the metabolism of clozapine, and plasma concentrations of clozapine are lower in smokers than in non-smokers. Conversely, sudden cessation of smoking can cause a rise in plasma clozapine concentrations. In one case, seizures have been reported as a result (226).

- A 35-year-old schizophrenic man successfully treated with clozapine 700–725 mg/day for more than 7 consecutive years abruptly stopped chronic heavy cigarette smoking and 2 weeks later suddenly developed tonic-clonic seizures followed by stupor and coma. After recovery, he successfully reduced the daily dose by about 40% before he stopped smoking.

Diagnosis of Adverse Drug Reactions

In an open study in 37 patients (27 men and 10 women; mean age 35 years) with treatment-resistant schizophrenia treated with clozapine for 18 weeks, there was no correlation between plasma clozapine concentrations and percentage improvement on the Positive and Negative Syndrome Scale (227). Plasma clozapine concentrations were not significantly different between those who responded to clozapine ($n = 19$) and those who did not ($n = 18$), nor between patients who smoked ($n = 28$) and those who did not ($n = 9$). Dosages were adjusted according to clinical response, and plasma concentrations of clozapine and its metabolites were measured weekly. The mean endpoint clozapine dosage was 487 mg/day and there was a significant correlation between the daily dosage of clozapine and the plasma concentrations of clozapine and its metabolites. Three patients dropped out of the study owing to adverse effects (two because of significant sedation and one because of hypersalivation); there were no cases of agranulocytosis.

Clusiaceae

See also Herbal medicines

General Information

The genera in the family of Clusiaceae (Table 1) include St. John's wort.

Hypericum perforatum

Hypericum perforatum (devil's scourge, goat weed, rosin rose, St. John's wort, Tipton weed, witch's herb) contains the naphthodianthrones hypericin and pseudohypericin, flavonoids, such as hyperoside, isoquercitin, and rutin, and phloroglucinols, such as adhyperforin and hyperforin. It is effective in mild to moderate depression (1).

Adverse effects

A meta-analysis of 23 randomized, controlled trials of St. John's wort showed that the herbal extract is more effective than placebo for mild to moderate depression, but that current evidence was inadequate to establish whether St. John's wort is as effective as standard antidepressants (2). In clinical trials, St. John's wort appeared to have fewer short-term adverse effects than some conventional antidepressants, but information on long-term adverse effects is lacking.

Two reviews have systematically addressed the safety of St. John's wort. One showed that the most common adverse events were gastrointestinal symptoms, dizziness, confusion, tiredness, sedation, and dry mouth (3). A second review compared the adverse effect profile of St. John's wort with those of conventional antidepressants (4). The adverse effects of St. John's wort were fewer and less serious than those associated with conventional antidepressant drugs.

A review of all reported adverse effects associated with St. John's wort has shown that it has an encouraging safety profile (3). Adverse effects reported in clinical trials were invariably mild and transient: gastrointestinal symptoms (8.5%), dizziness/confusion (4.5%), tiredness/sedation (4.5%), and dry mouth (4.0%). Synthetic drugs used in comparative trials were burdened with significantly higher rates of adverse effects. Data obtained from the WHO Collaborating Center for International Drug Monitoring are summarized in Table 2.

Cardiovascular

A 41-year-old man who had taken St. John's wort had a hypertensive crisis after taking cheese with red wine (5).

Table 1 The genera of Clusiaceae

Platonia (platonia)
Triadenum (marsh St. John's wort)

Table 2 Reports of adverse effects of formulations of St. John's wort (up to May 1998)

System	Number of cases
Cardiovascular (edema)	2
Cardiovascular (bradycardia)	1
Respiratory	4
Nervous system	5
Nervous system (stroke)	1
Psychiatric	15
Hematological (coagulation)	4
Gastrointestinal	2
Liver	4
Urinary tract (interstitial nephritis)	1
Skin (allergic reactions)	16
Skin (conjunctivitis)	1
Reduced therapeutic response	1

St. John's wort is a monoamine oxidase inhibitor, and the authors believed that this explained how the concomitant use of a tyramine-rich food with St. John's wort had caused this problem.

Nervous system

The mechanism of action of St. John's wort in depression is not understood, but serotonin re-uptake inhibition is one possibility, for which evidence is increasing. In one case this may have led to the serotonin syndrome in a 33-year-old woman who developed extreme acute anxiety after taking only three doses of extracts of St. John's wort and recovered after withdrawal (6).

- A 40-year-old man with a history of anxiety disorder and depression presented with flushing, sweating, agitation, weakness of the legs, dry mouth, tightness in the chest, and inability to focus (7). He was taking clonazepam (0.5 mg bd) and had started to take St. John's wort 10 days before. He had previously had two similar episodes after having taken sertraline.

The authors concluded that self-medication with St. John's wort, which has SSRI activity, had caused the serotonin syndrome.

Psychiatric

Delirium has been attributed to St. John's wort.

- A 76-year-old woman began taking an extract of St. John's wort (75 mg/day) and developed delirium and psychosis 3 weeks later (8). She had no relevant medical history and did not take any other medications. She was given risperidone and donepezil hydrochloride, and her paranoid delusions and visual hallucinations improved.

The final diagnosis was acute psychotic delirium associated with St. John's wort in a woman with underlying Alzheimer's dementia.

Hypomania has been reported with St. John's wort (9).

- A 47-year-old woman with an 8-year history of nocturnal panic attacks and a recent history of major depression had a poor response to SSRIs and instead took a 0.1% tincture of St. John's wort. After 10 days she

© 2006 Elsevier B.V. All rights reserved.

noted racing and distorted thoughts, increased irritability, hostility, aggressive behavior, and a reduced need for sleep. After discontinuing the herbal treatment, her symptoms resolved within 2 days.

The author suggested that St. John's wort had caused this episode of hypomania.

Two cases of mania have been associated with the use of St. John's wort (10). The authors pointed out that St. John's wort, like all antidepressants, can precipitate hypomania, mania, or increased cycling of mood states, particularly in patients with occult bipolar disorder. Alternatively, the mania experienced by these patients could simply be the expression of the natural cause of their psychiatric illness.

Endocrine

In a retrospective case-control study, 37 patients with raised TSH concentrations were compared with 37 individuals with normal TSH concentrations (11). Exposure to St. John's wort during the previous 3–6 months increased the odds of a raised TSH concentration by a factor of 2.12 (95% CI = 0.36, 12). The authors concluded that an association between St. John's wort and raised TSH concentrations is probable.

Skin

Photosensitivity has been attributed to St. John's wort (12).

- A 35-year-old woman took ground whole St. John's wort (500 mg/day) for mild depression. After 4 weeks she developed stinging pain on her face and the backs of both hands, which worsened with sun exposure. She was seen after the area of pain had spread following exposure to the sun. After withdrawal of St. John's wort, the symptoms gradually disappeared during the next 2 months.

The authors thought that photoactive hypericins had caused demyelination of cutaneous nerve axons. If they are correct, then this would be the first human case of photosensitivity after St. John's wort, a condition previously only reported in animals.

Of 43 users of St. John's wort surveyed by telephone, 47% reported adverse effects that they related to the remedy (13). The only potentially serious complaint was photosensitivity, which was noted by four individuals.

An Australian dermatologist has reported three cases of phototoxic reactions to St. John's wort (14). The patients were fair-skinned and had had significant exposure to ultraviolet light. In two cases St. John's wort was applied topically. In all cases complete recovery occurred after withdrawal of St. John's wort and cessation of exposure to ultraviolet light.

Hair

Alopecia has been attributed to St. John's wort.

- A 24-year-old woman with schizophrenia who self-medicated with St. John's wort while also taking olanzapine (5–10 mg/day) developed hair loss on her scalp and eyebrows 5 months later; it persisted for 12 months (7). Her medical history was otherwise unremarkable.

The authors speculated that, like SSRIs, St. John's wort can cause hair loss.

Pregnancy

Like all herbal remedies, there is insufficient evidence that it is safe to take St. John's wort during pregnancy. Two women who took St. John's wort during pregnancy in order to avoid potential harmful effects of synthetic antidepressants to the fetus also discontinued their prescribed medications and did not discuss their decisions with their doctor (15). Although the effects of St. John's wort on the fetus are not known, the authors cautioned against using it under these circumstances and argued that tricyclic antidepressants or fluoxetine would be safer.

Drug interactions

Interactions of St. John's wort with prescribed drugs are due to its ability to induce the activity of both CYP3A4 and the P glycoprotein transporter system (16). Prescribed drugs that interact with St. John's wort include ciclosporin, digoxin, HIV protease inhibitors, oral contraceptives, serotonin re-uptake inhibitors, theophylline, and warfarin (17).

The mechanism of hepatic enzyme induction by St. John's wort has been intensively researched (18,19). Treatment of human hepatocytes with extracts of St. John's wort or with hyperforin (one of its active constituents) resulted in induction of CYP3A4 expression (20).

Following reports about the potential for herb–drug interactions, many national regulatory agencies issued warnings about the use of St. John's wort and its safety was reviewed (21,22).

Ciclosporin

St. John's wort is a hepatic enzyme inducer (23) and can lower the plasma concentrations of various prescribed drugs, including oral anticoagulants and ciclosporin.

In 30 patients a fall in ciclosporin concentrations by 33–62% after self-medication with St. John's wort necessitated a gradual increase in the dose of ciclosporin of 187% (range 84–292%) (24). No patient suffered any permanent consequences as a result.

There have also been anecdotal reports of interactions of ciclosporin with St. John's wort.

- A 29-year-old woman, who had received a cadaveric kidney and pancreas transplant, had stable organ function with ciclosporin when she decided to take St. John's wort (25). Subsequently her ciclosporin concentrations became subtherapeutic and she developed signs of organ rejection. St. John's wort was withdrawn and her ciclosporin concentrations returned to the target range. However, she developed chronic kidney rejection and had to return to dialysis.
- A 63-year-old patient with a liver allograft developed severe acute rejection 14 months after transplantation (26). Two weeks before he had taken St. John's wort, which significantly reduced his ciclosporin concentration. The dose of ciclosporin was doubled, at the expense of adverse effects. He recovered fully after St. John's wort was withdrawn.
- A 55-year-old woman, who had received a kidney transplant and had stable organ function with ciclosporin, took St. John's wort and 4 weeks later her ciclosporin concentration fell sharply (27). The concentration rose again on withdrawal of St. John's wort and fell on

© 2006 Elsevier B.V. All rights reserved.

rechallenge. As the problem was identified early enough, the patient incurred no serious consequences.
- Two patients who took ciclosporin after kidney transplantation self-medicated with St. John's wort, and their ciclosporin concentrations became subtherapeutic (28). One subsequently had an acute transplant rejection. Withdrawal of St. John's wort resulted in normalization of ciclosporin concentrations.
- After a kidney transplant for end-stage renal insufficiency a 58-year-old man was given ciclosporin, azathioprine, and prednisolone (29). Four years later he started to take St. John's wort (300 mg bd) for depression, and 2 weeks later his previously stable ciclosporin concentrations had halved. Withdrawal of the St. John's wort resulted in normalization of his ciclosporin concentrations.

In a systematic review of all reports of interactions of St. John's wort with ciclosporin, 11 case reports and two case series were found (30). In most cases there was little doubt about causality.

Digoxin

In a randomized, placebo-controlled, double-blind study volunteers with steady-state digoxin concentrations took either placebo, a standardized extract of St. John's wort, encapsulated St. John's wort powder, St. John's wort tea, or an encapsulated fatty oil formulation of St. John's wort (31). The extract and the powder caused marked reductions in digoxin concentrations but the tea and the fatty oil formulation did not. The mechanism was not discussed, and it is not clear why the different formulations had different effects.

Irinotecan

In a randomized, crossover study five patients with cancer taking irinotecan were given St. John's wort (32). The plasma concentrations of irinotecan significantly fell in the presence of the herbal remedy. The authors pointed out that this is likely to reduce the effectiveness of the anticancer drug.

Oral contraceptives

- A 36-year-old woman became pregnant whilst taking an oral contraceptive, ethinylestradiol/dienogest (doses not stated) (33). She had also taken St. John's wort extract.

As no other cause for contraceptive failure could be identified, the authors concluded that the St. John's wort had been responsible.

Selective serotonin re-uptake inhibitors

Inhibition of serotonin re-uptake by St. John's wort can lead to interactions with SSRIs (34).

- A 28-year-old man without a previous psychiatric history was given sertraline 50 mg/day for depression after bilateral orchidectomy. Against medical advice, he also took St. John's wort and subsequently became manic.

The authors suggested that inhibition of serotonin re-uptake by sertraline had been potentiated by the use of St. John's wort.

Warfarin

In an open, crossover, randomized study in 12 healthy men St. John's wort significantly induced the apparent clearance of both *S*-warfarin and *R*-warfarin (by 29 and 23% respectively), which in turn resulted in a significant reduction in the pharmacological effect of racemic warfarin (35).

Coagulation proteins

See also Individual agents

General Information

The major coagulation and fibrinolytic proteins are listed in Table 1.

Coagulation protein concentrates became available in the 1970s, a significant step in the prevention and management of bleeding. The factors that are currently available are factor VII, factor VIIa, factor VIII, factor IX, factor XI, and factor XIII. There is also a factor VIII inhibitor bypassing factor, activated prothrombin

Table 1 Proteins involved in coagulation and fibrinolysis

Protein (synonym)	Function
Coagulation proteins	
Factor I (fibrinogen)	Activated to fibrin
Factor II* (prothrombin)	Activated to thrombin
Factor III (tissue thromboplastin)	Extrinsic pathway
Factor IV (calcium)	Co-factor
Factor V (Ac-globulin; proaccelerin)	Converts prothrombin to thrombin
Factor VI (unassigned)	
Factor VII* (proconvertin)	Extrinsic pathway
Factor VIII (antihemophilic factor)	Intrinsic pathway
Factor IX* (Christmas factor)	Intrinsic pathway
Factor X* (Stuart–Prower factor)	Extrinsic pathway
Factor XI (plasma thromboplastin antecedent)	Intrinsic pathway
Factor XII (Hageman factor)	Intrinsic pathway
Factor XIII (fibrin stabilizing factor)	Stabilizes fibrin
Von Willebrand factor (factor VIII-related antigen; vWF)	
High molecular weight kininogen (Fitzgerald factor)	Intrinsic pathway
Prekallikrein (Fletcher factor)	Intrinsic pathway
Fibrinolytic proteins	
Plasminogen	Converted to fibrinolysin
Prourokinase	Precursor of urokinase
Tissue plasminogen activator	Activates plasminogen
Antithrombin III	Inhibits thrombin, IXa, Xa, XIa, XIIa
Protein C*	Inhibits factors Va, VIIIa
Protein S*	Co-factor for protein C
α_2-Antiplasmin	Inhibits binding of fibrinolysin

*Vitamin K-dependent factor; the intrinstic and extrinsic pathways converge with the activation of factor X to Xa by factor VIII and IX.

© 2006 Elsevier B.V. All rights reserved.

complex concentrate. Fresh frozen plasma and prothrombin complex concentrate, which contain mixtures of coagulation proteins, are also available.

Two major classes of complications in the use of these proteins have emerged (1). First, transfusion-related infections with various blood-borne viruses, such as hepatitis B and C and human immunodeficiency virus (HIV). Secondly, alloimmune antibodies (inhibitors) against the deficient coagulation factors.

Organs and Systems

Cardiovascular

Two factor XI products, both containing antithrombin III and heparin, have been associated with evidence of coagulation activation and thrombotic events in patients with pre-existing vascular disease (2). It has been recommended that doses of more than 30 U/kg and factor XI peak concentrations in severely deficient patients of more than 500–700 U/l should be avoided. In addition, the concurrent use of tranexamic acid or other antifibrinolytic drugs should be avoided.

Immunologic

Patients with bleeding disorders are at risk of developing antibodies against the protein that is absent, present in reduced amounts, or present in an inactive form in their blood. Such coagulation inhibitors make treatment very difficult. Inhibitors of factor VIII are the most common and develop in 5–20% of patients with hemophilia A. Inhibitors of factor IX develop in 1–4% of patients with hemophilia B (3,4). Patients with factor VIII inhibitors present clinically either as "high responders" who show a strong anamnestic response and a sharp rise in inhibitor concentrations after exposure to factor VIII, or "low responders," who show little or no anamnestic response (5).

Because of the difference in prevalence of inhibitors in hemophilia B and hemophilia A, it has been postulated that there is a correlation between mutation type and inhibitor risk (6). Of the patients with gross deletion, nonsense, or frameshift mutations, 11% developed inhibitors compared with 0% and 0.36% of patients with hemophilia B with mis-sense or other mutations.

Recombinant and high-purity coagulation factor products appear to have a greater tendency to induce inhibitors than human-derived concentrates of intermediate or low purity (7). These intermediate-purity or low-purity human-derived concentrates are probably more suitable for inducing immune tolerance in patients with hemophilia with inhibitors. It has been suggested that for immune tolerance a high content of Von Willebrand factor in factor VIII concentrates is required, although direct comparisons of different products have not been made (8).

Risk factors for developing an inhibitor are the severity of the hemophilia, age (under 30 years), genetic predisposition, antigenicity of factor replacement therapy, and race (increased prevalence among black people) (9). In addition, it has been suggested that changing from one product to another can also stimulate the development of inhibitors (10).

Inhibitor formation has been observed in only a few patients with factor XI deficiency. Like patients with hemophilia A and B, these patients may be treated with prothrombin complex concentrates or recombinant factor VIIa (2).

Drug Administration

Drug contamination

In the past, plasma factor VIII products have exposed patients with hemophilia to foreign proteins as well as blood-borne viruses, including hepatitis B, hepatitis C, human parvovirus B19, and human immunodeficiency virus (11,12). Before the introduction of heat-treated concentrates in 1985, about 20% of patients with hemophilia in the UK became infected with HIV (13) and virtually all patients with hemophilia who were exposed to large-pool coagulation factor concentrates before the introduction of viral inactivation procedures developed hepatitis C (14). Studies using a second-generation enzyme-linked immunosorbent assay showed 89% anti-HCV positivity in a heterogeneous group of patients in the USA and in 98% of Dutch patients with hemophilia who had been exposed to large-pool, non-virally inactivated coagulation factor concentrates (14). In the UK and the Netherlands increased mortality due to liver disease in patients with hemophilia has been reported (14). In patients co-infected with HIV, liver disease was more severe, probably because of higher amounts of hepatitis C viral RNA (13). In addition, patients infected with hepatitis C virus genotype 1 had a more rapid course of disease due to HIV (14).

Since viral inactivation methods, such as solvent detergent and heat pasteurization, were implemented in the production process, the risks of HIV and hepatitis have virtually been eliminated. Dry heating at 60°C is insufficient to eliminate all hepatitis C virus, which requires dry heating at 80°C, pasteurization, or treatment with mixtures of solvents and detergents (14). Nevertheless, many viral inactivation methods currently used do not completely eliminate certain (non-enveloped) viruses, for example parvovirus and hepatitis A (11,15); removal of the small, non-lipid-enveloped parvovirus B19 requires 15 nm nanofiltration. HIV appears to progress more rapidly in patients co-infected with hepatitis B and cytomegalovirus (11). In addition, hepatitis C replicated more rapidly in patients infected with HIV (11).

In a mortality study amongst patients with hemophilia in the UK in 1977–91, AIDS was far the commonest cause of death, and liver disease ranked as the third commonest cause of death (15).

It has been postulated that transfusion-transmitted virus (TT virus) can be transmitted through heat-treated blood products (16). Transfusion-transmitted virus is a common DNA virus in healthy Japanese, and it lacks a lipid envelope, similar to parvovirus B19 (16,17). Transmission of transfusion-transmitted virus often occurs with blood transfusion and it can cause post-transfusion hepatitis with high postoperative peak alanine transaminase activity (17). No patients with hepatitis due to transfusion-transmitted virus have clinically apparent hepatitis (17). The incidence of transfusion-transmitted virus viremia in patients with hemophilia

© 2006 Elsevier B.V. All rights reserved.

was 43% of those who received only virus-inactivated concentrates and 78% in those who received non-inactivated products before 1984 (16).

Bacterial growth in infusion bags has not been detected, and complications such as infections during the postoperative period have not been observed (18).

Although transmission of classic Creutzfeldt–Jakob disease has never been observed, manufacturers have withdrawn plasma-derived products prepared from plasma obtained from donors who were subsequently found to have classic Creutzfeldt–Jakob disease (19). Although leukocytes are believed to play a key role in the pathogenesis of variant CJD, there may also be a theoretical risk of transmission by plasma products. However, various steps used in the manufacture of plasma-derived factors also contribute to reduced infectivity by bovine spongiform encephalopathy (20). The risk of transmission of nvCJD by recombinant products is unknown, as the cell cultures used for manufacturing them sometimes contain bovine proteins (21).

Cobalt

General Information

Cobalt is a metallic element (symbol Co; atomic no. 27). It is an important constituent of the cobalamins (vitamin B_{12}) and is found as arsenates and arsenides in naturally occurring minerals such as erythrite, skutterudite, and smaltite.

Cobalt has been used in the treatment of anemia, because of its erythropoietic action. However, it is toxic to many organs, and its medicinal benefits have repeatedly been questioned. In most countries the use of cobalt in anemia has been abandoned, although it is possible that in very rare cases there may be a need for it. If it is still to be used at all, the administration of cobalt ought to be entrusted to an experienced clinical hematologist.

Occupational exposure is mainly due to cobalt powders. Its main other uses are in metal alloys and medical devices (for example aneurysm clips) (1).

The toxicity of cobalt has been reviewed (SEDA-1, 185) (SED-9, 370) (2).

One tragic case in 1989 concerned a 13-month-old baby treated with a commercial iron–cobalt formulation that was still on sale, resulting in hypothyroidism, cardiomyopathy, polycythemia, and hypertrichosis (SEDA-16, 231).

Cobalt in metal implants and prostheses

Complications from the use of metal implants and prostheses can arise because of biochemical and histological reactions to some of the materials used (SEDA-22, 250). These include titanium, stainless steel (10–14% nickel, 17–20% chromium), and cobalt chrome alloys (27–30% chromium, 57–68% cobalt, and up to 2.5% nickel). All of these metals can produce sensitization or elicit toxic reactions when they are solubilized and come into contact with tissues; it can be difficult or even impossible to differentiate between hypersensitivity and toxic reactions.

Nickel plays a major role in sensitization of patients. Even the small amount present in cobalt chrome alloys often suffices to elicit allergic reactions. Reactions to cobalt are more generally toxic in nature (3). An increased rate of allergy to cobalt and nickel has been found in those patients bearing metallic implants who have developed bone infection in the surroundings of osteosynthesis material.

Metals from prostheses can continue to be released into the system for many years. The development of hypersensitivity takes time, and allergic reactions are usual delayed for weeks, months, or 1–2 years. The symptoms can assume a variety of forms. Local reactions can cause loosening of the device or local pain. Dermatological reactions include eczema, bullous pemphigoid, urticaria, and "muscle tumors."

Attempts continue to predict metal sensitivity in the individual patient so that the choice of material can be made accordingly. In vitro tests for metal allergies have been developed on the basis of lymphokine (MIF) release from sensitized T lymphocytes exposed to metal–protein complexes (4). About 6% of patients without a previous metal implant had positive reactions to nickel, chromium, or cobalt. However, it is still not clear whether such a positive reaction is a reliable predictor of clinical problems. In practice few patients have either local or systemic reactions; when symptoms occur and other causes are ruled out, the implant should be removed. Some workers recommend removal of an implant whenever there is both a positive MIF test and a positive skin test, even in the current absence of a serious reaction. Allergic dermatitis will clear up as soon as the metal has begun to be cleared from the tissue. The type of metal and the amount released into the tissue will affect the time taken for the disappearance of toxic dermatological phenomena.

Catastrophic failure of two cemented cobalt-containing femoral stems that had been used in conjunction with the impacting bone-grafting technique has been reported in two cases (5).

- A-59-year-old woman with degenerative arthritis of the hip was managed with bipolar arthroplasty and later with total hip replacement. A long-stem component, manufactured from forged cobalt-chromium, was later used for revision. She developed acute pain in the thigh and buttock, with tenderness and swelling in the thigh and hip and pain on movement. Hip X-rays showed catastrophic failure of the femoral component of the prosthesis, and at operation the prosthesis and the femur were fractured at the same level.
- A 51-year old woman sustained a fracture of the left femoral neck, later treated by total hip arthroplasty, which was revised several times with the impaction bone grafting technique and insertion of a prosthesis with cement. She developed a persistent weakness of the hip in flexion and abduction. Later the left hip buckled and she fell while walking. X-rays showed a periprosthetic fracture with bending of the femoral component.

It was thought that the mechanism of failure had been cantilever bending secondary to good distal fixation in the presence of poor proximal bone support resulting from poor proximal incorporation of the impacted allograft. In essence, a fatigue fracture had occurred in a forged cobalt–chromium stem that did not have an obvious manufacturing defect at the site of failure. Both failures were apparently related to implant design and operative technique rather than to defects introduced during the manufacturing process.

Cocaine

General Information

Cocaine is an alkaloid derived from the plant *Erythroxylon coca* and other *Erythroxylon* species in South America. The leaves contain cocaine as the principal alkaloid, plus a variety of minor alkaloids. Only decocainized coca products are legal in the USA, but some commercially available tea products have been found in the past to contain cocaine in a concentration normally found in coca leaves (about 5 mg of cocaine per 1 g tea-bag). This results in only mild symptoms when package directions to drink a few cups per day are followed, but massive overdosing can result in severe agitation, tachycardia, sweating, and raised blood pressure.

Cocaine, as the leaf or as an extracted substance in different forms, has been used for different purposes. Andean Indians have long chewed leaves of the coca plant to reduce hunger and increase stamina. Pure cocaine was first extracted from coca in the 19th century; it was used to treat exhaustion, depression, and morphine

© 2006 Elsevier B.V. All rights reserved.

addiction and was available in many patent medicines, tonics, and soft drinks. In the USA, after the Harrison Narcotic Act of 1914 and the Narcotic Drugs Import and Export Act of 1922, the use of cocaine fell, and the National Commission on Marihuana and Drug Abuse in 1973 reported that cocaine was little used. Since then, however, use has grown and there is now an epidemic in many countries. There may be about 5 million regular cocaine users in the USA, and users who have significant difficulties, including serious as well as fatal medical complications, continue to be reported frequently (1,2). Deaths occur not only from overdosage but also from drug-induced mental states, which can lead to serious injuries (3).

Cocaine was also the first aminoester local anesthetic, and its adverse effects differ from those of other local anesthetics. Owing to its rapid absorption by mucous membranes, cocaine applied topically can cause systemic toxic effects. There is a wide variation in the rate and amount of cocaine that is systemically absorbed. This variability can be affected by the type and concentration of vasoconstrictor used with cocaine and also accounts for the differences in cocaine pharmacokinetics in cocaine abusers (SEDA-20, 128).

As a recreational drug cocaine can be snorted (sniffed), swallowed, injected, or smoked. The street drug comes in the form of a white powder, cocaine hydrochloride. The hydrochloride salt and the cutting agents are removed to create the free base, which is smoked. The inexpensive widely available crack formulation is prepared by alkalinizing cocaine hydrochloride and precipitating the resultant alkaloidal free-base cocaine, which, unlike the hydrochloride, is not destroyed by heat when smoked. Smoking crack provides a rapid effect, comparable to that of intravenous injection. Intense euphoria, followed within minutes by dysphoria, leads to frequent dosing and a greater potential for rapid addiction (4). As with amphetamines, the euphoric effect can enhance craving, and repeated reinforcement can lead to conditioned drug responses, which facilitate dependence. Facilitated conditioned effects with cocaine may be due to its rapid elimination and the development of acute tolerance. Frequent repeated dosing becomes necessary to sustain euphoria, thereby promoting a tight temporal juxtaposition of euphoria with recent drug-taking (5).

Rapid intravenous or inhalational administration of cocaine can cause very high concentrations in areas of high vascular perfusion, for example the heart and brain, before eventual distribution to other tissues. Under these conditions there is a catecholaminergic storm in the heart and a local anesthetic effect, with prolongation of conduction. Once beyond the immediate period of vulnerability, accumulation (for example through frequent overdosing or accidents from body packing of condom-filled stimulants to avoid detection) leads to a different cascade of events over a period of hours, leading to death. This cascade includes a catecholaminergic hypermetabolic state, with hyperpyrexia and acidosis, anorexia, and repeated seizures, usually ending in cardiac collapse (1,6). On the other hand, chronic dosing can cause catecholaminergic cardiomyopathy, for example contraction bands, cardiomegaly (7,8), and repeated vasospastic insults to cerebral and coronary arteries (9). Whether these chronic effects predispose to increased sensitivity to acute toxicity has not been systematically explored, but autopsy studies suggest that they do.

In addition to other chronic changes in abusers, personality deterioration carries a significant association with high-risk behaviors, which are a source of physical and psychiatric morbidity and mortality. These include suicide, violent trauma and aggressive behavior, high-risk methods of drug use (for example needle sharing), and high-risk sexual behavior, with increased risks of HIV, hepatitis B, and other infections.

The stimulant properties of cocaine are similar to those of amphetamines, although the differences are notable, in part because of the very short half-life of cocaine. However, cocaine has the same problem of abuse potential as other stimulants, and at high doses causes stimulant psychosis (10). In addition, even when it is used as a local nasopharyngeal anesthetic, it has toxic, even fatal, effects in high doses.

Death from cocaine often occurs within 2–3 minutes, suggesting direct cardiac toxicity, fatal dysrhythmias, and depression of medullary respiratory centers as common causes of death (11,12). Thus, cocaine's local anesthetic properties can contribute additional hazards when high doses are used, reminiscent of deaths reported in the era when it was used as a mucous membrane paste for nasopharyngeal surgery (13).

Periods of increased cocaine use, especially intravenous administration, inhalation of the free base, and high-dose use, are associated with cocaine-related deaths. For example, according to the Drug Abuse Warning Network, there was a three-fold increase in such deaths from 195 to 580 per year in the USA between 1981 and 1985. Despite the importance of these mortality data, relatively little is known of the types of pathophysiological sequences involved in the cascade of events leading to death. More important, there is a paucity of guidelines to appropriate diagnostic and treatment strategies for the various prefatal conditions.

General adverse effects

Cocaine has a spectrum of pharmacological effects. It initially causes excitement and euphoria; later, with higher doses, lower centers become involved, producing reduced coordination, tremors, hyper-reflexia, increased respiratory rate, and at times nausea, vomiting, and convulsions. These symptoms are eventually followed by CNS depression.

Cardiovascular effects include tachycardia, hypertension, and increased cardiac irritability; large intravenous doses can cause cardiac failure. Cardiac dysrhythmias have been ascribed to a direct toxic effect of cocaine and a secondary sensitization of ventricular tissue to catecholamines (14), along with slowed cardiac conduction secondary to local anesthetic effects. Myocardial infarction has increased as a complication of cocaine abuse (7,8). Dilated cardiomyopathies, with subsequent recurrent myocardial infarction, have been associated with long-term use of cocaine, raising the possibility of chronic effects on the heart (15). Many victims have evidence of pre-existing fixed coronary artery disease precipitated by cocaine (SEDA-9, 35) (16–18). However, myocardial

© 2006 Elsevier B.V. All rights reserved.

infarction has been noted even in young intranasal users with no evidence of coronary disease (19), defined by autopsy or angiography (20,21). If applied to mucous membranes, cocaine causes local vasoconstriction, and, with chronic use, necrosis.

As a general rule, mortality is higher when cocaine is used intravenously or as smoked free base than if taken nasally or orally (22). The symptoms of acute cocaine poisoning include agitation, sweating, tachycardia, tonic-clonic seizures, severe respiratory and metabolic acidosis, apnea, and ventricular dysrhythmias. Seizures occur at high doses, and may be a major determinant of fatal outcomes; their control with sedatives is important to reduce lethality (23). Associated hyperthermia can contribute as a primary cause in cases of fatal hyperpyrexia, and can potentiate the hypoxic cardiovascular events in cardiac deaths in those who survive the initial acute dose (24,25). A study of a very large number of cocaine deaths showed that the morbidity rate increased by four times on days on which the ambient temperature rose above 31.1°C (26). The final agonal events in cocaine deaths involve the combination of sympathomimetic myocardial responses and/or cardiac conduction slowing, secondary to cocaine's local anesthetic effect, leading to dysrhythmias (27). In reported fatal overdoses, convulsions and death have usually occurred within minutes. Most patients who have survived for the first 3 hours after an initial acute overdose have been likely to recover. Treatment includes respiratory and cardiovascular resuscitative measures. Short-acting barbiturates, benzodiazepines, beta-blockers, and phentolamine have all been used with some success (20,28). Because of a possible risk of coronary vasodilatation with the use of propranolol to manage dysrhythmias in cocaine overdose, the use of labetalol for this indication is recommended, if a beta-blocker is required (29,30). In one study of 60 cocaine-related deaths, autopsy findings were non-specific but typical of those found in respiratory depression of central origin (31).

Organs and Systems

Cardiovascular

Cocaine abuse is a risk factor for myocardial ischemia, infarction, and dysrhythmias, as well as pulmonary edema, ruptured aortic aneurysm, infectious endocarditis, vascular thrombosis, myocarditis, and dilated cardiomyopathy (32). Acutely, cocaine suppresses myocardial contractility, reduces coronary caliber and coronary blood flow, induces electrical abnormalities in the heart, and increases heart rate and blood pressure. These effects can lead to myocardial ischemia (33,34). However, intranasal cocaine in doses used medicinally or recreationally does not have a deleterious effect on intracardiac pressures or left ventricular performance (35).

Tachycardia and vasoconstriction from cocaine can exacerbate coronary insufficiency, complicated by dysrhythmias and hypertensive and vascular hemorrhage (1). Sudden deaths have been reported in patients with angina (36). Chronic dosing includes cardiomyopathy and cardiomegaly; other chronic conditions include endocarditis and thrombophlebitis. Crack smoking has led to pneumopericardium (37).

The cardiac effects of intracoronary infusion of cocaine have been studied in dogs and humans (38). The procedure can be performed safely and does not alter coronary arterial blood flow. The effects of direct intracoronary infusion of cocaine on left ventricle systolic and diastolic performance have been studied in 20 patients referred for cardiac catheterization for evaluation of chest pain. They were given saline or cocaine hydrochloride (1 mg/minute) in 15-minute intracoronary infusions, and cardiac measurements were made during the final 2–3 minutes of each infusion. The blood cocaine concentration obtained from the coronary sinus was 3.0 μg/ml, which is similar in magnitude to the blood–cocaine concentration reported in abusers who die of cocaine intoxication. Minimal systemic effects were produced. The overall results were that cocaine caused measurable deterioration of left ventricular systolic and diastolic performance.

Possible predictors of cardiovascular responses to smoked cocaine have been studied in 62 crack cocaine users (24 women and 38 men, aged 20–45 years) who used a single dose of smoked cocaine 0.4 mg/kg (39). Physiological responses to smoked cocaine, such as changes in heart rate and blood pressure, were monitored. The findings suggested that higher baseline blood pressure and heart rate, a greater amount and frequency of current cocaine use, and current cocaine snorting predicted a reduced cardiovascular response to cocaine. By contrast, factors such as male sex, African-American race, higher body weight, and current marijuana use were associated with a greater cardiovascular response.

Fatal pulmonary edema developed in a 36-year-old man shortly after injecting free-base cocaine intravenously (40).

Symptoms of cardiac ischemia

Cocaine users often present with complaints suggestive of acute cardiac ischemia (chest pain, dyspnea, syncope, dizziness, and palpitation). Two studies have shown that the risk of actual acute cardiac ischemia among cocaine users with such symptoms was low. The first study reviewed the clinical database from the Acute Cardiac Ischemia–Time Insensitive Predictive Instrument Clinical Trial, a multicenter prospective clinical trial conducted in the USA in 1993 (41). Among 10 689 enrolled patients, 293 (2.7%) had cocaine-associated complaints. This rate varied from 0.3% to 8.4% in the 10 participating hospitals. Only six of these patients had a diagnosis of acute cardiac ischemia (2.0%), four with unstable angina and two with acute myocardial infarction. The cocaine users were admitted to the coronary care unit as often as other study participants (14 versus 18%), but were much less likely to have confirmed unstable angina (1.4 versus 9.3%). A second study also suggested that cocaine users who present with chest pain have a very low risk of adverse cardiac events (42). Emergency departments have instituted centers for the evaluation and treatment of patients with chest pain who are at low to moderate risk of acute coronary syndromes. In this particular study, patients with a history of coronary artery disease or presentations that included hemodynamic instability, electrocardiographic changes consistent with ischemia, or clinically unstable

© 2006 Elsevier B.V. All rights reserved.

angina were directly admitted to hospital. In a retrospective study of 179 patients with reliable 30-day follow-up in chest pain centers, there was one cardiac complication due to cocaine use.

Coronary artery disease

By one estimate, since the first report in 1982, over 250 cases of myocardial infarction due to cocaine have been reported, mostly in the USA. The first report from the UK was published in 1999 (43).

In a review of 114 cases, coronary anatomy, defined either by angiography or autopsy, was normal in 38% of chronic cocaine users who had had a myocardial infarction (20). The authors of another review concluded that "the vast majority of patients dying with cocaine toxicity, either have no pathological changes in the heart, or only minimal changes" (21). There can be a delay between the use of cocaine and the development of chest pain (44). The results of a study of 101 consecutive patients admitted with acute chest pain related to cocaine suggested that it commonly causes chest pain that may not be secondary to myocardial ischemia (45). The use of intranasal cocaine for therapeutic purposes (to treat epistaxis) was associated with myocardial infarction in a 57-year-old man with hypertension and stable angina (46).

In a review of the literature, 91 patients with cocaine-induced myocardial infarction were identified (47). Myocardial infarction occurred in 44 patients after intranasal use, in 27 after smoking, and in 19 after intravenous use. Almost half had a prior episode of chest pain. Two-thirds had their myocardial infarction within 3 hours of use. There were acute complications related to the myocardial infarction in 18 patients. Of 24 patients followed up, 58% had subsequent cardiac complications. Two-phase myocardial imaging with ^{99m}Tc-sestamibi can be helpful in the definitive diagnosis of cocaine-induced myocardial infarction in patients with a history of cocaine use, chest pain, and a non-diagnostic electrocardiogram (48). Damage to the myocardium associated with cocaine can be unrecognized by the abuser (49). Major electrocardiographic findings (including myocardial infarction, myocardial ischemia, and bundle branch block) were recorded during a review of 99 electrocardiograms of known cocaine abusers. None of the 11 patients with major electrocardiographic changes had a past history of cardiac disease or had complained of chest pain. The mechanism by which cocaine causes acute myocardial damage is unclear. Of 20 healthy cocaine abusers given intravenous cocaine, in doses commonly self-administered, or placebo, none developed myocardial ischemia or ventricular dysfunction on two-dimensional echocardiography during the test (50).

Myocardial infarction has been documented in 6% of patients who present to emergency departments with cocaine-associated chest pain (51,52). Treatment of cocaine-associated myocardial infarction has previously generally been conservative, using benzodiazepines, aspirin, glyceryl trinitrate, calcium channel blockers, and thrombolytic drugs. In the context of 10 patients with cocaine-associated myocardial infarction, who were treated with percutaneous interventions, including angioplasty, stenting, and AngioJet mechanical extraction of thrombus, the authors suggested that percutaneous intervention can be performed in such patients safely and with a high degree of procedural success (53). Patients with cocaine-associated chest pain and electrocardiographic ST-segment elevation should first undergo coronary angiography, if available, followed by percutaneous intervention. Alternatively, thrombolytic drugs can be used. However, the relative safety and efficacy of thrombolytic drugs compared with percutaneous intervention is undefined in patients with cocaine-associated myocardial infarction.

Other vascular disease

Dissection of the aorta has been reported during cocaine use (54,55). The authors of these two reports noted that all six cases of this rare complication reported in the past 5 years were in men with pre-existing essential hypertension. In a review of emergency visits to a hospital during a 20-year period, 14 of 38 cases of acute aortic dissection involved cocaine use; 6 were of type A and 8 of type B (56). Crack cocaine had been smoked in 13 cases and powder cocaine had been snorted in one case. The mean time of onset of chest pain was 12 hours after cocaine use. The chronicity of cocaine use was not known in most of the cases. The cocaine users were typically younger than the non-cocaine users. Chronic untreated hypertension and cigarette smoking were often present.

- A 43-year-old man with untreated hypertension developed transient mild chest pressure followed by shortness of breath for 4 hours (57). He had long used tobacco, alcohol, and cocaine and admitted to having used cocaine within the last 12 hours. He had a tachycardia with a pansystolic murmur suggesting mitral regurgitation. Urine drug screen was positive for cocaine metabolites. A chest X-ray showed mild cardiomegaly and prominent upper lobe vasculature. An electrocardiogram showed atrial flutter at a rate of 130/minute and non-specific T wave changes. The diagnoses were myocardial infarction due to cocaine, with mild congestive heart failure, mitral regurgitation and atrial flutter. However, transesophageal echocardiography showed severe aortic insufficiency and a dissection flap in the ascending aorta. He underwent emergency repair of the aortic root and resuspension of the aortic valve.

Intramural hematoma of the ascending aorta has been reported in a cocaine user (58).

- A healthy 39-year-old man developed retrosternal chest pain radiating to the back with nausea and sweating. About 10–15 minutes before, he had inhaled cocaine for 2 hours and then smoked crack cocaine. He had an aortic dissection, which was repaired surgically.

The authors identified hypertension secondary to the use of cocaine as the risk factor for this complication.

Coronary artery dissection associated with cocaine is rare. The first case was reported in 1994 (59) and two other cases have been reported (60,61).

© 2006 Elsevier B.V. All rights reserved.

- A healthy 33-year-old man with prior cocaine use had a small myocardial infarction and, 36 hours later, having inhaled cocaine, developed a dissection of the left main coronary artery, extending distally to the left anterior descending and circumflex arteries. There was marked anterolateral and apical hypokinesis.
- A 23-year-old man with a history of intravenous drug abuse and hepatitis C was found unconscious, hypoxic, and hypotensive. A urine drug screen was positive for cocaine metabolites, benzodiazepines, and opiates. An electrocardiogram suggested a myocardial infarction, verified by raised troponin I and the MB fraction of creatine kinase. He had severe hypokinesia with a left ventricular ejection fraction of 10%, falling to less than 5%. He became septic, developed multiorgan system failure, and died. The postmortem findings included dissection of the left anterior descending artery with complete occlusion of the true lumen and thrombosis of the false lumen. The left ventricle showed extensive transmural myocardial necrosis with adjacent contraction band necrosis. He also had deep vein thromboses in veins in the neck and abdomen and multiple pulmonary infarctions.

Peripheral vascular disease in the fingers has been attributed to cocaine.

- A 48-year-old man who smoked cigarettes and used cocaine developed ischemia of the right index finger due to occlusion of the distal ulnar artery (62). He had a history of recurrent deep vein thrombosis. A venous bypass graft was performed. Two years later he had non-healing gangrene of the left index finger. His blood pressure was normal in both arms. Urine toxicology was positive for cocaine. Angiography of the left arm showed small-vessel vasculitis.
- A healthy 36-year-old man, who had used intranasal crack cocaine daily in increasing doses for 2 weeks, developed pain, numbness, swelling, and cyanosis of the fingers and toes aggravated by cold and an ulcer on one finger (63). Ultrasound Doppler of the hand confirmed ischemic finger necrosis. He was treated unsuccessfully with aspirin, diltiazem, and heparin, but responded to intravenous infusions of iloprost for 5 days.

Another less common complication of cocaine use is cerebral vasculitis (64), and benign cocaine-induced cerebral angiopathy has been reported (65). (Stroke is discussed under the section Nervous system in this monograph).

Cardiac dysrhythmias

Dysrhythmias seem to be the most likely cause of sudden death from cocaine, but cardiac conduction disorders are more common in patients with acute cocaine toxicity. Severe cocaine toxicity also causes acidemia and cardiac dysfunction (66). Four patients developed seizures, psychomotor agitation, and cardiopulmonary arrest; two of these are briefly summarized here.

- A 43-year-old man injected a large dose of cocaine in a suicide attempt and had a seizure and cardiopulmonary arrest, from which he was resuscitated. His arterial blood pH was 6.72 and his electrocardiogram showed a wide complex tachycardia. An infusion of sodium bicarbonate maintained the blood pH at 7.50 and the electrocardiogram became normal. The bicarbonate infusion was discontinued after 12 hours.
- A 25-year-old man had a cardiac arrest after taking one "knot" or sealed bag of crack cocaine (2.5 g) and was resuscitated. His arterial blood pH was 6.92 and an electrocardiogram showed sinus rhythm, QRS axis 300°, and terminal 40 msec of the QRS axis 285°. After an infusion of sodium bicarbonate, his blood pH was 7.30, his QRS axis 15°, and the terminal 40 msec QRS axis 30°. He passed the bag of cocaine rectally within 12 hours of admission.

These patients' initial laboratory values showed acidosis, prolongation of the QRS complex and QT_c interval, and right axis deviation. Appropriate treatment included hyperventilation, sedation, active cooling, and sodium bicarbonate, which led to correction of the blood pH and of the cardiac conduction disorders. The authors suggested that when intracellular pH is lowered, myocardial contractility is depressed as a result of reduced calcium availability. During acidosis, there are abnormalities of repolarization and depolarization, which potentiate dysrhythmias.

The electrocardiographic PR interval increased with increasing abstinence from crack cocaine in a study of 441 chronic cocaine users who had smoked at least 10 g of cocaine in the 3 months before enrollment (67). The authors suggested that this may have reflected the normalization of a depolarization defect. Chronic cocaine users have shortened PR intervals, indicative of rapid cardiac depolarization.

Cardiovascular effects of cocaine as a local anesthetic

Cardiovascular effects due to enhanced sympathetic activity include tachycardia, increased cardiac output, vasoconstriction, and increased arterial pressure. Myocardial infarction is the most common adverse cardiac effect (39), and there is an increased risk of myocardial depression when amide-type local anesthetics, such as bupivacaine, levobupivacaine, lidocaine, or ropivacaine are administered with antidysrhythmic drugs.

- A woman who inappropriately used cocaine on the nasal mucosa to treat epistaxis had a myocardial infarction (49).
- A patient who was treated with intranasal cocaine and phenylephrine during a general anesthetic had a myocardial infarction and a cardiac arrest due to ventricular fibrillation (SEDA-20, 128).
- Myocardial ischemia was reported in a fit 29-year-old patient after the nasal application of cocaine for surgery. No relief was gained from vasodilators or intracoronary verapamil, and there were no other signs of cocaine toxicity. Although coronary vasoconstriction and platelet activation are systemic effects of cocaine, pre-existing thrombus may also have played a part (SEDA-22, 142).

Previous cocaine abuse has also been implicated in increasing the risk of myocardial ischemia when other local anesthetics are used.

© 2006 Elsevier B.V. All rights reserved.

Cardiac dysrhythmias have also been described in patients after the use of topical cocaine for nasal surgery (SEDA-20, 128).

- A patient who was treated with intranasal cocaine and submucosal lidocaine during general anesthesia developed ventricular fibrillation (SEDA-17, 142).

These events do not appear to have been related to the concomitant use of a vasoconstrictor, but more to excessive doses of cocaine.

Substantial systemic absorption of cocaine can cause severe cardiovascular complications (68).

- An 18-year-old man had both nasal cavities prepared with a pack soaked in 3–5 ml of Brompton solution (3% cocaine, about 3 mg/kg, plus adrenaline 1:4000) 2 hours preoperatively. In the anesthetic room he was anxious and withdrawn, with a mild tachycardia. Ten minutes later the nasal pack was removed and polypectomy was begun, with immediate sinus tachycardia and marked ST depression on lead II of the electrocardiogram. Increasing the depth of anesthesia and giving fentanyl had little effect, and the procedure was terminated. After extubation a further electrocardiogram showed T wave flattening in leads II, III, aVF, and aVL. Further cardiac investigations ruled out a myocardial infarction, an anatomical defect, or other pathological or metabolic processes. On day 4 a stress electrocardiogram showed no ischemic changes.

Absorption of cocaine from the nasal mucosa in eight patients using cotton pledglets soaked in 4 ml of 4% cocaine and applied for 10 or 20 minutes resulted in an absorption rate four times higher than expected, but was not associated with any cardiovascular disturbance; however, one of four patients who received 4 ml of 10% cocaine for 20 minutes developed intraoperative hypertension and another transient ventricular tachycardia (69). The authors advised against topical use of 10% cocaine.

Respiratory

The respiratory effects of cocaine are well known (70). In healthy crack cocaine users, there is evidence of cocaine-related injury to the pulmonary microcirculation, from fiberoptic bronchoscopy and examination of the bronchoalveolar fluid in 10 cocaine-only smokers, six cocaine-plus-tobacco smokers, 10 tobacco smokers, and 10 non-smokers, all with normal respiratory function (71). The percentages of hemosiderin-positive alveolar macrophages (a marker of recent alveolar hemorrhage) were markedly increased in the cocaine smokers compared with the others. Furthermore, the concentrations of endothelin (ET-1), an indicator of cell damage, were significantly raised in the cocaine smokers and to a lesser extent in the cocaine-and-tobacco smokers. These findings suggest that many asymptomatic healthy crack users have chronic alveolar hemorrhage that is not clinically evident.

In 177 heavy cocaine users (compared with 75 non-cocaine users), some of whom were also tobacco or marijuana users, cocaine use was associated with a higher prevalence of acute respiratory symptoms, including black sputum and chest pain. However, chronic respiratory symptoms occurred at similar frequencies in both groups. In cocaine-only smokers, mild impairment in carbon monoxide diffusing capacity suggested pulmonary capillary membrane damage, and abnormal airway conductance suggested injury to the upper airway or the large intrathoracic bronchi. Reported pulmonary complications of crack cocaine range from acute symptoms (coughing, chest pain, and palpitation) to acute syndromes (end-stage lung disease, eosinophilic infiltrates of the lung, and pulmonary infarction). The single-breath carbon monoxide diffusing capacity after the use of crack cocaine was reduced in three of six reports (70). If confirmed, a reduced carbon monoxide diffusing capacity after crack may signify damage to the alveolar capillary membrane or the pulmonary vasculature. It has been suggested that a well-designed controlled study to investigate the true impact of crack on the lung is necessary, since several confounding factors may account for the discrepancy in results (72).

Reports of acute pulmonary syndromes after the inhalation of cocaine have long been familiar.

- A 32-year-old woman rapidly developed progressive deterioration of respiratory function leading to end-stage lung disease (73). An open lung biopsy showed an inflammatory process with extensive accumulation of free silica.

The authors cautioned that some cocaine may contain silica, which could lead to severe pulmonary complications after smoking.

- A 27-year-old man twice developed inflammatory lung disease (with a predominance of eosinophils) after inhaling crack cocaine (74). Glucocorticoid treatment led to prompt resolution on both occasions.
- A 23-year-old woman developed pulmonary infarction associated with the use of crack (75).

Passive inhalation of free-base cocaine in small children can lead to serious consequences.

- A previously healthy 3-week-old boy developed pulmonary edema and autonomic manifestations of cocaine exposure from passive use (76). The urinary drug screen was positive for benzoylecgonine, a cocaine metabolite.
- Fatal pulmonary edema developed in a 36-year-old man shortly after he injected free-base cocaine intravenously (43).

A case of severe bullous emphysema in a cocaine smoker has been described (77).

- A 40-year-old man with cough, shortness of breath, and fever progressed to respiratory failure. He had smoked cocaine for the previous 17 years. His tobacco history was not known. His medical history included recurrent respiratory tract infections. A chest X-ray and CT scan showed findings consistent with bilateral bullous emphysema with a right lung abscess. He was ventilated and given antibiotics but died from respiratory failure secondary to pneumonia. Sputum cultures were positive for *Enterobacter cloacae* and *Streptococcus* species. Alpha-1 antitrypsin deficiency was ruled out.

© 2006 Elsevier B.V. All rights reserved.

Spontaneous pneumomediastinum has been reported (78).

- A 20-year-old obese Hispanic man awoke with severe, continuous retrosternal chest pain radiating to the neck and back (79). The pain was aggravated by deep breathing and local chest pressure. He denied substance abuse and gave a history of a flu-like illness 2 months before. His respiratory rate was 19/minute. He had a two-component pericardial rub. Laboratory blood testing ruled out myocardial infarction. His arterial blood gases and pH, electrocardiogram, chest X-ray, and echocardiogram were unremarkable. A later chest X-ray showed air in the mediastinum and chest CT confirmed the diagnosis of pneumomediastinum. Urine toxicology was positive for cocaine and cannabinoids. On further questioning, he admitted to substance use and performing a Valsalva maneuver during inhalation.

Handling cocaine pipes can cause thermal injury to the fingertips. The presence of bilateral thumb burns raised suspicion of crack lung in a young woman with suspected community-acquired pneumonia (80). When confronted with urine toxicology positive for cocaine, she admitted to having smoked large quantities of free-base cocaine only a few hours before the onset of symptoms.

Pneumothorax and pneumomediastinum

Two cases of spontaneous pneumothorax in intranasal cocaine users have been reported from Italy (81).

- A 30-year-old man, a cocaine sniffer, who had used cocaine more than five times a month for 4 years, complained of shortness of breath and acute chest pain. He had episodic cough and bloody sputum. A chest X-ray showed an 80% pneumothorax on the left side. On thoracoscopy the entire lung visceral pleura seemed to be covered by fibrinous exudate. After yttrium aluminium garnet (YAG) laser pleurodesis surgery, which abrades the pleura, he made a full recovery within 4 days.
- A 24-year-old man who had been inhaling cocaine nasally 4–5 times a month for a year developed respiratory distress and chest pain 2 days after the last use, because of a right-sided pneumothorax. He underwent video-assisted thoracoscopic surgery with laser pleurodesis and responded rapidly.

In both cases, pneumothorax occurred with a delay after cocaine inhalation. The authors suggested that it was therefore unlikely that these cases of pneumothorax were due to direct traumatic effects of the drug powder inhaled, to barotrauma due to exaggerated inspiration, or to a Valsalva maneuver. Histological examination in both cases showed small foreign body granulomas with polarized material in the subpleural parenchyma. The authors proposed that the pleural damage could have been directly caused by a filler substance known as mannite (a fine white powder comprised of insoluble cellulose fibers).

Spontaneous pneumomediastinum has been reported with the inhalation of free-base cocaine (78).

Asthma

Cocaine can cause exacerbation of asthma. All adult visits to an urban emergency room for an asthma attack during a 7-month period were reviewed (82). Of 163 patients (aged 18–55 years), 116 agreed to participate in a facilitated questionnaire and 103 provided urine samples for drug screening. African-Americans made up 89% of the group and 35% were cigarette smokers. Urine toxicology was positive for cocaine in 13% and for opiates in 5.8%. The severity of the exacerbation of asthma was greatest in the cocaine-positive group, 38% of whom were admitted to hospital (compared with 20% of the non-cocaine users). The length of stay was significantly longer in the cocaine-positive patients. Most of the patients did not use inhaled corticosteroids according to the treatment guidelines.

Ear, nose, throat

Intranasal use, a common method of cocaine abuse, can damage the sinonasal tract, causing acute and chronic inflammation, necrosis, and osteocartilaginous erosion (SEDA-17, 36). These conditions occur secondary to the combined effects of direct trauma from instrumentation, vasoconstriction of small blood vessels with resultant ischemic necrosis, and chemical irritation from adulterants. Intranasal cocaine users can develop septal perforation, saddle-nose deformities, and sinonasal structural damage.

- A 43-year-old woman with a past history of chronic heavy cocaine use and osteomyelitis of the hard palate and nasal cavity 10 years before had required continuous follow-up for recurrent ethmoid and sphenoid sinusitis (83). Endoscopy showed an absent nasal septum, middle turbinates, anterior two-thirds of the inferior turbinates, and lateral nasal wall.
- Pott's puffy tumor, a subperiosteal infection of the frontal bone, has been described in a 34-year-old man with a history of chronic intranasal cocaine use (84).

This rare complication of frontal sinusitis appeared to develop secondary to the insertion of foreign bodies into the nose to facilitate inhalation of cocaine. Local trauma plus cocaine-induced vasoconstriction may have led to the complication.

Midline nasal and hard palate destruction have been reported in two chronic users of intranasal cocaine (85). The pathophysiology of these lesions is multifactorial, including ischemia secondary to vasoconstriction, chemical irritation from adulterants, impaired mucociliary transport, reduced immunity, and infection secondary to trauma.

In another case there was progression of septal perforation to secondary bone infection in a chronic cocaine user (86).

- A 56-year-old chronic intranasal cocaine abuser with a visible nasal defect presented with a hole in the roof of his mouth. He had been reportedly drug free for 2 weeks. He had an oronasal fistula with adjacent black necrotic areas and erosive destruction of the nasal septum, turbinates, and antrum, with mucoperiosteal thickening of the sphenoid and maxillary sinuses. Treatment included antibiotics and a prosthesis plate construction

© 2006 Elsevier B.V. All rights reserved.

to cover the defect. Two years later, having continued to inhale cocaine, he had progressive destruction of his sinonasal tract, a fistula between his oral and nasal cavity, a saddle-nose deformity with total cartilage loss, and a complete palatal defect. Biopsy of the nasal septum showed acute osteomyelitis and extensive bacterial overgrowth (including anerobic *Actinomyces*-like organisms). He was given intravenous antibiotics for 6 weeks followed by long-term oral antibiotics.

Cocaine-related erosion of the external nasal structures has been described (87).

- A 43-year-old woman with a T12 paraplegia due to a car accident 24 years earlier and a sublabial abscess 2 years before developed progressive erosion of both the internal and external portions of her nose over 6 months, with nasal crusting and nose bleeds. Several antibiotics were unhelpful. There was partial destruction of the external nasal structure and two oronasal fistulae in the upper gingival sulcus. Intranasal biopsy showed acute and chronic inflammation. On two occasions urine drug screening was positive for cocaine, although she denied using cocaine.

Nervous system

Research in 21 cocaine users and 13 non-drug-using, age-matched controls has suggested that chronic cocaine use may be associated with specific neurochemical changes in the brains of habitual users (88). All the subjects underwent a spectral brain scan in a proton MRS scanner. The significant finding was that the concentration of *N*-acetylaspartate in the left thalamus (but not in the basal ganglia) was significantly lower (17%) in the chronic cocaine users than in the controls. *N*-acetylaspartate is found in adult neurons and not in glia; it is often used as a marker of neuronal viability; a reduction suggests neuronal damage and/or loss.

Assessment of smooth pursuit eye movements has been used in the study of neurophysiological effects of a variety of clinical and subclinical disorders. In 126 patients who met DSM-IIIR criteria for dependence on alcohol, cocaine, or heroin, or dual alcohol and cocaine abuse, there was a significant reduction in tracking accuracy in the heroin-dependent and the dually-dependent subjects relative to controls (89). However, eye movement dysfunction in the drug-dependent groups was not detectable when the effects of antisocial personality disorder were statistically removed. The magnitude of the dysfunction correlated significantly with several antisocial personality-related features, including an increased number of criminal charges, months of incarceration, increased problems associated with drug abuse, and lower intellectual functioning. The findings suggested that there may be an association between premorbid personality traits and eye movement impairment.

Cocaine use has been associated with a reduced inhibitory response of the P50 auditory evoked response, attributed to increased catecholaminergic and reduced cholinergic neurotransmission secondary to cocaine (90). In a double-blind, placebo-controlled study, 11 cocaine users in the first and third weeks of detoxification had electrophysiological testing 10 minutes before and 30 minutes after taking nicotine gum 6 mg. Nicotine briefly reversed the inhibitory deficit.

Chronic substance use has been associated with long-lasting changes in brain function (91). Five brain regions that may be affected (the orbitofrontal gyrus, rectal gyrus, anterior cingulate gyrus, basal ganglia, and thalamus) were selected for analyses of cerebral glucose metabolism by positron emission scanning in controls, cocaine users, and alcoholics (17 in each group), who performed the Stroop test, which assesses cognitive interference and response inhibition. In controls, higher brain glucose metabolism in the orbitofrontal gyrus correlated with poorer performance. In contrast, in substance users, higher brain glucose metabolism was associated with better performance. Chronic abuse appears to be associated with altered function of the orbitofrontal gyrus.

Cerebellar dysfunction

Cocaine has been associated with movement disorders, such as acute dystonias, choreoathetosis, and akathisia. Chronic pancerebellar dysfunction occurred in a cocaine user with schizophrenia treated with risperidone (92).

- A 38-year-old man was found comatose in a crack house. The ambient temperature was 13°C. He had earlier abused cocaine. His temperature was 43°C, heart rate 115, blood pressure 144/89 mmHg, and oxygen saturation 97% on air. His general muscle tone was flaccid. He had a mild leukocytosis and hypophosphatemia. Urine toxicology was positive for benzoylecgonine, a cocaine metabolite. He was mechanically ventilated, cooled, and given intravenous fluids. His temperature fell to 38°C, but he later developed acute disseminated intravascular coagulation and rhabdomyolysis. After 5 days he developed nystagmus, intention tremor, truncal ataxia, dysarthria, ocular dysmetria, and dysmetria of the arms and legs. There were no sensory or motor deficits. Finger-to-nose and heel-to-knee tests were slowed and uncoordinated. He could not stand. Brain imaging studies (CT and MRI scans) were unremarkable. He was given thiamine, propranolol, clonazepam, primidone, and baclofen every 8 hours without improvement. After 1 year he still had nystagmus, intention tremor, ataxic gait, and dysmetria. He could walk short distances slowly.

Cocaine and neuroleptic drugs can both cause hyperthermia and the authors proposed that the combination of cocaine and risperidone may have caused this problem.

Migraine

About 60–75% of chronic cocaine abusers report severe headaches (93), which can resemble migraine; migraine-like symptoms can include auras, visual field changes, and paraphasia (94). About 60–75% of chronic cocaine abusers report severe headaches (93,94). Of 21 patients who were admitted to hospital from January 1985 to December 1988 for acute headache associated with cocaine intoxication 15 had headaches with migrainous features in the absence of neurological or systemic complications (93). None had a history of cocaine-unrelated headaches or a family history of migraine, and all had a

© 2006 Elsevier B.V. All rights reserved.

favourable outcome. The authors discussed three possible mechanisms of cocaine-related vascular headaches, depending on the interval between cocaine ingestion and development of the headache. They postulated that acute headaches after cocaine use may relate to the sympathomimetic or vasoconstrictive effects of cocaine, while headaches after cocaine withdrawal or exacerbated during a cocaine binge may relate to cocaine-induced effects on the serotoninergic system.

Movement disorders

The effects of cocaine or its withdrawal on neurotransmitter activity have been evaluated in several studies. Although changes in dopaminergic activity appear to be associated with early cocaine abstinence, extrapyramidal symptoms (due to alterations in dopamine functioning) have only infrequently been reported in cocaine users. However, in a recent report, extrapyramidal symptoms of classic muscle stiffness and cogwheel rigidity at the elbow occurred during the "crash" phase of a 40-year-old man's cocaine withdrawal (95).

Cocaine can cause other movement disorders (96). Motor and vocal tics, pre-existing tremors, and generalized dystonia were induced or exacerbated by drug use, and continued even after cocaine use ended. Lastly, dopamine dysregulation (that is reduced dopamine receptor availability in association with reduced frontal metabolism) was demonstrated by positive emission tomography in 20 chronic cocaine abusers (97). The findings were prominent in the orbitofrontal, cingulate, and prefrontal cortex 3–4 months after detoxification. The author hypothesized that dysregulation of these brain areas may result in compulsive drug-taking behavior.

Dystonia has been described shortly after the use of cocaine (SEDA-16, 24). In a retrospective study of 116 patients taking neuroleptic drugs, 42% of cocaine users versus 14% of non-users developed dystonia (98). This suggests that the use of cocaine may be a major risk factor for acute dystonic reactions secondary to the use of neuroleptic drugs.

Cocaine-induced chronic tics have been reported (99), and cocaine has reportedly exacerbated Gilles de la Tourette syndrome (100).

Myasthenia gravis

A 24-year-old woman developed myasthenia gravis during cocaine use (101). The authors speculated that while cocaine did not cause impairment of motor axons for neuromuscular transmission, a reduction in the number of acetylcholine receptors per neuromuscular junction (as occurs in myasthenia gravis) could have increased the susceptibility to an effect of cocaine.

A rare case of polysubstance abuse, which unmasked myasthenia and caused complete external ophthalmoplegia, has been reported (102).

- A 29-year-old woman, who used cocaine 2 g/day, heroin 1 g/day, and methadone 40 mg/day, developed abscesses caused by drug injection. She had had generalized weakness, difficulty in swallowing, and lagging eyelids for 1 week. There was bilateral ptosis, and a diagnosis of myasthenia was made. Edrophonium 10 mg relieved the ptosis and improved ocular movements.

Seizures

Cocaine lowers the seizure threshold and may therefore be dangerous to patients already at risk of seizures (40). Exacerbation of generalized tonic-clonic seizures (which occurred initially during the use of crack but later continued independently of the drug) has been described, with progressive electroencephalographic abnormalities (103). In this case, the development of the seizures suggested that cocaine can stimulate kindling, with progressive intensification of after-discharges and the eventual emergence of seizure activity.

Cerebrovascular vasoconstriction and a sudden increase in blood pressure probably underlie the many reports of cocaine-induced strokes, CNS hemorrhage, and migraine (SEDA-17, 1).

Three cases of generalized seizures occurring shortly after the intravenous use of cocaine (104).

Sleep disturbance

The disruption of normal sleeping patterns during cocaine withdrawal may be related to effects on the cholinergic system. In a study of nine patients undergoing cocaine withdrawal, rapid eye movement (REM) latency was markedly shortened, REM sleep percentage was increased, REM density was very high, and the total sleep period was long during the first week (105). Changes in REM sleep are thought to be related to changes in cholinergic activity. At week 3, characteristic chronic insomnia was observed.

Stroke

Cocaine has been associated with cerebrovascular events, such as transient ischemic attacks (SEDA-24, 24), cerebral hemorrhage (106,107), and cerebral infarction (SEDA-22, 23) (SEDA-20, 26) (SEDA-20, 21).

Regional cerebral blood flow was assessed using single photon emission computed tomography (SPECT) and tracer HMPAO in 10 cocaine abusers within 72 hours of last cocaine use and then after 21 days of abstinence (108). Compared with controls, recent cocaine abusers had significantly reduced cerebral blood flow in 11 of 14 brain regions, with the largest reductions in the frontal cortex and parietal cortex and greater cerebral blood flow in the brain stem. These perfusion defects appeared to be primarily due to combined abuse of alcohol and cocaine. Frontal but not parietal defects appeared to resolve partially during 21 days of abstinence.

In a review of ischemic stroke in young American adults (aged 15–44 years) admitted to 46 regional hospitals between 1988 and 1991, illicit drug use was noted in 12% and was the probable cause of stroke in 4.7% (109). Multidrug use was common among users: 73% used cocaine, 29% used heroin, and 14% used phencyclidine. Drug-associated stroke in these young adults appeared to be related to vascular mechanisms (such as large and small vessel occlusive disease) rather than to hypertension or to diabetes. Cerebral infarction is significantly more common among users of cocaine alkaloid (crack) than cocaine hydrochloride (110).

© 2006 Elsevier B.V. All rights reserved.

Ischemic stroke has been attributed to combined use of cocaine and amphetamine (111).

- A previously healthy 16-year-old man developed an unsteady gait and double vision. His symptoms began 5 minutes after intranasal "amfetamine" (actually amfetamine cut with cocaine). He had a left-sided internuclear ophthalmoplegia, an incomplete fascicular paresis of the left oculomotor nerve, and saccadic vertical smooth pursuit. Cranial MRI showed a left-sided hyperintense lesion near the midline of the mesencephalon. A repeat MRI scan 9 days later showed that the lesion was much smaller. He made a full recovery within 3 weeks.

The cause of cocaine-related stroke and transient ischemic attacks has been studied by transcranial Doppler sonography, a continuous measure of cerebral blood flow velocity, to monitor the course of cerebral hemodynamic changes during acute intravenous injection of placebo, and of cocaine 10, 25, and 50 mg in seven cocaine abusers (112). There was a significant increase in mean and systolic velocity (lasting about 2 minutes) with all doses of cocaine but not with placebo. Cocaine produced an immediate brief period of vasoconstriction (as demonstrated by an increase in systolic velocity) in the large arteries of the brain.

"Spontaneous" acute subdural hematoma related to cocaine abuse has been described (113).

- A 38-year-old man with a 10-year history of cocaine use became comatose. He had had an acute severe headache and progressive deterioration after abusing cocaine. His Glasgow Coma Scale was 3 and his pupils were dilated but reactive to light. He had hypertension and bradycardia. Routine toxicology was positive for cocaine. Blood tests, including coagulation profile, were normal. A CT scan of the brain showed a left acute subdural hematoma with midline shift and obliteration of the basal cisterns. During emergency craniotomy the source of the bleed was identified as a pinhole rupture of a parietal cortical artery. The patient had no history of head injury and there were no intraoperative findings of head injury. He died 24 hours later without evidence of clot reaccumulation. An autopsy was not performed.

Hypertensive encephalopathy can follow the use of cocaine (114).

Brown–Séquard syndrome after esophageal sclerotherapy and recent crack cocaine abuse has been reported (115).

- A 44-year-old man with hepatitis C and cirrhosis, esophageal varices, and poorly controlled hypertension, who was also a chronic alcoholic and crack cocaine abuser, had his varices injected at endoscopy and developed right-sided weakness and numbness up to T4. There was flaccid right leg weakness, right T4-6 hypalgesia, left leg hypalgesia up to L1, and reduced sweating on the left up to T4-6. An MRI scan of the thoracic spine showed a lesion at T4-6 involving the anterior and central portions of the spinal cord. A urine screen was positive for cocaine. He recovered spontaneously 2 weeks later.

Cocaine-induced ischemia was the most likely cause of this adverse outcome.

Subarachnoid hemorrhage

There is an association between cocaine use and aneurysmal subarachnoid hemorrhage (SEDA-18, 36) (SEDA-21, 26) (116). Subarachnoid hemorrhage was temporally related to cocaine abuse in 12 young adult abusers who had underlying cerebral aneurysms; hypertension was a probable contributing factor (117) and cocaine is a risk factor for cerebral vasospasm after aneurysmal subarachnoid hemorrhage (118). In a retrospective analysis of the medical records of 440 patients who presented to a neurosurgery unit between 1992 and 1999 with aneurysmal subarachnoid hemorrhage, 27 patients (6.1%) had either a positive urine screen for cocaine metabolites ($n = 20$) or a history of cocaine use within 72 hours of subarachnoid hemorrhage ($n = 7$). Cocaine users were more likely to have cerebral vasospasm from 3 to 16 days after subarachnoid hemorrhage than non-exposed patients (63 versus 30%). They were also more likely to be younger and to have aneurysms of the anterior circulation than the control group (97 versus 84%).

Sensory systems

Ophthalmic effects associated with cocaine can occur during both active drug use and early abstinence. Cocaine abuse has been associated with ophthalmic complications, including ulceration of the cornea, vasoconstrictor effects on the retinal vasculature, irregularities in oculomotor performance, and secondary optic neuropathy.

Corneal ulceration secondary to smoking crack cocaine has been reported in a 27-year-old woman (119).

Cases of the "crack eye syndrome" continue to be reported. Of 14 crack cocaine users with corneal problems, 10 had corneal ulcers infected with both bacterial and fungal organisms; 4 had corneal epithelial defects (120). All were actively smoking crack daily. The authors suggested that crack smoking predisposes users, through an unknown mechanism, to corneal epithelial changes, infection, and perforation. Typical presentations include loss of vision with or without pain.

- A 29-year-old woman with a painful corneal ulcer related to cocaine abuse was found to be putting cocaine powder directly into the affected eye to reduce the pain (121). Her history included prior corneal perforations.

Such topical use of cocaine may aggravate the condition.

Acute iritis has been reported after intranasal use (122).

There has been a report of retinal changes in 60 users of crack (123). Microtalc retinopathy and retinal nerve fiber layer "rake" or "slit" defects were detected by threshold visual field testing and fundus photography.

Orbital infarction has been described after cocaine use (124).

- A 36-year-old woman drank alcohol and snorted cocaine and heroin at a party. She lost consciousness, with her head positioned down with her left face pressed against a desk. She awoke 3 hours later with severe left orbital pain. Her right eye was normal but there was complete visual loss in the left eye and a nearly complete left ptosis. The left pupil did not react to light but reacted consensually. Movements in the right eye were full, but movements in the left eye

© 2006 Elsevier B.V. All rights reserved.

were severely limited in all directions. In the left fundus there was retinal edema and retinal pigment epithelium disruption. An orbital MRI scan showed diffuse swelling of all the extraocular muscles in the left orbit. A week later the pain had abated and there was mild improvement in the eye movements and ptosis, but no change in vision. She was instructed to wear protective polycarbonate lenses at all times.

Central retinal artery occlusion has previously been reported in cases of intravenous and intranasal cocaine abuse and has also been reported in a man who smoked crack cocaine (125).

- A 42-year-old man smoked crack and developed sudden painless loss of vision in his right eye for 9 hours. He had smoked cigarettes for 20 years and crack cocaine twice a week for the previous 4 years. Visual acuity in the right eye was counting fingers at one meter, and in the left eye 6/4. There was a right relative afferent papillary defect. In the right fundus there was evidence of central retinal artery occlusion and the left fundus was unremarkable. Treatment included intravenous acetazolamide, intermittent ocular massage, and rebreathing into a paper bag. He was found to have sickle cell trait, a risk factor for central retinal artery occlusion.

Psychological, psychiatric

Single photon emission computerized tomography (SPECT) has suggested that some psychiatric symptoms in cocaine users are associated with changes in blood flow (126). Multiple scalloped areas of reduced cerebral blood flow (especially periventricular regions and deep portions of the brain) have been seen. Hypoperfusion has also been noted in the frontal lobes of cocaine users with mania.

Cognitive function

The effects of cocaine on cognitive functions have been measured in controlled studies. The preliminary results of a study of 20 heavy cocaine abusers and a group of matched controls showed impaired function on neuropsychological tests in 50% of the abusers compared with 15% of the controls (127). There were problems with concentration, memory, problem-solving, and abstract thinking in the cocaine users. The heavy users had the greatest loss of memory. Recent cocaine use was associated with poorer oral fluency and arithmetic scores.

The effect of cocaine on cognitive functioning has been studied in 20 crack users, 37 crack and alcohol users, and 29 controls at 6 weeks and 6 months of abstinence (128). The two substance-dependent groups had significant cognitive impairment in a range of neuropsychological tests compared with the controls at both times. Drug dose was strongly associated with the extent of impairment. Abstinent substance users were more depressed than controls during the test period, but depression had only a slight effect on neuropsychological performance.

Neuropsychological performance was examined in 355 incarcerated adult male felons, who were classified by DSM-IV criteria into four subgroups: alcohol dependence or abuse ($n = 101$), cocaine dependence or abuse ($n = 60$), multisubstance dependence or abuse ($n = 56$), and no history of drug abuse ($n = 138$) (129). The cocaine and control groups had similar neuropsychological test scores. However, both the multisubstance and alcohol groups performed significantly worse on nearly all measures. The multisubstance group had worse short-term memory, long-term memory, and visuomotor ability. Correlations between neuropsychological performance and length of abstinence from drug use showed that after abstinence the alcohol group had the greatest improvement on tests. Although the cocaine group had the least amount of improvement with abstinence, their overall performance was not significantly different from controls.

Even after 4 weeks of abstinence, chronic heavy cocaine users have poor cognitive functioning compared with non-drug-using controls (130). A battery of neuropsychological tests was administered to 30 abstinent chronic cocaine abusers and 21 non-drug-using matched controls. Decrements in areas such as executive functioning, visuoperception, psychomotor speed, and manual dexterity were associated with heavier use of cocaine. Neither frequency nor duration of cocaine use was a strong predictor of performance.

Neurolinguistic functioning has been assessed in six African-American male cocaine abusers undergoing drug rehabilitation (131). A test battery to assess language, cognition, and memory skills was administered at 1 week and 1 month of cocaine abstinence. Participants' performances were compared with the normative data for each test. There was reduced ability for general language knowledge, memory, and verbal learning ability during the period of early abstinence. However, the sample size was small and the duration of study short.

Mood disorders

The rate of co-morbidity has been studied in 208 female African-American crack cocaine users; 148 were in treatment, 54 were active crack users, and 61% reported a history of sexual abuse (132). Many had co-morbid depression (48%) and eating disorders (11%).

Delirium

Cocaine-induced delirium with severe acidosis has been reported (133).

- A 25-year-old man with agitation and paranoia who had consumed a lot of alcohol with cocaine the night before had a clonic seizure lasting 1 minute. In the emergency room, he responded to pain and made incomprehensible sounds. His pulse rate was 116/minute, blood pressure 100/40 mmHg, respiratory rate 28/minute, and temperature 38.3°C. He was acidotic (pH 6.53), with a $PaCO_2$ of 13.1 kPa, a base deficit of 36 mmol/l, a serum potassium concentration of 7 mmol/l, and sodium 153 mmol/l. He was hyperventilated and given sodium bicarbonate, dantrolene, and passive cooling. His acidosis quickly corrected and his temperature fell to 37.6°C within 1 hour.

Obsessive-compulsive disorder

Suspected risk factors for obsessive-compulsive disorder were investigated in a prospective epidemiological study,

© 2006 Elsevier B.V. All rights reserved.

using data from the Epidemiologic Catchment Area surveys (1980–1984) (134). Users of both cocaine and marijuana were at increased risk of obsessive-compulsive disorder compared with non-users of illicit drugs, but cocaine use alone was not associated with an increased risk, within the limited sample size.

Panic disorder

As with several other drugs, for example marijuana, PCP, and LSD, cocaine can precipitate panic disorder, which continues long after drug withdrawal (135). Among 280 patients in a methadone maintenance clinic, the prevalence of panic disorder increased from 1% to 6% over a decade (136). A marked rise in the frequency of cocaine abuse coincided with this outbreak. The authors suggested that episodes of panic occurring in cocaine users can result in hospitalization for either psychiatric or medical illnesses.

Paranoid psychoses

Of 55 individuals with cocaine dependence, 53% reported transient cocaine-induced psychotic symptoms (137). Paranoid delusions (related to drug use) and auditory hallucinations were often reported. In addition, almost one-third (all of whom also described psychotic symptoms) reported transient behavioral stereotypes.

Paranoid psychosis has also been described in a 64-year-old man who had first begun to use crack cocaine 6 months before. The paranoid symptoms continued for 3 weeks after he stopped using crack.

The author suggested that the man's age may have made him particularly sensitive to the psychiatric effects of cocaine (138).

The possible genetic basis of cocaine-induced paranoia has been studied in 45 European Americans with cocaine dependency (139). Low activity of the enzyme dopamine β-hydroxylase (the enzyme that catalyses the conversion of dopamine to noradrenaline) in the serum or cerebrospinal fluid was positively associated with the occurrence of positive psychotic symptoms in several psychiatric disorders. The activity of dopamine β-hydroxylase is a stable, genetically determined trait that is regulated by genes located at the DBH locus. The haplotype associated with low dopamine β-hydroxylase activity, Del-a, occurred more often in 29 subjects with cocaine-induced paranoia than in 16 without. These findings may have implications for the pharmacological treatment of cocaine dependence.

Endocrine

Blood sugar concentrations can become labile in people with diabetes mellitus who use cocaine, not only because their diet changes, but also because adrenaline concentrations affect the mobilization of glucose (36).

In a prospective study, endocrine responses to hyperthermic stress were assessed in 10 male cocaine users after 4 weeks of abstinence and again after 1 year of abstinence (140). They sat in a sauna for 30 minutes at a temperature of 90°F and a relative humidity of 10%. At the end of the sauna, they rested for another 30 minutes at room temperature. Sublingual temperature, pulse rate, and blood pressure were recorded just before and immediately after the sauna and 30 minutes after the period at room temperature. Venous β-erythropoietin, ACTH, metenkephalin, prolactin, and cortisol were also measured. There were no significant differences between the two groups in heart rate and blood pressure. At baseline and after 1 year of abstinence, plasma prolactin concentrations were higher in the cocaine users than in the controls. Moreover, the hormonal responses in the cocaine users were different from those in controls. Concentrations of all the hormones, except for metenkephalin, were significantly lower in the cocaine users than in the controls at the end of the sauna; the cocaine users did not have significant hormonal changes to hyperthermia after either 4 weeks or 1 year of abstinence. The authors concluded that cocaine abuse produces alterations in the hypothalamic-pituitary axis, which persist during abstinence.

Electrolyte balance

Cocaine-induced periodic paralysis with hypokalemia has been reported (141).

- A healthy 33-year-old man suddenly developed generalized weakness and became unable to walk or lift his limbs; he also had mild chest pain. He had had similar episodes 10 days and 5 years before, with spontaneous resolution. He had no spontaneous motor activity and his strength was 2/5 in all major muscle groups with a very mild left upper limb predominance. Cardiac enzymes and neuroimaging of the brain and spinal cord were normal. Creatinine kinase was raised (395 IU/l). Acetylcholine receptor antibodies were in the reference range. His serum potassium concentration was 1.9 mmol/l. Urine toxicology screen showed cocaine, cannabinoids, and benzodiazepines and he admitted to cocaine binge use the previous night and also before the previous two episodes. With potassium supplements his strength gradually improved.

Such severe generalized weakness and hypokalemia may be due to intracellular shift of potassium due to adrenergic stimulation by cocaine or a direct effect on potassium channels.

Hematologic

In an attempt to replicate the conclusions of an earlier study, there was no association between cocaine use during pregnancy and acute thrombocytopenia in 326 patients (142). There were similar prevalences of thrombocytopenia in cocaine-using women (13/160) and non-using women (11/160) during pregnancy. Thrombocytopenia occurred more often in the third trimester in both groups.

Gastrointestinal

Gastrointestinal symptoms, especially diarrhea, occur after cocaine use. Cases of more severe abdominal distress have required surgical intervention and have been due to bowel infarction (1,143) or pneumoperitoneum (144).

Esophageal damage

The esophagus can undergo thermal injury, in which the inner esophageal wall has a "candy-cane" appearance

© 2006 Elsevier B.V. All rights reserved.

(alternating pink and white linear bands), when boiling-hot liquids are consumed. This reversible condition is associated with chest pain, difficulty in swallowing, odynophagia, and abdominal pain. Candy-cane esophagus secondary to smoking crack cocaine has been reported (145).

- A 55-year-old man accidentally sucked into his mouth and swallowed a portion of boiling water during his last smoke of free base cocaine and 2 days later developed sudden constant pain in the left shoulder and arm accompanied by sweating. He had melena, a hematocrit of 30%, a blood urea nitrogen of 35 mmol/l, and a serum creatinine of 1.1 mmol/l. The initial electrocardiogram showed sinus rhythm, left atrial enlargement, and borderline left ventricular hypertrophy. However, 2 hours later he started to sweat and became hypotensive (blood pressure 85/50 mmHg). An electrocardiogram showed new biphasic T waves and T wave inversion. Urgent cardiac catheterization showed patent coronary arteries. Esophagogastroduodenoscopy within the hour showed a candy-cane appearance in the distal esophagus, patchy erythema and erosions in the gastric antrum, and an ulcer in the base of the duodenal bulb. Biopsies of the esophagus tissue showed parakeratosis, squamous hyperplasia with regeneration, and minimal inflammation. Biopsies of the stomach showed chronic gastritis and bacteria consistent with *Helicobacter pylori*. Later that day, the electrocardiogram normalized.

The most likely cause of the chest pain was microvascular spasm of the epicardial coronary arteries, due to either thermal injury to the esophagus or a direct effect of cocaine.

Peptic ulceration

There is a higher incidence of gastric ulcers in cocaine users, both perforated ulcers and giant gastroduodenal ulcers, thought to be due to localized ischemia secondary to vasoconstriction (146,147). Two reports have afforded data on gastrointestinal ulcers and cocaine. In one study the authors observed that since the advent of crack cocaine they had seen more than 70 cases of crack-related perforated ulcers (146). They suggested that an ischemic process rather than an acid-producing mechanism was to blame. They described three patients, all of whom had laparoscopic omental patches for ulcers, with good results. In a longitudinal assessment of patients with endoscopically diagnosed gastric ulcers ($n = 98$) or duodenal ulcers ($n = 116$) users of cocaine or metamfetamine were nearly 10 times more likely to have giant gastric or duodenal ulcers (over 2.5 cm) compared with non-users (147). The authors speculated that cocaine and amfetamine-induced catecholamine stimulation of α-adrenoceptors may cause intense vasoconstriction and thus a reduced blood supply to an ulcer, resulting in a giant ulcer.

Five cases of gastric perforation (rather than the more common duodenal perforation) have been reported in young male smokers of crack, all of whom had only brief histories of prodromal symptoms and none of whom had long-standing peptic ulcer disease (148).

Intestinal ischemia

Two women developed chronic mesenteric ischemia, successfully managed by revascularization (149). The authors concluded that in both cases chronic mesenteric ischemia had been caused by intravenous cocaine abuse.

Ischemia of the small bowel and colon after the use of cocaine has been reported (SEDA-22, 33).

- A 38-year-old man presented with a 2-day history of severe abdominal pain and bloody stools after smoking cocaine 48 hours earlier (150). He had abdominal pain, guarding, rebound tenderness, and high-pitched, hypoactive bowel sounds. His white blood cell count was 31×10^9/l. Radiography showed thumb-printing in the transverse colon. Endoscopy showed friable edematous mucosa with submucosal hemorrhage and patches of yellowish fibrinous material. He recovered fully with intravenous nutrition and supportive measures after 30 days.
- A 36-year-old man who had injected cocaine the day before admission and who occasionally sniffed, smoked, or injected cocaine, presented with a 3-day history of severe abdominal pain and bloody diarrhea (151). His mid-abdomen was very tender, with rebound tenderness and guarding; bowel sounds were absent. Radiography showed a dilated transverse colon and dilated small bowel loops. He underwent emergency surgery and an edematous dilated transverse colon was removed. The pathology was consistent with ischemic colitis. The blood vessels were dilated but showed no structural abnormalities or thrombosis.

Liver

Cocaine has been associated with liver toxicity (SEDA-14, 32) (SEDA-13, 27).

- A 23-year-old man became unresponsive and had a seizure after taking cocaine and alcohol (152). Severe liver necrosis developed and hepatocellular damage was documented with ^{99m}Tc-PYP imaging.

Acute hepatitis induced by intranasal cocaine, with transient increases in liver enzymes, has been reported in three HIV-positive patients (153). All had non-active chronic viral hepatitis with normal immunological status; one was seropositive for hepatitis B virus and two were positive for hepatitis C virus. A few days after intranasal cocaine use, serum transaminases rose to high values, and two of the patients had fever, stiffness, sweats, and hepatomegaly. Alcohol and hepatotoxic agents were ruled out. Within a few days, the clinical and laboratory signs of hepatitis improved in all three cases.

Urinary tract

Cocaine can cause acute renal insufficiency (SEDA-21,19) (SEDA-24, 38). Acute renal insufficiency, with malignant hypertension, apparently precipitated by cocaine-induced vasoconstriction, has been described in a 33-year-old woman who had pre-existing scleroderma and normal renal function (154). She was successfully treated with hemodialysis.

Cocaine can also cause chronic renal insufficiency (155). Of hemodialysis patients from an urban center in California, 55 who reported a history of significant

© 2006 Elsevier B.V. All rights reserved.

cocaine use were compared with 138 non-users. A diagnosis of hypertension-related end-stage renal disease was reported in 49 of the 55 cocaine users (89%) and 64 of the 138 non-users (46%). Of 113 patients with end-stage renal disease, 49 had a history of cocaine use. The patients who had used cocaine had hypertension for a shorter duration (5.3 versus 12.7 years). They were also younger (41 versus 54 years). The authors proposed that this outcome had been caused by several mechanisms: renal vasoconstriction or stenosis, resulting in ischemic nephropathy and secondary hypertension, direct renal damage with progressive renal insufficiency, and recurrent episodes of accelerated hypertension, vasculitis, acute tubular necrosis, and rhabdomyolysis.

Chronic cocaine use can exacerbate pre-existing hypertension, when renal blood vessels narrow secondary to cocaine-induced intimal fibrosis. Acute renal insufficiency with concomitant rhabdomyolysis after cocaine use has been reported (156,157), but it can also occur, albeit rarely, in the absence of rhabdomyolysis (158).

- A healthy 31-year-old man developed acute renal insufficiency 18 hours after inhaling cocaine 5 g. His blood pressure was 150/100 mmHg, his serum creatinine 177 μmol/l, creatine phosphokinase activity 107 U/l, and serum potassium concentration 3.8 mmol/l. The urinary sodium concentration was 30 mmol/l and there was a trace of protein and 1–2 red blood cells per high-power field. Immunological studies were unremarkable. Ultrasound showed kidneys of normal size with hyperechogenity of the right kidney. Over the next 10 days he recovered spontaneously.

The authors suggested that intense cocaine-induced renal vasoconstriction had been the likely underlying mechanism.

Renal infarction is an uncommon adverse effect of cocaine (159).

- After using intranasal cocaine, a 25-year-old African man developed fever and progressive right flank pain over 4 days. He had a temperature of 38.3°C, a blood pressure of 106/54 mmHg, and severe tenderness in the right flank and right lower quadrant of the abdomen. His urine contained cocaine. A CT scan showed reduced uptake in the lower pole of the kidney, confirming renal infarction. Other causes were ruled out.

Sexual function

The practice of trading sex for drugs in places where there is a high prevalence of cocaine abuse has been noted in both metropolitan areas and smaller communities along major interstate highways. In Baltimore, there was a 97% increase in the number of primary and secondary cases of syphilis from 1993 to 1995 (160).

Priapism has been reported in men who have used cocaine by inhalation or applied it topically to the glans penis or intraurethrally (SEDA-19, 26).

- Three men developed priapism and delayed seeking treatment (161). Cocaine use within the previous 24 hours was the singular contributing factor in all three cases. Two of the men had had previous episodes of priapism, which had resolved spontaneously. Initial duplex ultrasonography confirmed low penile blood flow. Manual aspiration and irrigation failed in all three cases. Surgical shunting failed in the first two cases. One man required partial penile amputation for infected, gangrenous, distal penile tissue; one responded to angiographic embolization; and one had only a partial response to angiographic embolization, but then refused further intervention; his erection resolved during the next 24 hours.

The authors suggested that acute sexual excitement during cocaine intoxication can cause penile erection, with impaired detumescence. Cocaine can inhibit the reuptake of noradrenaline (by blocking transport in presynaptic sympathetic neurons), thus preventing sinusoidal contraction and the efflux of penile blood.

- A 44-year-old black man developed priapism 2 hours after having overdosed on 30–40 trazodone tablets 50 mg and 10 Tylenol No. 3 (paracetamol plus codeine) tablets (162). Toxicology analysis was positive for cocaine and opiates. The priapism required detumescence twice, on initial presentation and then 6 hours later, and 8 hours after presentation he again developed painless priapism, which resolved spontaneously after 1.5 hours.

Trazodone-induced priapism may be mediated by alpha-adrenoceptor antagonism. While the mechanism for cocaine-induced priapism is unclear, it may result from vasospasm, venous pooling, and sludging of blood in the penis. The authors proposed that the two drugs may act in an additive or synergistic manner, posing a greater hazard than either alone.

Priapism associated with intracavernosal injection of cocaine has also been reported.

- A 43-year-old man developed persistent painful erection after intracavernosal injection of cocaine (163). He had previously administered cocaine in this way to prolong erections. Cavernosal aspiration resulted in partial detumescence, but the condition recurred. Urine screen was positive for cocaine. Aspiration and irrigation fully alleviated the condition.

During penile erection, nitric oxide is released from the endothelium of the cavernous spaces and from nerve endings (non-adrenergic and non-cholinergic). Nitric oxide stimulates guanylate cyclase, which is involved in the conversion of guanosine triphosphate to cyclic guanosine monophosphate (cGMP); the latter relaxes the smooth muscle in the corpora cavernosa, allowing influx of blood for erection. The authors suggested that cocaine directly applied to the cavernosal endothelium can cause nitric oxide production.

Immunologic

The prevalence of infection with the human immunodeficiency virus (HIV) among drug abusers, including cocaine users, is increasing (164). Two separate reports have suggested that cocaine may compromise immunological function. In one study, human mononuclear cells were stimulated in vitro with mitogens in the presence and absence of cocaine; cocaine inhibited the proliferation of the mononuclear cells (165). In a second study, cocaine

© 2006 Elsevier B.V. All rights reserved.

amplified HIV-1 replication in co-cultures containing cytomegalovirus-activated peripheral blood mononuclear cells (166).

Two cases of connective tissue disease have been reported (167).

A case of urticarial vasculitis, a type III hypersensitivity reaction, has been reported after cocaine use (168).

- A 24-year-old man with acute malaise and fever had a pruritic rash with multiple erythematous circumscribed weals on the trunk, arms, legs, neck, and scalp. He admitted to using intranasal cocaine 6 months, 4 days, and 1 day before the onset of the symptoms. His temperature was 39°C. His erythrocyte sedimentation rate was 80 mm in the first hour, C-reactive protein was 283 mg/l (reference range below 10), and the white blood cell count was 12.4×10^9/l with 89% neutrophils. A biopsy of an urticarial lesion showed a perivascular inflammatory infiltrate in the upper and middle dermis. Bed rest, oral prednisone, oral hydroxyzine, and topical polidocanol led to improvement within 24 hours.

Two cases of cocaine-induced type I hypersensitivity reactions, have been reported (169).

- A 23-year-old woman developed tongue swelling and difficulty in breathing immediately after having sniffed cocaine. The anterior half of her tongue was edematous with bleeding lesions caused by her fingernails. There were cocaine metabolites in the urine. The diagnosis was angioedema of the tongue induced by cocaine or its contaminants, and it resolved with subcutaneous adrenaline, H_1 receptor antihistamines, and intravenous glucocorticoids.
- A 19-year-old man developed generalized urticaria, intense pruritus, and mild bronchospasm 30 minutes after injecting cocaine for the third time. He had weals on the face, neck, arms, and chest, and scattered wheezing in the lungs. Urine toxicology screen was positive for cocaine metabolites. His symptoms resolved several hours after the administration of H_1 receptor antihistamines and intravenous glucocorticoids.

Body temperature

Cocaine can cause hyperthermia, primarily in hot weather, perhaps through a hypermetabolic state; impaired heat dissipation may be another contributing factor. Seven healthy, cocaine-naïve subjects participated in tests of progressive passive heat stress, during which each received intranasal cocaine or lidocaine as placebo (170). Esophageal temperature, skin blood flow, sweat rate, and perceived thermal sensation were measured. Cocaine augmented the temperature increase during heat stress and also increased the temperature threshold for the onset of both cutaneous vasodilatation and sweating. It also impaired the perception of heat. This study elicited commentary, in which it was pointed out that measured effects of small doses of cocaine may not be reflective of true cocaine poisoning (171). Also, the subjects in the study did not have psychomotor agitation, which is often prominent in cocaine toxicity and which improves with sedatives.

Death

Poisoning can occur with doses of cocaine as low as 20 mg (10 drops of cocaine 4%). Victims generally collapse and die after associated cardiovascular abnormalities, dysrhythmias, and respiratory failure. Signs and symptoms of intoxication include excitement, restlessness, headache, nausea, vomiting, abdominal pain, convulsions, and delirium.

In a retrospective study of 48 men who suffered cocaine-related deaths and a control group of 51 male cocaine users who died of trauma, the blood cocaine concentrations measured in the two groups were similar (172). However, concentrations of the cocaine metabolite benzoylecgonine were higher in those with cocaine-related deaths. This group also had a significantly lower body mass index, with larger hearts and heavier lungs, livers, and spleens than the control subjects. Reduced body weight, an adverse effect of long-term cocaine use, is probably related to its effects on the serotonergic system and therefore appetite. Cardiomegaly is thought to result from chronic cocaine-induced excessive catecholamine stimulation, with circulatory overload, and increased organ weight is a result of passive visceral congestion in cocaine-induced heart failure. Cardiac alterations may explain why similar blood cocaine concentrations can be lethal in some cases but benign in others. This study shows that isolated measurements of postmortem cocaine and benzoylecgonine blood concentrations cannot be used to assess or predict cocaine toxicity.

The increasing prevalence of multisubstance abuse can influence morbidity and mortality (173).

- An 18-year-old man experienced sudden and severe chest pain while drinking alcohol. He vomited, collapsed, and died. On postmortem examination, thrombosis of the left coronary artery, dilated cardiomyopathy with congestive heart failure, and pulmonary embolism were noted. Blood analysis showed raised cocaine and marijuana concentrations and a trace of alcohol.

The author's opinion was that although multidrug use had played a part, the high blood concentration of cocaine had been the main cause of death. He also noted that marijuana can interact with cocaine to produce pronounced sympathomimetic effects.

The smuggling of illicit drugs by the technique called "body packing" carries medical risks. Drug packages can rupture and digestive secretions can seep into packets and allow drug absorption. Consequently, drug intoxication, intestinal obstruction, peritonitis, and death can occur. A man carrying 99 cocaine powder packages weighing 10 g died as a result (174), and the death of a drug dealer has been reported (175).

- A 17-year-old man swallowed a small plastic bag of cocaine in order to avoid arrest. After 1 hour he complained of a headache and 30 minutes later developed palpitation and agitation and collapsed. Histological examination of his heart showed myocardial necrosis. The blood concentration of cocaine was high at 98 μg/ml. The tissue concentrations of cocaine and its metabolites in various organs and fluids were recorded; the highest concentrations of cocaine and metabolites were detected in the liver, lungs, brain, and blood (in descending order).

The cause of sudden death in this case was probably a cardiac dysrhythmia.

© 2006 Elsevier B.V. All rights reserved.

Long-Term Effects

Drug tolerance

Chronic cocaine exposure and long-term adaptation at the molecular level have been investigated; changes in transcription factor gene expression may be involved (176). NURR1 is a key factor that regulates transcription of the gene that encodes the cocaine-sensitive dopamine transporter and functions in the development of dopamine neurons. In a recent study, postmortem human midbrain specimens from cocaine users and controls underwent various analyses. Human NURR1 gene expression was markedly reduced in dopamine neurons in the cocaine users and normal in the controls. NURR1-deficient cocaine abusers also had dopamine neurons with markedly reduced dopamine transporter gene expression. NURR1 appears to have a critical role in the brain's adaptation to repeated cocaine exposure and in maintenance of dopamine neurons.

Drug dependence

There has been considerable interest in evaluating drugs such as amfepramone (diethylpropion) for attenuating the negative emotional state induced by craving for cocaine, in the hope of finding a drug for long-term treatment of cocaine dependence. However, in 50 cocaine-dependent patients amfepramone was ineffective and caused significant adverse effects (177). Of the patients who took amfepramone 25–75 mg/day, 12% were withdrawn from the study: one developed coronary vasospasm and another atrial fibrillation. These poor results are comparable to those of earlier studies with methylphenidate in cocaine addicts (178,179).

Drug withdrawal

There have been reports of the effects of cocaine withdrawal on cognition. There was impairment of memory, visuospatial abilities, and concentration in 16 cocaine abusers during the first 2 weeks of abstinence (55). Measured deficits were independent of withdrawal-related depression.

Tumorigenicity

Chronic cocaine use, which is associated with immunosuppression, may be carcinogenic. The possible association between chronic cocaine exposure and pancreatic adenocarcinoma has been investigated (180,181). A study of hospital records in Brazil for the years 1986–1998 showed that of 198 patients with pancreatic adenocarcinoma, 13 (6.5%) were younger than 40 years; of these, five had a history of chronic cocaine inhalation and one had abused marijuana.

Second-Generation Effects

Pregnancy

Some of the risks run by the pregnant cocaine-using mother and her child (such as preterm labor and premature delivery) have been reported (182). However, the literature on maternal cocaine use and its possible outcomes is problematic, because many studies have been methodologically flawed (183).

A retrospective study of data from a large perinatal registry showed that there was an increased risk of placenta previa among women who used cocaine, compared with those who did not use drugs or alcohol (184).

Another apparent obstetric risk of cocaine use is rupture of a uterine scar (from a previous cesarean section).

- There was extensive laceration of the maternal urinary bladder after a vaginal birth in a 34-year-old woman whose urine tested positive for cocaine (185).

The authors postulated that the injury may have resulted from a cocaine-augmented contractile response of the pregnant uterus.

A "pre-eclampsia–like" syndrome has been described, characterized by acute hypertension and a low platelet count, in a 33-year-old cocaine user; her 20-week-old fetus died (186).

One of the serious medical conditions linked with cocaine use during pregnancy is premature delivery, with an incidence in cocaine users of 17–27%. The mechanism of the effect of cocaine on both spontaneous and agonist-induced contractility of pregnant human myometrium has been evaluated (187). Myometrium samples from 42 women who were undergoing cesarean section at term were examined after exposure to various pharmacological probes in combination with cocaine. The results suggested that cocaine augments the contractility of uterine tissue by both adrenergic and non-adrenergic mechanisms. Cocaine increased spontaneous myometrial contractility over three-fold. Prazosin, an alpha-adrenoceptor antagonist, blocked this effect, but only for the first 35 minutes. Cocaine increased both the sensitivity and maximal tissue response to the alpha-adrenoceptor agonist methoxamine. The maximal response to oxytocin, but not sensitivity, was increased by cocaine; prazosin did not inhibit this effect.

Cocaine has been associated with both preterm delivery and premature rupture of the membranes (188). Among 85 of 604 expectant mothers with premature rupture of the membranes with documented cocaine exposure compared with women with no drug exposure for six conditions of major neonatal morbidity, cocaine users were older and of higher parity. The non-cocaine users had more morbidity, in particular neonatal infection and sepsis. The authors proposed that the mechanism of premature rupture of the membranes in the presence of cocaine may not be related to infection. Instead, cocaine may have a direct effect on the myometrium, stimulating uterine contractility.

The Maternal Lifestyle Study has reported that the prevalence of adverse perinatal complications associated with the use of cocaine or opiates during pregnancy was lower than has been previously reported (189). In 11 811 mother–infant pairs followed prospectively, 11% of the exposed and non-exposed groups were hospitalized at least once. However, violence was a factor (20%) in admissions among the cocaine-exposed women.

© 2006 Elsevier B.V. All rights reserved.

Teratogenicity

The data suggest that cocaine-exposed infants may be at increased risk of congenital malformations (190). However, it is unclear by what mechanism cocaine affects the fetus. Interruption of the intrauterine blood supply, with subsequent destruction of fetal structures, may account for some of its effects (191).

There are frequent reports of intrauterine growth retardation, neurobehavioral abnormalities, cerebral injury, and cardiac anomalies in "coke babies" (SEDA-14, 15) (SEDA-21, 4) (SEDA-21, 129) (192,193). Brain hemorrhages (194) and asymmetrical growth retardation (195) associated with maternal cocaine abuse have been discussed.

In 500 neonates ankyloglossia, a defect in the attachment of the tongue within the mouth, was 3.5 times more common in cocaine-exposed neonates than in others (196). Other facial, vertebral, and cardiovascular defects have been described (SEDA-17, 4) (19).

Two other clinical syndromes involving anomalies of multiple organ systems in fetuses of cocaine-abusing women have been described.

- An infant with Pena–Shokeir phenotype (including facial, musculoskeletal, pulmonary, and cardiac malformations accompanied by extensive brain damage) was born to a cocaine-abusing mother (197). The infant died shortly after birth.
- An infant exposed to cocaine in utero had a combination of facial, ear, eye, and vertebral anomalies, accompanied by cardiac, central nervous system, and other malformations (198).

In contrast, in 34 light-to-moderate cocaine users compared with 600 non-users attending a public prenatal care clinic, pronounced untoward effects on the fetus were reportedly less common than in other studies (199). In all cases the cocaine had been taken intranasally, and the majority of users reduced their intake during pregnancy; none had been referred for drug abuse counseling and none was taking drug treatment. There was no significant difference in obstetric complications among these mild cocaine users compared with non-users, and no significant differences in infant growth, morphology, or behavior. However, the cocaine users had histories of more fetal losses and during pregnancy they suffered more infectious diseases, such as hepatitis, *Herpes simplex*, and gonorrhea.

Fetal growth

Among the adverse outcomes of prenatal cocaine exposure, low birth weight and reduced length and head circumference have been reported. In a prospective study in New York City, 386 pairs of cocaine- and crack-using mothers and their infants and 130 matched control pairs were followed during the course of pregnancy and delivery (200). The neonates were assessed by physical and neurological examination, the Brazelton Neonatal Behavioral Assessment Scale (BNBAS), and the Neonatal Stress Scale during the first 48 hours of life. The results corroborated earlier findings of reduced fetal growth in cocaine-exposed infants. Significantly more (17%) of the babies of cocaine users had a head circumference less than the tenth percentile compared with the controls (3%). They performed less well on the BNBA Scale and had higher measures on the Neonatal Stress Scale. They had clinically significant neurological impairment, with jitteriness, increased tone, and an exaggerated Moro reflex. However, some of these findings may have reflected a direct neurotoxic effect of cocaine, since testing was done during the first 48 hours of life. The authors observed that crack had a more adverse outcome than cocaine. They concluded that the most important predictor of neonatal outcome may be the frequency, quantity, and type of cocaine used.

The effect of maternal cocaine use on infant outcome has been prospectively assessed in 224 women, of whom 105 were cocaine users and 119 were controls (201). The infants were of gestational age 34 weeks or more and were not asphyxiated. The infants exposed to cocaine were more likely to be admitted to the newborn intensive care unit, to be treated for congenital syphilis or presumed sepsis, to have a greater length of stay, to have lower birth weight and head circumference, and to be discharged to the care of someone other than the mother. However, the two groups were similar in the incidence of abnormal cranial and renal ultrasonography and abnormal pneumocardiography. Moreover, when controlled for cigarette use and other confounders, there were no significant differences in the groups on growth retardation factors.

Cardiovascular

Intrauterine cocaine exposure is associated with neonatal cardiovascular dysfunction and malformations. The long-term effects of cocaine on the neonate's cardiovascular system and development are unknown. The effect of cocaine on the infant's autonomic function and subsequent development has been reported (202). Heart rate variability, a non-invasive test of autonomic function, was evaluated in 77 prenatally cocaine-exposed infants, 77 healthy controls, and 89 infants who had been exposed prenatally to drugs other than cocaine (alcohol, marijuana, and/or nicotine). Within the first 72 hours of life, the cocaine-exposed infants were asymptomatic but had lower heart rate variability and lower vagal tone than the two comparison groups. At follow-up, the cocaine-exposed infants had recovered at 2–6 months of age and now had higher heart rate variability and vagal tone than the two non-exposed groups. Most of the increase in heart rate variability and vagal tone was seen in the infants who had had light cocaine exposure and was not apparent in those who had had heavy exposure.

The same researchers have published two reports on the cardiovascular effects of intrauterine cocaine. In the first study, 82 healthy neonates with intrauterine cocaine exposure, 108 exposed to drugs other than cocaine, and 87 healthy controls were evaluated for global and segmental systolic and diastolic cardiac function (203). During the first 48 hours of life, the neonates with intrauterine cocaine exposure had significant left ventricular diastolic segmental abnormalities. They had a higher index of asynchrony and global and segmental fractional area changes in contrast to the other two groups. The degree of abnormality in the index of asynchrony was greater in the neonates with

© 2006 Elsevier B.V. All rights reserved.

heavier cocaine exposure. In a second study at 2–6 months of age, 56 cocaine-exposed infants were compared with 72 who had been exposed to drugs other than cocaine and 60 healthy controls (204). The cocaine-exposed infants had recovered left ventricular diastolic function. Only in infants with heavy cocaine exposure was there an alteration in septal wall diastolic filling.

- A 6-month-old fetus who had been exposed to cocaine had a single-ventricle heart; the authors suggested that coronary spasm, resulting in infarction, may have destroyed the right ventricle (205).

Nervous system

In two reports it was suggested that brain hemorrhage (194) and asymmetrical growth retardation (195,206) can occur.

Cognitive effects

The influence of exposure to cocaine in utero on the developing human nervous system is not yet clearly understood (SEDA-22, 21). Prenatal cocaine exposure has been associated with neurobehavioral effects in infancy, ranging from no effect to effects on arousal and state regulation, as well as on neurophysiological and neurological functions. A prospective controlled study in 154 cocaine-using pregnant mothers and suitable matched controls from a rural community produced neurobehavioral effects that supported those from previous controlled studies (207). The mothers underwent drug testing and medical examination during each trimester. Their infants were assessed as near to 40 weeks after conception as possible, using the BNBA Scale. When controlled for the effects of marijuana, alcohol, and tobacco use, the use of cocaine in the third trimester was negatively related to state regulation, attention, and responsiveness among the exposed infants. Twice as many cocaine-exposed infants as controls failed to come to and maintain the quiet alert state required for orientation testing.

It is unclear whether abnormalities in early infancy are associated with neurodevelopmental impairment at a later age. Several studies have suggested that the findings are limited to early childhood. The possible effects of prenatal cocaine exposure on later cognitive functioning and difficulties have been reported in three studies. In the first, 236 infants at 8 and 18 months of age were evaluated; 37 had heavy exposure to cocaine in utero, 30 had light exposure, and 169 had no exposure (208). Cognitive functioning was assessed with the Bayley Scales of Infant Development. Information processing was tested with an infant-controlled habituation procedure. At 8 months, cocaine-exposed infants and controls had no differences in cognitive functioning. Their abilities to process information indexed by habituation and response to novelty were comparable. However, at 18 months the infants with high cocaine exposure performed poorly on the Mental Development Index (MDI). The 18-month index covers a wider range of cognitive tasks requiring integrated learning, responsiveness to environmental cues, and memory than the 8-month index. These results suggest that the effects of cocaine are more likely to show up when more challenging measures are used. Infants raised in high-risk environments, with stressors and low support, scored lower at both 8 and 18 months.

In a second study, intellectual functioning at 6–9 years was measured in 88 cocaine-exposed children and 96 unexposed children in New York City (209). The participants were interviewed and underwent medical and neurological examination and psychological assessment. Child intelligence was measured with the Wechsler Intelligence Scale for Children-III (WISC-III). Intelligence quotient scores did not differ between the two groups of children, even when adjustments for co-variables were made.

In a third study the Robert Wood Johnson database of published literature on prenatal cocaine exposure and child outcome was examined (210). Only 8 of 101 studies focused on school-age children. Intelligence quotient (IQ), receptive language, and expressive language were measured. This meta-analysis showed an average difference of 3.12 IQ points between cocaine-exposed and control groups. When the IQ distribution is shifted downwards by this amount, there is a 1.6-fold increase in the number of children with IQs under 70. The authors noted that the calculated decrement in IQ in exposed children is subtle and does not include the possible effect of the drug on domains of function such as language abilities.

Research on the relation between prenatal cocaine exposure and childhood behavior also continues. In a pilot study, 27 children exposed to cocaine in utero and 75 control children were assessed (211). The children had a mean age of 80 months and most were first-grade students. The child's first-grade teacher (blinded to exposure status and study design) rated the children's behavior with the Conners' Teacher Rating Scale (CTRS) and the Problem Behavior Scale (PROBS 14), an investigator-developed scale that measures behaviors associated with cocaine exposure. The drug-exposed children had higher CTRS scores (that is more problematic behavior), but the difference was not significant. On subscales of the PROBS 14, the drug-exposed group had significantly more problematic behavior. These results appear to substantiate teachers' reports of problematic behavior in children with prenatal cocaine exposure.

The effects of prenatal cocaine exposure on information processing and developmental assessment have been studied in 108 infants aged 3 months, 61 of whom had been exposed to cocaine, and 47 controls using an infant-control habituation and novelty responsiveness procedure in a developmental assessment using the Bayley Scales of Infant Development (212). Infants exposed to cocaine prenatally were significantly more likely than controls to fail to start the habituation procedure, and those who did were significantly more likely than controls to react with irritability early in the procedure. Cocaine-exposed infants had a comparatively depressed performance on the motor but not the mental Bayley scales. This information was obtained by raters blind to the history and was controlled for both perinatal and sociodemographic factors. Most of the infants in both groups reached the habituation criteria, and among those who did there were no significant differences between cocaine-exposed and non-exposed infants in habituation or in recovery to a novel stimulus. Thus, differences in reactivity to novelty, but not information processing, between cocaine-exposed and

© 2006 Elsevier B.V. All rights reserved.

non-cocaine-exposed infants suggested that the effects of prenatal cocaine exposure may be on arousal and attention regulation, rather than on early cognitive processes.

Developmental correlates have been assessed in three groups of children aged 4–6 years (213). In 18 children there had been prenatal exposure to cocaine and the mothers had continued to use crack. Another 28 children had had no prenatal exposure but their mothers had used crack after the children were born. The control group were 28 children whose mothers had never used cocaine. Prenatally exposed children performed significantly worse than the others in tests of receptive language and visual motor drawing. Prenatal crack exposure was associated with poor visual motor performance, even after controlling for intrauterine alcohol and marijuana exposure, age, birth weight, and duration of maternal crack use.

There have been two studies of the neurodevelopmental effects of cocaine during the first 48 hours of life. In the first, 23 cocaine-exposed and 29 non-exposed infants were prospectively assessed within the first 48 hours of life; infant meconium was used to detect cocaine and the BNBA Scale was used for clinical assessment (214). One-third of the cocaine-exposed neonates were born to women who denied cocaine use. In six of the seven clusters assessed, cocaine-exposed infants fared badly compared with control infants. The cocaine-exposed infants had poor autonomic stability and there was a dose–response relation between meconium cocaine concentration and poor performance in relation to orientation and so-called "regulation of state," which refers to how the infant responds when aroused. The authors concluded that cocaine exposure is independently related to poor behavioral performance in areas that are central to optimal infant development. They emphasized the value of the identification and quantification of cocaine in infants.

In another blinded study, neurodevelopmental and neurobehavioral performance were prospectively assessed in 131 neonates (mean age 43 hours) exposed in utero to cocaine, with or without other drugs (215). Cocaine-exposed neonates were developmentally at risk in the tests compared with infants exposed to other drugs alone or in combination. As in the previous study, larger amounts of cocaine were associated with higher neurobehavioral risk scores.

In a study of immediate and late dose–response effects of cocaine exposure in utero on neurobehavioral performance, 251 full-term urban neonates were examined by blinded raters at 2 and 17 days (216). The babies were classified as having been heavily exposed, lightly exposed, or not exposed to cocaine. After controlling for covariates, in contrast to the studies mentioned above (211,215), there were no neurobehavioral effects of exposure at 2 days of age. However, at 17 days there was a significant dose-related effect: heavily exposed infants had poorer state regulation and greater excitability, implying impairment of their ability to modulate arousal. The authors postulated that these late effects might be expected if cocaine exposure in utero is associated with evolving neuroanatomical damage or disruption of the monoaminergic neurotransmitter systems. These effects did not appear to be related to intrauterine growth retardation, as has been suggested by others.

Arousal and attention have been investigated in 180 healthy nursery infants before hospital discharge and at 1 month of age (217). Cocaine-exposed infants showed a lack of arousal-modulated attention and preferred faster frequencies of stimulation, regardless of arousal condition compared with non-exposed infants. There were similar differences 1 month after birth, showing that these effects persisted beyond the period of presence of cocaine or its metabolites at birth. These effects were independent of absence of prenatal care, alcohol use, minority status, or sex, suggesting a direct and even chronic effect of intrauterine cocaine exposure on arousal-modulated attention and presumably on the developing nervous system of the infants.

The behavioral and hormonal responses in 30 preterm cocaine-exposed infants were compared with the responses in 30 non-cocaine-exposed infants of similar gestational age (218). The mothers of cocaine-exposed infants were more often single, had higher parity and more obstetric complications, and were less likely to visit, touch, hold, and feed their infants than the other mothers. Cocaine-exposed infants had smaller head circumferences at birth, spent more time in the neonatal intensive care unit, and had a greater incidence of periventricular or intraventricular hemorrhages. They also had poorer state regulation and difficulty in maintaining alert states and in regulating their own behavior. They spent more time in indeterminate sleep (suggesting nervous system immaturity), with reduced periods of quiet sleep and increased amounts of agitation, tremulousness, mouthing, multiple limb movements, and clenched fists. There were higher urinary noradrenaline, dopamine, and cortisol concentrations and lower plasma insulin concentrations in the cocaine-exposed infants, suggesting that they may have experienced a high degree of stress in the perinatal period.

In a study of 464 inner-city black infants, whose mothers were recruited prenatally based on alcohol and cocaine use during pregnancy, gestational age of less than 38 weeks was significantly correlated with cocaine use in the mothers (219). The infants were tested at 6.5, 12, and 13 months of age; the cocaine-exposed infants were more excitable, preferred faster frequencies of stimulation, had more difficulty habituating, were more reactive, and showed a greater startle response to noise. Moreover, these effects of cocaine on cognitive function were documented beyond the neonatal period, thus eliminating effects from acute cocaine exposure or withdrawal. The authors suggested that two separate mechanisms may underlie the effects of cocaine on gestational age and cognition. The nervous system deficits, poorer cognitive performance, and faster reactivity are probably mediated by a direct action of cocaine (requiring heavy exposure) on neurotransmitters, whereas shortened gestation may be mediated by vasoconstriction, which occurs at lower exposure. Timing of exposure during pregnancy may also play a critical role in determining the type of deficits.

The effects of prenatal maternal cocaine use on neurobehavior have been reported in 2-week old infants (220). The BNBA Scale was administered to the infants of mothers who had a reported high frequency of cocaine use during pregnancy: ($n = 23$, >75th percentile reported days of use) or a low frequency ($n = 32$, <75th percentile).

Infants with high intrauterine exposure had higher scores on the BNBAS excitability cluster than infants with low exposure. Infants with a high BNBAS excitability score had poorer tone and motor movement, were more irritable and hard to console, and had difficulties in self-quieting.

In a meta-analysis of 18 published reports (1985–1988, 13 of which failed to meet the inclusion criteria and were excluded) on the effect of in utero exposure to cocaine on infant neurobehavioral outcome, cocaine-exposed infants were compared to non-exposed infants on BNBAS cluster scales at birth and at 3–4 weeks of age (221). Although the sample size was large enough to detect statistical significance in most of the tests of difference between the two groups, the magnitude of all the effects was small. This was true for differences in the motor performance and abnormal reflex clusters in the infant groups (with a slight trend toward increasing standard differences over time) and in the orientation and autonomic regular clusters (with a trend toward a reduced effect size over time). However, the main finding of the study was the small magnitude of the neurobehavior dysfunction at both times. The authors cautioned that these data may not be generalizable, since polydrug exposure, the amount of cocaine exposure, and other variables could have confounded the data.

In 158 cocaine-exposed (82 heavily and 76 lightly exposed) and 161 non-cocaine exposed infants, neurobehavioral function was assessed at 43 weeks after conception (222). Mediating factors (the timing and amount of drug exposure) and maternal psychological distress as a confounding factor were considered in the design and statistical analysis. The infants with heavy cocaine exposure had significantly more jitteriness and attentional difficulties. They were also more likely to be identified with an abnormality and less likely to cooperate with testing procedures than infants in the other groups. Higher concentrations of cocaine metabolites, cocaethylene and benzoylecgonine, were associated with a higher incidence of movement and tone abnormalities, jitteriness, and the presence of any abnormality. Higher cocaethylene concentrations were associated with attentional abnormalities; higher concentrations of metahydroxybenzoylecgonine were associated with jitteriness.

Cognitive, motor, and behavior development, as measured by the Mullen Scales of Early Learning and the Bayley Scales of Infant Development-II, were compared in 56 prenatally cocaine-exposed infants and toddlers (aged 1–3 years) and 56 non-exposed matched controls (223). There were developmental problems in expressive and receptive language areas in those who had been exposed prenatally.

The effect of intrauterine cocaine exposure on visual attention, cognition, and behavior has been investigated in 14 cocaine-exposed children and 20 controls aged 14–60 months (224). The cocaine-exposed children were slower in tests of disengagement and sustained attention. They also had greater difficulties in behavioral regulation.

Research on the effects of prenatal cocaine exposure on development in the first 2 years of life has been reported in 203 full-term infants (225). The infants, who were defined as having had no cocaine exposure, light exposure, or heavy exposure, were tested with the Bayley Scales of Infant Development at 6, 12, and 24 months. Assays of neonatal meconium for cocaine metabolites along with mothers' self-reports were used to evaluate the dose–response relation. There were no significant adverse effects due to cocaine exposure on scores in the major tests up to 24 months of age. Cocaine-exposed infants with the lowest 10th percentile birth weight and those placed with kinship caregivers had less optimal development. Cocaine-exposed infants who participated in child-focused early intervention programs scored higher than the others.

The behavioral effects of prenatal cocaine exposure at age 5 years have been studied in 140 children exposed to cocaine, 61 exposed to alcohol, tobacco, and/or marijuana, and 120 not exposed to any drugs (226). They were evaluated with the Achenbach Child Behavior Checklist. There was no association between behavior and intrauterine cocaine exposure. However, the current behavioral health of the mother, including recent drug use and psychological functioning, did affect the child's internalizing and externalizing behavior.

Gastrointestinal

Cocaine exposure in utero can affect various fetal organs. Gastrointestinal disorders, including ten cases of necrotizing enterocolitis (227), one of intestinal atresia, and one of spontaneous colonic perforation, have been reported (228).

Reproductive system

An increased incidence of genital malformations has often been noted (229).

Fetotoxicity

The prevalence rate of cocaine use during pregnancy is 10–45% in some centers in North America. As cocaine use is increasing and widespread, information on the possible adverse effects secondary to fetal cocaine exposure continues to amass in case reports and studies.

However, in a prospective, large-scale, longitudinal study there was no association between prenatal cocaine exposure and congenital anomalies in 272 offspring of 154 cocaine-using mothers and 154 non-using matched controls (230). The cocaine-exposed group had significantly more premature infants, who were significantly smaller in birth weight, length, and head circumference than the control infants. However, there were no differences in the type or number of abnormalities.

The impact of prenatal exposure to cocaine on fetal growth and fetal head circumference has been studied in 476 African-American neonates, including 253 full-term infants prenatally exposed to cocaine (with or without alcohol, tobacco, or marijuana) and 223 non-cocaine exposed infants (147 drug-free, 76 exposed to alcohol, tobacco, or marijuana) (231). The cocaine-associated deficit in fetal growth was 0.63 standard deviations and for gestational age 0.33 standard deviations. There were also cocaine-associated deficits in birth weight and length, but no evidence of a disproportionate effect on head circumference.

The relation between prenatal cocaine exposure and early childhood outcome has been reviewed (232). Prospective longitudinal studies of perinatal cocaine exposure and associated outcomes were studied in a

© 2006 Elsevier B.V. All rights reserved.

survey of 36 of 74 reports, published from 1984 to October 2000, in which the examiners were blinded to cocaine exposure. Prenatal cocaine exposure did not alter physical growth, developmental test scores, or receptive and expressive language among children aged 6 years or less. The authors concluded that there is no convincing evidence that prenatal cocaine exposure is associated with effects on a child's physical or behavioral development, and that many findings once thought to be specific effects of in utero cocaine exposure instead correlated with factors such as the quality of the child's environment and prenatal exposure to tobacco, marijuana, or alcohol.

This review generated responses from other authorities in the field. Some commented that the conclusions may be premature, given the age of the subjects, and drew attention to several studies that have shown subtle but consistent deficits in cognitive and attentional processes in 6- and 7-year-old children (233). These effects may become more prominent as development continues and may persist into adulthood. Others criticized the attempt to isolate cocaine exposure from all other associated risk factors; from a public health perspective, prenatal cocaine exposure clusters with other risk factors, such as poor caregiving, child maltreatment, domestic violence, and prenatal exposure to other substances (234). Furthermore, the selection criteria narrowed the total articles reviewed to under half of the 74 articles found. Others suggested that the study had been misinterpreted (235).

The effects of prenatal cocaine exposure have been assessed prospectively in 217 infants, 95 (44%) of whom had benzoylecgonine, a cocaine metabolite, in their meconium (214). Among these infants, benzoylecgonine concentration was inversely related to fetal growth (birth weight, length, and head circumference), whereas maternal self-report of days of cocaine use did not correlate with either fetal growth or meconium benzoylecgonine concentration. The report suggested a dose–response relation between the magnitude of prenatal cocaine exposure and impaired fetal growth.

In 39 cocaine-exposed infants and 39 control infants aged 35 weeks or older, head size was smaller and birth weight tended to be lower in the cocaine-exposed infants (236). Moreover, the head circumference of the cocaine-exposed infants was significantly smaller at any given birth weight than in the control infants. The behavioral scores were significantly higher (on days 1 and 2) in the cocaine-exposed infants; the higher scores were most frequently attributed to increased jitteriness, a hyperactive Moro response, and excessive sucking. Lastly, cocaine-exposed infants had an increase in flow velocity in the anterior cerebral arteries between days 1 and 2; however, there was no increased propensity to ischemic and/or hemorrhagic cerebral injury in the infants exposed to cocaine. The blood flow changes on the second day may have reflected falling infant cocaine concentrations after birth.

In a longitudinal evaluation of 28 infants exposed to cocaine in utero and 22 unexposed controls for 15 months, the cocaine-exposed infants weighed significantly less at birth than the control infants, but not subsequently (237). Compared with controls, motor development was compromised in the cocaine-exposed infants at 4 and 7 months, but not at 1 and 15 months, suggesting that compromised motor performance in the exposed group normalized for later milestones, probably through a self-righting process. A disturbing aspect of this study was the extremely poor performance in all-motor assessments at every age by every infant (including the controls). The investigators postulated that in an inner-city population (such as that studied here), once an infant accumulates three or more risk points (as most infants in the study did), additional risk factors (including exposure to cocaine) have little further negative impact on their development.

The complex interplay between the relative effects of prenatal cocaine exposure and the perinatal and environmental factors on development has been evaluated, using a structural model to describe the direct and indirect effects of prenatal drug exposure on developmental outcome from birth to age 6 months (238). Key variables included prenatal drug exposure, perinatal medical characteristics, maternal/caregiver/family characteristics, the home environment, and neurobehavioral outcomes. The study was based on 154 predominantly crack-using women and 154 control subjects matched for pregnancy risk, parity, race, and socioeconomic status. Prior exclusion criteria included age under 18 years, a major illness diagnosed before pregnancy, chronic use of legal drugs, and any use of illicit drugs other than cocaine and marijuana. Urine specimens were collected at two unanticipated times and positive serum samples were confirmed by gas chromatography/mass spectroscopy. Measures analysed by blinded evaluators included medical assessment at birth and developmental assessments at birth, 1 month, and 6 months, as well as caregiver characteristics and environmental factors at birth and 1 month.

Exposure to cocaine affected development at birth. Increasing exposure was significantly related to poor developmental outcomes, as measured by the Brazelton qualifier scores. Although no direct effects of cocaine were found at either 1 month or 6 months analysed separately, time-dependent analysis showed an effect on development at 6 months. The indirect effects of cocaine exposure were mediated through maternal psychosocial well-being at delivery and birth head circumference. In addition, indirect effects of prenatal cocaine exposure were also related to concomitant alcohol and tobacco use and the birth head circumference. Neither maternal nor caregiver factors at 1 month was directly related to developmental outcome at any time. These findings support previous findings (239–241) that suggest that cocaine is a mild teratogen with regard to neurodevelopmental outcome.

The presence of cocaine during the prenatal period disrupts the development of neural systems involved in mediating visual attention. Of 14 cocaine-exposed children and 20 control children aged 14–60 months, whose visual attention, cognition, and behavior were assessed, the cocaine-exposed children had slower reaction times, supporting the hypothesis that impairment in disengagement and sustained attention are associated with prenatal cocaine exposure (242). There was a trend to slower reaction times to targets presented in the right visual field, but not the left visual field. Cocaine-exposed children also had greater difficulties in behavioral regulation, especially related to an ability to cope with heightened levels of positive and negative emotions (243).

© 2006 Elsevier B.V. All rights reserved.

An association between prenatal cocaine exposure and deficits in total language functioning was found in 236 cocaine-exposed and 207 non-cocaine exposed full-term children (244). The link between prenatal cocaine exposure and language deficits during early childhood was not related to cocaine-associated deficits in birth weight, length, or head circumference. Three different but potentially interacting mechanisms whereby maternal cocaine use might affect early language development have been proposed (245):

- subtle dysregulation of attentional systems, with potential for disrupting an infant's ability to extract and process available linguistic information;
- disruptions in parent–child linguistic interactions due to cocaine and other drug use;
- impoverished, unstable, and endangering social and care-giving environments.

Early detection of language deficits allowed ameliorative intervention aimed at improving academic performance and social adaptation in preschool and school-aged children.

Cardiovascular

In a retrospective review of all dysrhythmias in children with prenatal cocaine exposure, 18 cases were detected in 554 infants who had positive urine screens for cocaine (246). In 13 neonates the dysrhythmia occurred beyond the period of direct cocaine exposure and six of the children had dysrhythmias after the neonatal period. Most of the dysrhythmias were supraventricular extra beats. Overall, the rate of consultations for dysrhythmias was higher among cocaine-exposed neonates than expected. Some cocaine-exposed children had symptomatic dysrhythmias that were persistent or recurrent and required treatment to maintain cardiac output and restore normal cardiac rhythm. Children who were exposed prenatally to cocaine appeared to be at increased risk of abnormal responses to stress, manifested by symptomatic dysrhythmias beyond the period of cocaine exposure.

- A child presented at 12 months of age with status epilepticus, sustained ventricular tachycardia, and a positive urine screen for cocaine. At 22 months he returned with a cardiac arrest, a history of a fall, a head injury, and a positive test for cocaine in the urine. He died soon after.

There has been a recent report of a myocardial infarct in a full-term infant born to a 28-year-old woman who had used cocaine 2–3 times per week and methadone 40 mg/day (247).

Respiratory

Respiratory rates in the 3-week-old babies of mothers who had used cocaine during pregnancy were higher than expected; in addition newborn babies who had been exposed prenatally to both cocaine and narcotic analgesics had abnormal control of breathing (following hypercapnia challenge) during the first few months of life (248). The preliminary results of another study are also of some interest; this prospective study of maternal drug abuse showed a reduced incidence of respiratory distress syndrome among premature infants prenatally exposed to cocaine (249). The authors noted that while this finding needs to be confirmed, it may suggest that fetal lung maturation can be accelerated by exposure to cocaine.

Prenatal cocaine exposure appears to have short-term effects on respiratory function in very low birth weight infants. In a retrospective study of 149 such infants, 48 cocaine-exposed and 101 non-exposed, the cocaine-exposed infants had transiently improved respiratory status at time of delivery; they needed surfactant treatment in lower doses and at a lower frequency and intubation less often (250). At 24 and 48 hours there was no significant difference between the treatment requirements in the two groups. The development of bronchopulmonary dysplasia was also similar. The authors suggested that prenatal cocaine exposure affects the fetus by two mechanisms: indirectly through reduced uterine blood flow with placental insufficiency and directly through an adrenergic effect on the fetus. The fetus may experience cocaine as a stressor that leads to accelerated fetal lung maturity.

Nervous system

Fetal microcephaly has been attributed to cocaine abuse during pregnancy (251). Urine toxicology confirmed the presence of morphine, benzoylecgonine, barbiturates, paracetamol, and propoxyphene. Analyses of amniotic fluid, placenta, and fetal serum and urine were also positive for these substances. The authors suggested that vascular disruption was the likely major mechanism of anomalies, both behavioral and malformative, due to prolonged exposure to cocaine in utero.

- An infant born at 37 weeks gestation to a mother who had engaged in discontinuous cocaine abuse during the first and second trimesters of pregnancy had microcrania (below the 10th percentile), a closed anterior fontanelle, and overlapping of all sutures (252). The infant was of low birth weight (2290 g; 25th percentile). There were deep scalp rugae, a prominent occipital bone, and normal hair pattern. An MRI scan of the brain showed enlargement of the lateral ventricles and pericerebral spaces, with severe reduction of the cerebral and cerebellar parenchyma and white matter abnormalities.

These findings are part of the recognizable pattern of defects in the rare condition termed fetal brain disruption sequence. The presence of a normal hair pattern suggests normal brain development during the first 18 weeks of gestation. At a later stage partial destruction of the brain results in reduced intracranial pressure and subsequent collapse of the fetal skull.

Prenatal cocaine exposure has been associated with subependymal hemorrhage and subependymal cyst formation in term neonates and more recently in preterm neonates (<36 weeks of gestation) (253). Medical records and cranial sonograms obtained during 1 year on 122 premature infants showed an increased incidence of subependymal cysts in preterm cocaine-exposed infants (8 of 18) compared with non-exposed infants (8 of 99). There was no increase in the incidence of major structural abnormalities. All subependymal cysts resolved by 4 months of age. The authors noted

© 2006 Elsevier B.V. All rights reserved.

that the neurodevelopmental implications of such cyst formation are unknown.

An unusual congenital malformation, the cloverleaf skull, has been associated with cocaine exposure in utero (254). In this condition, the cranium is trilobed, with severe brain deformity and hydrocephalus, because of premature fusion of the coronal and lambdoid sutures.

- A girl born by cesarean section at 38 weeks gestation weighed 3515 g and measured 54 cm in length and needed cardiopulmonary resuscitation. She had feeding and respiratory problems. Cranial sonography on day 11 showed a trilobed cranial mass with ventricular enlargement. She was discharged on day 35. The mother, a 24-year-old cocaine user, had engaged in active drug use for the 2 years before and during the first 2 months of pregnancy; she had also used alcohol (three units per day) and smoked marijuana (1–2 joints per day) during the first 5 months, and she had smoked 10 joints per day throughout the entire pregnancy. The father was also a marijuana smoker. The infant failed to thrive (body weight at 6 months 3120 g, height 57 cm), developed sepsis, and died. Autopsy showed adrenal infarction secondary to systemic infection.

Psychological

A study in 105 African-American infants suggested that infants exposed prenatally to cocaine are at a high risk of significant problems in arousal and attention (255). The 8-week-old infants had their heart rates recorded when presented with a series of stimuli. The order of the stimuli was as follows: auditory (rattle), visual (red ring), and social (examiner's face and voice). There were four groups of infants: preterm drug-exposed ($n = 25$), full-term drug-exposed ($n = 32$), preterm non-exposed ($n = 22$), and full-term non-exposed ($n = 26$). Preterm infants' ages were corrected to match those of the full-term infants. There were significant differences in the responses to social stimuli. Drug-exposed infants had an accelerated heart rate (indicating distress or arousal), whereas non-drug exposed infants had a slowed response (indicating focused attention). However, there were no heart rate differences among the groups in the auditory or visual conditions.

There have been two studies of the adverse effect of prenatal cocaine on behavior of the offspring. In the first, 31 cocaine-exposed, very low birth weight infants and matched very low birth weight controls followed longitudinally were assessed at 3 years (256). The cocaine-exposed children had delayed cognitive, motor, and language development compared with the controls. Of the exposed children 45% scored in the range of mental retardation compared with 16% of the controls. Infants in the exposed group during the neonatal period were less responsive in their interactions and their mothers were less nurturing and less emotionally available.

In contrast, in a second study there were few differences in interactive behaviors between prenatally cocaine-exposed and non-exposed 12-month-old infants and their mothers (257). Videotapes recorded African-American infants and their mothers engaged in interactions (49 cocaine-exposed, 63 non-exposed). Children who were prenatally exposed to cocaine ignored their mother's departure during separation significantly more often than controls. Mothers who abused cocaine used more verbal behavior with their children than non-abusers.

The effects of prenatal cocaine exposure on later learning abilities, including language, have been further investigated in 265 infants aged 1 year (134 cocaine-exposed and 131 matched non-exposed), who were tested using the Preschool Language Scale-3 (PLS-3) by blinded examiners (258). The infants were assigned to three cocaine exposure groups (as defined by maternal self-report and infant meconium assay): non-exposure ($n = 131$), heavier exposure ($n = 66$), and lighter exposure ($n = 68$). Fetal cocaine exposure was associated with deficits in developmental precursors of speech/language skills. At 1 year of age, more heavily exposed infants had poorer auditory comprehension than the non-exposed infants and worse total language performance than lighter and non-exposed infants. The more heavily exposed infants were also more likely to be classified as mildly delayed than non-exposed infants. Moreover, the degree of cocaine exposure had an inverse relation to auditory comprehension.

Drug Administration

Drug administration route

With the use of cocaine eye-drops, poisoning can occur with doses as small as 20 mg (10 drops of cocaine 4%). Victims generally collapse and die after associated cardiovascular abnormalities, dysrhythmias, and respiratory failure. Signs and symptoms of intoxication include excitement, restlessness, headache, nausea, vomiting, abdominal pain, convulsions, and delirium.

Drug overdose

Body packing, the act of swallowing packets holding illegal drugs in order to hide the evidence from legal authorities, can cause symptoms of drug intoxication or overdose (SEDA-22, 44) (259). In an analysis of all cases of cocaine body packers reported to a metropolitan poisons control center from January 1993 to May 1994, 34 of 46 individuals were symptom-free. Eight had mild symptoms (hypertension and tachycardia) that resolved with decontamination (activated charcoal or whole body irrigation) or tranquilizers (one received benzodiazepines). Two had severe symptoms, including seizures and cardiac dysrhythmias, and both died.

An increase in the number of deaths of all body packers in New York has been associated with an increase in deaths among opiate body packers: of 50 deaths among body packers from 1990 to 2001, 42 were due to opiates (260). Four were related to cocaine and four to both opiates and cocaine. In 37 cases open or leaking drug packets in the gastrointestinal tract resulted in acute intoxication and death. Five cases involved intestinal obstruction or perforation, one a gunshot wound, one an intracerebral hemorrhage due to hypertensive disease,

© 2006 Elsevier B.V. All rights reserved.

and one was undetermined. The number of packets recovered was 1–111 (average 46).

- A 49-year-old man became ill during a plane flight (261). He admitted to having swallowed 102 latex packages of cocaine 5 g each and 20 tablets of activated charcoal 125 mg. After stabilization in an emergency room, he suffered a seizure. After restabilization he had not defecated and was given a laxative of a mineral oil liquid paraffin. During the next 24 hours his condition worsened. His serum cocaine concentration increased from 1.95 to 2.2 μg/ml. During preparation for surgery he developed an untreatable dysrhythmia and died. Autopsy showed cocaine packages in the gut, 71 ruptured and 95 intact.

The reported lethal oral dose of cocaine is 1–3 g. In this case, paraffin may have contributed to rupture of the packages by dissolving the latex.

In another cocaine body packer, non-surgical management was followed by the development of a giant gastric ulcer (262).

- A 35-year-old man presented to the emergency room 5 days after swallowing 35 latex-wrapped packages of cocaine. He was asymptomatic but concerned that only 10 of the 35 packets had passed in his stools. He was treated with laxatives and passed only 8 packages during the next 8 days. Radiography showed that 10–15 foreign bodies remained clustered in the stomach 14 days after ingestion. Several fragments of latex wrapping were found in his stools. On exploratory laparotomy, 15 latex packages were found impacted in the antrum just proximal to the pylorus. Beneath the packages there was a giant gastric ulcer, 2.5 cm in diameter. He had an uneventful postoperative course.

Fatal crack cocaine ingestion has been reported in an infant (263).

- A 10-month-old girl developed apnea, ventricular fibrillation, and a metabolic acidosis, and died shortly afterwards. Her 2-year-old brother had fed her crack cocaine. At autopsy the brain had a thinned corpus callosum, ranging in thickness from 0.2 to 0.5 cm. There were two pieces of crack cocaine in the duodenum and high concentrations of cocaine in the blood and other tissues.

The authors noted that the thinned corpus callosum suggested that the infant had been exposed to cocaine in utero or during the early postnatal period.

Drug–Drug Interactions

Alcohol

Cocaine abusers have reported that alcohol prolongs the euphoriant properties of cocaine, while ameliorating the acutely unpleasant physical and psychological sequelae, primarily paranoia and agitation. It may also lessen the dysphoria associated with acute cocaine abstinence. It has also been proposed that concurrent alcohol abuse may be an integral part of cocaine abuse. The combination of cocaine with alcohol can cause enhanced hepatotoxicity and enhanced cardiotoxicity (264). Trauma in patients who use cocaine plus alcohol has been reported (265). Those who use cocaine plus alcohol are 3–5 times more likely to have homicidal ideation and plans; this is particularly prominent in patients with antisocial personality disorder (266). A large high school survey by the Centers for Disease Control and Prevention showed that illicit substance abuse, prevalence of weapon carrying, and physical fighting were higher among the adolescents who reported recent use of cocaine, marijuana, alcohol, and corticosteroids. Among 215 female homicide offenders, 70% had been regular drug users at some time before imprisonment. Alcohol, crack, and powdered cocaine were the drugs most likely to be related to these homicides (267).

In a double-blind study, subjects meeting DSM-IV criteria for cocaine dependence and alcohol abuse participated in three drug administration sessions, involving intranasal cocaine with oral alcohol, cocaine with oral placebo alcohol, and cocaine placebo with oral alcohol (268). Cocaine plus alcohol produced greater euphoria and increased perception of well-being than cocaine alone. Heart rate was significantly higher with cocaine plus alcohol than with either alone. Cocaine concentrations were higher after cocaine plus alcohol than after cocaine alone. Metabolism of cocaine to cocaethylene was observed only during administration of cocaine plus alcohol. The authors concluded that enhanced psychological effects during abuse of cocaine plus alcohol may encourage the ingestion of larger amounts of these substances, placing users at increased risk of toxicity than with either drug alone.

The adverse effects of the combined use of alcohol and cocaine have been reviewed (269). There is little evidence that this combination acts synergistically or that either drug enhances the negative effects of the other. However, the combination leads to the formation of cocaethylene, which may potentiate cardiotoxic effects and the combination has a greater than additive effect on heart rate. Lastly, cocaine antagonizes the learning and psychomotor performance deficits and driving impairment caused by alcohol.

Reports of liver complications after cocaine use are infrequent. However, fulminant hepatitis with acute renal insufficiency requiring liver transplantation occurred after the use of cocaine and alcohol (270).

- A 33-year-old chronic alcoholic with hepatitis C developed acute liver and renal insufficiency with grade III encephalopathy. Hemodialysis was begun and emergency liver transplantation was performed. The explanted liver showed marked diffuse macrovesicular steatosis with massive coagulative-type necrosis. The postoperative course included a persistently raised gamma-glutamyltransferase, but he recovered fully after 60 days.

Macrovesicular steatosis can be attributed to alcohol or cocaine, but massive liver necrosis is more probably due to cocaine. The mechanisms of cocaine hepatotoxicity, such as increased lipid peroxidation, free radical activity, and impaired calcium sequestration, may be potentiated by alcohol.

Atropine

Anticholinergic poisoning involving adulterated cocaine has been reported (271).

- A 39-year-old man who was a recreational user of alcohol and cocaine presented with agitation, hallucinations, and delirium. He had a dry flushed skin, tachycardia, dilated, minimally reactive pupils, urinary retention, and absent bowel sounds. He was treated with intravenous fluids and a sedative. There were cocaine metabolites in the urine. Reanalysis of a urine sample by thin layer chromatography confirmed the presence of the anticholinergic drug atropine.

Clozapine

An interaction of clozapine with cocaine has been reported (272). Eight male cocaine addicts underwent four oral challenges with increasing doses of clozapine (12.5, 25, and 50 mg) and placebo, followed 2 hours later by cocaine 2 mg/kg intranasally (273). Subjective and physiological responses, and serum cocaine concentrations were measured over 4 hours. Clozapine pretreatment increased cocaine concentrations during the study and significantly increased the peak serum cocaine concentrations dose-dependently. Despite this rise in blood concentrations, clozapine pretreatment significantly reduced subjective responses to cocaine, including "expected high," "high," and "rush" effects, notably at the 50 mg dose. There were also significant effects on "sleepiness," "paranoia" and "nervousness." Clozapine caused a significant near-syncopal episode in one subject, requiring withdrawal. Clozapine had no significant effect on baseline pulse rate or systolic blood pressure, but it attenuated the significant pressor effects of a single dose of intranasal cocaine. These data suggested a possible therapeutic role for clozapine in the treatment of cocaine addiction in humans, but also suggest caution due to the near-syncopal event and the increase in serum cocaine concentrations.

Diamorphine

Rhabdomyolysis and ventricular fibrillation has been attributed to cocaine plus diamorphine (heroin) ingestion (274).

- A 28-year-old man went into cardiorespiratory arrest after using intravenous cocaine and diamorphine. He was intubated and ventilated and given adrenaline, naloxone, and sodium bicarbonate. During a thoracotomy he developed ventricular fibrillation and was electrically converted to sinus rhythm. He had hyperkalemia and myoglobinuria. He developed acute renal insufficiency, disseminated intravascular coagulopathy, and a right leg compartment syndrome. There were cocaine metabolites and opioids in his urine. Hemodialysis and fasciotomy were performed, but he died 2 months later with a complicating bronchopneumonia.

The authors discussed the possibility that naloxone, an effective opioid antidote, may have been harmful in this case.

Ephedrine

Chronic cocaine use sensitizes coronary arterial α-adrenoceptors to agonists (SEDA-22, 154).

Indometacin

Cocaine combined with indometacin in a 23-year-old pregnant woman at 34 weeks gestation may have caused fetal anuria and neonatal gastric hemorrhage (275).

Monoamine oxidase inhibitors

The combination of monoamine oxidase inhibitors with cocaine can cause hyperpyrexia (270).

Neuroleptic drugs

Cocaine-abusing psychiatric patients significantly more often develop neuroleptic drug-induced acute dystonia according to a 2-year study carried out on the island of Curaçao, Antilles, where cocaine and cannabis are often abused (277). The sample consisted of 29 men with neuroleptic drug-induced acute dystonia aged 17–45 years who had received high potency neuroleptic drugs in the month before admission; nine were cocaine users and 20 non-users. Cocaine use was a major risk factor for neuroleptic drug-induced acute dystonia and should be added to the list of well-known risk factors, such as male sex, younger age, neuroleptic drug dosage and potency, and a history of neuroleptic drug-induced acute dystonia. The authors suggested that high-risk cocaine-using psychiatric patients who start to take neuroleptic drugs should be provided with an anticholinergic drug as a prophylactic measure to prevent neuroleptic drug-induced acute dystonia.

Nimodipine

It has been suggested that calcium channel blockers can be used to treat cocaine dependence, and some studies have shown reductions in cocaine-induced subjective and cardiovascular responses with nifedipine and diltiazem. The cardiovascular and subjective responses to cocaine have been evaluated in a double-blind, placebo-controlled, crossover study in five subjects pretreated with two dosage of nimodipine (278). Nimodipine 60 mg attenuated the rise in systolic, but not diastolic, blood pressure after cocaine. In three subjects nimodipine 90 mg produced greater attenuation than 60 mg. The subjective effects of cocaine were not altered by either dose of nimodipine.

Suxamethonium

Procaine and cocaine are esters that are hydrolysed by plasma cholinesterase and may therefore competitively enhance the action of suxamethonium (succinylcholine) (279). Chloroprocaine may have a similar action. Lidocaine also interacts, although the mechanism is not clear unless very high doses are used (280).

Cocamidopropyl betaine

General Information

Cocamidopropyl betaine is the most commonly used amphoteric surfactant in shampoos, bath products, and other cosmetic products. It is popular because of its relatively low irritation potential.

Organs and Systems

Immunologic

Contact allergic reactions are infrequent and have been attributed to sensitizing intermediates rather than cocamidopropyl betaine itself. Of 30 patients who were allergic to cocamidopropyl betaine, all reacted to 3-dimethylaminopropylamine (1). Two studies have shown that cocamidopropylamine is the more relevant impurity (2,3).

Codeine

See also Opioid analgesics

General Information

The pharmacodynamic and adverse effects of codeine are mainly due to *O*-demethylation by CYP2D6 to morphine or a metabolite of morphine (SEDA-21, 86) (SEDA-22, 5). Poor metabolizers may lack the analgesic effect of codeine.

In a retrospective study of patients with chronic rheumatological conditions, 290 of 644 clinic patients had received either codeine or oxycodone analgesia, of whom 137 had been given opioids for a continuous period of over 3 months (1). Adverse effects were described in 38% of both long-term and short-term opioid users, of which the most common were constipation, nausea, and sedation. Headache, dizziness, rash or itching, confusion, insomnia, depression, diarrhea, and myoclonic jerking were also reported. No significant differences in the adverse effects profile were reported between the groups and no subjects discontinued medication because of adverse effects. There were opioid abuse behaviors in 3% of the long-term users, but no association with a history of substance misuse was established.

A prospective double-blind, randomized study in 184 patients with cancers involved three treatment regimens (2): diclofenac alone (50 mg qds), diclofenac plus codeine (40 mg qds), or diclofenac plus imipramine (10–25 mg tds). There was no significant difference between the different treatments in terms of their analgesic effects, as measured on a visual analogue scale after 4 days. However, 10 of 61 subjects taking codeine withdrew because of adverse effects, compared with three taking imipramine group and two taking diclofenac alone. Gastrointestinal disturbances, dry mouth, and central nervous system disturbances were all more frequent in those taking codeine. These results suggest that the addition of a low-potency opioid to diclofenac fails to give enhanced analgesia while the frequency of opioid-related adverse effects increases.

Organs and Systems

Nervous system

Patients with migraine who use daily codeine or other opioids can be more susceptible to chronic daily headaches; this is evident in opiate overuse. In a pilot questionnaire study of 32 patients who used codeine or other opioids for control of their bowel motility after colectomy, chronic daily headaches occurred in those who were misusing opioids, but only if they had pre-existing migraine (3). The study had significant limitations, including the small sample size, diagnosis by means of a mailed questionnaire, a short duration of overuse of opioids, and the fact that it was uncontrolled.

Twelve cases of analgesic-related headache have been reported in children aged 6–16 years, half of whom were taking paracetamol in combination with codeine (4). Headaches occurred on at least 4 days per week and analgesic withdrawal led to symptom resolution in 50% and some improvement in the other cases.

Sensory systems

Reduced pupil size has been related to plasma codeine concentration (5).

Pancreas

Acute pancreatitis has been attributed to codeine (SEDA-21, 86), in one case in a patient taking co-codamol (paracetamol plus codeine) (6).

- A 20-year-old woman, who had previously taken paracetamol without adverse effects, took paracetamol 1 g and codeine 60 mg for a headache. After 3 hours she developed severe upper abdominal pain radiating to the back. The abdominal pain resolved within 24 hours of the administration of phloroglucinol and tiemonium. Her serum amylase activity was raised 3-fold and the serum lipase 15-fold. Other biochemical parameters, abdominal ultrasound, and an MRI scan were normal. Contrast-enhanced computed tomography showed pancreatic edema.

The previous use of paracetamol without adverse reactions supports the theory that the reaction was linked to the addition of codeine.

Four other cases of acute pancreatitis related to codeine have been reported (7).

- A 65-year-old man presented with severe abdominal pain 90 minutes after taking codeine and low-dose paracetamol. Serum amylase and lipase were significantly raised. Liver function tests were moderately abnormal. Abdominal ultrasound and CT scan showed edematous pancreatitis. Endoscopic retrograde cholangiography showed a papilla with a spastic appearance and an abnormal bile duct. He recovered completely, but 3 months later took codeine and paracetamol after a hemorrhoidectomy; abdominal pain recurred 1 hour later and acute pancreatitis was confirmed.
- A 26-year-old woman developed abdominal pain 2 days after taking codeine for a respiratory tract infection. Three hours later she complained of epigastric pain and vomiting. Her serum amylase and lipase were raised. Her symptoms resolved and the diagnosis was mild idiopathic pancreatitis. One week later she took codeine for similar respiratory symptoms. Two hours later she developed similar symptoms and a CT scan showed an enlarged and heterogeneous pancreas, with necrosis of the tail of the pancreas involving the left kidney. She responded to conservative treatment.
- A 53-year-old woman developed severe central abdominal and epigastric pain 90 minutes after taking codeine for migraine. Pancreatic amylase, lipase, and liver function tests were mildly raised. Abdominal ultrasound was consistent with acute pancreatitis.
- A 57-year-old woman developed severe abdominal pain 2 hours after taking codeine. She had had two similar episodes in the past, once with loperamide and once with codeine. An abdominal CT scan showed edematous acute pancreatitis.

© 2006 Elsevier B.V. All rights reserved.

In three of these cases unintentional rechallenge with codeine resulted in recurrence of the symptoms, and the diagnosis was confirmed radiologically and biochemically. All the patients had previously had a cholecystectomy, suggesting that this may increase the likelihood of codeine-induced pancreatitis. The authors speculated that codeine could cause a rise in biliary and/or pancreatic sphincter pressure in cholecystectomized patients, either by exacerbating pre-existing disease of the sphincter of Oddi or as a consequence of reduced storage capacity of the biliary tract, initiating acute pancreatitis. They cautioned that codeine-associated acute pancreatitis can be misconstrued—it may seem as if patients are taking codeine for pancreatic pain when in fact the codeine is producing the pain.

Skin

Rashes have been attributed to codeine.

- A 72-year-old man developed a generalized maculopapular rash 12 hours after taking co-codamol (codeine 10 mg plus paracetamol 500 mg) (8). The lesions persisted for 7 days, became scaly, and disappeared. He later reported a similar skin condition after having taken a combination of acetylsalicylic acid, codeine, and caffeine. Patch tests gave a positive result for codeine, suggesting a type IV allergic reaction.
- A 58-year-old man developed a maculopapular rash on the dorsal aspects of the hand and upper body 6 days after taking codeine as an analgesic for hemoptysis secondary to tuberculosis; on withdrawal of codeine, the rash subsided after 48 hours (9).

Two reports have highlighted the importance of using an oral provocation test and not a patch test to determine if codeine is the causative agent in non-urticarial skin lesions (10,11).

- A 58-year-old man developed a pruritic rash on the body and face, with periorbital swelling 3 hours after taking codeine 20 mg, acetylcysteine 600 mg, and acetylsalicylic acid 500 mg. An oral provocation test over 2 hours with codeine phosphate (1 mg, 4 mg, and 8 mg) precipitated a pruritic scarlatiniform rash for 24 hours, with swelling of the arms, starting 7 hours after the 8 mg dose. A rechallenge test confirmed the effect of codeine. Throughout this period, histamine release tests (CAST-ELISA with codeine) were negative.
- A 57-year-old patient presented with generalized malaise, fever, pruritus, and palpebral and labial angioedema 6 hours after taking a tablet containing paracetamol 500 mg, saccharin 10 mg, and codeine phosphate 30 mg. There was complete resolution in 8 hours, after treatment with prednisolone, hydroxyzine, and metamizole. Later a patch test with 1% codeine and an oral provocation test with paracetamol were both negative. Following an oral provocation test with codeine 5 mg, the patient developed similar symptoms.

Immunologic

True allergy to opioids is extremely rare. However, a near anaphylactic reaction in a patient taking codeine has been reported; the management of true codeine allergy was discussed and agents with different structures, such as phenylpiperidines or methadone-like compounds, are recommended (SEDA-17, 80).

Long-Term Effects

Drug abuse

Recreational use and abuse of codeine cough syrup is becoming more frequent. In a literature search of scientific journals and news media, complemented with in-depth interviews of 12 professionals working in the law enforcement or treatment aspects of drug abuse and 25 adults who reported using codeine syrup in the 30 days before their interview, the information provided useful insights into the different types of cough formulations, the reported reasons for their use, and the various types of administration (12). The effects of cough syrup, including their adverse effects, were reported. The most frequently mentioned negative effects included taste disturbance, prolonged sedation beyond the desired effect, loss of co-ordination, lethargy, constipation, and urinary retention. This qualitative study cannot be described as authoritative or representative, because of its limited nature, involving as it did only a small number of individuals living in the Houston area.

Drug dependence

In an exploratory survey among long-term codeine users recruited via newspaper advertisements in Toronto, Canada, more than 300 individuals who used codeine on at least 3 days per week for a minimum of 6 months and were older than 16 years were studied (13). Those who used codeine for pain related to malignancy were excluded. The mean age of the respondents included in the final analysis ($n = 339$) was 44 years and 51% were women. On average, the total number of years of regular codeine use was 12, with a current mean daily dose of 115 mg. About 60% ($n = 213$) had sought help for mental health problems, most commonly for depression (70%), followed by generalized anxiety (55%) and panic attacks (24%). One-third of the subjects ($n = 339$) identified at least one family member as having a mental health problem, with depression as the most frequent. Current antidepressant use was reported by 14% of the whole sample. Men used significantly higher doses of codeine than women; they also used the drug for a longer period and more commonly took it for pleasurable effects and under social pressure. Regular codeine users, in addition to having high rates of drug dependence, had raised scores on general measures of psychological distress and depressive symptoms. From the survey it was not clear to what extent these symptoms preceded codeine use and may have initiated the use and to what extent they were caused by codeine. The authors speculated that many respondents used codeine to modulate mood, particularly dysphoria, in the absence of more appropriate interventions. They suggested that understanding long-term codeine use and its relation to dysphoria may be

© 2006 Elsevier B.V. All rights reserved.

important in designing both preventive and secondary treatment interventions.

The same investigators further analysed the data according to codeine abuse/dependent and non-dependent status (14). There was codeine abuse/dependence in 41% of the subjects. The most common psychological and physical problems attributed to codeine use in the dependent/abuse group ($n = 124$) were depression (23%), anxiety (22%), gastrointestinal disturbances (15%), constipation (6%), and headache/migraine (5%). The codeine-dependent subjects were younger than those who were not dependent. The mean age of the respondents when they first started using codeine was 26 (range 2–78) years. A total of 563 codeine products had been used on a regular basis; the most common combination involved codeine with paracetamol (70%). Codeine was used for headaches (41%), back pain (22%), and other types of pain (25%). Those in the dependent group were more likely to have used codeine initially for other reasons, for example for pleasure and to relax or reduce stress. Most subjects said that they had obtained their codeine from one physician (66%) or by purchasing it over the counter (54%). Subjects in the dependent group also obtained codeine from friends (32%), from family (11%), "off the street" (19%), and through prescriptions from more than one physician (11%). Overall, more subjects in the dependent group considered themselves to have problems with a larger number of substances (3.3: range 0–15) compared with those in the non-dependent group (1.2: range 0–8). In the dependent group, more subjects said that their physical or mental health problems interfered with normal social activities at least "quite a bit." Significantly more subjects in the dependent group had sought help for a mental health problem, had had an inpatient psychiatric admission, or had sought help for a substance-use disorder, especially alcohol and stimulants. A larger number of subjects in the dependent group identified at least one family member (usually male) with substance-use problems compared with those in the non-dependent group.

This study suggests that codeine dependence may be more common in the general population than has been previously thought. The authors suggested that it is important to identify those with codeine abuse or codeine dependence, since they may be using substantial doses of codeine for apparently little benefit compared to the risks. Furthermore, there are also health risks of associated chronic use of paracetamol and a potential for analgesic rebound headache.

Drug Administration

Drug dosage regimens

In a comparison of the adverse effects of 30, 60, and 90 mg codeine the most frequent adverse effects, headache, drowsiness, nausea, thirst, and a feeling of strangeness, occurred after 60 and 90 mg doses only. Visuomotor co-ordination was altered with 60 and 90 mg and dynamic visual acuity with 90 mg only (15).

Drug–Drug Interactions

Amitriptyline

There were signs of opiate toxicity, reversible with naloxone, in an 80-year-old woman after concomitant treatment with amitriptyline and co-codamol (codeine plus paracetamol) (SEDA-18, 79).

Inhibitors of CYP2D6

Inhibitors of CYP2D6 can reduce or abolish the analgesic effects of codeine (16).

Quinidine

Quinidine inhibits the hepatic metabolism of codeine to morphine. Whether this diminishes or abolishes the analgesic effect of codeine is uncertain (17,18).

Co-dergocrine

General Information

Co-dergocrine is the British Approved Name for a formulation that contains a combination of dihydrogenated ergot alkaloids: dihydroergocornine mesilate, dihydroergocristine mesilate, and (in the ratio 2:1) α- and β-dihydroergocryptine mesilates. It has been used for its supposed therapeutic effects on mood depression, confusion, and lack of self-care in the elderly, and purportedly acts by improving cerebral blood flow. The basis of these indications has been reviewed and has not been fully validated (1)(2)(3).

Surprisingly few adverse effects have been reported. They include sinus bradycardia, nausea, and a single report of vasospastic angiitis (4).

Colchicine

General Information

Colchicine is an antimitotic agent, highly effective in the treatment of gout, but associated with considerable toxicity. Diarrhea is used as a criterion for adequate dosage. Accidental overdosage occurs relatively often and can be dangerous. For these reasons, NSAIDs (except aspirin) are often used in acute gout instead of colchicine.

There is controversy about the long-term toxicity of colchicine. In familial Mediterranean fever, low dosages of colchicine (1–2 mg/day) for 15–18 years have been well tolerated, even by young patients (SEDA-16, 114).

Organs and Systems

Nervous system

Neuropathy, polyneuritis, toxic encephalitis, delirium, and coma have occurred only in severe colchicine intoxication. During prolonged treatment, neuritis, muscular weakness and myopathy occur more commonly than was previously thought in patients with impaired renal function. In some cases the neuromyopathy was part of multiorgan system failure, but in others the syndrome was not accompanied by other features of colchicine toxicity. Patients taking long-term colchicine should take low dosages (probably no more than 0.6 mg/day) and have their serum creatine kinase monitored (SEDA-12, 94).

Metabolism

Transient diabetes and hyperlipidemia have been reported. Metabolic acidosis is probably a consequence of heavy, cholera-like diarrhea. Progressive reduction of libido was attributed to colchicine in patients with familial Mediterranean fever (1).

Electrolyte balance

Water and electrolyte disturbances, including inappropriate antidiuresis, can occur in patients who have taken high doses of colchicine (2,3), including hypernatremia and polyuria (4).

Hematologic

Bone marrow depression is common after colchicine overdose and intoxication and less common in therapeutic doses. Fatal cases of agranulocytosis are more often associated with bone marrow aplasia (SEDA-4, 70) (5). Bone marrow depression usually occurs between the third and sixth days of acute intoxication. Cytoplasmic inclusions in neutrophils and megaloblastic anemia have been described. Administration of therapeutic doses intravenously and orally to two patients with reduced renal function caused profound prolonged neutropenia complicated by septicemia, which ended in death (SEDA-13, 84).

© 2006 Elsevier B.V. All rights reserved.

Gastrointestinal

Gastrointestinal symptoms often develop after therapeutic doses and are even used for dose titration. Diarrhea is often followed by nausea, vomiting, and abdominal pain. Long-term therapy can provoke steatorrhea, malabsorption, and defects in intestinal enzyme activity (6).

Urinary tract

Acute renal insufficiency has been associated with colchicine intoxication (7).

Skin

Blood dyscrasias are associated with ecchymosis and purpura. Allergic skin changes are rare. Alopecia is common after acute intoxication and prolonged treatment (SEDA-5, 109). A fixed drug eruption has been reported (SEDA-21, 109).

Musculoskeletal

Acute rhabdomyolysis with fever, muscle cramps, rises in creatine phosphokinase and lactic acid dehydrogenase activity, phlebitis at the injection site, and transitory leukopenia and thrombocytopenia have been reported (8).

Second-Generation Effects

Fertility

Reversible azoospermia (later not confirmed) was observed after long-term treatment with colchicines (9).

Pregnancy

Owing to its antimitotic properties, colchicine should not be given during pregnancy (SED-9, 158) (10).

Susceptibility Factors

Renal disease

The dosage of colchicine should be adjusted according to creatinine clearance during long-term use to avoid the risk of myoneuropathy (SEDA-16, 114). Colchicine should not be used in patients undergoing hemodialysis, since it cannot be removed by either dialysis or exchange transfusion (11).

Drug Administration

Drug administration route

Intravenous administration is potentially much more toxic than oral administration; because of its unfavorable benefit to harm, balance and the availability of less dangerous treatments, colchicine should not be given intravenously (SEDA-5, 109) (SEDA-13, 84) (SEDA-16, 115).

Drug overdose

Acute intoxication with colchicine occurs relatively often, because the therapeutic dose is close to the toxic dose. Gastrointestinal, hematological, and neurological reactions are the most frequent effects (SEDA-7, 118). An accidental overdose of colchicine by nasal insufflation has been reported in a young male drug abuser who had mistaken it for metamfetamine. The effects included gastrointestinal distress, myalgia, thrombocytopenia, hypocalcemia, and hypophosphatemia (12). Electrolyte disturbances can occur (2–4). Deaths have been reported (3).

Drug–Drug Interactions

Ciclosporin

Acute reversible ciclosporin toxicity occurred in a renal transplant patient a few days after colchicine was administered for an acute attack of gout (SEDA-16, 115). Other potential adverse effects of combining colchicine with ciclosporin include diarrhea, increases in serum liver enzymes, bilirubin, and creatinine, and less often severe myalgia (SEDA-19, 101). Acute myopathy, associated with neuropathy in one case, has been observed in two young renal transplant recipients (SEDA-22, 119).

Collagen and gelatin

General Information

Collagen is a natural fibrous protein found in human cartilage, connective tissue, and bone. Glutaraldehyde cross-linked bovine collagen is a sterile, biocompatible, biodegradable, purified bovine dermocollagen cross-linked with glutaraldehyde, mixed in a phosphate-buffered saline solution.

Purified solubilized bovine collagen is used as biomaterial for the treatment of soft tissue defects and has been used for the treatment of stress urinary incontinence since the late 1980s (1). Injected material precipitates at body temperature, forming a matrix allowing fibroblastic infiltration and formation of new tissue. It has been used for cosmetic purposes by injection in the dermis to correct scars and other contour deformities of the skin.

Urethral injection of bovine collagen under local anesthesia is considered safe and effective, with minimal complications (2,3). It has low antigenicity and is associated with a minimal inflammatory response, although foreign body reactions have occasionally been reported (4). However, antibody formation is not impossible (5). Patients with a history of allergic reactions to bovine collagen-derived products should be investigated because of the widespread use of collagen-derived therapeutic devices, the potential for immunological cross-reactivity with dietary collagen (gelatin), and the potential for anaphylaxis.

Gelatin is an important constituent of many drug formulations, including capsules and suppositories. It is also found in some volume replacement solutions (for example Gelofusine). Gelofusine is a colloidal plasma volume expander used in the treatment of hypotension. It is prepared from bovine collagen. Severe anaphylactoid reactions after gelofusine occur with an incidence that has been reported at between 0.066 and 0.345% of cases. They are more common in those with known drug allergy and in men. The mechanism may be triggering of non-immune complement C3 activation by colloid particles in the gelatine formulation or by combination with components in the patient's blood (6).

Organs and Systems

Cardiovascular

Hypotension has been described in a patient who received 500 ml of gelofusine during surgery for an infrarenal abdominal aneurysm (7). Within 5 minutes there was a significant fall in blood pressure, in the absence of surgical bleeding and ischemic changes on the electrocardiogram. There was no change in oxygenation. A further 500 ml of gelofusine was rapidly infused, with an additional fall in blood pressure to 50/30. Subsequently, after recovery, a small test dose (100 ml) of gelofusine reproduced the transient hypotension.

A patient undergoing anesthesia for coronary artery bypass surgery developed a probable anaphylactic reaction to Gelofusine (8). The principal feature of the reaction was cardiovascular depression. An infusion of the angiotensin analogue angiotensinamide was effective in treating the reaction.

Urinary tract

Few complications of urethral injection of collagen have been reported, including urinary tract infection, bleeding, and transient urinary retention. During a prospective, cohort study in 337 women to determine the effectiveness of and adverse effects associated with transurethral collagen injection for treatment of stress urinary incontinence, there were three cases of delayed allergic reactions at the skin test site associated with arthralgia (9). Delayed reactions at the skin test site occurred in three patients (0.9%), and were associated with arthralgias in two. The incidence and systemic nature of this type of reaction led the authors of the study to conclude that glutaraldehyde cross-linked collagen injection is not as innocuous as previously believed, and clinicians were advised to consider double skin testing before treatment. The overall risk of complications in any given individual of this study population was 20% (1), although irritating lower urinary tract symptoms after collagen injection could be related to local inflammatory changes, persistence and eventually worsening of these symptoms should suggest the presence of iatrogenic bladder outlet obstruction (10). Urethral prolapse (11) and unusually long collagen persistence (12) after periurethral collagen injection have also been reported.

Immunologic

Bovine collagen is contraindicated in patients with immunological disorders and reports of delayed allergic reactions underline the need for adequate follow-up when collagen implants are used. Patients should be tested with bovine collagen and reassessed at 4 weeks. About 3% of the patients tested in this way developed hypersensitivity reactions to collagen, whereas 1% of treated patients have symptoms of hypersensitivity at treatment sites (13). In this series, erythema was the sole symptom in 24%, and erythema and induration occurred in an additional 42%. Of the patients with complications, 45% reported an onset of symptoms within 10 days while in 22% the onset was more than 30 days following treatment with collagen. Abscesses as a manifestation of hypersensitivity to bovine collagen occur rarely (four in 10 000 cases), but the possibility of contamination should always be considered. Local tissue necrosis occurs rarely after implantation (nine reported in 10 000 cases) and this is thought to be the result of local vascular interruption rather than a hypersensitivity reaction. The incidence varies widely according to the site of implantation, but more than one-half of the cases involve the glabellar region, probably because of its special vascular distribution (14).

Anaphylactic reactions to collagen have been described (15). Despite pretreatment collagen testing, anaphylactic shock has been reported in one patient, necessitating adrenergic agents and glucocorticoids.

An allergic rash has been described after collagen injection (16).

© 2006 Elsevier B.V. All rights reserved.

Delayed hypersensitivity reactions after bovine collagen injection for stress urinary incontinence have been reported.

- A 50-year-old woman had a negative collagen skin test for 4 weeks (9). After an injection of transurethral collagen, she developed a flare-up at the skin test site and subsequently had recurrent flares at 21–26 day intervals for six cycles, which corresponded to her menses and were thought to be hormone-related.
- A 64-year-old woman with recurrent urinary leakage elected to undergo conservative therapy with collagen injection, had no reaction to a collagen skin test, and had an uneventful transurethral injection of collagen 30 days later (17). Her postoperative course was complicated by urethritis, trigonitis, severe urge, bilateral leg arthralgias, leg pain relieved by massage, and leg edema at 6 weeks. She had a total voided volume of 300 ml and a postvoid residual of 180 ml, and was started on intermittent self-catheterization for urinary retention. Induration at the skin injection test site was noticeable 9 weeks after the injection. Her severe urge, leg edema, and pain gradually resolved after 13 months, but her stress incontinence continued without relief.
- A 50-year-old woman with stress urinary incontinence chose a trial of transurethral injection of collagen (18). A skin test showed no evidence of allergy at 1 month and collagen 2.5 ml was injected transurethrally without problems but with little improvement. A second injection of 2.5 ml 5 weeks later was again uneventful, but 2 weeks later she began to have difficulty in emptying her bladder, with a poor stream and a sense of incomplete emptying. At the same time she noticed redness and firmness at the initial skin test site on her arm, which had previously been benign.

Several reports have highlighted the importance of gelatin allergy in young children, with some deaths due to anaphylaxis. Elsewhere, anaphylactoid reactions have been reported to gelatin-containing injectables (SEDA-20, 310).

- A 2-year-old and a 4-year-old boy developed anaphylactic symptoms after being given a chloral hydrate suppository, which contained gelatin, for sedation before electroencephalography (19).

The authors suggested using gelatin-free formulations in children.

Complementary and alternative medicine

General Information

Complementary and alternative medicine (also referred to as "non-orthodox," "unconventional," "holistic," and "integrative" medicine) comprises a heterogeneous array of treatments, from acupuncture to spinal manipulation

© 2006 Elsevier B.V. All rights reserved.

and from herbal medicine to homeopathy. The techniques covered in this monograph are:

- Acupuncture
- Aromatherapy
- Cell therapy
- Homeopathy
- Hypnosis
- Manipulation
- Massage.

Herbal products and animal products are covered in separate monographs.

Complementary medicine continues to be a growth area (1). A survey conducted in South Australia showed that almost half of the 3004 respondents had used at least one type of complementary remedy in the previous 12 months and that one-fifth had consulted a practitioner of complementary medicine (2). In European countries for which estimates on the annual utilization of complementary medicine are available, estimates range from 20 to 50% of the population (3). In the UK, retail sales of complementary medicines (licensed herbal medicines, homoeopathic remedies, essential oils used in aromatherapy) were estimated to be £72 million in 1996, an increase of 36% in real terms since 1991 (4). This, however, is likely to be a gross underestimate as popular products sold as food supplements, including *Ginkgo biloba* and garlic, were not included. According to a detailed analysis of the herbal medicines market in Germany and France, total sales of herbal products in those countries in 1997 were US$1.8 billion and US$1.1 billion respectively (5). In 1994, annual retail sales of botanical medicines in the US were estimated to be around US$1.6 billion; in 1998, the figure was closer to US$4 billion (6).

Some of the most useful data on trends in complementary medicine use come from two surveys of US adults carried out in 1991 and 1997/8, which involved over 1500 and over 2000 individuals respectively (7,8). The use of at least one form of complementary therapy in the 12 months preceding the survey increased significantly from 34% in 1990 to 42% in 1997 (8) and in November 1998 all 10 journals of the American Medical Association published theme issues on the subject.

The reasons for the popularity of complementary medicine are many and diverse. It appears that complementary medicine is not usually used because of an outright rejection of conventional medicine, but more because users desire to control their own health (9) and because they find complementary medicine to be more congruent with their own values, beliefs, and philosophical orientations toward health and life (10). Also, users may consult different practitioners for different reasons (9). An important reason for the increase in use is that consumers (often motivated by the lay press) consider complementary medicine to be "natural" and assume it is "safe." Of all patients attending an emergency department in the USA 43% had used at least one complementary therapy at some time and 24% were current users (11). All complementary treatments were considered to be safe by 16% of the patients and 33% of all users failed to tell their physicians. Furthermore, 15% of the women and 7% of the men believed that complementary therapies do not interact with other medications. As the popularity of complementary medicine rises, so does the research interest in this subject (12), including research into direct and indirect risks (13–15).

However, this notion is dangerously misleading; adverse effects have been associated with the use of complementary therapies (16). Furthermore, complementary therapies may not only be directly harmful (for example adverse effects of herbal formulations), but like other medical treatments have the potential to be indirectly harmful (for example through being applied incompetently, by delaying appropriate effective treatment, or by causing needless expense) (17).

The efficacy of many complementary therapies is largely unknown, and more definitive evidence is urgently needed (18). Like any other interventions, complementary therapies are associated with adverse effects, and for responsible therapeutic decision-making, the balance of benefits and harms must be considered (19).

Incidence of adverse effects

Most of the data on adverse effects associated with complementary therapies is anecdotal, and assessment and classification of causality is often not possible. Likewise, there have been few attempts to determine systematically the incidence of adverse effects of non-orthodox therapies.

Two prospective interview surveys have generated incidence figures for adverse effects associated with chiropractic treatment. In a Norwegian investigation (20), 102 chiropractors were asked to monitor 1058 new patients. At least one adverse effect was reported by 55% of the patients at some time during the course of a maximum of six treatments. The most common adverse effects were local discomfort (53% of total), headache (12%), tiredness (11%), or radiating discomfort (10%). A Swedish survey used similar methods to monitor 1858 chiropractic consultations and demonstrated an incidence rate for adverse effects of 44% (21). In both studies, all effects noted were mild and transient; no serious effects were recorded.

In a prospective Japanese survey of adverse effects of acupuncture, 55 291 treatments were monitored between 1992 and 1997 (22). There were 64 adverse events in all; none was serious or led to permanent damage.

General adverse effects

Even a perfectly safe remedy (mainstream or unorthodox) can become unsafe when used incompetently. Medical competence can be defined as doing everything in the best interest of the patient according to the best available evidence. There are numerous circumstances, both in orthodox and complementary medicine, when competence is jeopardized:

- missed diagnosis
- misdiagnosis
- disregarding contraindications
- preventing/delaying more effective treatments (for example misinformation about effective therapies, loss of herd immunity through negative attitude towards immunization)

© 2006 Elsevier B.V. All rights reserved.

- clinical deterioration not diagnosed
- adverse reaction not diagnosed
- discontinuation of prescribed drugs
- self-medication.

The most obvious danger is that some patients (or their parents) may elect to abandon conventional therapies for serious diseases in favor of alternative approaches. This can have fatal consequences (23). Survey data suggest that a sizeable proportion of complementary practitioners advise their clients to reduce their prescribed medication (24).

Diagnostic techniques can also cause serious risks; an example is the apparent over-use of X-rays by chiropractors (25). Although this practice seems to be in decline, it can put patients at risk through the mutagenic effects of X-rays.

The attitude of consumers towards complementary medicine may also constitute a risk. When 515 users of herbal remedies were interviewed about their behavior vis-a-vis adverse effects of herbal versus synthetic over-the-counter drugs, a clear difference emerged. While 26% would consult their doctor for a serious adverse effect of a synthetic medication, only 0.8% would do the same in relation to an herbal remedy (26). A further risk might lie in the plethora of lay books on complementary medicine now available in every High Street bookstore. A pilot project has attempted to evaluate the value of a random selection of such books and concluded that the lay literature on complementary medicine is far from adequate and has the potential to put the health of the reader at risk (27).

The fear has been expressed that "with the increased interest in alternative medicine, we [shall] see a reversion to irrational approaches to medical practice" (28). The only way to minimize incompetence is proper education and training, combined with responsible regulatory control. While training and control are self-evident features of mainstream medicine they are often not fully incorporated in complementary medicine. Thus the issue of indirect health risk is particularly pertinent to complementary medicine. Whenever complementary practitioners take full responsibility for a patient, this should be matched with full medical competence; if on the other hand, competence is not demonstrably complete, the practitioner in question should not assume full responsibility (29).

Misinformation

More and more patients seek advice on complementary medicine via the Internet. It is therefore important to monitor the validity of such advice. In one survey, most of the 13 most popular websites on complementary medicine for cancer recommended cancer therapies for which there was no evidence of efficacy (30). Three of the sites overtly discouraged cancer patients from using conventional therapies. When the study was repeated, this time focussing on HIV instead of cancer, the results were virtually identical (31). These findings were similar to those of another study of 61 popular websites on herbal medicines for cancer (32). Most of these sites were commercial by nature and claimed cancer cures through herbal medicines, with little regard for current regulations.

Herbalists readily volunteer advice about the administration of herbal medicines during pregnancy, but the nature of their advice is misleading at best and dangerous at worst (33). Others have studied the impact of herbal medicine on the use of conventional treatments (34). Their results showed that 32% of female patients in internal medicine delayed obtaining conventional care while waiting for an herbal medicine to work.

Attitudes to immunization

The indirect risks of complementary medicine are grossly under-researched, and at present we can but guess the size of the problem (35). There are, however, particular aspects on which some data do exist. One is the attitude of practitioners towards immunization. The majority of homeopaths (36–38) and chiropractors (39) are unconvinced of the benefit of immunization. They claim that it causes more illness than it prevents disease and advise, in many instances successfully, their patients against it (40).

When 1593 visitors to a "health fair" were surveyed on their use of complementary medicine, it emerged that elderly users were significantly less likely to use influenza immunization (41). Students of a Canadian chiropractic college were questioned about whether they agreed with immunization in general. The longer they had attended college, the less favorable their attitude toward immunization became (42). An analysis of the contents of 22 leading anti-immunization websites showed that about 70% of these sites claimed that homeopathy represented an alternative to conventional vaccination (43). In a similar study it was found that 39% of the anti-immunization websites claimed that natural lifestyle conveys immunity to infections, thus allegedly rendering immunization unnecessary, and 45% claimed that "alternative health" is superior to immunization (44). In another study homeopaths and chiropractors were specifically asked about their advice regarding MMR immunization; 40% of the homeopaths and 19% of the chiropractors admitted advising mothers against it (45).

This attitude not only exposes individual patients to unjustifiable risks, but also jeopardizes herd immunity, thus representing a threat to public health. A homeopathic remedy might be totally safe, but the homeopath might not be (46).

Acupuncture

On a global basis, acupuncture is one of the most commonly used forms of complementary and alternative medicine. It is used predominantly to alleviate pain, but many other indications have been proposed. Contrary to prevailing public opinion it is not entirely risk free (47). Several review articles have addressed this issue, and it has been pointed out that tissue trauma (for example pneumothorax) and infections (for example hepatitis B) are the most common complications of acupuncture (48). Both are rare and both could be avoidable with adequate training and experience of acupuncturists.

Acupuncture can cause various minor adverse effects (49) and there have been many reports of serious complications (Table 1). The authors of a review of the risks

© 2006 Elsevier B.V. All rights reserved.

Table 1 The most common serious complications of acupuncture

Condition	Number of cases in the world literature
Cardiac trauma	<10
Contact dermatitis	<10
Drowsiness	~100
Endocarditis	<10
Erythema	<10
Hepatitis	~130
Perichondritis	~10
Peripheral nerve injury	<10
Pneumothorax	>90
Renal injury	~20
Retained needle	~10
Septicemia	<10
Spinal cord injury	~20
Syncope	~50

associated with acupuncture mentioned pneumothorax (more than 90 cases on record), cardiac tamponade ($n = 6$), injuries of the spinal cord ($n = 10$), and infections ($n = 126$), particularly hepatitis (50).

Some reports of complications after acupuncture are summarized in Table 2.

Acupuncture keeps being associated with serious adverse events (61), and several attempts to define the size of this problem more closely have been published.

In a prospective investigation of the adverse effects of Japanese acupuncture, all adverse effects experienced by patients in an acupuncture clinic seen between November 1992 and October 1997 were recorded (22). There were 64 adverse events. Failure to remove the needles, dizziness, discomfort, and sweating were the most frequent adverse reactions. There were no serious adverse events. These data suggest that superficial needling as used in Japanese acupuncture is relatively safe.

A Japanese survey of 391 patients who received acupuncture in 1441 treatment sessions involving a total of 30 338 needle insertions showed the following systemic adverse effects: tiredness (8.2%), drowsiness (2.8%), aggravation of the presenting condition (2.8%), itching in the punctured region (1.0%), dizziness or vertigo (0.8%), faintness or nausea during treatment (0.8%), headache (0.5%), and chest pain (0.3%) (62). The incidences of local reactions were: minor bleeding after withdrawal of the needle (2.6%), pain on insertion of the needle (0.7%), petechiae or ecchymoses (0.3%), local pain after treatment (0.1%), subcutaneous hematomas (0.1%).

Norwegian researchers sent questionnaires about acupuncture to a random sample of the Norwegian general population (63). Of the 653 respondents, 7% claimed to have had adverse effects. The most common were dizziness, fatigue, and pain from the needles. No serious adverse effects were reported.

In a prospective UK survey of members of the medical and physiotherapy acupuncture organizations in Britain the preliminary data included 25 500 treatments given by 77 acupuncturists (64). There were 29 major events, including four episodes of loss of consciousness and one tonic-clonic seizure. The most common minor events were bleeding or hematoma (3%), aggravation of symptoms (1%), and pain during needling (0.9%).

In a survey of 1100 Australian providers of traditional Chinese medicine the adverse events of acupuncture were also monitored (65). There were 3222 events, including 64 cases of pneumothorax and 80 convulsions. No deaths were recorded.

A systematic review of case reports from the Japanese literature yielded 105 cases of suspected acupuncture adverse effects not previously reported in Western publications (66). These included 21 spinal lesions, 21 cases of pneumothorax, 19 infections, 15 cases of foreign bodies in organs, 10 instances of argyria, 10 neural injuries, and 11 other adverse events, including two cases of cardiac tamponade.

A systematic review of all prospective studies of adverse effects associated with acupuncture included nine primary investigations (67). The most commonly reported adverse events were needle pain (1–45%), tiredness (2–41%), and bleeding (0.03–38%). Pneumothorax was the only serious complication in these studies; it was reported twice in about 250 000 patients.

Table 2 Reports of adverse events associated with acupuncture

Indications	Adverse event	Site of acupuncture	Causality	Reference
Presumably local pain	A closed ankle fracture was converted to an open fracture and open joint by acupuncture	Local	Likely, but insufficient details reported	(51)
Intermittent claudication	Occlusion of the popliteal artery	Local	Likely	(52)
Back pain	Rupture of a pseudoaneurysm	Local	Likely	(53)
Arthritis	Pneumothorax	The neck	Likely	(54)
Shoulder stiffness	High cervical epidural abscess and vertebral osteomyelitis	Posterior nuchal region	Fairly certain	(55)
Not stated	Peritemporomandibular abscess	Local	Fairly certain	(56)
Back pain	Unilateral septic sacroileitis	Local	Likely	(57)
Arthritis	Death due to streptococcal toxic shock-like syndrome	Right shoulder	Probable	(58)
Back pain	Argyria 10 years after acupuncture with a silver needle	Ear	Possible	(59)
Stroke (2 cases)	Angina pectoris during electroacupuncture	Scalp	Possible	(60)

© 2006 Elsevier B.V. All rights reserved.

Two prospective UK studies with a total of about 70 000 consultations have confirmed that serious adverse events of acupuncture are true rarities in Britain (68,69). Bleeding and needle pain were the most frequent adverse events, with a prevalence of about 1:1000.

A systematic review of all adverse events associated with acupuncture in the Japanese medical literature located 124 cases (70). These included 25 cases of pneumothorax, 18 cases of spinal cord injury, 11 cases of hepatitis B, and 10 cases of localized argyria.

- An 82-year-old woman was scheduled for gastrectomy with an epidural anesthetic (71). She had previously had many acupuncture treatments with a Japanese technique (okibari), in which small needles are left in situ. Her preoperative chest and abdominal X-rays showed hundreds of needles around the vertebrae. The anesthesiologists feared that an epidural anesthetic might lead to spinal cord injury or pneumothorax, and general anesthesia was chosen instead.

Cardiovascular

Acupuncture has been associated with hemopericardium due to ventricular puncture (72).

- An 83-year-old Austrian woman developed syncope and cardiogenic shock shortly after acupuncture over the sternum. Echocardiography showed cardiac tamponade and pericardiocentesis revealed hemopericardium. At operation a small bleeding perforation of the right ventricle was found and closed. The acupuncture at the point "Ren 17" was above a sternal foramen, which allowed the needle to penetrate the heart.

A case in which acupuncture was apparently responsible for cardiac dysrhythmias has been reported (73).

Respiratory

Pneumothorax has been reported in association with acupuncture (74,75).

- A 28-year-old Chinese woman developed bilateral pneumothoraces after receiving acupuncture in the upper thoracic and paraspinal regions (75). She was treated conservatively and was discharged after 2 days.
- A 30-year-old woman developed bilateral chest pain and dyspnea after paraspinal acupuncture resulted in bilateral pneumothorax; she recovered fully within 2 days (76).

Nervous system

Acupuncture has been associated with subarachnoid hemorrhage due to arterial puncture (77).

- A 44-year-old Chinese man had severe occipital headache, nausea, and vomiting during acupuncture in the posterior neck. A CT scan showed hemorrhage in the third, fourth, and lateral ventricles, and blood was found in the lumbar fluid. The problem was due to puncture of a branch of the vertebral artery at the "feng fu" point, which coincides with the site for performing cisternal puncture. The patient made a spontaneous full recovery within 28 days.

Convulsions, inadvertent anesthesia, loss of co-ordination, and tinnitus have been associated with acupuncture (78).

Endocrine

Galactorrhea has been associated with acupuncture.

- A 41-year-old woman with breast cancer was treated with acupuncture for pain control (79). She had an episode of galactorrhea 6 days after the first treatment and also during the second acupuncture treatment. No reason for this unusual phenomenon other than acupuncture could be found.

The authors pointed out that in Chinese medicine acupuncture at the points used in this patient promotes lactation.

Skin

Acupuncture needles can cause local reactions (80).

- A 55-year-old Japanese woman developed papules at sites where she had had acupuncture 4 years and 3 weeks before. Histological examination showed that the papules were silicone granulomas.

The authors postulated that the papules were reactions to the silicone from the coating of the acupuncture needles.

Skin malignancy (78) and Koebner phenomenon (81) have been associated with acupuncture.

- A 52-year-old man received acupuncture in the backs of both hands for chronic back pain and subsequently developed bilateral swelling of both hands and fingers (82).

No reason for this adverse effect could be found, and the authors considered infection or allergy as the most likely cause, but without finding strong evidence of either.

- A 59-year-old woman presented with a 1-month history of non-pruritic papules on the dorsa of both feet (83). During the previous year she had repeatedly received acupuncture in this area. A biopsy showed mixed lichenoid, spongiotic, and granulomatous dermatitis. Ultrastructural examination showed macrophages containing silicone. At follow-up new lesions on her mid calves were noted, and again she explained she had recently received acupuncture at these sites.

It was discovered that the acupuncturist used silicone-coated needles and silicone deposition was thus caused by acupuncture.

Immunologic

Allergies to the various metals used in acupuncture needles have been described (84).

Infection risk

Acupuncture needles must be handled meticulously to guarantee sterility of the needle on insertion. If such safety rules are not strictly adhered to, there is a high risk of transmitting infectious diseases. In principle one can assume that any blood-borne infection is transmittable through the misuse of acupuncture needles.

© 2006 Elsevier B.V. All rights reserved.

Bacterial infections

Osteomyelitis (85), endocarditis (86,87), or generalized *Staphylococcus aureus* infections (88) have been associated with acupuncture.

- A 67-year-old Japanese man was treated with "depot acupuncture," an unusual technique involving the implantation of a sheep gut thread through a spinal anesthesia needle into the abdomen (89). He subsequently developed intractable pain, high fever, and other signs of infection. A CT scan showed a low density mass in the left psoas muscle and the ventral portion of the distal aorta, corresponding to an abscess and a false infected aneurysm. The affected part of the aorta was replaced with a Gore-Tex graft and the patient was treated with antibiotics. He eventually made a full recovery.

In a review of serious complications there were three cases of infection, one of auricular perichondritis that resulted in permanent disfigurement, one of bacterial meningitis with full recovery, and one of pyarthrosis also with full recovery (90).

Microbiologists from Hong Kong have reported four cases of mycobacterial infections within 2 years (91). All the patients had lesions at acupuncture points. Acid-fast bacilli were present in two cases. Gene sequencing identified the strain from two patients as *Mycobacterium chelonae* and from two patients as *Mycobacterium nonchromogenium*.

- A 37-year-old man with diabetes had septicemia and compartment syndrome of the leg after acupuncture in the calf area (92). Decompression fasciotomy was performed and Gram-positive cocci were grown from the wound swab and group A streptococci from blood cultures. He required intensive care, including intravenous antibiotics, and eventually recovered.
- Endophthalmitis occurred in a patient from Singapore (93). Group B streptococci were isolated from the blood. Despite aggressive intravitreal antibiotic therapy the affected eye lost its light perception.
- A 79-year-old woman presented with induration of the right leg three months after receiving acupuncture in this area (94). Radiography showed a focal dystrophic calcification at this point and histological studies showed suppurative granulomatous inflammation with microabscesses and caseous necrosis due to infection with *Mycobacterium chelonae*. She made a full recovery after antibiotic treatment.
- A 42-year-old woman with Marfan's syndrome, who had previously had an aortic root and valve replacement, presented with fever and polyarthralgia 6 days after receiving acupuncture for back pain (95). Examination of the valve showed no abnormalities, but *S. aureus* was grown from blood cultures. Extensive investigations did not identify a cause for the infection. Her condition deteriorated despite antibiotic therapy, and emergency aortic root and valve replacement became necessary. She eventually made a full recovery.

Virus infections

In at least three published case reports, acupuncture was the only plausible explanation for infections with HIV (96,97).

Hepatitis infections may be transmitted in this way (98–100). A retrospective cohort serological study identified five confirmed cases of acute hepatitis B virus infection within 3.5 years related to one London acupuncture clinic (101). The acupuncturist was hepatitis B-positive and the strain of his virus was identical to that from the patient. Nine further patients of his had antibodies to the hepatitis B core antigen but had other risk factors for hepatitis B infection.

After a patient of a London doctor (who practiced an unusual acupuncture technique involving re-injection of native blood) acquired hepatitis B, 352 of his patients treated by this method were investigated; 33 were positive for hepatitis B antigen and 30 showed complete nucleotide identity in the DNA segments derived from the surface and core genes (102). Contaminated saline used in the treatment was identified as the probable vehicle of transmission.

An epidemiological screening program in 2231 subjects in Japan was aimed at defining the risk factors of hepatitis C infection (103). It showed that the relative risk was increased (1.30, CI = 0.65, 2.61) in those participants who had received acupuncture. A newspaper article reported that 21 confirmed cases of hepatitis B were related to a London-based physician who practiced an obscure variation of acupuncture (104).

A nationwide community-based survey in Taiwan has been carried out in seven locations in a total of 11 904 men tested for antibodies against hepatitis C virus. Exposure to acupuncture was a risk factor for hepatitis C positivity (105).

Korean epidemiologists have studied the prevalence of hepatitis C virus infection in a rural population ($n = 1033$) with a high incidence of liver cancer (106). They noted that the strongest associations in a multivariate analysis were with anti-HCV positivity and the use of acupuncture (OR = 2.2, 95% CI = 1.0, 4.7).

French investigators have evaluated the presence of serum markers of hepatitis A, B, and C viruses in a rural population of 303 volunteers (107). The main risk factors for positivity were past hospitalizations (72%), acupuncture (18%), conjugal unfaithfulness (11%), blood transfusion (9.4%), tattoos (5.8%), homosexuality (1.1%), and intravenous drug addiction (0.73%).

Trauma

If acupuncture, which entails tissue trauma, is performed properly and on the correct acupuncture points, trauma will affect only the skin and the connective tissue below. If, however, acupuncture needles are inserted at the wrong site or penetrate too deeply, other tissues or organs can be affected. Traumatic complications of acupuncture have been reviewed (108). They have been described in relation to the thoracic and abdominal viscera, in the peripheral and central nervous systems, and in blood vessels. Several deaths have been reported from pneumothorax and cardiac tamponade. The anatomical tissues at several acupuncture points are such that needles can injure vulnerable structures. Thus, good knowledge of anatomy is an essential precondition for acupuncturists.

One review identified 32 cases of pneumothorax and two of hemothorax (109). Damage to the middle ear

© 2006 Elsevier B.V. All rights reserved.

(following auriculoacupuncture), injury to the spinal cord (49), and cardiac tamponade have been other serious traumatic complications (110,111). Needles can also break while in situ, and parts of acupuncture needles have been found in patients' kidneys (112), carpal tunnel (113), cervical spine (114), spinal cord (115), and heart (116). Petechiae and other forms of bleeding have also been reported (109). If a nerve is punctured the patient might experience unnecessary pain and even sustain minor nerve damage, which in extreme cases can be persistent. In another case there was a delayed traumatic effect of an acupuncture needle fragment (117).

- A 43-year-old man developed a false aneurysm of the popliteal artery after a penetrating injury from an acupuncture needle (118). The aneurysm ruptured spontaneously, but the patient was successfully managed by vascular surgery.

A review of serious complications included one case of cardiac tamponade (with full recovery of the patient after surgery), one case of peripheral nerve damage (foot drop with residual weakness after 6 years), and three cases of pneumothorax (all with full recovery) (90).

A further case of pneumothorax has been reported (119).

- A 60-year-old woman was treated by a non-medically qualified acupuncturist for chronic rib pain. About 15 needles were inserted along either side of her back, and one (in the right lower thoracic region) caused immediate discomfort. After removal of the needle she noted pain and breathlessness. A chest X-ray 2 days later confirmed a small right pneumothorax, which resolved spontaneously within one week.

Pregnancy

Abortion and miscarriage (49) have been associated with acupuncture.

Fetotoxicity

Acupuncture in pregnant women might carry a risk for the fetus, since it is postulated that acupuncture can increase oxytocin release in the mother, which might harm the unborn child (120).

Aromatherapy

Aromatherapy is a highly popular form of complementary medicine usually entailing the application of essential plant oils to the skin by gentle massage. It has been shown to have relaxing effects but other claims have not been substantiated by reliable trial evidence (121). Allergic airborne contact dermatitis occurred in a patient who had previously used several essential oils for aromatherapy (122). The toxicity of essential oils has been reviewed (123).

Four cases of allergic contact dermatitis caused by essential oils used in aromatherapy have been described (124). A survey of UK aromatherapists (no details provided) yielded 11 reports of adverse effects (125). Most of these cases seemed to relate to allergic reactions to the essential oils. A therapist also reportedly developed an allergy to ylang-ylang oil used in aromatherapy (126).

Japanese dermatologists have reported an increase in positive patch tests to lavender oil from 1.1% in 1990 to 14% in 1998 (127). The authors argued that this rise coincided with a similar increase in the use of lavender aromatherapy in Japan and that the latter had caused the former.

See also monographs on substances that affect the skin.

Cell therapy

Cell therapy consists of the parenteral or enteral administration of cells or parts of cell obtained from animal organs and/or tissues from cattle, sheep, pigs, or rabbits. Two different types of cell preparations are in use: fresh cells, which are administered in fresh form, and dried cells or so-called sicca cells, which are prepared for later use. The most prevailing risks of cell therapy are local and generalized allergic reactions (fever, nausea, vomiting, urticaria, and anaphylactic shock). Other untoward consequences include fatal and non-fatal encephalomyelitis, polyneuritis, Landry–Guillain–Barré syndrome, fatal serum sickness, perivenous leukoencephalitis, and immune-complex vasculitis.

Homeopathy

Most, although not all, homeopathic remedies are too dilute to cause toxic effects. However, potentially toxic concentrations of arsenic (128) and cadmium (129) in homeopathic remedies have been described. Concern has also been voiced about potentially carcinogenic effects of low potencies of *Aristolochia* (130). Acute pancreatitis has been reported after the administration of a complex homeopathic formulation containing 19 different ingredients (131). Low potencies can also cause allergic reactions (132,133) and cases of severe allergic and anaphylactic reactions have been reported. In cases of concomitant drug treatments, interactions are conceivable, even though there is no published evidence on this matter. Generally speaking, adverse reactions to homeopathic medications are probably rare. However, we cannot at present tell their true incidence, as no definitive study of this has been carried out.

A systematic review of all data on the safety of such medicines has challenged the view that because homeopathic remedies are often highly dilute they are therefore devoid of adverse effects (134). It showed that in placebo-controlled trials the mean incidence of adverse effects of homeopathic remedies was 9.4%, higher than that of placebo (6.1%). All the adverse effects were minor and transient. Anecdotal reports of more serious adverse effects mainly related to aggravation of presenting symptoms, which, from the homeopathic point of view, can be looked on as confirmation that the optimal remedy has been found, and thus interpreted as a positive event. Since the homeopathic principle is that like cures like, exacerbation of symptoms by what can be presumed to be toxic doses of a supposed remedy confirms that the remedy causes the problem and will therefore cure it if given in homeopathic doses.

Harm can also be done when an ineffective homeopathic intervention replaces an effective conventional one (135).

© 2006 Elsevier B.V. All rights reserved.

- A 40-year-old woman travelling to a malaria-infested region took her homeopath's advice and was "immunized" with homeopathic remedies (*Ledum palustre* 5CH and *Malaria officinalis* 4CH) instead of taking conventional protection. She contracted malaria and had to be treated for 2 months in intensive care for multiple organ system failure due to *Plasmodium falciparum*.

Seven Israeli children were seriously harmed when their parents used homeopaths and other providers of complementary medicine instead of conventional doctors; four died (136). Similarly, it has been reported that seeing a traditional healer in Kenya increased the risk of dying from an acute pneumonia by 5.3 times (137).

The author of a review of the safety of homeopathic products concluded that they are usually safe, but that continued vigilance is in order, not least because of the currently high popularity of homeopathy (138). In response, it was pointed out that under-reporting is high, that homeopathic products are often mistaken for herbal medicines, and that the main risks of homeopathy relate to the prescriber rather than the medicine (139).

Hypnosis

Hypnosis is not usually seen as a treatment burdened with adverse effects. However, an authoritative review has reminded us that it is by no means completely safe (140). Complications include amnesia, catharsis, paralysis, disorientation, literalness of response, accelerated transference, and memory contamination. A further unwanted effect of hypnosis is an inability to dehypnotize the patient. A review of the literature has shown several such cases and has contributed two new such incidents (141).

Manipulation

Manipulative therapies (chiropractic and osteopathy) are amongst the most prevalent of complementary treatments. Spinal manipulation is carried out by chiropractors, osteopaths, physiotherapists, and other healthcare professionals to treat back and neck pain as well as other (predominantly musculoskeletal) disorders.

A literature review has provided reassurance about the relative safety of spinal manipulation (142). When the serious adverse effects of non-steroidal anti-inflammatory drugs were compared with those of spinal manipulation, both used for neck pain, manipulation emerged as being safer by more than two orders of magnitude. However, these procedures can be associated with serious complications, particularly when they involve the cervical spine (143).

In a survey of UK physiotherapists trained in spinal manipulation, 19% reported having encountered complications of spinal manipulation (144). These related mostly to the upper spine and were mostly not serious. A further survey of 686 general practitioners in the UK disclosed 28 serious adverse effects related to spinal manipulation (145).

An authoritative summary of all cases of complications of spinal manipulation of the cervical spine published since 1925 has appeared (146). There were 177 cases of severe injury. The most common injuries involved arterial dissection or spasm and brain stem lesions. In 32 instances (18%) they were fatal. The author concluded that high velocity thrusts of the cervical spine are not demonstrably associated with more benefit than harm and should therefore be avoided.

In the UK 108 consecutive patients of chiropractors were asked to complete a questionnaire, which 80% of them returned (147). Of the questionnaires 68% were suitable for analysis. Adverse effects at 1 hour after treatment were reported by 28 patients and eight had adverse effects the morning after treatment. The most common adverse effects were extra local pain or radiating pain. No serious adverse effects were reported.

Some chiropractors tend to advise clients against any type of immunization. The basis of this attitude seems to lie in early chiropractic philosophy. Eschewing the germ theory of infectious disease, this philosophy considered any disease to be the result of spinal nerve dysfunction caused by misalignment of vertebrae (148). When 150 US chiropractors were questioned about their attitude towards immunization, only 30% reported recommending childhood immunizations (149).

A systematic review of all prospective studies of the risks associated with spinal manipulation included five primary investigations (150). The most valid studies suggested that about half of all patients who see a chiropractor will have adverse effects, which are usually mild and transient. No reliable data about serious adverse events were uncovered. However, a review of recent case reports has shown that spinal manipulation was associated with several serious adverse effects, including dissection of the vertebral and internal carotid arteries, resulting in strokes and at least one death (151). Other instances relate to epidural hematoma, intracranial aneurysm, cauda equina syndrome, contusion of the spinal cord, myelopathy, radiculopathy, and palsy of the long thoracic nerve.

A report on malpractice suits in the USA has shown that in 1990–96 claims against chiropractors have been constant (between 2.3 and 3.0 claims per 100 policy holders per year) (152). There were about four times more claims against primary care physicians. The percentage of claims paid varied between 46 and 57% for the chiropractors and 29 and 33% for the physicians. The three most frequent reasons for the claims against chiropractors were disc herniation, failure to diagnose, and bone fractures produced through treatment.

The frequency with which chiropractors use radiology of the spine might be a cause for concern. Among Dutch chiropractors 40% have been reported to use X-rays "often or always" (153). In the USA, 96% of chiropractors use X-rays routinely on all new patients, and 80% use them in follow-up (154).

Cardiovascular

The Stroke Council of the American Heart Association registered 359 cases of vascular accidents until 1981 (155). In Switzerland 1255 such incidents were recorded in 1 535 000 manipulations (156). Others estimated the incidence of reported vascular accidents at 1–4 per million treatments (157–159). The mortality/severe long-term

© 2006 Elsevier B.V. All rights reserved.

impairment rate is 28% (160). The incidence is higher if minor symptoms are included and specifically searched for: out of a total of 75 500 procedures applied, 25 such cases were reported (161). The reported incidence rates are probably a gross under-estimation of the true figures; in a series of 13 cases of clinically and radiologically verified vertebral artery dissection, eight were spontaneous, two occurred after manipulation, and three occurred after minor injury (162).

The mechanisms of vascular complications of cervical manipulations involve vertebral artery dissection, intramural bleeding or pseudo-aneurysm leading to thrombosis or embolism (160) as well as transient cerebral ischemia through mechanical artery compression during cervical rotation (163) and vasospasm (164). The vertebral artery at the C1/C2 segment is most often affected. Combined rotation, extension and traction movements apparently create the highest risk, particularly when executed forcefully (165). The most frequent clinical findings are Wallenberg's syndrome (28%), other brain stem syndromes (49%), cerebellar syndromes (8%), occipital lobe syndromes (5%) and unclassified syndromes (160). They usually occur during or promptly after the intervention, but delays of hours or days have also been observed (159,166,167). Symptoms can start as headache and neck pain, which are frequent reasons for applying manipulative therapies in the first place. In at least one case neck pain was the first sign of dissection, which was treated by manipulation, resulting in a fatal stroke (168).

- Two patients had oculosympathetic palsy after self-treatment with a "shiatsu massager" (169). A thorough diagnostic work-up, including MRI and MRA scans, identified dissection of the carotid artery as the cause of the problem. In the absence of other causes, the authors believed that the self-treatment had caused dissection.
- A 32-year-old woman who had seen a traditional American "bone-setter" for shoulder problems was subjected to a "sudden thrusting of the head upward and to the right" (170). She had neck discomfort immediately afterwards. The pain persisted for 6 days, when she noted vertigo and left-sided ataxia. An MRI scan showed acute infarction in the middle left cerebellar hemisphere and vermis. An MRA scan showed left vertebral artery dissection with a probable embolus.

When all 26 cases of vertebral artery dissection during the period 1989–99 were retrospectively analysed in a tertiary Canadian academic center, possible precipitating factors were identified in 14 patients (171). Chiropractic spinal manipulation and sporting activity were the most common factors (11% and 15% respectively).

Nervous system

Several reports of nervous system adverse effects after spinal manipulation have been published (172–174). They are summarized in Table 3.

Of 13 consultant neurologists in the Republic of Ireland 11 had seen a total of 16 patients with neurological complications after chiropractic spinal manipulation within 5 years; strokes were the most frequently reported problem, and in 13 cases had led to persistent neurological deficits (175).

A survey of 177 members of the American Academy of Neurology aimed to find out how many adverse events related to chiropractice had been noted by these doctors within a 2-year period. Chiropractic interventions were associated with 55 strokes, 16 cases of myelopathy, and 30 cases of radiculopathy (176).

A Ukrainian doctor has reported a series of 49 additional cases with neurological complications after spinal manipulation (177).

Swedish authors have summarized cases reported to three Swedish insurance companies within 2 years (178). They found 21 cases associated with the cervical spine, six associated with the thoracic spine, 13 with the lumbar spine, and 14 with the sacro-iliac joints. Cervical spinal manipulation had caused damage to the vertebral artery with subsequent paralysis in three cases and disk herniation in three cases. Lumbar spinal manipulation had caused disk herniation in six cases, three of whom suffered severe and persistent problems.

German neurologists have reported 10 cases of ischemic stroke due to either vertebral arterial dissection ($n = 8$) or internal carotid artery dissection ($n = 2$) after chiropractic spinal manipulation (179). There were no identifiable predisposing factors. In three cases the dissections were bilateral. The onset of symptoms was immediate ($n = 5$) or delayed by up to 2 days. Neurological deficits developed during up to 3 weeks. In five patients the eventual clinical outcome was good while marked deficits persisted in three patients. One patient continued to suffer from a locked-in syndrome and another was in a persistent vegetative state.

- A 34-year-old woman had pain, dizziness, vomiting, and diplopia immediately after cervical spinal manipulation (180). An MRI scan showed a left cerebellar infarction, and duplex sonography showed dissection of both vertebral arteries leading to 50% occlusion on the right side and total occlusion on the left side.
- A 46-year-old man consulted a traditional Chinese "bone setter" for persistent neck pain (181). The healer had "forcefully rotated his head to one side and then to the other side." The patient immediately developed numbness of the whole body and dyspnea. An MRI

Table 3 Reports of adverse events associated with spinal manipulation

Indication	Adverse event	Site of manipulation	Therapist	Causality	Reference
Back pain	Cauda equina syndrome	Lumbar	Traditional healer	Likely	(172)
Cervical pain	Brown–Séquard syndrome due to contusion of the spinal cord	Cervical	Chiropractor	Fairly certain	(173)
Neck pain	Vertigo, profuse vomiting	Cervical	Chiropractor	Certain	(174)

© 2006 Elsevier B.V. All rights reserved.

scan showed incomplete cervical cord injury with mild cervical cord swelling. He was treated with high-dose methylprednisolone and made a good recovery with only minimal persistent deficits.

- A 67-year-old woman had spinal manipulation for neck pain and experienced severe pain (182). She subsequently noted weakness of her left side, which worsened rapidly and also affected bladder function. She had a left-sided ptosis, all sensation was impaired below C6, and she had urinary incontinence. An MRI scan showed an epidural hematoma in the left posterolateral aspect of the spinal cord at C3–C5. Laminectomy was performed and a large epidural hematoma was removed. She subsequently made a full recovery.
- A 34-year-old man with a whiplash injury consulted a chiropractor for his neck pain, and 36 hours after one particularly painful treatment he experienced throbbing, positional headache, dizziness, diplopia, otorrhea, and rhinorrhea (183). After thorough neurological examination the author concluded that the patient had suffered a dural tear due to cervical manipulation.
- A 34-year-old woman had memory loss, ataxia, and poor co-ordination of the right arm associated with right neck pain after consulting a chiropractor (184). An MRI scan confirmed a right cerebellar infarct, most probably caused by upper spinal manipulation. She made a full recovery within 1 month.
- A 41-year-old man with neck pain sought chiropractic care and the evening after felt unable to breathe in the recumbent position (185). Diaphragmatic paralysis was attributed to phrenic nerve injury during cervical manipulation. He remained short of breath and had persistent difficulties breathing in the supine position.

A highly unusual case of thoracic epidural hematoma after spinal manipulation of the lumbar spine has been reported (186).

- A 64-year-old woman experienced acute severe pain and progressive neurological defects for the first time during spinal manipulation. Swift surgical intervention was initiated and a thoracic epidural hematoma was evacuated. This resulted in complete recovery.

A survey of 323 UK neurologists disclosed 35 previously unreported cases of serious neurological complications of spinal manipulation (187). This means that in this particular series, under-reporting of adverse events had been 100%.

Musculoskeletal

Dislocations and fractures of vertebrae have also been reported and are not confined to the upper spine (188,189). Patients with osteoporosis are at high risk; manipulation is therefore contraindicated in these individuals. Nerve lesions range from plexus paralysis and ophthalmoplegia to tetraplegia, disk herniation, and phrenic nerve palsy (188,190). A review of the English language literature included 89 neurological complications after manipulation; the number of unreported cases could be considerably higher.

Massage

There are many different forms of massage therapy, which are not normally associated with serious adverse effects. However, trauma can occur (191).

- A 39-year-old woman with an unremarkable medical history underwent deep body massage, including the abdomen. Within 24 hours she experienced discomfort and nausea and after 72 hours she had a CT scan, which showed a large hematoma in the right hepatic lobe. There was no evidence of a plausible cause for this. In spite of adequate medical treatment, her recovery was slow and she had nausea and low-grade fever for about 6 months.
- An 80-year-old Japanese man with a recent history of cerebral infarction received a shiatsu massage in the neck area to relieve a headache (192). Immediately after he had right visual field impairment. Thorough ophthalmological and neurological show multiple branch occlusions of the central retinal artery and multiple small infarctions in the right frontoparietal lobe. He was given urokinase for 7 days, and made an almost complete recovery.

The authors of the second report concluded that forceful neck massage had caused the problem.

Conorfone

See also Opioid analgesics

General Information

Conorfone is an opioid analgesic, a codeine derivative, with mixed agonist–antagonist activity (SED-11, 150). It has adverse effects similar to those of codeine, but causes more drowsiness (1).

Reference

1. Dionne RA, Wirdezk PR, Butler DP, Fox PC. Comparison of conorphone, a mixed agonist-antagonist analgesic, to codeine for postoperative dental pain. Anesth Prog 1984;31(2):77–81.

Contact lenses and solutions

General Information

There are two types of contact lenses, soft and hard; most are manufactured from methacrylate polymer (http://www.eyecarecontacts.com/contact_lenses_reports.html).

Soft lenses are made of hydrophilic hydrogel polymers that contain 36–74% water. Other plastics and copolymers are added to alter the physical characteristics of the lens. The diameter is 10.5–15.5 mm and the thickness at the center 0.03–20 mm. Soft lenses can correct most optical defects, including myopia, hyperopia, and astigmatism. Bifocal lenses are also available. They can be colored with either transparent hues or opaque patterns to change apparent eye color or to mask malformations of the cornea or iris. They are available for daily, weekly, and twice-weekly disposable use, 1–3 months frequent replacement, and annual replacement.

Hard lenses are made from gas-permeable materials that contain silicon and fluorine. They can correct most optical defects and have diameters of 8–10 mm.

Some lenses combine soft and hard materials, including hard lenses with soft surfaces and lenses with a hard center and a soft periphery.

The ocular risks related to the use of contact lenses are due not only to the lenses themselves, but also to the toxic or allergic effects of cleaning solutions (1) and the preservatives that they contain. The latter are also found in various eye-drops. Preservatives have adverse effects on the corneal epithelium and endothelium. Eye-drops that contain preservatives should not be used during surgery or in patients with ocular surface disease, in cases of perforating injury.

Organs and Systems

Sensory systems

Ulcerative keratitis is considered the most serious adverse effect of the use of soft contact lenses.

The risk can be greatly reduced by avoiding overnight wear of the lenses (2,3). In one study extended wear was associated with a 5–6 times higher risk of keratitis than daily wear was (4).

Soft contact lenses, especially extended-wear lenses, carry a significantly higher risk of keratitis than hard lenses do. In a case-control study, the relative risk for overnight wear soft lenses was 21, for daily-wear soft lenses 3.6, and for polymethylmethacrylate hard lenses 1.3, as compared with gas-permeable hard lenses (5).

Microorganisms can infiltrate into soft hydrophilic lenses, causing infection and possibly corneal ulcers. *Acanthamoeba* is the most common cause. In a case-control study there was an increased risk of *Acanthamoeba* infection largely attributable to lack of disinfection or the use of chlorine-based disinfection (the latter having little protective effect against the organism). Around 80% of cases of *Acanthamoeba* keratitis could have been avoided by the use of lens disinfection systems that are effective against this organism (6). *Pseudomonas aeruginosa* adherence to corneal epithelial cells was also enhanced in those who used extended-wear soft contact lenses (7). Because acanthamoebae are more commonly found in stagnant water tanks, contact lens wearers should be advised to use water from downstairs kitchen taps rather than upstairs bathroom taps.

Oxygen deficiency can occur under the lens. The dimension of the lens, duration of wear, and hygiene are determining factors. Tolerance is individual, and less hydrophilic materials produce a higher degree of corneal hypoxia. This is manifested by edema, and sometimes by vascularization and even limbus hyperemia and pannus corneae (8,9). Tear-film disruption can be a contributing factor.

Cases of allergic conjunctivitis and blepharitis have been reported with the preservatives benzalkonium chloride and mercurial salts, although benzalkonium at the commonly used concentration of 0.01% produces no evident damage. These adverse reactions can be prevented by rinsing hard lenses in clean water before insertion in the eye and by boiling soft lenses in normal saline after cleaning.

Chlorhexidine digluconate is a biguanide surfactant with low toxicity, but it is a strong contact sensitizer. Its mucus-binding capacity limits its use: it binds to hydrophilic (soft) contact lenses. Build-up of proteinaceous debris in lenses may greatly increase the binding of chlorhexidine to the lens.

The use of chlorobutanol is limited to pHs below 6. It is subject to thermal degradation and can be adsorbed on to the walls of containers. However, it has no major adverse effects. Chlorobutanol has no effect on wetting of the cornea or contact lenses, as surface-active agents do. When tested with soft lenses, chlorobutanol, concentrated in the lenses, causes mild conjunctivitis.

Continuous ambulatory peritoneal dialysis

General Information

One complication of long-term CAPD is peritoneal calcification. The cause is unclear, but it may be associated with multiple bouts of peritonitis combined with hyercalcemia. In one case there was evidence that the effect may be reversible (1).

- A 48-year-old woman undergoing CAPD had several bouts of peritonitis, with four admissions for treatment between 1988 and 1993. In 1993, moderate amounts of calcification surrounding the small bowel were identified by CT scan, and this progressively increased over the following year. CAPD was discontinued and hemodialysis with a low dialysate calcium concentration was used instead. After a further admission 4 months later, parenteral nutrition was begun. Over the following three years, CT scans showed a progressive reduction in the extent of peritoneal calcification surrounding the small bowel.

The authors speculated that hemodialysis and long-term parenteral nutrition may result in reversal of peritoneal calcification caused by CAPD.

Convolvulaceae

See also Herbal medicines

General Information

The genera in the family of Convolvulaceae (Table 1) include bindweed and morning glory.

Table 1 The genera of Convolvulaceae

Aniseia (aniseia)
Argyreia (argyreia)
Bonamia (lady's nightcap)
Calystegia (false bindweed)
Convolvulus (bindweed)
Cressa (alkaliweed)
Dichondra (pony's foot)
Evolvulus (dwarf morning glory)
Ipomoea (morning glory)
Jacquemontia (cluster vine)
Merremia (wood rose)
Operculina (lidpod)
Poranopsis (poranopsis)
Stictocardia (stictocardia)
Stylisma (dawn flower)
Turbina (turbina)
Xenostegia (morning vine)

Convolvulus scammonia

Convolvulus scammonia (Mexican scammony) contains alkaloids that are drastic purgatives with irritant properties. It has now been superseded.

Ipomoea purga

Ipomoea purga (jalap) is a drastic cathartic with irritant action, which has been superseded by less toxic laxatives.

Copper

General Information

Copper is a reddish metallic element (symbol Cu; atomic no. 29). Its symbol derives from the Latin word cuprum, because it was originally discovered in Cyprus. It is widely found as different salts in minerals such as atacamite (chloride); azurite and malachite (carbonates); bornite, chalcocite, chalcopyrite, stannite, tennantite, and tetrahedrite (sulfides); chalcanthite (sulfate); dioptase (silicate); erinite and olivenite (arsenates); tenorite (oxide); torbernite (phosphate); and zorgite (selenide). Copper is an essential constituent of several enzymes. It is carried in the blood by a specific copper-binding protein, ceruloplasmin.

The bulk of publications on copper deal with its metabolism as an essential trace element, its role in

Menkes' disease (associated with copper deficiency) and Wilson's disease (associated with copper excess) (1,2), and its possible role in Alzheimer's disease (3), prion disease (4), and familial amyotrophic lateral sclerosis (5). Copper metabolism and toxicity have been reviewed (6). The potential use of novel chelating agents for copper isotopes with short half-lives in radiopharmacy has been discussed (7).

Copper histidine is increasingly being used in Menkes' disease and allows survival into adolescence (8). The neurological abnormalities respond better than the connective tissue abnormalities.

A boy with Menkes' disease and low plasma concentrations of copper (3.6 μmol/l) and ceruloplasmin (50 mg/l) received copper histidine and died aged 10. Postmortem examination showed significant pathology of the mesenchymal tissues, including skeletal abnormalities, vascular degeneration, and bladder diverticula. The central nervous system, in contrast, showed minimal pathology of copper metabolism compared with classical Menkes' disease.

The differential sensitivity of central nervous system and mesenchymal tissues to copper histidine may be due to heterogeneity in the responses of different copper-dependent enzymes.

There is also contact with copper in daily life. When copper comes into contact with biological materials it becomes corroded, and the compounds that are formed can produce irritation and other reactions.

Some copper compounds have been used therapeutically in the past. Small quantities of copper salts enhance the physiological utilization of iron and are thus often present in hemopoietic formulations. Copper chloride and copper sulfate are used in parenteral nutrition solutions. The artificial radioactive copper isotope ^{64}Cu has been used in mineral metabolic studies. Excess accumulation of copper can occur due to an abnormality of ceruloplasmin and causes Wilson's disease and Menkes' disease, which are both characterized by copper accumulation (SEDA-22, 244) (9).

Copper-containing intrauterine contraceptive devices

Copper-containing intrauterine contraceptive devices (10–12) became popular because local inflammatory reactions in the endometrium are more marked and the contraceptive effect is thus more pronounced (SEDA-21, 234) (13). In addition, copper ions released from intrauterine contraceptive devices reach concentrations in the luminal fluids of the genital tract that are toxic to spermatozoa and embryos. The ability of copper to induce the generation of free radicals and the formation of malonaldehyde may be involved in its contraceptive effect.

There is a positive correlation between high copper loss from an intrauterine contraceptive device and the development of menorrhagia or pathological lesions, such as cervical dysplasia and endometrial cytopathology (14). Evidence of endometrial carcinoma was not found in endometrial aspirates from 189 women who had used Copper-T-200 devices for 1–10 years, but five cases of endometrial hyperplasia (2.67%) were encountered in women in the series, all of whom had worn copper devices for 6 years or more. Inflammatory changes in the endometrial cells were found in 12 cases (6.2%), 11 of 12 having worn the device for over 3 years. It is possible that constant exposure to copper may be responsible for persistence of chronic inflammatory changes in endometrial cells, which could be the precursors of hyperplastic changes. It is not clear whether the dissolved copper is also responsible for the temporarily increased predisposition to bacterial contamination and the somewhat increased risk of pelvic inflammatory disease, seen especially in young nulliparous women using this type of contraceptive method.

Migration of intrauterine contraceptive devices is relatively rare, although they have been found in the omentum, rectosigmoid, peritoneum, bladder, appendix, small bowel, adnexa, and iliac vein. Most authors have recommended removal of copper-containing devices, because of the potential for inflammatory reactions, which can cause bowel obstruction and perforation (15). Two cases of migration of intrauterine contraceptive devices to the bowel have been reported.

- A Copper-T intrauterine contraceptive device migrated to the rectal lumen in a 36-year-old woman with menorrhagia for 3 months and a history of Copper-T insertion 6 years before (16).
- A 28-year-old pregnant woman developed an ileal perforation 4 weeks after the insertion of a Multiload-Cu 375 intrauterine contraceptive device (17).

The second report documents the shortest interval between insertion and proven bowel injury by an intrauterine contraceptive device.

Immunological and hypersensitivity reactions beyond the uterus are uncommon, but they can occur. Rashes, including generalized urticaria and eczematoid eruptions, have occurred as a result of allergy to the copper released from intrauterine contraceptive devices, although they are extremely rare (SEDA-11, 204) (SEDA-12, 186) (SEDA-21, 235). One woman who had worn a copper-containing device for 12 months developed widespread urticaria and angioedema of the eyelids and the labia majora and minora for about 6 months (18). She also had persistent symptoms of premenstrual and postmenstrual spotting and leukorrhea for about 6 months. A patch test was positive with 1% copper sulfate, as was an in vitro lymphocyte stimulating test with copper. An endometrial biopsy showed vulvovaginitis, with hyperplasia of the cervical canal and T cell and eosinophilic granulocyte infiltration. Removal of the device caused complete remission.

Genital tract actinomycosis has come increasingly to the fore (19,20). In one study in Britain, the pelvic smears of nearly one-third of women using plastic devices were positive for *Actinomyces*-like organisms, compared with two of 165 women using copper-loaded IUCDs and none in a series of oral contraceptive users. There was a highly significant correlation between the presence of these organisms on smear and pain and other symptoms of pelvic inflammatory disease.

- A 32-year-old woman, who had had a copper intrauterine contraceptive device for more than 5 years,

© 2006 Elsevier B.V. All rights reserved.

developed acyclic menstrual bleedings and had a uterine biopsy after removal of the intrauterine device (21). Histology of the abraded tissue showed an actinomycotic endometritis, with brown to black deposits in or around typical *Actinomyces druses*, but there was no carcinoma. Electron microscopy showed copper deposits in the shell and matrix of the druses and inside the bacteria. Electron-dense accumulations showed high signals for copper and sulfur, and to a lesser extent also for phosphorus and oxygen.

Copper accumulation in this case may have been caused by active uptake and concentration by the *Actinomycetes*.

If copper-containing fragments of intrauterine contraceptive devices perforate the uterine wall and enter the peritoneal cavity, acute inflammatory reactions and peritoneal adhesions can occur. Laparoscopic removal is then not only as a rule impossible but may also be dangerous because of the marked peritoneal reaction surrounding the copper part of the device. Laparotomy has therefore been suggested as the primary measure in such cases. Whether copper devices result more commonly in perforation than non-copper devices is not entirely clear, nor is the question answered whether copper increases the risk of extrauterine pregnancies, although older evidence suggested this as a risk (SED-9, 371).

Although copper-containing intrauterine contraceptive devices are very effective, pregnancies do occur and the question of possible second-generation effects has to be considered. In one case the neonate showed significantly increased copper and ceruloplasmin concentrations, whereas maternal concentrations were within the reference range. Whether such exposure to copper can cause harm is not clear; because of the pharmacological effects of copper, it has been suspected of having mutagenic and carcinogenic potential. Until now, there is no clear evidence that harm is actually done. Five published cases scattered throughout the literature in which incomplete closure of the neural tube was found (22) could have been coincidental, bearing in mind the large number of pregnancies in which exposure to copper must occur in this way. In various species of animals which have been studied (rat, rabbit, hamster, sheep) no teratogenicity of intrauterine copper was detected (SED-11, 442).

Organs and Systems

Nervous system

It has been suggested that copper-mediated toxicity in some neurodegenerative diseases (Alzheimer's disease and familial amyotrophic lateral sclerosis) may contribute to neurodegeneration (23). It should be borne in mind that similar but unproven theories have been raised regarding other metals, notably aluminium.

Sensory systems

Penetration of the eye by copper wire has been reported to produce a recurrent chronic uveitis (24).

Ocular chalcosis has been attributed to injury with a copper-containing foreign body (25).

- After having suffered an open-globe injury, presumably due to a small foreign body after a grenade explosion, a 30-year-old man presented 6 years later with ocular chalcosis, including sunflower cataract, a multitude of tiny brownish particles in the anterior vitreous, fibrillar degeneration of the posterior vitreous, and brilliant patches overriding the foveal region. The patches were measured by confocal scanning laser tomography and optical coherence tomography. Besides acquired cyandyschromatopsia, psychophysical and electrophysiological tests were unremarkable. Vision was 20/20. The central patches measured 200–700 μm in diameter and 150–200 μm in height above the inner retinal surface. With the exception of a Kayser–Fleischer ring of the cornea the patient presented all the morphological signs of ocular chalcosis. Since signs of inflammation were absent no further therapy was planned.

This man had probably suffered from a penetrating damage of the left eye caused by a copper-containing body, which had eventually dissolved. Although the observed patches on the central retina in ocular chalcosis have previously been described, their nature is not known.

Hematologic

The effects of combined oral contraceptives, depot medroxyprogesterone acetate injections, levonorgestrel subdermal implants (Norplant), copper-containing intrauterine contraceptive devices (IUCDs), and Chinese stainless steel ring IUCDs on hemoglobin and ferritin have been studied in 2507, non-pregnant non-lactating women, aged 18–40 years, in seven countries (Bangladesh, Chile, China, the Dominican Republic, Pakistan, Thailand, and Tunisia) (26). In 1295 current users of the contraceptive methods hemoglobin and ferritin concentrations were higher than in 1212 women who were starting to use contraceptives. The current users of copper IUCDs had higher hemoglobin concentrations (difference in mean concentrations of 0.3 g/dl), but lower ferritin concentrations (difference of 10 g/l) than non-users. Current use of the stainless steel ring had an adverse effect on both hemoglobin and ferritin. In 285 anemic women there were significant mean increases of hemoglobin at 12 months among the users of the hormonal contraceptives, but not among users of copper or stainless steel ring IUCDs. The authors concluded that hemoglobin and ferritin concentrations are affected by contraceptives and that the hormonal contraceptives included in this study have a beneficial effect, while the effects of copper IUCDs should be studied further.

Liver

Copper poisoning can cause hepatic cirrhosis in Wilson's disease (SEDA-21, 234) (27), but no cases appear to be known in which this resulted from medicinal exposure. Apart from Wilson's disease and Menkes' disease, much attention has been given to copper-associated liver disease in infancy and childhood, in which excessive dietary copper overload and a genetic predisposition can lead to high liver copper concentrations and progressive liver disease (28).

© 2006 Elsevier B.V. All rights reserved.

Skin

Perimenstrual dermatitis has been attributed to a copper-containing intrauterine contraceptive device (29).

- A 41-year-old woman had a 2-year history of a recurrent, self-healing skin rash associated with abdominal pain. She had had cholinergic urticaria since 1995 and had had a copper-containing intrauterine contraceptive device inserted 12 years before. The eruption followed a cyclical pattern, invariably appearing 3–7 days before the menses and tending to improve spontaneously with the onset of bleeding. This non-itchy rash was associated with abdominal distension and cramps that followed a similar course. She had multiple non-itchy symmetrical erythematous papules on the upper trunk, neck, and arms. Patch-testing was positive for copper sulfate. The intrauterine contraceptive device was removed and the abdominal symptoms subsided at the following cycle. Progressive resolution of the dermatitis was observed. No cutaneous eruption was observed after 8 months and no new lesions developed after a further 5 months.

Hair

A remarkable (although non-medical) case reported in 1996 concerned a man who developed green hair as a result of drinking tap water with a high copper concentration (30). The discoloration disappeared promptly after the use of a shampoo containing penicillamine.

Reproductive system

The fibrinolytic activity of menstrual blood in wearers of Lippes loops exceeds that of patients with menorrhagia, while the values in users of the Cu-T (200) are in the same range as in normally menstruating and untreated women. In users of Lippes loops no fibrin was found in the endometrial stroma. This may explain the increased blood loss associated with the use of the Lippes loop, which can be severe enough to cause anemia (31).

Susceptibility Factors

Hepatic disease

In primary sclerosing cholangitis there is increased hepatic retention of both copper and selenium (32)

Drug Administration

Drug overdose

Overdose of copper sulfate can cause nephrotoxicity.

- A 21-year-old pharmacist developed acute renal insufficiency (33). Three days before he had dissolved a small quantity of copper sulfate in 5 ml of tap water and injected it intravenously in a suicide attempt. The serum copper concentration was 1.950 μg/ml (31 μmol/l). He was dialysed and gradually improved over 6 weeks. His serum copper concentration a month after the incident was 0.5 μg/ml (8 μmol/l). At 8 weeks a renal biopsy showed marked patchy tubular atrophy with interstitial fibrosis and mild focal chronic interstitial inflammation. Some tubules showed regenerating epithelial cells with multilayering and mitosis, with a predominant loss of proximal tubules. The findings were suggestive of chronic tubulointerstitial nephritis.

Coriariaceae

See also Herbal medicines

General Information

The family of Coriariaceae contains the single genus *Coriaria*.

Coriaria species

Coriaria arborea (tutu) plant is a traditional Maori medicine. It contains various sesquiterpenoids, including a toxin, tutin, that is allied to picrotoxin (1).

Adverse effects

Ingestion of portions or concoctions of *Coriaria* plants can result in tonic-clonic seizures, respiratory arrest, and death.

Three sisters who ate berries of *Coriaria myrtifolia* (redoul) suffered from acute poisoning; the adverse effects affected the gastrointestinal tract (nausea, vomiting, abdominal pain), the nervous system (obnubilation, convulsions, and their complications), and respiratory function (hyperpnea, apnea, short and superficial respiration), together with myositis of the pupils; one died (2).

Of 25 children who ate the fruits of *C. myrtifolia*, 13 had gastrointestinal digestive symptoms and nine had nervous system toxicity, including seizures and coma (3).

Corticorelin (corticotropin-releasing hormone (CRH))

General Information

For complete functional evaluation of the hypothalamic–hypophyseal–adrenal axis one can use synthetic corticorelin (corticotropin-releasing hormone), which is available in both human (hCRH) and ovine (oCRH) forms (1).

Single bolus injections in standard doses (for example 200 μg of hCRH or oCRH), whether given on a single occasion or at fixed intervals, have a very low rate of complications. At higher doses adverse effects occur in

© 2006 Elsevier B.V. All rights reserved.

almost 40% of patients (2). At a dose of 1 mg/kg they mainly comprise flushing or a feeling of warmth (30%), a sensation of discomfort (5%), palpitation (3%), and dyspnea (1%). Higher doses (more than 200 mg) can cause hypotension or coronary ischemia. Patients with brain injury are more susceptible to adverse reactions (2). No serious allergic reactions have been reported. Continuous infusions of hCRH or oCRH for several hours have also been well tolerated, but adverse effects occurred with cumulative doses of 200–300 μg/hour.

High doses can provoke marked adverse effects in patients with neurological disorders, coronary heart disease, or disorders of the pituitary–adrenal axis, especially if the blood–brain barrier has been damaged (for example by a head injury or during intracranial surgery). Nonstandard doses should only be used in experimental work with well-designed safety precautions.

Corticosteroids—glucocorticoids

General Information

Nomenclature

The two main classes of adrenal corticosteroids are properly known as glucocorticoids and mineralocorticosteroids. The former are often known by shorter names and are commonly referred to as "glucocorticoids", "corticosteroids", "corticoids", or even simply "steroids"; the latter are often referred to as "mineralocorticoids". Here we shall use the terms "glucocorticoids" and "mineralocorticoids". When referring to both we shall use the term "corticosteroids".

Relative potencies

The main human anti-inflammatory corticosteroid, the glucocorticoid cortisol (hydrocortisone), as secreted by the adrenal gland, has generally been replaced by related glucocorticoids of synthetic origin for therapeutic purposes. These Δ^1-dehydrated glucocorticoids are designed to imitate the physiological hormone. They have marked glucocorticoid potency but only minor effects on sodium retention and potassium excretion; the relative glucocorticoid and mineralocorticoid potencies of the best-known compounds, insofar as these potencies are agreed, are compared in Table 1.

Over many years, a great deal of research has been devoted to producing better glucocorticoids for therapeutic use. Those endeavors have succeeded only in part; from the start the mineralocorticoid effects were sufficiently minor to be nonproblematic; the fact that successive synthetic glucocorticoids had an increasing potency in terms of weight was not of direct therapeutic significance; and the most hoped-for aim, that of dissociating wanted from unwanted glucocorticoid effects has not been achieved (1). Most untoward effects, such as those due to the catabolic and gluconeogenic activities of the glucocorticoid family, probably cannot be dissociated entirely from the anti-inflammatory activity (2) it is possible that myopathy and muscle wasting are actually more common when triamcinolone or dexamethasone are used, but this may merely reflect overdosage of these potent drugs. However, some progress in achieving a dissociation of effects has been made. Beclomethasone does have a relatively greater local than systemic effect. Deflazacort, one of the few new glucocorticoids to have been developed in recent years, originally promised reduced intensity of adverse effects, for example on bone mineral density, but the early promise has not held up (SEDA-18, 389). Cloprednol seems to affect the hypothalamic–pituitary–adrenal axis much less than other glucocorticoids, and to cause less excretion of nitrogen and calcium (3).

Uses

Most patients who are treated therapeutically with glucocorticoids do not have glucocorticoid deficiency. Adverse

reactions to glucocorticoids depend very largely on the ways in which, and the purposes for which, they are used. There are four groups of uses.

(1) Substitution therapy is used in cases of primary and secondary adrenocortical insufficiency; the aim is to provide glucocorticoids and mineralocorticoids in physiological amounts, and the better the dosage regimen is adapted to the individual's needs, the less the chance of adverse effects (1).
(2) Anti-inflammatory and immunosuppressive therapy exploits the immunosuppressive, anti-allergic, anti-inflammatory, anti-exudative, and anti-proliferative effects of the glucocorticoids (2). The desired pharmacodynamic effects reflect a general influence of these substances on the mesenchyme, where they suppress reactions that result in the symptoms of inflammation, exudation, and proliferation; the non-specific effects of glucocorticoids on the mesenchyme are part of their physiological actions, but they can only be obtained to a clinically useful extent by using dosages at which the more specific (and unwanted) physiological effects also occur. High doses sufficient to suppress immune reactions are used in patients who have undergone organ transplantation.
(3) Hormone suppression therapy can be used, for example, to inhibit the adrenogenital syndrome (3). Higher doses are used. The treatment of the adrenogenital syndrome is only partly substitutive and has to be adapted to the individual case, but doses are needed at which various hormonal effects of the glucocorticoids and mineralocorticoids are likely to become troublesome.
(4) Massive doses of glucocorticoids, far exceeding physiological amounts, are given in the immediate management of anaphylaxis, although their beneficial effects are delayed for several hours. This is because, in severely ill patients, early administration of hydrocortisone 100–300 mg as the sodium succinate salt can gradually enhance the actions of adrenaline (4). Glucocorticoids have been used as an adjunct to the use of inotropic and vasopressor drugs for septic shock. Their efficacy, as well as their proposed mechanisms of action, is controversial; inhibition of complement-mediated aggregation and resultant endothelial injury, and inhibition of the release of beta-endorphin are current theories of their mechanism of action. However, controlled studies have not indicated a beneficial effect of high-dose glucocorticoid therapy in treating septic shock (5,6). Hence, there is no established role for glucocorticoids in the treatment of shock, except shock caused by adrenal insufficiency.

Routes of administration

Glucocorticoids can be given by the following routes:

- oral
- rectal
- intravenous
- intramuscular
- inhalation
- nasal
- topical (skin, eyes, ears)
- intradermal
- intra-articular and periarticular
- intraspinal (epidural, intrathecal)
- intracapsular (breast)

All of these routes are covered in this monograph, except the inhalation route, which is the subject of a separate monograph.

Therapeutic studies

Although there have been several trials of early dexamethasone to determine whether it would reduce mortality and chronic lung disease in infants with respiratory distress, the optimal duration and adverse effects of such therapy are unknown. The purpose of one study was: (a) to determine if a 3-day course of early dexamethasone therapy would reduce chronic lung disease and increase survival without chronic lung disease in neonates who received surfactant therapy for respiratory distress syndrome and (b) to determine the associated adverse effects (7). This was a prospective, placebo-controlled, multicenter, randomized study of a 3-day course of early dexamethasone therapy, beginning at 24–48 hours of life in 241 neonates, who weighed 500–1500 g, had received surfactant therapy, and were at significant risk of chronic lung disease or death. Infants randomized to dexamethasone received a 3-day tapering course (total dose 1.35 mg/kg) given in six doses at 12-hour intervals. Chronic lung disease was defined by the need for supplementary oxygen at a gestational age of 36 weeks. Neonates randomized to early dexamethasone were more likely to survive without chronic lung disease (RR = 1.3; CI = 1.0, 1.7) and were less likely to develop chronic lung disease (RR = 0.6; CI = 0.3, 0.98). Mortality rates were not significantly different. Subsequent dexamethasone therapy was less in early dexamethasone-treated neonates (RR = 0.8; CI = 0.70, 0.96). Very early (before 7 days of life) intestinal perforations were more common among dexamethasone-treated neonates (8 versus 1%). The authors concluded that an early 3-day course of dexamethasone increases survival without chronic lung disease, reduces chronic lung disease, and reduces late dexamethasone therapy in high-risk, low birthweight infants who receive surfactant therapy for respiratory distress syndrome. The potential benefits of early dexamethasone therapy in the regimen used in this trial need to be weighed against the risk of early intestinal perforation.

In another randomized trial, the effects and adverse effects of early dexamethasone on the incidence of chronic lung disease have been evaluated in 50 high-risk preterm infants (8). The treated infants received dexamethasone intravenously from the fourth day of life for 7 days (0.5 mg/kg/day for the first 3 days, 0.25 mg/kg/day for the next 3 days, and 0.125 mg/kg/day on the seventh day). The incidence of chronic lung disease at 28 days of life and at 36 weeks of postconceptional age was significantly lower in the infants who were given dexamethasone, who also remained intubated and required oxygen therapy for a shorter period. Hyperglycemia, hypertension, growth failure, and left ventricular hypertrophy were the transient adverse effects associated with early

© 2006 Elsevier B.V. All rights reserved.

glucocorticoid administration. Early dexamethasone administration may be useful in preventing chronic lung disease, but its use should be restricted to preterm high-risk infants.

A systematic review of randomized controlled trials has been performed to determine whether dexamethasone therapy in the first 15 days of life prevents chronic lung disease in premature infants (9). Studies were identified by a literature search using Medline (1970–97) supplemented by a search of the Cochrane Library (1998, Issue 4). Inclusion criteria were: (a) prospective randomized design with initiation of dexamethasone therapy within the first 15 days of life; (b) report of the outcome of interest; and (c) less than 20% crossover between the treatment and control groups during the study period. The primary outcomes were mortality at hospital discharge and the development of chronic lung disease at 28 days of life and 36 weeks postconceptional age. The secondary outcomes were the presence of a patent ductus arteriosus and treatment adverse effects. Dexamethasone reduced the incidence of chronic lung disease by 26% at 28 days (RR = 0.74; CI = 0.57, 0.96) and 48% at 36 weeks postconceptional age (RR = 0.52; CI = 0.33, 0.81). These reductions were more significant when dexamethasone was started in the first 72 hours of life. The 24% relative risk reduction of deaths was marginally significant (RR = 0.76; CI = 0.56, 1.04). The 27% reduction in patent ductus arteriosus and the 11% increase in infections were not statistically significant, nor were any other changes. The conclusion from this meta-analysis was that systemic dexamethasone given to at-risk infants soon after birth may reduce the incidence of chronic lung disease. There was no evidence of significant short-term adverse effects.

Although dexamethasone is commonly associated with transient adverse effects, several randomized trials have shown that it rapidly reduces oxygen requirements and shortens the duration of ventilation. A randomized study was designed to evaluate the effects of two different dexamethasone courses on growth in preterm infants (10). The first phase included 30 preterm infants at high risk of chronic lung disease, of whom 15 (8 boys) were given dexamethasone for 14 days, from the tenth day of life; they received a total dose of 4.75 mg/kg; 15 babies were assigned to the control group (8 boys). The second phase included 30 preterm infants at high risk of chronic lung disease, of whom 15 babies (7 boys) were treated with dexamethasone for 7 days, from the fourth day of life; they received a total dose of 2.38 mg/kg; 15 babies were assigned to the control group (9 boys). Infants given dexamethasone had significantly less weight gain than controls, but they caught up soon after the end of treatment. At 30 days of life, the gains in weight and length in each group were similar to those in control infants, but those given dexamethasone had significantly less head growth. There were no differences between the groups at discharge. The longer-term impact of postnatal dexamethasone on mortality and morbidity is less clear. Better data, from larger clinical trials with longer follow-up, will determine whether this kind of treatment enhances lives, makes little difference, causes significant harm, or does several of these things (11).

General adverse effects

The incidence and severity of adverse reactions to glucocorticoids depend on the dose and duration of treatment. Even the very high single doses of glucocorticoids, such as methylprednisolone, which are sometimes used, do not cause serious adverse effects, whereas an equivalent dose given over a long period of time can cause many long-term effects.

The two major risks of long-term glucocorticoid therapy are adrenal suppression and Cushingoid changes. During prolonged treatment with anti-inflammatory doses, glucose intolerance, osteoporosis, acne vulgaris, and a greater or lesser degree of mineralocorticoid-induced changes can occur. In children, growth can be retarded, and adults who take high doses can have mental changes. There may be a risk of gastroduodenal ulceration, although this is much less certain than was once thought. Infections and abdominal crises can be masked. Some of these effects reflect the catabolic properties of the glucocorticoids, that is their ability to accelerate tissue breakdown and impair healing. Allergic reactions can occur.

Anyone who prescribes long-term glucocorticoids should have a checklist in mind of the undesired effects that they can exert, both during treatment and on withdrawal, so that any harm that occurs can be promptly detected and countered. The main groups of risks arising from long-term treatment with glucocorticoids are summarized in Table 2.

The adverse reactions that were reported in a study of 213 children are listed in Table 3 (12).

Table 2 Risks of long-term glucocorticoid therapy

1. Exogenous hypercorticalism with Cushing's syndrome
Moon face (facial rounding)
Central obesity
Striae
Hirsutism
Acne vulgaris
Ecchymoses
Hypertension
Osteoporosis
Proximal myopathy
Disorders of sexual function
Diabetes mellitus
Hyperlipidemia
Disorders of mineral and fluid balance (depending on the type of glucocorticoid)
2. Adrenal insufficiency
Insufficient or absent stress reaction
Withdrawal effects
3. Unwanted results accompanying desired effects
Increased risk of infection
Impaired wound healing
Peptic ulceration, bleeding, and perforation
Growth retardation
4. Other adverse effects
Mental disturbances
Encephalopathy
Increased risk of thrombosis
Posterior cataract
Increased intraocular pressure and glaucoma
Aseptic necrosis of bone

Drug interactions that affect the efficacy of glucocorticoids have been reviewed (13).

Organs and Systems

Cardiovascular

The considerable body of evidence that glucocorticoids can cause increased rates of vascular mortality and the underlying mechanisms (increased blood pressure, impaired glucose tolerance, dyslipidemia, hypercoagulability, and increased fibrinogen production) have been reviewed (14). In view of their adverse cardiovascular effects, the therapeutic options should be carefully considered before long-term glucocorticoids are begun; although they can be life-saving, dosages should be regularly reviewed during long-term therapy, in order to minimize complications.

Hypertension

The secondary mineralocorticoid activity of glucocorticoids can lead to salt and water retention, which can cause hypertension. Although the detailed mechanisms are as yet uncertain, glucocorticoid-induced hypertension often occurs in elderly patients and is more common in patients with total serum calcium concentrations below the reference range and/or in those with a family history of essential hypertension (SEDA-20, 368) (15).

Hemangioma is the most common tumor of infancy, with a natural history of spontaneous involution. Some hemangiomas, however, as a result of their proximity to vital structures, destruction of facial anatomy, or excessive bleeding, can be successfully treated with systemic glucocorticoids between other therapies. The risk of hypertension is poorly documented in this setting. In one prospective study of 37 infants (7 boys, 17 girls; mean age 3.5 months, range 1.5–10) with rapidly growing complicated hemangiomas treated with oral prednisone 1–5 mg/kg/day, blood pressure increased in seven cases (16). Cardiac ultrasound examination in five showed two cases of myocardial hypertrophy, which was unrelated to the hypertension and which regressed after withdrawal of the prednisone.

Myocardial ischemia

Cortisone-induced cardiac lesions are sometimes reported and electrocardiographic changes have been seen in patients taking glucocorticoids (17). Whereas abnormal myocardial hypertrophy in children has perhaps been associated more readily with corticotropin, it has been seen on occasion during treatment with high dosages of glucocorticoids, with normalization after dosage reduction and withdrawal.

Fatal myocardial infarction occurred after intravenous methylprednisolone for an episode of ulcerative colitis (18).

- A day after a dose of intravenous methylprednisolone 60 mg a 79-year-old woman developed acute thoracic pain and collapsed. An electrocardiogram showed signs of a myocardial infarction and her cardiac enzyme activities were raised. She died within several hours. Autopsy showed an anterior transmural myocardial infarction and mild atheromatous lesions in the coronary arteries.

This report highlights the risk of cardiovascular adverse effects with short courses of glucocorticoid therapy in elderly patients with inflammatory bowel disease, even with rather low-dosage regimens. Acute myocardial infarction occurred in an old man with coronary insufficiency and giant cell arteritis after treatment with prednisolone (SEDA-10, 343) but could well have been coincidental.

Myocardial ischemia has been reportedly precipitated by intramuscular administration of betamethasone (SEDA-21, 413) (19). It has been suggested that long-term glucocorticoid therapy accelerates atherosclerosis and the formation of aortic aneurysms, with a high risk of rupture (SEDA-20, 369) (20).

Patients with seropositive rheumatoid arthritis taking long-term systemic glucocorticoids are at risk of accelerated cardiac rupture in the setting of transmural acute myocardial infarction treated with thrombolytic drugs (21).

- Two women and one man, aged 53–74 years, died after they received thrombolytic therapy for acute myocardial infarction. All three had a long history of seropositive rheumatoid arthritis treated with prednisone 5–20 mg/day for many years.

Cardiomyopathy

Postnatal exposure to glucocorticoids has been associated with hypertrophic cardiomyopathy in neonates. Such an effect has not previously been described in infants born to mothers who received antenatal glucocorticoids. Three neonates (gestational ages 36, 29, and 34 weeks), whose mothers had been treated with betamethasone prenatally in doses of 12 mg twice weekly for 16 doses, 8 doses, and 5 doses respectively, developed various degrees of hypertrophic cardiomyopathy diagnosed by echocardiography (22). There was no maternal evidence of diabetes, except for one infant whose mother had a normal fasting and postprandial blood glucose before glucocorticoid therapy, but an abnormal 1-hour postprandial glucose after 8 weeks of betamethasone therapy, with a normal HbA_{1C} concentration. There was no family history of hypertrophic cardiomyopathy, no history of maternal intake of other relevant medications, no hypertension,

© 2006 Elsevier B.V. All rights reserved.

and none of the infants received glucocorticoids postnatally. Follow-up echocardiography showed complete resolution in all infants. The authors suggested that repeated antenatal maternal glucocorticoids might cause hypertrophic cardiomyopathy in neonates. These changes appear to be dose- and duration-related and are mostly reversible.

Transient hypertrophic cardiomyopathy is a rare sequel of the concurrent administration of glucocorticoid and insulin excess (SEDA-21, 412) (23). The heart is also almost certainly a site for myopathic changes analogous to those that affect other muscles.

Transient hypertrophic cardiomyopathy has been attributed to systemic glucocorticoid administration for a craniofacial hemangioma (24).

- A 69-day-old white child presented with a rapidly growing 2.5 × 1.5 cm hemangioma of the external left nasal side wall. He was normotensive and there was no family history of cardiomyopathy or maternal gestational diabetes. Because of nasal obstruction and possible visual obstruction, he was given prednisolone 3 mg/kg/day. After 10 weeks his weight had fallen from 7.6 to 7.1 kg and 2 weeks later he became tachypneic with a respiratory rate of 40/minutes. A chest X-ray showed cardiomegaly and pulmonary venous congestion. An echocardiogram showed hypertrophic cardiomyopathy. The left ventricular posterior wall thickness was 10 mm (normal under 4 mm), and the peak left ventricular outflow gradient was 64 mmHg. He was given a beta-blocker and a diuretic and the glucocorticoid dose was tapered. The cardiomyopathy eventually resolved.

Dilated cardiomyopathy caused by occult pheochromocytoma has been described infrequently.

- A 34-year-old woman had acute congestive heart failure 12 hours after administration of dexamethasone 16 mg for an atypical migraine (25). The authors postulated that the acute episode had been induced by the dexamethasone, which increased the production of adrenaline, causing $beta_2$-adrenoceptor stimulation, peripheral vasodilatation, and congestive heart failure.

In an addendum the authors reported another similar case.

Cardiac dysrhythmias

Serious cardiac dysrhythmias and sudden death have been reported with pulsed methylprednisolone. Oral methylprednisolone has been implicated in a case of sinus bradycardia (26).

- A 14-year-old boy received an intravenous dose of methylprednisolone 30 mg/kg for progressive glomerulonephritis. After 5 hours, his heart rate had fallen to 50/minute and an electrocardiogram showed sinus bradycardia. His heart rate then fell to 40/minutes and a temporary transvenous pacemaker was inserted and methylprednisolone was withdrawn. His heart rate increased to 80/minutes over 3 days. After a further 3 days, he was treated with oral methylprednisolone 60 mg/m^2/day and his heart rate fell to 40/minutes in 5 days. Oral methylprednisolone was stopped on day 8 of treatment and his heart rate normalized.

Hypokalemia, secondary to mineralocorticoid effects, can cause cardiac dysrhythmias and cardiac arrest.

Recurrent cardiocirculatory arrest has been reported (27).

- A 60-year-old white man was admitted for kidney transplantation. Immediately after reperfusion and intravenous methylprednisolone 500 mg, he developed severe bradycardia with hypotension and then cardiac arrest. After resuscitation, his clinical state improved quickly, but on the morning of the first postoperative day directly after the intravenous administration of methylprednisolone 250 mg, he had another episode of severe bradycardia, hypotension, and successful cardiopulmonary resuscitation. A third episode occurred 24 hours later after intravenous methylprednisolone 100 mg, again followed by rapid recovery after resuscitation. Two weeks later, during a bout of acute rejection, he was given intravenous methylprednisolone 500 mg, after which he collapsed and no heartbeat or breathing was detectable; after cardiopulmonary resuscitation he was transferred to the intensive care unit, where he died a few hours later.

If patients at risk are identified, glucocorticoid bolus therapy should be avoided or, if that is not possible, should only be done under close monitoring.

Pericarditis

- Disseminated *Varicella* and staphylococcal pericarditis developed in a previously healthy girl after a single application of triamcinolone cream 0.1% to relieve pruritus associated with *Varicella* skin lesions (SEDA-22, 443) (28).

Vasculitis

Long-term treatment with glucocorticoids can cause arteritis, but patients with rheumatoid arthritis have a special susceptibility to vascular reactions, and cases of periarteritis nodosa after withdrawal of long-term glucocorticoids have been reported (29).

Respiratory

Local adverse effects are common in patients with asthma who use inhaled glucocorticoids, as suggested by a survey of the prevalence of throat and voice symptoms in patients with asthma using glucocorticoids by metered-dose pressurized aerosol (SEDA-20, 369) (30).

There have been no reports of an increased frequency of lower respiratory tract infections. However, patients with aspiration of gastric material who were treated with glucocorticoids did not have improved survival but had a higher incidence of pneumonia (SED-12, 982).

In cases of pneumothorax with closed thoracotomy tube drainage, chronic glucocorticoid treatment has been reported to delay and impede re-expansion of the lung (SED-8, 820).

Hiccup is a rare complication of glucocorticoid therapy; five cases have been published at various times (31).

- A 59-year-old man had intractable hiccups during treatment with dexamethasone for multiple myeloma (32).
- Persistent hiccupping has been described in a 30-year-old man after the administration of a single

© 2006 Elsevier B.V. All rights reserved.

intravenous dose of dexamethasone (16 mg) (33). The symptom was resistant to metoclopramide and resolved spontaneously after 4 days. On rechallenge, the hiccups recurred within 2 hours and disappeared after 36 hours.

Low-dose metoclopramide can be effective and may allow a patient to continue beneficial therapy without the discomfort and exhaustion that can accompany intractable hiccups.

Ear, nose, throat

Atrophic changes and fungal and other infections can alter the nasal mucosa after aerosol treatment (34), and since most systematic published documentation on these intranasal products is limited to 1–2 years of experience (although they have been in use for a far longer period), some reserve is warranted with respect to their long-term safety and the wisdom of continual use.

Nervous system

Cerebral venous thrombosis associated with glucocorticoid treatment has rarely been reported. A relation between glucocorticoids and venous thrombosis has already been suggested but has never been clearly understood. Three young patients, two women (aged 28 and 45) and one man (aged 38 years), developed cerebral venous thrombosis after intravenous high-dose glucocorticoids (35). All presented with probable multiple sclerosis according to clinical, CSF, and MRI criteria. All had a lumbar puncture and were then treated with methylprednisolone 1 g/day for 5 days. All the usual causes of cerebral venous thrombosis were systematically excluded. The authors proposed that glucocorticoids interfere with blood coagulation and suggested that the administration of glucocorticoids after a lumbar puncture carries a particular risk of complications.

Dexamethasone is widely used for the prevention and treatment of chronic lung disease in premature infants, in whom follow-up studies have raised the possibility of an association with alterations in neuromotor function and somatic growth. In 159 survivors (mean age 53 months) of a previous placebo-controlled study, the children who had received dexamethasone had a significantly higher incidence of cerebral palsy (39/80 versus 12/79; OR = 4.62; 95% CI = 2.38, 8.98) (36). The most common form of cerebral palsy was spastic diplegia. Developmental delay was more frequent in the dexamethasone group (44/80 versus 23/79; OR = 2.9; CI = 1.5, 5.4).

Long-term treatment with glucocorticoids can cause cerebral atrophy (37).

Severe organic brain syndrome has been seen in six patients taking long-term glucocorticoids (SEDA-3, 304). The manifestations included confusion, disorientation, apathy, confabulation, irrelevant speech, and slow thinking; the symptoms occurred abruptly.

Latent epilepsy can be made manifest by glucocorticoid treatment. Seizures in patients with lung transplants were related to glucocorticoids, which had been used in high dosages to prevent organ rejection. There was an increased risk of seizures in younger patients (under 25 years) and with intravenous methylprednisolone (SEDA-21, 413) (38).

Long-term glucocorticoid treatment can result in papilledema and increased intracranial pressure (the syndrome of pseudotumor cerebri or so-called "benign intracranial hypertension"), particularly in children.

- Benign intracranial hypertension occurred in a 7-month-old child after withdrawal of topical betamethasone ointment and in a 7-year-old boy treated with a 1% cortisol ointment in large amounts.
- A 6-year-old girl, who had taken prednisone for 2.5 years for nephrotic syndrome with seven relapses in 3 years, developed symptoms of benign intracranial hypertension after oral glucocorticoid dosage reduction over 10 months from 30 mg/day to 2.5 mg/every other day (39). Laboratory studies and head CT scan were normal, but there was bilateral papilledema and the cerebrospinal fluid pressure was increased. She was given prednisone 1 mg/kg/day initially, with acetazolamide, and 25 ml of cerebrospinal fluid was removed. All her symptoms resolved and treatment was gradually withdrawn. She developed no further visual failure.

The symptoms can simulate those of an intracranial tumor. All patients taking large doses of glucocorticoids who complain of headache or blurred vision, particularly after a reduction in dosage, should have an ophthalmoscopic examination to exclude this complication. Paradoxically, cerebral edema occurring during a surgical procedure can be partly prevented by glucocorticoids (40).

An encephalopathy can occur at any age (SEDA-18, 387), not necessarily in association with intracranial hypertension.

There have been repeated reports of epidural lipomatosis, which can lead to spinal cord compression (41,42) or spinal fracture (43); in one instance, the excised lipomata contained brown fat, a phenomenon that may prove to be not unusual in glucocorticoid-induced lipomata (SEDA-16, 451).

- A 40-year-old woman with ulcerative colitis took cortisone 20 mg/day and developed progressive paraplegia (43). There was kyphosis of the thoracic spine from T7 to T9, with pathological fractures. An MRI scan showed massive epidural fat extending from T1 to T9. She recovered 3 months after surgical removal of the epidural fat.
- A 78-year-old man was given methylprednisolone (60 mg/day reducing to 8 mg/day) for temporal arteritis (44). After 4 months, he developed numbness and paresis of the legs and hyperalgesia at dermatomes T3 and T4. After 10 months he had marked disturbance of proprioception combined with spinal ataxia and an increasing loss of motor bladder control. There was an intraspinal epidural lipoma in the dorsal part of the spine from T1-10. The fat was removed surgically and within 4 weeks his gait disturbance and proprioception improved, the sensory deficit abated, and the bladder disorder disappeared completely.
- A 57-year-old man took prednisone 20–30 mg/day for 13 years for rheumatoid arthritis (45). He had been treated unsuccessfully with gold, azathioprine, hydroxychloroquine, and sulfasalazine; tapering his glucocorticoid dosage had been unsuccessful. He developed worsening back pain in his thoracic spine and lateral

© 2006 Elsevier B.V. All rights reserved.

leg weakness. He was unable to walk. He was Cushingoid and had marked thoracic kyphosis associated with multiple vertebral body fractures in T5-8. An MRI scan at T5-6 showed displacement and compression of the spinal cord by high-signal epidural fat, which had caused anterior thecal displacement and total effacement of cerebrospinal fluid.

The authors of the last report commented on the high dose of prednisone used.

In the past there was reason to think that glucocorticoids might precipitate multiple sclerosis. However, this has not been confirmed, and there is evidence that a special glucocorticoid regimen can actually be capable of retarding deterioration in multiple sclerosis (SEDA-18, 387).

A Guillain–Barré-like syndrome occurred in a patient receiving high-dose intravenous glucocorticoid therapy (SEDA-16, 449). Although glucocorticoids have been used successfully to treat weakness due to chronic inflammatory demyelinating sensorimotor neuropathy, other types of acquired chronic demyelinating neuropathies can be impaired by these drugs.

- In four patients with a pure motor demyelinating neuropathy treated with oral prednisolone (60 mg/day) motor function rapidly deteriorated within 4 weeks of starting prednisolone (SEDA-19, 375) (46). Intravenous immunoglobulin some months later in two of them produced clear improvement in strength and motor nerve conduction.

Sensory systems

The eye can be involved in generalized adverse reactions to systemically administered glucocorticoids. For example, conjunctivitis can occur as part of an allergic reaction and infections of the eye can be masked as a result of anti-inflammatory and analgesic effects. Ophthalmoplegia can occur as one of the consequences of glucocorticoid myopathy (SEDA-16, 450). Two complications that require special discussion are cataract and glaucoma.

Cataract

Oral glucocorticoid treatment is a risk factor for the development of posterior subcapsular cataract. A review of nine studies including 343 asthmatics treated with oral glucocorticoids showed a prevalence of posterior subcapsular cataracts of 0–54% with a mean value of 9% (47). In a 1993 study in children taking low-dose prednisone there were cataracts in seven of 23 cases (48). Some studies have shown a clear correlation with the duration of treatment and total dosage, others have not (SEDA-17, 449). The use of inhaled glucocorticoids was associated with a dose-dependent increased risk of posterior subcapsular and nuclear cataracts in 3654 patients aged 49–97 years (SEDA-22, 446) (49). Data on glucocorticoid use were available for 3313 of these patients; glucocorticoid use was classified as none in 2784 patients, inhaled only in 241, systemic only in 177, and both inhaled and systemic in 111. Compared with nonuse, current or prior use of inhaled glucocorticoids was associated with a significant increase in the prevalence of nuclear cataracts (adjusted relative prevalence = 1.5; 95% CI = 1.2, 1.9) and posterior subcapsular cataracts (1.9; 1.3, 2.8), but not cortical cataracts. The increased prevalence of posterior subcapsular cataracts was significantly associated with current use of inhaled glucocorticoids (2.6; 1.7, 4.0); there was no association with past use. Current use of inhaled glucocorticoids was also associated with an increased prevalence of cortical cataracts (1.4; 1.1, 1.7). The highest prevalences of posterior subcapsular and grade 4 or 5 nuclear cataracts were found in patients who had taken a cumulative dose of beclomethasone over 2000 mg.

It has been suggested that the risk of cataract is higher in patients with rheumatoid arthritis than in patients with bronchial asthma, and it is also higher in children. The reversibility of the lenticular changes has often been discussed (50,51), but even without glucocorticoid withdrawal regression has been found in children taking long-term treatment (52). Nevertheless, some 7% of the patients who develop cataract caused by glucocorticoid treatment have to be operated on. A change in permeability of the lens capsule, followed by altered electrolyte concentrations in the lens and a change in the mucopolysaccharides in the lens have been advanced as reasons for the development of cataract.

Increased intraocular pressure and glaucoma

Ocular hypertension and open-angle glaucoma are well-known adverse effects of ophthalmic administration of glucocorticoids (SEDA-17, 449).

Frequency

A total of 113 patients with angiographically proven subretinal neovascularization were enrolled into a prospective study of the effects of intravitreal triamcinolone (53). About 30% developed a significant rise in intraocular pressure (at least 5 mmHg) above baseline during the first 3 months.

A large case-control study, in which 9793 elderly patients with ocular hypertension or open-angle glaucoma were compared with 38 325 controls, has shown an increased risk of these complications with oral glucocorticoids (SEDA-22, 446) (54). The risk of ocular hypertension or open-angle glaucoma increased with increasing dose and duration of use of the oral glucocorticoid. There was no significant increase in the risk of ocular hypertension or open-angle glaucoma in patients who had stopped taking oral glucocorticoids 15–45 days before. The authors estimated that the excess risk of ocular hypertension or open-angle glaucoma with current oral glucocorticoid use is 43 additional cases per 10 000 patients per year. However, in patients taking over 80 mg/day of hydrocortisone equivalents, the excess risk is 93 additional cases per 10 000 patients per year. Monitoring of intraocular pressure may be justified in long-term users of oral glucocorticoids, as it is in long-term users of topical glucocorticoids.

Prolonged use of high doses of inhaled glucocorticoids also increases the risk of ocular hypertension and open-angle glaucoma (SEDA-22, 446) (55). In a case-control study of the records of 9793 elderly patients with ocular hypertension or open-angle glaucoma over a 6-year period, there was a significantly increased risk of ocular hypertension and open-angle glaucoma in patients who had taken high doses of inhaled glucocorticoids

© 2006 Elsevier B.V. All rights reserved.

(1500–1600 micrograms) for 3 months or longer (OR = 1.44; 95% CI = 1.01, 2.06). Both a high dosage of inhaled glucocorticoid and prolonged continuous duration of therapy had to be present to increase the risk.

Glaucoma and ocular hypertension have been reported after dermal application of glucocorticoids for facial atopic eczema (SEDA-19, 376) (56), and after treatment with beclomethasone by nasal spray and inhalation (SEDA-20, 373) (57).

The effects of topical dexamethasone on intraocular pressure have been compared with those of fluorometholone (SEDA-22, 446) (58). The ocular hypertensive response to topical dexamethasone in children occurs more often, more severely, and more rapidly than that reported in adults. It should be avoided in children if possible and it is desirable to monitor the intraocular pressure when it is being used. Fluorometholone may be more acceptable.

Pathogenesis

The pathogenesis of glucocorticoid-induced glaucoma is still unknown, but there is reduced outflow, and excessive accumulation of mucopolysaccharides may be a major factor. An association with cataract and papilledema has often been observed. The rise in intraocular pressure is variable: in the pediatric study of low dose cited above there was a reversible effect in only two of 23 subjects compared with controls, but in other studies serious increases in pressure have occurred, with a risk of blindness.

There is almost certainly a genetic predisposition to glucocorticoid-induced glaucoma, as there is to glaucoma in general.

Chorioretinopathy

Systemic glucocorticoid treatment can cause severe exacerbation of bullous exudative retinal detachment and lasting visual loss in some patients with idiopathic central serous chorioretinopathy (SEDA-20, 374) (59). The atypical presentation of this condition can include peripheral retinal capillary nonperfusion and retinal neovascularization. The treatment of choice in patients with idiopathic central serous chorioretinopathy is laser photocoagulation.

Keratopathy and keratitis

Band-shaped keratopathy is caused by the deposition of calcium salts in the basement membrane of the corneal epithelium and superficial stroma. It is typically a chronic process that develops over a period of months and years, and is associated with chronic corneal or intraocular inflammation.

- Infectious crystalline keratopathy developed in a 73-year-old woman with noninsulin-dependent diabetes mellitus after the use of topical prednisolone 1% eye-drops, for conjunctival injection over 12 months (SEDA-20, 372) (60).
- Acute-onset calcific band keratopathy has been reported in a woman using topical prednisolone (SEDA-20, 372) (61).

Patients with severe keratoconjunctivitis sicca are at definite risk of this complication, and the addition of phosphate-containing eye-drops tilted the precariously balanced situation toward precipitation of calcium in the cornea and bandage contact lens. Acetate-containing rather than phosphate-containing glucocorticoid eye drops may be a safer alternative in patients with such predisposing factors.

Bacterial keratitis is one of the most frequent ophthalmic infections. In a meta-analysis of publications from 1950 to 2000, the use of a topical glucocorticoid before the diagnosis of bacterial keratitis significantly predisposed to ulcerative keratitis in eyes with pre-existing corneal disease (OR = 2.63; 95% CI = 1.41, 4.91). Previous glucocorticoid use significantly increased the risk of antibiotic failure or other infectious complications (OR = 3.75; 95% CI = 2.52, 5.58). The use of glucocorticoids with an antibiotic for the treatment of bacterial keratitis did not increase the risk of complications, but neither did it improve the outcome of treatment.

Retinal damage

An apparent association between severe retinopathy of prematurity and dexamethasone therapy has been shown in a retrospective study (SEDA-20, 372) (62). Infants treated with dexamethasone required longer periods of mechanical ventilation (44 versus 26 days), had a longer duration of supplemental oxygen (57 versus 29 days), had a higher incidence of patent ductus arteriosus (28/38 versus 18/52), and required surfactant therapy more often for respiratory distress syndrome (17/38 versus 11/52). Prospective, randomized, controlled studies are needed to correct for differences in severity of cardiorespiratory disease. Until such studies are available, careful consideration must be given to indications, dosage, time of initiation, and duration of treatment with dexamethasone in infants of extremely low birthweight.

Retinal hemorrhage occurred in four women after they had received epidural methylprednisolone for chronic back and hip pain (SEDA-20, 373) (63). Retinal and choroidal vascular occlusions are a serious and sometimes lasting complication of periocular and facial injections of glucocorticoids (SEDA-21, 416).

Toxic optic neuropathy

Toxic optic neuropathy can occur and may underlie various reports of sudden blindness in patients taking glucocorticoids. In one case, transient visual loss occurred on several occasions, each time after administration of a glucocorticoid (SEDA-17, 447). In another case, blindness occurred suddenly and paradoxically after glucocorticoid injections into the nasal turbinates (64). Although glucocorticoids are sometimes used successfully to relieve pre-existing optic neuritis, a number of such patients react adversely with increased episodes of visual loss.

Exophthalmos

Exophthalmos has been described incidentally as a complication of long-term glucocorticoid therapy and there has been a series of 21 cases (65).

Psychological, psychiatric

The psychostimulant effects of the glucocorticoids are well known (66), and their dose dependency is recognized (SED-11, 817); they may amount to little more than

© 2006 Elsevier B.V. All rights reserved.

euphoria or comprise severe mental derangement, for example mania in an adult with no previous psychiatric history (SEDA-17, 446) or catatonic stupor demanding electroconvulsive therapy (67). In their mildest form, and especially in children, the mental changes may be detectable only by specific tests of mental function (68). Mental effects can occur in patients treated with fairly low doses; they can also occur after withdrawal or omission of treatment, apparently because of adrenal suppression (69,70).

- A 32-year-old woman developed irritability, anger, and insomnia after taking oral prednisone (60 mg/day) for a relapse of ileal Crohn's disease (71). The prednisone was withdrawn and replaced by budesonide (9 mg/day), and the psychiatric adverse effects were relieved after 3 days. A good clinical response was maintained, with no relapse after 2 months of budesonide therapy.

Development

Dexamethasone has been used in ventilator-dependent preterm infants to reduce the risk and severity of chronic lung disease. Usually it is given in a tapering course over a long period (42 days). The effects of dexamethasone on developmental outcome at 1 year of age has been evaluated in 118 infants of very low birthweights (47 boys and 71 girls, aged 15–25 days), who were not weaning from assisted ventilation (72). They were randomly assigned double-blind to receive placebo or dexamethasone (initial dose 0.25 mg/kg) tapered over 42 days. A neurological examination, including ultrasonography, was done at 1 year of age. Survival was 88% with dexamethasone and 74% with placebo. Both groups obtained similar scores in mental and psychomotor developmental indexes. More dexamethasone-treated infants had major intracranial abnormalities (21 versus 11%), cerebral palsy (25 versus 7%; OR = 5.3; CI = 1.3, 21), and unspecified neurological abnormalities (45 versus 16%; OR = 3.6; CI = 1.2, 11). Although the authors suggested an adverse effect, they added other possible explanations for these increased risks (improved survival in those with neurological injuries or at increased risk of such injuries).

Behavioral disorders

Children have marked increases in behavioral problems during treatment with high-dose prednisone for relapse of nephrotic syndrome, according to the results of a study conducted in the USA (73). Ten children aged 2.9–15 years (mean 8.2 years) received prednisone 2 mg/kg/day, tapering at the time of remission, which was at week 2 in seven patients. At baseline, eight children had normal behavioral patterns and two had anxious/depressed and aggressive behavior using the Child Behaviour Checklist (CBCL). During high-dose prednisone therapy, five of the eight children with normal baseline scores had CBCL scores for anxiety, depression, and aggressive behavior above the 95th percentile for age. The two children with high baseline CBCL scores had worsening behavioral problems during high-dose prednisone. Behavioral problems occurred almost exclusively in the children who received over 1 mg/kg every 48 hours. Regression analysis showed that prednisone dosage was a strong predictor of increased aggressive behaviour.

Intravenous methylprednisolone was associated with a spectrum of adverse reactions, most frequently behavioral disorders, in 213 children with rheumatic disease, according to the results of a US study (12). However, intravenous methylprednisolone was generally well tolerated. The children received their first dose of intravenous methylprednisolone 30 mg/kg over at least 60 minutes, and if the first dose was well tolerated they were given further infusions at home under the supervision of a nurse. There was at least one adverse reaction in 46 children (22%) of whom 18 had an adverse reaction within the first three doses. The most commonly reported adverse reactions were behavioral disorders (21 children), including mood changes, hyperactivity, hallucinations, disorientation, and sleep disorders. Several children had serious acute reactions, which were readily controlled. Most of them were able to continue methylprednisolone therapy with premedication or were given an alternative glucocorticoid. The researchers emphasized the need to monitor treatment closely and to have appropriate drugs readily available to treat adverse reactions.

Large doses are most likely to cause the more serious behavioral and personality changes, ranging from extreme nervousness, severe insomnia, or mood swings to psychotic episodes, which can include both manic and depressive states, paranoid states, and acute toxic psychoses. A history of emotional disorders does not necessarily preclude glucocorticoid treatment, but existing emotional instability or psychotic tendencies can be aggravated by glucocorticoids. Such patients as these should be carefully and continuously observed for signs of mental changes, including alterations in the sleep pattern. Aggravation of psychiatric symptoms can occur not only during high-dose oral treatment, but also after any increase in dosage during long-term maintenance therapy; it can also occur with inhalation therapy (74). The psychomotor stimulant effect is said to be most pronounced with dexamethasone and to be much less with methylprednisolone, but this concept of a differential psychotropic effect still has to be confirmed.

Memory

The effects of prednisone on memory have been assessed (SEDA-21, 413) (75). Glucocorticoid-treated patients performed worse than controls in tests of explicit memory. Pulsed intravenous methylprednisolone (2.5 g over 5 days, 5 g over 7 days, or 10 g over 5 days) caused impaired memory in patients with relapsing-remitting multiple sclerosis, but this effect is reversible, according to the results of an Italian study (76). Compared with ten control patients, there was marked selective impairment of explicit memory in 14 patients with relapsing-remitting multiple sclerosis treated with pulsed intravenous methylprednisolone. However, this memory impairment completely resolved 60 days after methylprednisolone treatment.

Glucocorticoids can regulate hippocampal metabolism, physiological functions, and memory. Despite evidence of memory loss during glucocorticoid treatment (SEDA-23, 428), and correlations between memory and cortisol

© 2006 Elsevier B.V. All rights reserved.

concentrations in certain diseases, it is unclear whether exposure to the endogenous glucocorticoid cortisol in amounts seen during physical and psychological stress in humans can inhibit memory performance in otherwise healthy individuals. In an elegant experiment on the effect of cortisol on memory, 51 young healthy volunteers (24 men and 27 women) participated in a double-blind, randomized, crossover, placebo-controlled trial of cortisol 40 mg/day or 160 mg/day for 4 days (77). The lower dose of cortisol was equivalent to the cortisol delivered during a mild stress and the higher dose to major stress. Cognitive performance and plasma cortisol were evaluated before and until 10 days after drug administration. Cortisol produced a dose-related reversible reduction in verbal declarative memory without effects on nonverbal memory, sustained or selective attention, or executive function. Exposure to cortisol at doses and plasma concentrations associated with physical and psychological stress in humans can reversibly reduce some elements of memory performance.

Prednisone, 10 mg/day for 1 year, has been evaluated in 136 patients with probable Alzheimer's disease in a double-blind, randomized, placebo-controlled trial (78). There were no differences in the primary measures of efficacy (cognitive subscale of the Alzheimer Disease Assessment Scale), but those treated with prednisone had significantly greater memory impairment (Clinical Dementia sum of boxes), and agitation and hostility/suspicion (Brief Psychiatric Rating Scale). Other adverse effects in those who took prednisone were reduced bone density and a small rise in intraocular pressure.

In healthy individuals undergoing acute stress, there was specifically impaired retrieval of declarative long-term memory for a word list, suggesting that cortisol-induced impairment of retrieval may add significantly to the memory deficits caused by prolonged treatment (79).

Sleep

The effects of acute systemic dexamethasone administration on sleep structure have been investigated. Dexamethasone caused significant increases in REM latency, the percentage time spent awake, and the percentage time spent in slow-wave sleep. There were also significant reductions in the percentage time spent in REM sleep and the number of REM periods (SEDA-21, 413) (80).

Psychoses

Mania has been attributed to glucocorticoids (81).

- A 46-year-old man, with an 8-year history of cluster headaches and some episodes of endogenous depression, took glucocorticoids 120 mg/day for a week and then a tapering dosage at the start of his latest cluster episode. His headaches stopped but then recurred after 10 days. He was treated prophylactically with verapamil, but a few days later, while the dose of glucocorticoid was being tapered, he developed symptoms of mania. The glucocorticoids were withdrawn, he was given valproic acid, and his mania resolved after 10 days. Verapamil prophylaxis was restarted and he had no more cluster headaches.

The authors commented that the manic symptoms had probably been caused by glucocorticoids or glucocorticoid withdrawal. They concluded that patients with cluster headache and a history of affective disorder should not be treated with glucocorticoids, but with valproate or lithium, which are effective in both conditions. Lamotrigine, an anticonvulsive drug with mood-stabilizing effects, may prevent glucocorticoid-induced mania in patients for whom valproate or lithium are not possible (82).

Glucocorticoids can cause neuropsychiatric adverse effects that dictate a reduction in dose and sometimes withdrawal of treatment. Of 32 patients with asthma (mean age 47 years) who took prednisone in a mean dosage of 42 mg/day for a mean duration of 5 days, those with past or current symptoms of depression had a significant reduction in depressive symptoms during prednisone therapy compared with those without depression (83). After 3–7 days of therapy there was a significant increase in the risk of mania, with return to baseline after withdrawal.

The management of a psychotic reaction in an Addisonian patient taking a glucocorticoid needs special care (SED-8, 820). Psychotic reactions that do not abate promptly when the glucocorticoid dosage is reduced to the lowest effective value (or withdrawn) may need to be treated with neuroleptic drugs; occasionally these fail and antidepressants are needed (SEDA-18, 387). However, in other cases, antidepressants appear to aggravate the symptoms.

- Two patients with prednisolone-induced psychosis improved on giving the drug in three divided daily doses. Recurrence was avoided by switching to enteric-coated tablets.

This suggests that in susceptible patients the margin of safety may be quite narrow (SED-12, 982). It is possible that reduced absorption accounted for the improvement in this case, but attention should perhaps be focused on peak plasma concentrations rather than average steady-state concentrations.

In one case, glucocorticoid-induced catatonic psychosis unexpectedly responded to etomidate (84).

- A 27-year-old woman with myasthenia gravis taking prednisolone 100 mg/day became unresponsive and had respiratory difficulties. She was given etomidate 20 mg intravenously to facilitate endotracheal intubation. One minute later she became alert and oriented, with normal muscle strength, and became very emotional. Eight hours later she again became catatonic and had a similar response to etomidate 10 mg. Glucocorticoid-induced catatonia was diagnosed, her glucocorticoid dosage was reduced, and she left hospital uneventfully 4 days later.

The effect of etomidate on catatonia, similar to that of amobarbital, was thought to be due to enhanced GABA receptor function in patients with an overactive reticular system.

A case report has suggested that risperidone, an atypical neuroleptic drug, can be useful in treating adolescents with glucocorticoid-induced psychosis and may hasten its resolution (85).

- A 14-year-old African-American girl with acute lymphocytic leukemia was treated with dexamethasone

© 2006 Elsevier B.V. All rights reserved.

24 mg/day for 25 days. Four days after starting to taper the dose she had a psychotic reaction with visual hallucinations, disorientation, agitation, and attempts to leave the floor. Her mother refused treatment with haloperidol. Steroids were withdrawn and lorazepam was given as needed. Nine days later the symptoms had not improved. She was given risperidone 1 mg/day; within 3 days the psychotic reaction began to improve and by 3 weeks the symptoms had completely resolved.

Obsessive-compulsive disorder

Obsessive-compulsive behavior after oral cortisone has been described (86).

- A 75-year-old white man, without a history of psychiatric disorders, took cortisone 50 mg/day for 6 weeks for pulmonary fibrosis and developed severe obsessive-compulsive behavior without affective or psychotic symptoms. He was given risperidone without any beneficial effect. The dose of cortisone was tapered over 18 days. An MRI scan showed no signs of organic brain disease and an electroencephalogram was normal. His symptoms improved 16 days after withdrawal and resolved completely after 24 days. Risperidone was withdrawn without recurrence.

Endocrine

The endocrine effects of the glucocorticoids variously involve the pituitary–adrenal axis, the ovaries and testes, the parathyroid glands, and the thyroid gland.

Pituitary gland

Empty sella syndrome occurred in a boy who developed hypopituitarism after long-term pulse therapy with prednisone for nephrotic syndrome (87).

- A 16-year-old Japanese boy's growth and development was normal until the age of 2 years. He then developed nephrotic syndrome and was treated with pulsed glucocorticoid therapy nine times over the next 14 years. After the age of 3 years, his rate of growth had fallen. At 16 years, when he was taking prednisone 60 mg/m^2/day he was given prednisone on alternate days and the dose was gradually tapered. The secretion of pituitary hormones, except antidiuretic hormone, was impaired and an MRI scan of his brain showed an empty sella and atrophy of the pituitary gland.

When markedly impaired growth is noted in patients treated with glucocorticoids long-term or in pulses, it is necessary to assess pituitary function and the anatomy of the pituitary gland. Children who receive glucocorticoid pulse therapy may develop an empty sella more frequently than is usually recognized.

Pituitary–adrenal axis

Raised glucocorticoid plasma concentrations usually result, after 2 weeks, in the first signs of iatrogenic Cushing's syndrome. The characteristic symptoms can occur individually or in combination. Whereas in Cushing's disease or corticotropin–induced Cushing's syndrome, the predominant symptoms are in part determined by hyperandrogenicity and tend to comprise hypertension, acne, impaired sight, disorders of sexual function, hirsutism or virilism, striae of the skin, and plethora, Cushing's syndrome due to glucocorticoid therapy is likely to cause benign intracranial hypertension, glaucoma, subcapsular cataract, pancreatitis, aseptic necrosis of the bones, and panniculitis. Obesity, facial rounding, psychiatric symptoms, edema, and delayed wound healing are common to these different forms of Cushing's syndrome.

It has been said that Cushing-like effects are to be expected if the function of the adrenal cortex is suppressed by daily doses of more than 50 mg hydrocortisone or its equivalent. However, pituitary–adrenal suppression has been described at lower dosage equivalents, for example during prolonged intermittent therapy with dexamethasone (88). The secondary adrenal insufficiency caused by therapeutically effective doses can be observed even after giving prednisone 5 mg tds for only 1 week; after withdrawal, adrenal suppression lasts for some days. If one continues this treatment for about 20 weeks, maximal atrophy of the adrenal cortex results, and lasts for some months. This effect begins with inhibition of the hypothalamus, and culminates in true atrophy of the adrenal cortex. It can occur even with glucocorticoids given by inhalation (89). Inhaled fluticasone is associated with at least a twofold greater suppression of adrenal function than inhaled budesonide microgram for microgram, according to the results of a crossover study (SEDA-21, 415) (90). Patients with liver disease may experience adrenal suppression with lower doses of glucocorticoids (91). It is advisable to use alternate-day therapy to avoid suppression of corticotropin secretion in patients who will need long-term therapy; it will produce the same therapeutic effect as daily dosage. It can be helpful to measure the degree of suppression of corticotropin secretion during long-term glucocorticoid treatment of asthmatic children, as a means of optimizing therapy and avoiding excessive dosage (92). The period of time during which the patient should be considered at risk of adrenal insufficiency after withdrawal of oral prednisolone treatment in childhood nephrotic syndrome is still controversial. A study in such patients has suggested that adrenal insufficiency may occur up to 9 months after treatment has ended (SEDA-19, 376) (93).

Many protocols for treating children with early B cell acute lymphoblastic leukemia involve 28 consecutive days of high-dose glucocorticoids during induction. The effect of this therapy on adrenal function has been prospectively evaluated (94) in 10 children by tetracosactide stimulation before the start of dexamethasone therapy and every 4 weeks thereafter until adrenal function returned to normal. All had normal adrenal function before dexamethasone treatment and impaired adrenal responses 24 hours after completing therapy. Each child felt ill for 2–4 weeks after completing therapy. Seven patients recovered normal adrenal function after 4 weeks, but three did not have normal adrenal function until 8 weeks after withdrawal. Thus, high-dose dexamethasone therapy can cause adrenal insufficiency lasting more than 4 weeks after the end of treatment. This problem might be avoided by tapering doses of glucocorticoids and providing supplementary glucocorticoids during periods of increased stress.

© 2006 Elsevier B.V. All rights reserved.

Tolerance to glucocorticoids in this, as in some other respects, varies from individual to individual; some patients tolerate 30 mg of prednisone for a long time without developing Cushing's syndrome, while others develop symptoms at 7.5 mg; the doses recommended today to avoid Cushing's syndrome in most patients are usually equivalent to hydrocortisone 20 mg. Cushing's syndrome and other systemic adverse effects can occur not only from oral and injected glucocorticoids, but also from topical and intranasal treatment (95) and intrapulmonary or epidural administration (SEDA-19, 376) (SEDA-20, 370) (96,97).

- Two patients developed hypopituitarism and empty sella syndrome during glucocorticoid pulse therapy for nephrotic syndrome (SEDA-22, 444) (98).

Glucocorticoid-treated patients with inadequate adrenal function who have an intercurrent illness or are due to undergo surgery will have an inadequate reaction to the resulting stress and need to be temporarily protected by additional glucocorticoid (99).

Pseudohyperaldosteronism has been reported even after intranasal application of 9-alpha-fluoroprednisolone (SEDA-11, 340).

Parathyroid function

There is antagonism between the parathyroid hormone and glucocorticoids (100). Latent hyperparathyroidism can be unmasked by glucocorticoids (101).

Thyroid function

Even a single dose of corticotropin briefly inhibits the secretion of thyrotrophic hormone. The uptake of radioactive iodine is also suppressed by corticotropin and by glucocorticoids, but this has no clinical relevance. Pathological changes in thyroid function induced by glucocorticoid treatment are reportedly rare.

Metabolism

Glucose metabolism

All glucocorticoids increase gluconeogenesis. The turnover of glucose is increased, more being metabolized to fat, and blood glucose concentration is increased by 10–20%. Glucose tolerance and sensitivity to insulin are reduced, but provided pancreatic islet function is normal, carbohydrate metabolism will not be noticeably altered. So-called "steroid diabetes," a benign diabetes without a tendency to ketosis, but with a low sensitivity to insulin and a low renal threshold to glucose, only develops in one-fifth of patients treated with high glucocorticoid dosages. Even in patients with diabetes, ketosis is not to be expected, since glucocorticoids have antiketotic activity, presumably through suppression of growth hormone secretion.

Glucocorticoid treatment of known diabetics normally leads to deregulation, but this can be compensated for by adjusting the dose of insulin. The increased gluconeogenesis induced by glucocorticoids mainly takes place in the liver, but glucocorticoid treatment is especially likely to disturb carbohydrate metabolism in liver disease.

When hyperglycemic coma occurs it is almost always of the hyperosmolar nonketotic type. After termination of glucocorticoid treatment, steroid diabetes normally disappears. An apparent exception to these findings is provided by the case of a patient in whom glucocorticoid treatment was followed by severe diabetes with diabetic nephropathy, but this was a seriously ill individual who had already undergone renal transplantation (SEDA-17, 449). Gestational diabetes mellitus was more common in women who had received glucocorticoids with or without beta-adrenoceptor agonists for threatened preterm delivery compared with controls (SEDA-22, 445) (102).

Glucocorticoids probably have more than one effect on carbohydrate metabolism. An increase in fasting glucagon concentration has been observed in volunteers given prednisolone 40 mg/day for 4 days, and this effect may be involved, alongside gluconeogenesis, in glucocorticoid-induced hyperglycemia. Some newer glucocorticoids have been claimed to have smaller effects on blood glucose (as well as less salt and water retention), but further studies are needed to confirm whether this interesting therapeutic approach has been successful (SEDA-13, 353).

Deflazacort, an oxazoline derivative of prednisolone, was introduced as a potential substitute for conventional glucocorticoids in order to ameliorate glucose intolerance. In a randomized study in kidney transplant recipients with pre- or post-transplantation diabetes mellitus, 42 patients who switched from prednisone to deflazacort (in the ratio 5:6 mg) were prospectively compared with 40 patients who continued to take prednisone (SEDA-22, 445) (103). During the mean follow-up period of 13 months, neither graft dysfunction nor acute rejection developed in the conversion group, and there was improvement in blood glucose control. When the conversion group was stratified into those with pre- or post-transplantation diabetes, there were promising effects in the patients with post-transplantation diabetes. More than a 50% dosage reduction of hypoglycemic drugs was possible in 42% of those with post-transplantation diabetes.

The risk of hyperglycemia requiring treatment in patients receiving oral glucocorticoids has been quantified in a case-control study of 11 855 patients, 35 years of age or older, with newly initiated treatment with a hypoglycemic drug (SEDA-19, 375) (104). The risk for initiating hypoglycemic therapy increased with the recent use of a glucocorticoid. The risk grew with increasing average daily glucocorticoid dosage (in mg of hydrocortisone equivalents): 1.77 for 1–39 mg/day, 3.02 for 40–79 mg/day, 5.82 for 80–119 mg/day, and 10.34 for 120 mg/day or more.

Lipid metabolism

High-dose glucocorticoid therapy can cause marked hypertriglyceridemia, with milky plasma (SEDA-15, 421) (SEDA-16, 450). It has been suggested that this is caused by abnormal accumulation of dietary fat, reduced postheparin lipolytic activity, and glucose intolerance (105). An association between glucocorticoid exposure and hypercholesterolemia has been found in several studies (106) and can contribute to an increased risk of atherosclerotic vascular disease.

Most premature neonates need intravenous lipids during the first few weeks of life to acquire adequate energy

© 2006 Elsevier B.V. All rights reserved.

intake and prevent essential fatty acid deficiency before they can tolerate all nutrition via enteral feeds. Dexamethasone is associated with multiple adverse effects in neonates, including poor weight gain and impairment of glucose and protein metabolism. In ten neonates (four boys, mean age 17.3 days) taking dexamethasone for bronchopulmonary dysplasia, intravenous lipids (3 g/kg/day) caused hypertriglyceridemia in the presence of hyperinsulinemia and increased free fatty acid concentrations (107). Because of concomitant hyperinsulinemia, the authors speculated that dexamethasone reduced fatty acid oxidation, explaining poor weight gain.

Altered fat deposition has been repeatedly reported. Fat can be deposited epidurally and at other sites. Adiposis dolora, which involves the symmetrical appearance of multiple painful fat deposits in the subcutaneous tissues, has on one occasion been attributed to glucocorticoids (SEDA-16, 451).

Tumor lysis syndrome

Acute tumor lysis syndrome is a life-threatening metabolic emergency that results from rapid massive necrosis of tumor cells. There have been repeated reports of an acute tumor lysis syndrome when glucocorticoids are administered in patients with pre-existing lymphoid tumors (108).

- A 60-year-old woman took dexamethasone 4 mg 8-hourly for dyspnea due to a precursor T lymphoblastic lymphoma-leukemia with bilateral pleural effusions and a large mass in the anterior mediastinum (109). She developed acute renal insufficiency and laboratory evidence of the metabolic effects of massive cytolysis. She received vigorous hydration, a diuretic, allopurinol, and hemodialysis. She recovered within 2 weeks and then underwent six courses of CHOP chemotherapy. The mediastinal mass regressed completely. She remained asymptomatic until she developed full-blown acute lymphoblastic leukemia, which was resistant to treatment.

Electrolyte balance

The severity of potassium loss due to glucocorticoids depends partly on the amount of sodium in the diet; the most widely used synthetic glucocorticoids cause less potassium excretion than natural hydrocortisone does. Prednisone and prednisolone have a glucocorticoid activity 4–5 times that of hydrocortisone, but their mineralocorticoid activity is less (see Table 1); even at high dosages they do not cause noteworthy sodium and water retention. Of the major synthetic glucocorticoids, dexamethasone has the strongest anti-inflammatory, hyperglycemic, and corticotropin-inhibitory activity; sodium retention is completely absent; the degree of glucocorticoid-induced metabolic alkalosis may also be less with dexamethasone than with hydrocortisone or methylprednisolone (SEDA-10, 343).

Mineral balance

There can be increases in calcium and phosphorus loss because of effects on both the kidney and the bowel, with increased excretion and reduced resorption (110). Tetany, which has been seen in patients receiving high-dose long-term intravenous glucocorticoids, has been explained as being due to hypocalcemia, and there are also effects on bone. Tetany has also been reported in a patient with latent hyperparathyroidism after the administration of a glucocorticoid (101).

Hypocalcemic encephalopathy occurred in a 35-year-old woman with hypoparathyroidism. It was believed that the administration of methylprednisolone intramuscularly had precipitated severe hypocalcemia, which had led to a metabolic encephalopathy (SEDA-20, 371) (111).

The administration of large doses of glucocorticoids to patients with major burns presenting with low cardiac output has been reported to produce a reversible drop in serum zinc, which might lead to impaired tissue repair (SED-8, 824), but it is not clear whether this has clinical effects.

Metal metabolism

Glucocorticoids increase chromium losses and glucocorticoid-induced diabetes can be reversed by chromium supplementation (112). Doses of hypoglycemic drugs were also reduced by 50% in all patients when they were given supplementary chromium.

Hematologic

Erythrocytes

Polycythemia is a symptom of Cushing's syndrome, and conversely anemia correlates with Addison's disease, but polycythemia is not generally encountered as a consequence of treatment with glucocorticoids, perhaps because there is no increased secretion of androgens; an increase in hemoglobin was nevertheless the most frequent adverse effect observed in a study over 8 years of 77 patients treated for hyperergic-allergic reactions. At the beginning of treatment more than 40% (and during continuous therapy more than 70%) of patients showed this change in erythrocytes (113). There was leukocytosis in more than 60% in the early phases and in more than 40% later (113). Thrombocytosis occurred in 5–10% during continuous treatment. This report agrees fairly well with some older publications, but it has been noted in the past that in the long run very high-dose glucocorticoid treatment can result in suppression of the activity of the bone marrow with fatty infiltration replacing hemopoietic tissue.

Leukocytes

Not all classes of leukocytes are affected by glucocorticoids in the same way. The total leukocyte count is increased, but the number of eosinophilic leukocytes falls, as does the lymphocyte count. The number of monocytes is reduced, as is their capacity to perform phagocytosis.

In children, a leukemoid reaction has been induced by betamethasone treatment (114); this possibility must always be borne in mind, since glucocorticoids can actually be used to treat leukemia or its complications. A case of very high white blood cell count with neutrophilia in a preterm infant whose mother had received two doses of betamethasone prenatally to enhance fetal lung maturation is one of a short list of leukemoid reactions possibly attributable to antenatal glucocorticoid treatment (115).

© 2006 Elsevier B.V. All rights reserved.

It is possible that in children with acute lymphoblastic leukemia, glucocorticoid therapy adversely affects the duration of remissions, and it has therefore been suggested that leukemia should be ruled out in children before starting long-term therapy with glucocorticoids (SEDA-11, 340). Depression of the lymphocyte count seems to be a general and direct action of the glucocorticoids (116), but the mechanism is still incompletely understood; certainly, lymphocytolysis seems to be increased by glucocorticoids. Studies of lymphocyte subpopulations show a preferential reduction in T cells, while B cells are constant or slightly reduced. B lymphocyte function (measured as immunoglobulin synthesis) falls, suppressor T lymphocyte activity is suppressed, and helper T lymphocyte function is unaffected by glucocorticoids (SEDA-3, 308) (117).

- Fever and leukopenia with methylprednisolone and prednisolone has been reported in a 29-year-old woman with systemic lupus erythematosus (118).

The authors commented that fever associated with glucocorticoids occurs frequently, whereas leukopenia is rare. Fever and leukopenia are important signs of an exacerbation of systemic lupus erythematosus, and it would be difficult to distinguish between an exacerbation of the disease and an adverse effect of glucocorticoids.

Platelets and coagulation

In heart transplant recipients, intramuscular glucocorticoids can impair fibrinolysis, producing susceptibility to thrombotic disease (SEDA-22, 443) (119). They can also increase the platelet count. In one patient the blue toe syndrome occurred repeatedly when glucocorticoids were used to increase the platelet count (SEDA-16, 451).

Mouth and teeth

Oral candidiasis is seen in some 5–10% of patients who use inhaled glucocorticoids, particularly when oral hygiene is poor, but is rarely symptomatic. The risk can be reduced by the use of a large-volume spacer (120,121).

Hypertrophy of the tongue has been attributed to inhaled beclomethasone and may have been related to edema of the buccal mucosa and tongue from direct contact with the glucocorticoid, infection, glossitis caused by glucocorticoid therapy, a direct effect of glucocorticoids on the tongue muscle, or excess localized deposition of fat, as is seen in patients given systemic glucocorticoids (SEDA-20, 371) (122).

Gastrointestinal

Peptic ulceration

It is no longer seriously believed that glucocorticoid treatment in adults markedly increases the risk of peptic ulceration (123,124). However, the symptoms of an existing peptic ulcer can certainly be masked. There may also be a genuine risk of ulcerative disorders in premature children. The issue has often been complicated by the simultaneous (sometimes unrecorded) use of ulcerogenic non-steroidal anti-inflammatory agents. A meta-analysis of whether glucocorticoid therapy caused peptic ulcer and other putative complications of glucocorticoid therapy was negative: peptic ulcers occurred in nine of 3267 patients in the placebo group (0.03%) and 13 of 3335 patients in the glucocorticoid group (0.04%).

Peptic ulcer should not be considered a contraindication when glucocorticoid therapy is indicated (SEDA-19, 376) (125). However, the risk of a fatal outcome due to ulcer complications was increased about fourfold in a previous case-control study. Gastrointestinal hemorrhage occurred more often in glucocorticoid-treated patients (2.25%) than in controls (1.6%) (126). The frequency of gastrointestinal bleeding in these studies compares well with earlier observations in the Boston Collaborative Surveillance Program's 1978 report, according to which 0.5% of a large series of medical inpatients taking glucocorticoids had gastrointestinal bleeding sufficiently severe to require transfusions and 28% had minor bleeding (SED-12, 986).

- A 47-year-old woman developed a gastrocolic fistula during treatment with aspirin (dosage and duration of therapy not stated) and prednisone for chronic rheumatoid arthritis (127).

The author commented that 50–75% of gastrocolic fistulas are related to benign gastric ulcers secondary to the use of NSAIDs. The use of aspirin plus prednisone, as in this patient, increases the risk of complication of peptic ulcer disease two- to fourfold.

The mechanism of whatever harm glucocorticoids may do to the stomach is not clear; cortisol neither consistently increases acid or pepsinogen secretion, nor reduces the protective production of mucin by the gastric mucosa. Serum gastrin concentrations are raised in Cushing's syndrome and in patients taking prolonged glucocorticoid treatment. On the other hand, the secretion of prostaglandin E_2 in gastric juice in response to pentagastrin was impaired during glucocorticoid therapy in children. Since PGE_2 has a cytoprotective effect on the gastric mucosa, impaired secretion in response to increased acid secretion during glucocorticoid therapy may be related to the development of peptic ulcer (SEDA-19, 376) (128).

Some reports suggest that people with hepatic cirrhosis or nephrotic syndrome are particularly at risk. Whatever the degree of risk, patients taking long-term glucocorticoids should be regularly checked to detect peptic ulcers, which can bleed and even perforate without producing pain. There do not seem to be differences in gastric tolerance between the various synthetic glucocorticoids.

Regional ileitis

While glucocorticoids may have a beneficial effect on regional ileitis, perforation of the ileum, lymphatic dilatation, and microscopic fistulae have been observed after treatment.

Ischemic colitis

Glucocorticoids should be used with caution in progressive systemic sclerosis, and concomitant administration of anticoagulants to prevent ischemic colitis is recommended when administering glucocorticoids in high doses, especially by pulse therapy (SEDA-21, 415) (129).

© 2006 Elsevier B.V. All rights reserved.

Ulcerative colitis

A possible risk of glucocorticoid treatment of ulcerative colitis is the development of toxic megacolon or colonic perforation. A change from ulcerative colitis to Crohn's disease may have been induced by prolonged treatment with glucocorticoids (SEDA-19, 376) (130). This case provides further evidence for the view that ulcerative colitis and Crohn's disease may represent a continuous spectrum of inflammatory bowel disease and raises the possibility that reduced polymorphonuclear leukocyte function caused by glucocorticoids may have provoked the development of granulomata.

Diverticular disease

Existing diverticula can perforate during glucocorticoid therapy (SEDA-18, 387). Abdominal tenderness is the most common and often the only early sign of perforated diverticula in patients taking glucocorticoids. However, in some cases, even abdominal tenderness is absent (SEDA-22, 445) (131).

- Perforation of the sigmoid colon occurred in a 61-year-old Caucasian man with colonic diverticular disease and rheumatoid arthritis treated with pulses of methylprednisolone 1 g (132).

The authors suggested that methylprednisolone pulses should be used carefully in patients over 50 years of age and/or people with demonstrated or suspected diverticular disease.

Liver

The process of gluconeogenesis, which is promoted by glucocorticoids, takes place mainly in the liver. The glycolytic enzymes of the liver are also activated by these glucocorticoids. The synthesis of ribonucleic acid and of enzymes involved in protein catabolism is increased, but the process of protein catabolism takes place outside the liver as well, for example in the muscles. There is experimental evidence for glucocorticoid-induced enhancement of hepatic lipid synthesis (SEDA-3, 308), but the main effect of glucocorticoids in this connection is lipid mobilization from adipose tissue. The influence of long-term glucocorticoid treatment on liver function is still unknown. If pathological changes are diagnosed, the possible influence of the disease which is being treated has to be borne in mind.

Liver damage from glucocorticoids is rarely severe, but fatal liver failure has been reported.

- A 71-year-old white woman with a compressive optic neuropathy was given five cycles of intravenous methylprednisolone 1 g/day for 3 days followed by tapering oral cortisone for 10–14 days (133). The intervals between cycles were 14 days to 6 weeks. She was otherwise healthy and had no history of liver disease. Her liver function tests were normal or only slightly raised during the first five cycles. She then developed raised liver enzymes, a prolonged prothrombin time, and fatal liver failure. Postmortem examination showed necrosis of the liver parenchyma. Hepatitis serology (A, B, and C) was negative as was in situ hybridization for immunohistochemical proof of hepatitis Bs and Bc or delta virus antibodies in the liver.
- A 53-year-old woman who took prednisolone 20 mg/day for systemic lupus erythematosus for 38 days developed increased aspartate transaminase and alanine transaminase activities (175 and 144 IU/l respectively on day 38 and 871 and 658 IU/l on day 69) (134). She denied taking hepatotoxic drugs. Serological tests for hepatitis viruses were all negative. Autoantibodies against mitochondria and smooth muscle were not detected. Ultrasound and CT scan were consistent with fatty infiltration. Histology showed macrovesicular fat infiltration, periportal cell infiltration with fibrosis, and a few Mallory bodies. The glucocorticoid was gradually tapered and the transaminases gradually fell.
- A 67-year-old teetotaler was given intravenous prednisolone 25 mg tds for primary dermatomyositis and 8 days later developed painless icteric hepatitis, with daily progressive marked deterioration of liver biochemistry (135). She had not taken any other hepatotoxic drugs, and serological tests for hepatitis and hepatotropic viruses were all negative. Antinuclear, antimitochondrial, and smooth muscle autoantibodies were negative. Ultrasound and CT scan of the upper abdomen showed liver fatty infiltration. Prednisolone was tapered gradually, and she gradually improved. However, on day 26 she developed pneumonia and died 6 days later.

Glucocorticoid treatment in the early phase of acute viral hepatitis carries the risk of transition to chronic active hepatitis (SEDA-3, 308).

Three children developed hepatomegaly and raised liver enzymes after receiving high-dose dexamethasone therapy (0.66–1.09 mg/kg/day) (136).

Pancreas

Pancreatitis and altered pancreatic secretion can occur at any time during long-term glucocorticoid treatment (SED-12, 986) (SEDA-14, 339) (137). Necrosis of the pancreas during glucocorticoid treatment has been described and can be lethal. Impairment of pancreatic function can predispose to glucocorticoid-induced pancreatitis. Two other cases of glucocorticoid-induced pancreatitis have been reported (138).

- A 74-year-old woman with seronegative rheumatoid arthritis was given sulfasalazine followed by methotrexate, both of which were withdrawn because of adverse effects. She also took prednisone 10 mg/day. She developed acute abdominal pain and fever (38.7°C) with no chills. Her serum amylase was 269 IU/l, serum lipase 300 IU/l, and urinary amylase 2895 IU/l. There was no evidence of tumor, hypertriglyceridemia, or lithiasis. In addition to prednisone, she was taking amlodipine, bromazepam, and omeprazole, none of which have been reported to cause pancreatitis. A marked improvement was noted after prednisone withdrawal.
- A 68-year-old woman who had taken prednisone 30 mg/day for polymyalgia rheumatica for 6 months developed sharp stabbing abdominal pain, fever (39°C), and vomiting. Her serum amylase was 310 IU/l, serum lipase 340 IU/l, and urinary amylase 1560 IU/l.

© 2006 Elsevier B.V. All rights reserved.

Other causes of pancreatitis were ruled out. She had been taking a thiazide diuretic therapy for the past 10 years. Her symptoms improved noticeably after prednisone withdrawal.

Although the literature suggests a causal relation between glucocorticoid therapy and these various pancreatic complications there is still no certainty; glucocorticoid treatment is, after all, often given simultaneously with other forms of therapy which can cause pancreatitis (SED-11, 82). The strongest evidence that there is a causal relation is provided by a Japanese report on 52 autopsies, which showed marked changes in pancreatic histology in glucocorticoid-treated patients compared with controls (SEDA-17, 449).

Urinary tract

Urinary calculi are more likely during glucocorticoid treatment because of increased excretion of calcium and phosphate (110).

Prednisolone can cause an abrupt rise in proteinuria in patients with nephrotic syndrome. A placebo-controlled study in 26 patients aged 18–68 years with nephrotic syndrome has clarified the mechanisms responsible for this (139). Systemic and renal hemodynamics and urinary protein excretion were measured after prednisolone (125 mg or 150 mg when body weight exceeded 75 kg) and after placebo. Prednisolone increased proteinuria by changing the size–selective barrier of the glomerular capillaries. Neither the renin–angiotensin axis nor prostaglandins were involved in these effects of prednisolone on proteinuria.

Changes resembling diabetic nodular glomerular sclerosis have been seen in glucocorticoid-treated nephrosis.

Treatment with glucocorticoids can result in minor increases in the urinary content of leukocytes and erythrocytes without clear renal injury (140).

The use of high doses of glucocorticoids to counter rejection of renal transplants is still a matter of intensive study; the optimal dose to ensure an effect without undue risk of complications has yet to be agreed on (141).

Vasopressin-resistant polyuria induced by intravenous administration of a therapeutic dose of dexamethasone has been reported (SEDA-20, 370) (142) and nocturia is fairly common during glucocorticoid treatment (143).

The administration of glucocorticoids should be undertaken with caution in progressive systemic sclerosis and the concomitant administration of anticoagulants to prevent scleroderma renal crisis is recommended when administering glucocorticoids in high doses, especially by pulse therapy (SEDA-21, 415) (129).

Skin

Acne is common during treatment, particularly after topical application, and is said to be correlated with the use of compounds that have a particularly strong local effect (144), although this is not proven.

Leukoderma can occur, accompanied by normal melanocyte function but reduced phagocytic activity of the keratinocytes to eliminate the melanosomes (145). Depigmentation can occur at the site of injection of glucocorticoids.

Three cases of severe lipoatrophy, one also with leukoderma, occurring within the same family after intramuscular injection of triamcinolone, suggested genetic susceptibility to this adverse effect (SEDA-3, 303).

Inhibition of the function of the sebaceous glands in the skin is caused by glucocorticoids whilst androgens stimulate their function (146).

A delayed hypersensitivity reaction, characterized by a skin rash, due to dexamethasone has been reported (147). These kinds of reactions to systemic glucocorticoids are rarely reported.

- A 59-year-old woman, who had not used glucocorticoids before, developed an exfoliative rash on her face, upper chest, and skin folds after 3 days treatment with oral dexamethasone (dosage not stated) for an acute episode of encephalomyelitis disseminata. Dexamethasone was immediately withdrawn and her skin lesions resolved over several days. Patch tests were positive to dexamethasone, betamethasone, and clobetasol, but negative to other glucocorticoids, including prednisolone, hydrocortisone butyrate, methylprednisolone, and triamcinolone. Prick tests with all of these glucocorticoids were negative. She tolerated oral methylprednisolone without adverse effects.

Reduced skin thickness and bruising

The glucocorticoids reduce subcutaneous collagen and cause atrophic changes in the skin (148). Subcutaneous atrophy after intramuscular and intra-articular injection has often been reported. Ecchymosis and paper-thin skin folds recall those seen in old people. An increased incidence of subcutaneous ecchymosis in older women has been observed during treatment with triamcinolone acetate (149). Purpura has been observed during glucocorticoid treatment and an increased fragility of the capillaries is thought to occur in about 60% of these patients. There have been reports of cutaneous bruising after the use of high doses of inhaled glucocorticoids (budesonide and beclomethasone), suggesting systemic absorption (SEDA-21, 416) (150).

Prednicarbate is a topical glucocorticoid that seems to have an improved benefit–harm balance, as has been shown in 24 healthy volunteers (7 men, 17 women, aged 25–49 years) in a double-blind, randomized, placebo-controlled study of the effects of prednicarbate, mometasone furoate, and betamethasone 17-valerate on total skin thickness over 6 weeks (151). On day 36, total skin thickness was reduced by a mean of 1% in test fields treated with vehicle; the relative reductions were 13, 17, and 24% for prednicarbate, mometasone furoate, and betamethasone 17-valerate respectively. There were visible signs of atrophy or telangiectasia in two subjects each with betamethasone 17-valerate and mometasone furoate, but not with prednicarbate or its vehicle.

Contact allergy

Topical glucocorticoids are well-known contact sensitizers. Immediate allergic or allergic-like reactions to systemic glucocorticoids also occur, but less often. Two atopic patients developed urticaria, possibly IgE-mediated, from a hydrocortisone injection or infusion (152) and other reactions have been reported.

© 2006 Elsevier B.V. All rights reserved.

- A 50-year-old woman developed contact dermatitis on her legs after she applied hydrocortisone aceponate cream (Efficort) to psoriatic lesions on her lower back (153). Similar lesions also occurred on her legs after she used topical betamethasone cream (Diprosone). However, no eczema developed on or around the site of application. Patch tests were negative to a range of glucocorticoids, including Efficort and Diprosone creams. However, a repeated open application test was positive with Efficort cream, hydrocortisone aceponate 0.127% in petroleum, and tixocortol pivalate 1% in petroleum.
- A 42-year-old woman developed a nonpigmented fixed drug eruption after skin testing and an intra-articular injection of triamcinolone acetonide, which has not been previously reported (154).

Contact allergy to glucocorticoids was evaluated in 7238 patients in a multicenter multinational study of five drugs: budesonide, betamethasone-17-valerate, clobetasol-17-propionate, hydrocortisone-17-butyrate, and tixocortol-21-pivalate. There was a positive patch-test reaction to at least one of the glucocorticoids in 189 patients (2.6%). The incidence ranged from 0.4% in Spain to 6.4% in Belgium. Positive reactions were more frequent with budesonide (100 results) and tixocortol (98 reactions) (SEDA-21, 415) (155). Contact allergic reactions to intranasal budesonide and fluticasone propionate have been described. Many of these cases were characterized by perinasal eczema, often with vesicles, and edema as the initial symptoms. Lesions sometimes spread to the upper lip, cheeks, and eyelids. For fluticasone propionate, analysis of data on adverse events from the Spontaneous Reporting System of the US FDA Division of Epidemiology and Surveillance showed that, in the first 5 months after its introduction into the USA in 1995, 46 patients reported 89 adverse events suspected to be caused by fluticasone propionate intranasal spray. Central nervous system symptoms occurred in 46%, cardiac symptoms in 28%, dermatological symptoms in 39%, and epistaxis in 6.5%. These numbers may underestimate the problem, since no cases reported by the drug manufacturer were included. These results suggest that safety issues may differentiate budesonide and fluticasone propionate from other intranasal glucocorticoids, such as beclomethasone dipropionate (SEDA-21, 415) (156).

Budesonide is advocated as a marker molecule for glucocorticoid contact allergy. When patch testing glucocorticoids, one must consider both their sensitizing potential and their anti-inflammatory properties, as well as the possibility of different time courses of such properties. The dose–response relation for budesonide has therefore been investigated with regard to dose, occlusion time, and reading time in 10 patients (ages not stated) who were patch tested with budesonide in ethanol in serial dilutions from 2.0% down to 0.0002%, with occlusion times of 48, 24, and 5 hours (157). Readings were on days 2, 4, and 7. The 48-hour occlusion detected most positive reactors (8/10) at a reading time of 4 days and 0.002% detected most contact allergies. The "edge effect" (reactions with a peripheral ring due to suppression of the allergic reaction under the patch because of the intrinsic anti-inflammatory effect of the glucocorticoid itself) was noted with several concentrations at early readings. That lower concentrations can detect budesonide allergy better at early readings and that patients with an "edge reaction" can have positive reactions to lower concentrations can be explained by individual glucocorticoid reactivity, the dose–response relation, and the time-courses of the elicitation and the anti-inflammatory capacity.

- A 36-year-old man, who had a long history of atopic dermatitis of the neck, chest, and arms, developed allergic contact dermatitis after topical administration of clobetasone ointment 0.05% (Kindavate) and prednisolone ointment 0.3% (Lidomex) (158). Patch tests with both ointments showed a positive reaction only to Kindavate. Further testing with the separate ingredients of Kindavate showed positive reactions to 0.05, 0.01, and 0.005% clobetasone on day 7.
- A 40-year-old woman had a flare-up of her eczema (159). She had had previous negative patch tests 10 years before. She had taken topical glucocorticoids and emollients for a few months, but had not used budesonide. Patch testing with the European standard series showed a positive reaction to budesonide 0.1% at 3 days. All other allergens were negative. The only antecedent exposure was that she had three children with asthma, all of whom regularly used inhaled budesonide and occasionally nebulizers. She had not used the inhaler but had helped her children to manage the devices. A subsequent patch test with powdered budesonide from the inhaler was positive.
- A 14-year-old girl with newly diagnosed systemic lupus erythematosus developed a pruritic bullous eruption while taking prednisone 20 mg/day (160). She was given a single daily dose of intravenous methylprednisolone 60 mg with rapid improvement. In preparation for discharge, the glucocorticoid was changed to oral prednisone 60 mg/day, to which she developed a pruritic bullous eruption consistent with erythema multiforme. She underwent immediate and delayed hypersensitivity tests. Intradermal and patch tests to liquid prednisone were positive. She was given oral methylprednisolone 48 mg/day and has not had recurrence of the skin lesions.
- A 27-year-old woman, a pharmacist, had dermatitis on three separate occasions a few hours after she started to take oral deflazacort 6 mg for vesicular hand eczema (161). On each occasion, her symptoms included a widespread macular rash mainly on the inner aspects of her arms and legs and buttocks. She also had severe scaling, fever, nausea, vomiting, malaise, and hypotension. A skin biopsy was consistent with erythema multiforme, and direct immunofluorescence showed granular deposits at the dermoepidermal junction. Patch tests to the commercial formulation of deflazacort 6 mg (1% aqueous solution) and to pure deflazacort (1% aqueous solution) were positive, but there were no cross-reactions to other glucocorticoids.

The author of the last report commented that the patient probably developed hypersensitivity to deflazacort as a result of occupational exposure.

Other cases of erythema multiforme-like contact dermatitis after topical budesonide have been reported (SEDA-21, 415) (162). In a large case-control study, potential cases of severe forms of erythema multiforme,

© 2006 Elsevier B.V. All rights reserved.

toxic epidermal necrolysis and Stevens–Johnson syndrome, were collected in four European countries (France, Portugal, Italy, and Germany) (SEDA-20, 371) (163). There was a significant relation with glucocorticoid use in the preceding week (multivariate analysis relative risk = 4.4; 95% CI = 1.9, 10), or when prescribed for long-term therapy (crude relative risk for use less than 2 months = 54; 95% CI = 23, 124). The estimates of excess risks associated with glucocorticoids or sulfonamides (which are well-known to cause these syndromes), expressed as the number of cases attributable to the drug per million users in 1 week, were 1.5 and 4.5 respectively.

Cross-reactivity between glucocorticoids and progestogens has been described (164).

- A 68-year-old woman, with a prolonged history of pityriasis lichenoides chronica treated with topical glucocorticoids, including hydrocortisone, took a formulation containing conjugated estrogens 0.625 mg and hydroxyprogesterone acetate 5 mg (frequency of administration not stated) for late menopausal syndrome. Years later she started to have pruritus, a maculopapular rash, and flu-like symptoms for several days before menstruation. On this occasion, she presented with a severe, pruritic, papulovesicular eruption on her chest, back, abdomen, and legs. The eruption had developed after treatment for 7 days with the estrogen–progestogen formulation; she had developed similar symptoms on several previous occasions after taking the same medication. She was treated with antihistamines and her skin eruption resolved within a few days. Patch tests were positive to 17-OH-progesterone, tixocortol pivalate, and budesonide.

The authors hypothesized that this patient, who had taken topical glucocorticoids for several years, had become sensitive and that the recurrent episodes of autoimmune progestogen dermatitis were related to endogenous progestogen sensitivity following cross-sensitivity to glucocorticoids. This hypothesis was supported by the development of recurrent eczema several times after she took an estrogen–progestogen preparation.

Musculoskeletal

Osteoporosis

The use of glucocorticoids is associated with reduced bone mineral density, bone loss, osteoporosis, and fractures. This has been described during the long-term use of glucocorticoid by any route of administration (SEDA-19, 377) (SEDA-20, 374). The effects of glucocorticoids on bone have been reviewed (SEDA-21, 417) (165). Biochemical markers of bone mineral density are listed in Table 4. In patients with secondary hypoadrenalism, hydrocortisone 30 mg/day for replacement produced a significant fall in osteocalcin, indicating bone loss. Lower doses of hydrocortisone (10 mg and 20 mg) produced similar efficacy in terms of quality of life but smaller effects on osteocalcin concentrations and therefore a reduction in bone loss (166).

The fluorinated glucocorticoids are said to have relatively more catabolic activity than others and might have a greater effect on the skeleton but such impressions may merely reflect the general potency of some newer glucocorticoids and a tendency to use them in inappropriate doses. A relatively new glucocorticoid, deflazacort, has been proposed to have less effect on bone metabolism, but a double-blind study has failed to show an advantage compared with prednisolone (SEDA-21, 417) (167).

Osteoporosis induced by chronic glucocorticoid therapy has been reviewed in patients with obstructive lung diseases (168) and patients with skin diseases (169).

Presentation

Of the effects of glucocorticoids on the skeleton, osteoporosis is the most important clinically; manifestations can include vertebral compression fractures, scoliosis resulting in respiratory embarrassment, and fractures of the long bones. The risk of vertebral fractures is not different in patients taking or not taking glucocorticoids in whom bone mineral density is similar (170).

Glucocorticoids can even cause osteoporosis when they are used for long-term replacement therapy in the Addison's disease, as has been shown by a study of 91 patients who had taken glucocorticoids for a mean of 10.6 years, in whom bone mineral density was reduced by 32% compared with age-matched controls (SEDA-19, 377) (171). However, these results contrasted with the results of a Spanish study in patients with Addison's disease, in which no direct relation was found between replacement therapy and either bone density or biochemical markers of bone turnover of calcium metabolism (alkaline phosphatase, osteocalcin, procollagen I type, parathormone, and 1,25-dihydroxycolecalciferol) (SEDA-19, 377) (172).

Atraumatic posterior pelvic ring fractures that simulate the form of presentation of metastatic diseases can be produced by glucocorticoid administration (SEDA-19, 377) (173).

Accelerated bone loss, with an increased risk of first hip fracture, occurred in elderly women taking oral glucocorticoids (174). At baseline, 122 (1.5%) women were taking inhaled glucocorticoids only (median dose equivalent to inhaled beclomethasone 168 micrograms/day), 228 (2.8%) were taking oral glucocorticoids (median dose equivalent to prednisone 5 mg/day) with or without inhaled glucocorticoids, and 7718 were not taking any glucocorticoids. The women who were taking oral glucocorticoids had lower mean bone mineral density at 3.6 years than nonusers, with an interim fall that was twice as fast. First hip fracture

© 2006 Elsevier B.V. All rights reserved.

occurred in 4.8% of the women who were taking oral glucocorticoids and in 2.8% of the women who were not (RR = 2.1; CI = 1.0, 4.4). The researchers said that the power of the study was not sufficient to determine the relative risk of hip fracture in women taking inhaled glucocorticoids.

A reduction in bone mineral density has been described in 23 patients (19 men) with chronic fatigue syndrome taking low-dose glucocorticoids in a double-blind, randomized, placebo-controlled study (175). The patients took hydrocortisone 25–35 mg/day or matched placebo for 3 months. Mean bone mineral density in the spine fell by 2% with hydrocortisone and increased by 1% with placebo.

A group of 367 patients with lung disease taking oral glucocorticoids (177 women, mean age 68 years, 190 men, mean age 70 years) and 734 matched controls completed a questionnaire about lifestyle, fractures, and other possible adverse effects of glucocorticoids (176). The cumulative incidence of fractures from the time of diagnosis was 23% in patients taking oral glucocorticoids and 15% in the controls (OR = 1.8; 95% CI = 1.3, 2.6). Fractures of the vertebrae were more likely (OR = 10; 95% CI = 2.9, 35). The adverse effects were dose-related, with a higher risk of all fractures (OR = 2.22; 95% CI = 1.04, 4.8) and vertebral fractures (OR = 9.2; 95% CI = 2.4, 36) in those who took the highest compared with the lowest cumulative doses (61 versus 5 g).

Systemic glucocorticoids are often prescribed for rheumatoid arthritis. Even in low doses they can have clinical benefits and can inhibit joint damage, but they can cause osteoporotic fractures. In a 2-year double-blind, randomized, placebo-controlled trial in 81 patients (29 men, mean age 62 years) with early active rheumatoid arthritis who had not been treated with disease-modifying antirheumatic drugs, 41 were assigned to oral prednisone 10 mg/day and 40 to placebo. NSAIDs were allowed in both groups and after 6 months, sulfasalazine (2 g/day) could be prescribed as rescue medication. Those who took prednisone had more clinical improvement with less use of concomitant drugs. After month 6, radiological scores had progressed significantly less in those who took prednisone. After 24 months, seven patients had new vertebral fractures, five in the prednisone group and two in the placebo group (177).

Mechanisms

Several mechanisms underlie the effect of glucocorticoids on bone, both biochemical and cellular. Effects on calcium are:

(a) increased excretion of calcium into the bowel and inhibition of its absorption;
(b) inhibition of the tubular re-absorption of calcium in the kidney;
(c) increased mobilization of calcium from the skeleton.

When calcium homeostasis cannot be maintained, the resulting hypocalcemia can have serious consequences (SEDA-18, 388) (178,179). This so-called "glucocorticoid hyperparathyroidism" was the explanation traditionally most prominently advanced for glucocorticoid osteoporosis, but it is not the only one and may not be the most central. Other biochemical effects include:

(a) a catabolic effect on protein metabolism, causing a reduction in the bone matrix;
(b) altered vitamin D metabolism, with reduced concentrations of vitamin D metabolites (180);
(c) a dose-dependent reduction of serum osteocalcin, a bone matrix protein that appears to correlate with bone formation.

Measurement of serum osteocalcin is a useful marker for glucocorticoid-induced osteoporosis, and can be used alongside other measures noted below.

Various cellular mechanisms are involved in the production of glucocorticoid-induced osteoporosis (SEDA-20, 375) (181). The major change is a reduction in osteoblast activity that results in a reduced working rate (mean appositional rate), and a reduced active lifespan of osteoblasts. The cellular mechanism seems to be related to diminished production of cytokines and other locally acting factors. Increased bone resorption and reduced calcium absorption have also been described. A sophisticated mathematical model has been used to describe changes in calcium kinetics in patients treated with glucocorticoids (SEDA-20, 375) (182). Plasma calcium concentrations were higher than in controls, with a marked reduction in calcium flow into the irreversible stable bone compartment in glucocorticoid-treated patients. The authors concluded that prednisone has direct effects on osteoblast function.

Osteoprotegerin (osteoclastogenesis inhibitory factor, OCIF) has been identified as a novelly secreted cytokine receptor that plays an important role in the negative regulation of osteoclastic bone resorption. There are reports that suggest that glucocorticoids promote osteoclastogenesis by inhibiting osteoprotegerin production in vitro, thereby enhancing bone resorption. However, there are only a few clinical reports in which the regulatory functions of osteoprotegerin have been explored. In order to clarify the potential role of osteoprotegerin in the pathogenesis of glucocorticoid-induced osteoporosis, Japanese investigators have measured serum osteoprotegerin and other markers of bone metabolism before and after glucocorticoid therapy in patients with various renal diseases (183). The findings suggested that short-term administration of glucocorticoids significantly suppresses serum osteoprotegerin and osteocalcin. This might be relevant to the development of glucocorticoid-induced osteoporosis via enhancement of bone resorption and suppression of bone formation. Further long-term studies are needed to elucidate the mechanism of the glucocorticoid-induced reduction in circulating osteoprotegerin and its participation in the pathogenesis of osteoporosis.

Although glucocorticoids can cause changes in trabecular microarchitecture, loss of bone (reduced bone density) seems to be the major determinant of osteoporosis (184).

Although glucocorticoid use seems to be an important factor for low mineral density, sex hormones have also been suggested as an important determinant of bone mineral content. Bone mineral density and sex hormone status have been studied in 99 men with rheumatoid arthritis and 68 age-matched controls (SEDA-20, 375) (185). There were significant reductions in lumbar and

© 2006 Elsevier B.V. All rights reserved.

femoral density, and salivary testosterone, androstenedione, and dehydroepiandrosterone in the patients. Salivary testosterone correlated with femoral density. By multiple regression analysis, weight, serum testosterone concentrations, and cumulative dose of glucocorticoid were significant predictors of lumbar bone density. Weight, age, androstenedione concentrations, and cumulative dose of glucocorticoids were significant predictors of femoral bone density.

Dose relation

Lumbar spine bone mineral density has been assessed in 76 prepubertal asthmatics (mean age 7.7 years, 26 girls) using glucocorticoids (186). After stratification for dose and route of administration, the children who used over 800 micrograms/day of inhaled glucocorticoids, with or without intermittent oral glucocorticoids, had a significant lower weight-adjusted bone density than children who used 400–800 micrograms/day of inhaled glucocorticoids (mean difference –0.05 g/cm^2; 95% CI = –0.02, –0.09). Bone mass was similar in children who did not use inhaled glucocorticoids and those who used 400–800 micrograms/day.

In kidney transplant recipients, lumbar bone loss was significantly higher in 20 patients who took daily prednisone (5.9%, mean dosage 0.19 mg/kg/day) than in 27 patients who used alternate-day prednisone (1.1%, mean dosage 0.15 mg/kg/day) (187).

Time course

The loss of bone mineral after organ and tissue transplant associated with immunosuppressive therapy follows a delayed time course. The long-term effects of immunosuppressive therapy on bone density have been determined in 25 cardiac transplant patients (SEDA-20, 375) (188). As expected, there was bone loss in the spine during the first year, but this was not maintained during the second and third years after transplantation, despite continuing maintenance immunosuppression with prednisolone. Only four patients, all of whom were hypogonadal, continued to lose bone.

Susceptibility factors

The overall effect of glucocorticoids on bone mineral content differs between patients on comparable treatments, which suggests that some patients are more predisposed than others (SEDA-3, 306), and probably also that the standards of evaluation used in different clinics are not comparable. This variability and the wide range of products and dosage schemes used mean that one does not have a clear impression of what constitutes a safe regimen as far as the skeleton is concerned (SEDA-20, 374), or whether any regimen is safe in this respect. Certainly, in a series of men with rheumatoid arthritis, even a very low dose of glucocorticoids (for example 10 mg or less of prednisolone daily) has proved to have a significant effect on bone mineral density (189); other work has provided similar results (SEDA-20, 374) (190). In another published study, patients who took 1–4 mg/day had the same density as those who were not taking glucocorticoids. Patients who took 5–9 mg/day and those who took more than 10 mg/day had significantly lower bone density (84 and 81% of control values respectively) (SEDA-20, 374) (191).

Glucocorticoid-related complications have been described in 748 adult kidney transplant recipients, followed for at least 1 year. For bone/joint complications, the multivariate analysis showed that the only significant variable was the cumulative duration of glucocorticoid therapy. For avascular necrosis, no variables were significant (SEDA-19, 377) (192).

In a similar study of 65 renal transplant patients treated with immunosuppressive drugs for at least 6 months, multivariate analysis showed that cumulative glucocorticoid dose and female sex were the major predictors of low vertebral bone density (SEDA-19, 377) (193).

In another study, the loss of bone density correlated with the cumulative dose of prednisolone (21 g total dose at 11.4 mg/day) and renal function (SEDA-21, 417) (194).

In a review of renal transplantation during 1974–94, 166 patients were classified into those with osteonecrosis of the femoral head (22 patients) and those without (47 patients) (SEDA-21, 417) (195). The total dose of methylprednisolone was higher in those with osteonecrosis. All five patients who had received intravenous pulse doses over 2000 mg had osteonecrosis.

The risk of vertebral deformity is increased by the combination of an oral glucocorticoid and advanced age, according to the findings in 229 patients (69% women) taking long-term oral glucocorticoids (prednisone equivalents of 5 mg/day or more) and 286 untreated controls (196). The duration of treatment was 0.5–37 (median 4.8) years. More than 60% of the treatment group were aged over 60 years, and most (62%) had been treated for rheumatoid arthritis. Bone mineral density data were analysed in 194 patients. The researchers identified at least one vertebral deformity (defined as a more than 20% reduction in anterior, middle, or posterior vertebral height) in 65 (28%) of the patients in the treatment group, and two or more fractures were identified in 25 (11%). In the treatment group, vertebral deformities were significantly more common in men than in women, and the prevalence of deformities increased with age. Compared with patients aged under 60 years, glucocorticoid-treated patients aged 70–79 years had a five-fold increased risk of vertebral deformity (OR = 5.1; 95% CI = 2.0, 13). The prevalence of vertebral deformities increased significantly with age in the glucocorticoid group. While the mean spine and femoral bone mineral density scores were lower in the glucocorticoid group, logistic regression analysis showed that bone mineral density was only a modest predictor of deformity. Age is an important independent risk factor, with very high prevalence rates in those over 70 years. Increasing duration of glucocorticoid use may increase the risk of fracture.

Comparisons of glucocorticoids

Bone loss induced by glucocorticoids has been assessed in three different populations. A group of 374 subjects (mean age 35 years, 55% women) with mild asthma taking beta-adrenoceptor agonists only, were randomized to inhaled glucocorticoids (budesonide or beclomethasone) or non-glucocorticoid treatment for 2 years (197). Bone mineral density was measured blind after 6, 12, and 24 months. Mean doses of budesonide and beclomethasone were 389 micrograms/day and 499 micrograms/day,

© 2006 Elsevier B.V. All rights reserved.

respectively. At the end of follow-up, the subjects who had used glucocorticoids had better asthma control. The mean changes in bone density over 2 years in the budesonide, beclomethasone, and control groups were 0.1%, –0.4%, and 0.4% for the lumbar spine and –0.9%, –0.9%, and –0.4% for the neck of the femur. The daily dose of inhaled glucocorticoid was related to the reduction in bone mineral density only at the lumbar spine. Low to moderate doses of inhaled glucocorticoids caused little change in bone mineral density over 2 years and provided better asthma control.

Diagnosis

Several techniques are used to measure bone density. Cortical bone can be assessed in peripheral sites by single-photon absorptiometry and a combination of cortical and trabecular bone in central sites by dual X-ray absorptiometry. Trabecular bone can be assessed by quantitative computer tomography scanning of the lumbar spine. Since single-photon absorptiometry and dual X-ray absorptiometry give a negligible dose of radiation, they are useful for population screening. However, these two techniques are not sensitive enough to show subtle changes in bone density over short periods of time. Quantitative computed tomography gives a significant dose of radiation (of the order of one-tenth of a lateral X-ray of the spine) but can focus on trabecular bone, which has a tenfold greater turnover, compared with cortical bone. Quantitative computed tomography is more sensitive to changing bone density over time.

Other methods, such as the fasting urinary hydroxyproline/creatinine ratio, alkaline phosphatase activity, dual-absorption photometry of the hip, and serum osteocalcin measurements, can also be used, depending on an individual clinic's equipment and experience (SEDA-17, 447).

Management

The prevention and treatment of glucocorticoid bone loss in patients with skin diseases have been reviewed (169). Strategies for the management of this problem have been discussed (SEDA-22, 184) and the clinical implications of trials in the management of glucocorticoid-induced osteoporosis have been reviewed (198). Provided no fractures have occurred, loss of bone mineral density seems to be reversible when treatment is withdrawn (SEDA-18, 389). The management of glucocorticoid-induced osteoporosis has been revised by the UK Consensus Group Meeting on Osteoporosis (SEDA-20, 376) (183) and by the American College of Rheumatology (SEDA-21, 417) (199).

Guidelines for the prevention and treatment of glucocorticoid-induced osteoporosis have been published (200). Although there are several consensus statements and recommendations for prophylactic measures against glucocorticoid-induced osteoporosis in patients with rheumatoid arthritis, prophylaxis is commonly underprescribed. In two recent studies of 191 and 92 patients taking long-term glucocorticoids, relatively few were taking primary prevention, although some were taking vitamin D and calcium tablets. Around 65–68% of all those who qualified for prophylaxis for glucocorticoid-induced osteoporosis did not receive therapy, and only 9% of those in one study and 21% in the other were taking bisphosphonates (201,202).

Low availability compounds

Bone loss in patients taking oral budesonide has been evaluated in a longitudinal study in which bone mineral density was measured annually for 2 years in 138 patients (67 men, mean age 36 years old) with quiescent Crohn's disease (203). They took budesonide (8.5 mg/day; $n = 48$), prednisone (10.5 mg/day, $n = 45$), or non-steroidal drugs ($n = 45$). After 1 year, the bone mineral density in the lumbar spine fell by 2.36% in those who took budesonide, by 0.61% in those who took prednisone, and by 0.09% in those who took non-steroidal drugs. In the second year, the largest fall occurred in those who took budesonide (1.97%), but the differences between the groups were not significant. After 2 years, bone mineral density in the femoral neck fell by 2.94% with budesonide, 0.36% with prednisone, and 1.05% with the non-steroidal drugs. These results suggest that budesonide can cause bone loss, but the non-randomized design of the study limits conclusions about the comparison between budesonide and prednisone.

Pulse administration

The administration of glucocorticoids in sporadic pulses has been shown not to reduce bone density in patients with multiple sclerosis. In a prospective study, 30 patients were given 1000 mg/day of methylprednisolone intravenously for 3 days, followed by oral prednisone in tapering dosage for 2 weeks. Bone density was determined in the lumbar spine and femoral neck before and at 2, 4, and 6 months after therapy. At baseline, the patients had a reduced bone mass compared with controls; this reduction did not correlate with previous exposure to glucocorticoids. Ambulant patients during follow-up after glucocorticoid pulse therapy had an increase in lumbar bone density (+1.7% at 6 months). Average femoral density did not change; however, in patients who required a walking stick or other aid, femoral density fell (–1.6%), while in those with better ambulation it increased (+2.9%). These results suggest that inactivity is the main factor causing bone loss in patients treated with sporadic pulses of glucocorticoids (SEDA-21, 417) (204).

Calcium and vitamin D

Infusion of ionic calcium has sometimes been used to counteract the malabsorption of calcium in patients taking long-term glucocorticoids, particularly in patients who develop secondary hypoparathyroidism (SEDA-3, 306). There is also evidence that in amenorrheic or menopausal women requiring glucocorticoids, the adverse effects on the vertebrae can be countered by hormonal replacement therapy with estrogen and progesterone (205); progestogens similarly seem to have a promising effect in men, and while they cause a fall in serum testosterone they apparently do not undermine the desired effects of glucocorticoids (SEDA-16, 449).

The administration of calcium and vitamin D3 can prevent bone loss induced by glucocorticoids, and trials have confirmed its efficacy when given for 2 years. Patients taking prednisone and placebo lost bone density in the

© 2006 Elsevier B.V. All rights reserved.

lumbar spine at a rate of 2% per year. Those taking prednisone and calcium plus vitamin D3 gained bone mineral density at a rate of 0.72% per year. Calcium plus vitamin D3 did not improve bone mineral density in patients who were not taking prednisone (SEDA-21, 417) (206).

In a similar randomized double-blind study, the effects of vitamin D (50 000 units/week) and calcium (1000 mg/day) were evaluated in 62 patients with different rheumatic diseases treated with prednisone (10–100 mg/day) (SEDA-21, 418) (207). The primary outcome was bone mineral density in the lumbar spine at 36 months. Patients taking placebo had reductions of 4.1, 3.8, and 1.5% at 12, 24, and 36 months respectively. Patients taking calcium and vitamin D had reductions of 2.6, 3.7, and 2.2% respectively. The results suggested that preventive therapy could be beneficial early in the prevention of glucocorticoid-induced bone loss, but there was no evidence of long-term beneficial effects. In kidney transplant patients, the preventive administration of 25-hydroxycolecalciferol and calcium reduced bone loss in the spine and femoral neck and the number of new vertebral crush fractures (SEDA-21, 418) (208). In children with rheumatic diseases taking glucocorticoids, calcium and vitamin D supplementation improved spinal bone density, although osteocalcin concentrations remained low (SEDA-19, 378) (209).

Calcitonin

Less clear are the results observed after the administration of salmon calcitonin. The usefulness of intranasally administered salmon calcitonin for 2 years has been evaluated in 44 glucocorticoid-dependent asthmatics (SEDA-19, 378) (210). All were taking calcium supplements (1000 mg/day), but one group also took calcitonin (100 IU every other day). Calcitonin increased spinal bone mass during first year of treatment, and maintained bone mass in a steady state during the second year. However, the rate of vertebral fractures was similar in the two groups. The addition of salmon calcitonin did not increase the efficacy of calcium plus vitamin D in the prevention of bone loss in 48 newly diagnosed patients taking glucocorticoids for temporal arteritis and polymyalgia rheumatica in a double-blind, randomized, placebo-controlled trial (SEDA-21, 418) (211). However, salmon calcitonin nasal spray prevented bone loss in the lumbar spine of 31 patients treated with prednisone for polymyalgia rheumatica (SEDA-22, 448) (212). They were randomized to salmon calcitonin nasal spray (200 IU/day) or matched placebo for 1 year. Both groups were treated with calcium supplements if their dietary intake was below 800 mg/day. With calcitonin, the mean bone mineral density in the lumbar spine fell by 1.3% and with placebo by 5% after 1 year. There were no differences in the hip, including the femoral neck and trochanter, or in total body bone density.

Bisphosphonates

There have been several studies of the use of bisphosphonates in preventing glucocorticoid-induced osteoporosis.

Intermittent cyclical etidronate prevented bone loss induced by prednisone in 10 postmenopausal women with temporal arteritis (SEDA-19, 378) (213). Cyclical etidronate (400 mg/day for 2 weeks every 3 months) plus ergocalciferol (0.5 mg/week) was given to 15 postmenopausal women (mean age 63 years) starting glucocorticoid therapy (prednisone 5–20 mg/day). A control group of 11 postmenopausal women (mean age 60 years) with glucocorticoid-induced osteoporosis were treated with calcium supplements only (1 g/day). During the first year, the cyclical regimen significantly increased lumbar and femoral neck bone density compared with placebo (7 and 2.5% for spine and femur respectively). After the second year of cyclical therapy, femoral neck bone density continued to increase while lumbar spine density remained stable (SEDA-20, 376) (214). The effect of intermittent cyclical therapy with etidronate has been investigated in the prevention of bone loss in 117 patients taking high-dose glucocorticoid therapy (a mean daily dose of at least 7.5 mg for 90 days followed by at least 2.5 mg/day for at least 12 months) (215). The patients were randomized to oral etidronate 400 mg/day or placebo for 14 days, followed by 76 days of oral calcium carbonate (500 mg elemental calcium), cycled over 12 months. The mean lumbar spine bone density changed 0.30% and –2.79% in the etidronate and placebo groups respectively. The mean difference between the groups after 1 year (3.0%) was significant. The changes in the femoral neck and greater trochanter were not different between the groups. There was a reduction in pyridinium cross-links, significant from baseline at both 6 and 12 months, in the etidronate group. Osteocalcin increased in the placebo group, and the differences between the groups at 6 and 12 months were –25% and –35% respectively. There was no significant difference between the groups in the number of adverse events, including gastrointestinal disorders. In a placebo-controlled study of the effects of 104 weeks of intermittent cyclical etidronate therapy in 49 patients, the same dose and cycles were used as in the previous study, but calcium (97 mg/day) was given with vitamin D (400 IU) (216). Intermittent cyclical etidronate therapy with vitamin D supplementation significantly increased lumbar spine bone mineral density by 4.5 in patients with osteoporosis resulting from long-term treatment with glucocorticoids.

Contradictory results have been published about the prophylactic use of two other bisphosphonates in patients treated with glucocorticoids. There were no bone losses after therapy, and no differences in bone density or biochemical bone markers between placebo and clodronate (SEDA-22, 447) (217).

Pamidronate disodium has been compared with calcium supplementation in an open trial of primary prevention of glucocorticoid-induced osteoporosis in 27 patients with different rheumatic conditions, randomly assigned to pamidronate (90 mg intravenously every 3 months) plus calcium (800 mg calcium carbonate) or calcium only for 1 year (SEDA-22, 448) (218). The glucocorticoids were given in a starting dosage of 10–80 mg/day. With pamidronate there was a significant increase in bone density (3.6% lumbar, 2.2% femoral neck), but there was a significant reduction with calcium (–5.3% in both spine and femoral neck).

The effects of risedronate on bone density and vertebral fracture have been studied in 518 patients (mean age 59 years, 40% with rheumatoid arthritis, 56% men, 64% of the women postmenopausal) taking moderate to high

© 2006 Elsevier B.V. All rights reserved.

doses of oral glucocorticoids (equivalent to prednisone 7.5 mg/day or more) (219). The patients were randomized double-blind to placebo, or risedronate 2.5 or 5 mg/day for 1 year. All took elemental calcium 1000 mg/day and vitamin D 400 IU/day. The mean density of the lumbar spine fell by 1% in the placebo group and increased by 1.3% and 1.9% with risedronate 2.5 and 5 mg respectively. There was a significant reduction of 70% in the risk of vertebral fracture with risedronate 5 mg compared with placebo. There were similar incidences of adverse effects in all the groups.

Similar results have been reported in a clinical trial in 290 patients (38% men, 55% of the women postmenopausal) taking high-dose glucocorticoid therapy (prednisone over 7.5 mg/day or equivalent) (220). The subjects were randomized to receive placebo or risedronate 2.5 or 5 mg/day for 1 year. All took elemental calcium 1000 mg/day and vitamin D 400 IU/day. Risedronate 5 mg increased bone mineral density at 1 year by a mean of 2.9% in the lumbar spine, 1.8% in the femoral neck, and 2.4% in the trochanter. The values for placebo were 0.4%, –0.3%, and 1.0% respectively. The results for risedronate 2.5 mg were positive but not significant compared with placebo. The incidence of spinal fractures was reduced by 70% in the combined risedronate treatment groups compared with placebo. Risedronate and placebo caused similar adverse effects.

In a 1-year extension of a previous double-blind, randomized, placebo-controlled study, two doses of alendronate (5 and 10 mg/day) were compared in 66 men and 142 women taking glucocorticoids (at least 7.5 mg/day of prednisone or equivalent) (221). The extension was also double-blind, but those who had taken alendronate 2.5 mg/day in the previous study were given 10 mg/day. All the patients took supplementary calcium and vitamin D. The primary end-point was the mean percentage change in lumbar spine bone mineral density from baseline to 2 years. In those who took alendronate 5, 10, and 2.5/10 mg/day, bone mineral density increased significantly by 2.8, 3.9, and 3.7% respectively, and fell by –0.8% with placebo. There were significantly fewer patients with new vertebral fractures in the alendronate group compared with placebo (0.7 versus 6.8%). Adverse events were similar across the groups.

Fluoride

Fluoride is a potent stimulator of trabecular bone formation. Sodium monofluorophosphate was given to 48 patients with osteoporosis due to glucocorticoids (more than 10 mg of prednisone equivalents/day). Patients were randomly allocated to 1 g of calcium carbonate (control) or 200 mg of sodium monofluorophosphate plus 1 g of calcium carbonate for 18 months. At the end of the study lumbar spine bone density had increased by 7.8% in the fluoride group versus 3.3% in the controls. There were no changes in femoral neck density (SEDA-20, 376) (222).

Growth hormone

Growth hormone is a potent anabolic agent that stimulates protein synthesis, cell growth, and osteoblast activity. Recombinant human growth hormone has been used in patients taking long-term glucocorticoid treatment with suppressed endogenous growth hormone responses to GH-releasing hormone (SEDA-20, 376) (223). A single daily dose of 0.1 IU/kg of human growth hormone was given subcutaneously to nine nonobese patients. There was a significant increase in nitrogen balance, osteocalcin, carboxy-terminal propeptide of type I procollagen, and carboxy-terminal telopeptide of type I collagen. Growth hormone also lowered total high density lipoprotein, and low density lipoprotein cholesterol. These preliminary data suggest that growth hormone could ameliorate some adverse effects induced by long-term glucocorticoids.

Others

Other agents are effective in special populations. Vitamin K prevented bone loss in 20 patients with chronic glomerulonephritis treated with prednisolone (224) and ciclosporin 4.8 mg/kg/day prevented glucocorticoid-induced osteopenia in 52 patients taking prednisone 10 mg/day after kidney transplantation (225).

Avascular necrosis

Avascular aseptic necrosis of bone (SEDA-19, 377) (226,227) is a well-recognized adverse effect related to high-dose glucocorticoid therapy (equivalent to more than 4000 mg of prednisone) for extended periods (3 months or longer) but can occur after short-term glucocorticoid therapy. It occurs in a wide range of patients with many different disorders and is particularly likely to involve the femoral and humeral heads. The first lesions are often localized small osteolytic areas in the subchondral bone, where they can be diagnosed early by X-radiography. Magnetic resonance imaging (MRI) is one of the more sensitive techniques to diagnose avascular necrosis of the femoral head. The development and changes in avascular necrosis of the femoral head had been studied by MRI in patients with systemic lupus erythematosus treated with long-term prednisolone administration (SEDA-19, 377) (SEDA-19, 164). MRI abnormalities could be detected soon after the start of glucocorticoid therapy or were associated with increased dosages for treating exacerbation of the disease. Normal hips are rarely involved in avascular osteonecrosis. However, aseptic osteonecrosis of the femoral head is often seen in young patients; the lunate, capitate, and patella are their locations. Usually only one joint is involved, although lesions can be multiple. Whether intra-articular injections of glucocorticoids can cause necrosis of bone is still uncertain.

Femoral head necrosis in kidney transplant recipients who receive postoperative immunosuppression with prednisone can be prevented, at least to some extent, by minimizing the dosage of prednisone whenever feasible (228). Of 750 patients (445 men and 305 women) who had undergone kidney transplantation in 1968–95, 374 had received an average of 12.5 g of prednisone during the first year after surgery (high-dose prednisone group) and 276 had received an average of 6.5 g during this time (low-dose prednisone group) plus ciclosporin. Femoral head necrosis occurred in 42/374 patients (11%) in the high-dose prednisone group, an average of 26 months

© 2006 Elsevier B.V. All rights reserved.

after transplantation. In contrast, femoral head necrosis occurred in only 19/376 patients (5.1%) in the low-dose group an average of 21 months after transplantation. The difference between the high- and low-dose groups was highly significant.

The risk of avascular necrosis has been assessed in a nested case-control study using computer records (229). There were 31 cases during 720 000 person-years Avascular necrosis was strongly associated with glucocorticoid exposure (RR = 16). When total prednisone exposure over 35 months was stratified into three levels (under 440 mg, 440–1290 mg, and over 1290 mg), there was no excess risk for cumulative doses of up to 440 mg (RR = 0; 95% CI = 0, 5). The relative risk was increased for doses between 440 and 1290 mg (RR = 6; CI = 1, 43) and indeterminately increased at doses over 1290 mg (CI = 26, infinity).

In 15 men with osteonecrosis of the femoral head after short-term therapy the mean duration of therapy was 21 (range 7–39) days and the mean dose in milligram equivalents of prednisone was 850 (range 290–3300) mg (230). The time from administration of glucocorticoids to hip pain was 17 (range 6–33) months. A new case of bilateral avascular necrosis of the femoral heads after high-dose short-term dexamethasone therapy as an antiemetic in cancer chemotherapy has been reported (231).

Myopathy

The presence of physiological amounts of glucocorticoids is necessary for the normal functioning of muscle. Excessive glucocorticoid concentrations, in contrast, result in protein catabolism and a reduced rate of muscle protein synthesis (232), and hence in muscle atrophy and fibrosis. The molecular and biochemical basis of myopathy has been widely studied, and the mechanism has been attributed to impairment of glycogen synthesis. Muscle glycogen synthase protein content and activity was measured in samples from 14 patients taking glucocorticoids after kidney transplantation and from 20 healthy subjects (SEDA-21, 418) (233). The patients had impaired activation of glycogen synthase and reduced enzyme activity. Muscular weakness can of course also result from glucocorticoid-induced hypokalemia. In spontaneous Cushing's syndrome, there is muscle involvement in some 50% of cases (234).

Among reports of myopathy in patients taking glucocorticoids, involvement of the respiratory muscles is often mentioned (235,236), possibly because this is particularly likely to have clinical consequences. Patients on mechanically assisted ventilation may be particularly at risk of myopathy (SEDA-18, 390). However, any muscle can be affected; one often sees weakness and atrophy of the hip muscles and (in about half the cases) the shoulder muscles and the proximal muscles of the limbs.

The myopathy usually develops gradually, without pain, and symmetrically. However, a single epidural injection of a glucocorticoid for lumbar radicular pain has caused Cushing's syndrome and myopathy (SEDA-20, 370) (97).

There is a suggestion that the incidence of myopathy is greatest during treatment with compounds that are fluorinated at the 9-alpha position, such as triamcinolone, but this may simply reflect its general potency. In children, the risk of effects on muscles is relatively high.

Biopsy is not justified as a routine, but it is useful as a diagnostic tool in distinguishing suspected corticoid myopathy from diseases of the muscles or vascular system with inflammation that may have been the indication for giving glucocorticoids in the first place; electromyographic measurements cannot confirm the diagnosis.

After termination of treatment the myopathy normally improves over a period of several months.

Damage to tendons and fascia

Tendons can be injured by glucocorticoids and can rupture (237). Ten cases of Achilles tendon rupture were seen in a single clinic over a 10-year period (SEDA-17, 448). The risk seems to be greater if local (for example intra-articular) injections are used.

Rupture of the plantar fascia induced by glucocorticoids has usually been reported in athletes. However, a case of spontaneous degenerative rupture has been reported in a 72-year-old man who had received four glucocorticoid injections over 1 year for plantar fasciitis (SEDA-21, 418) (238).

Growth in children

The possibility that inhaled glucocorticoids may impair growth in children is of concern, but difficult to assess, as severe chronic asthma can impair growth. If not adequately controlled, asthma modifies the prepubertal growth spurt, the pubertal growth spurt, and the catch-up phase, which allows the child to attain adult height. There is a wide range of individual responses and some children have adverse effects with relatively small doses of glucocorticoids. It is still not clear whether this is a transient phenomenon, causing a slowing of growth and maturational delay with no adverse effect on adult height, or whether growth can be permanently impaired. Ideally studies should establish the effect of asthma treatments on final adult height (compared with predicted values for sex and parental height). Such studies pose considerable logistic problems. For this reason most studies have measured growth over shorter time spans. Outcome measures have been expressed as the height velocity or growth rate, that is changes in height over a defined time. Alternatively height is measured and compared with that of age- and sex-matched controls. Such relatively short-term studies do not necessarily predict the effects of treatment on eventual adult height.

The growth-inhibiting effects of glucocorticoids in children are related not only to inhibition of growth hormone secretion, but also to the sensitivity of the peripheral tissues to the effects of growth hormone. By means of overnight profile analysis it was shown that glucocorticoid treatment reduces the amplitude but not the number of pulses of the physiological growth hormone secretion (SEDA-14, 335) (239).

Effects on growth occur early in treatment: with sensitive testing methods they can be detected in growing children within a few weeks of starting therapy. The effects can be produced by any route of administration, including even inhalation therapy (at least with

© 2006 Elsevier B.V. All rights reserved.

dexamethasone) (SEDA-18, 391). Comparisons of attained heights with expected heights in children who have used inhaled or oral glucocorticoids have been summarized in a meta-analysis (SEDA-19, 375) (240). There was a significant but small tendency for glucocorticoid therapy in general to be associated with reduced final height. However, this effect varied according to the route of administration. As expected, there was significant impairment of growth with prednisone and other oral glucocorticoids. On the other hand, inhaled beclomethasone dipropionate was associated with normal stature, even when it was used in higher dosages, for longer durations, or in patients with more severe asthma. In another study in 94 children aged 7–9 years, beclomethasone in a dosage taken by many children with mild asthma (400 micrograms/day) significantly reduced growth (SEDA-20, 369) (241). In children with growth suppression during therapy with inhaled beclomethasone or budesonide (200–400 micrograms/day) there was catch-up growth when they switched to equipotent dosages of inhaled fluticasone (100–200 micrograms/day) (SEDA-21, 414) (242). However, in six children with severe asthma, treatment with inhaled high-dosage fluticasone 1000 micrograms/day was associated with growth retardation and adrenal insufficiency (SEDA-21, 414) (243). In one child, growth rate and adrenal function normalized 9 months after the fluticasone dosage was reduced to 500 micrograms/day.

It is generally agreed that the use of single doses of prednisone on alternate mornings minimizes growth retardation but does not avoid it; in children it has been shown that biochemical markers of growth are lower in patients receiving daily glucocorticoid therapy than in patients treated with an alternate-day regimen or not receiving glucocorticoids (SED-12, 988) (244).

It has long been thought by some physicians that the impairment of growth caused by glucocorticoids can be lessened by switching to corticotropin, but this is uncertain. Compensatory treatment with anabolic hormones is definitely not recommended today, since they do not stimulate growth but actually impede it by promoting closure of the epiphyses. Recombinant growth hormone (rGH) treatment of poorly growing children with glucocorticoid-dependent renal disease has often been observed to improve linear growth. However, the dosage of prednisone has been reported to be a critical factor in determining the efficacy of rGH therapy in glucocorticoid-dependent children (SEDA-19, 375) (245). When the dose of prednisone was greater than 0.35 mg/kg/day, rGH did not increase the linear growth rate. At lower doses, the response was inversely related to the amount of prednisone.

Provided glucocorticoid treatment is terminated before the end of puberty, total growth may catch up with the physiological norm (SEDA-17, 448). Concern has been expressed that fear of growth retardation can result in unjustifiable denial of glucocorticoid therapy. It does, however, seem highly advisable to keep doses as low as possible and to switch to a therapeutic regimen that excludes glucocorticoids as children approach the expected onset of puberty (SEDA-14, 335).

Serum osteocalcin determinations appear to be a helpful marker to evaluate the effects of glucocorticoids on growth in children.

One unanswered question is whether the growth suppression that occurs in children during glucocorticoid treatment persists after treatment is withdrawn and affects final adult height. In an attempt to answer this question, growth 6–7 years after withdrawal of alternate-day prednisone has been evaluated in children (aged 6–14 years) with cystic fibrosis who had participated in a multicenter trial from 1986 to 1991 (246). Of 224 children, 161 had been randomized to prednisone (1 or 2 mg/kg) and 73 to placebo. At the time of the study, 68% were aged 18 years or more. Height fell during prednisone therapy, but catch-up growth began 2 years after withdrawal. However, the heights of the boys treated with prednisone remained significantly lower by 4 cm than those who took placebo. In contrast, in the girls there were no differences in height at 2–3 years after prednisone withdrawal.

Reproductive system

Reduced sperm count and motility and inhibition of the secretory function of the testicles during glucocorticoid treatment have been reported and discussed in relation to the suppression of adrenal androgen production. These reports still await confirmation.

Since amenorrhea is a symptom of Cushing's syndrome, disorders of menstruation are common in fertile women taking higher doses of glucocorticoids (SEDA-3, 305). On the other hand, plasma cortisol concentrations in normally menstruating women have marked circadian variation, the extent of which can reach 200% or more (247), with the peak of the cortisol plasma concentrations at mid-cycle and near its end. Inhibition of ovulation by triamcinolone 25 mg has been reported when the drug is given on day 1 or 2 of the cycle. How glucocorticoids interfere with the hormonal control of the menstrual cycle is still unknown (248).

Women should be warned about the possibility of menstrual disorders after local triamcinolone injections (249). When premenopausal women received their first injection of triamcinolone intra-articularly ($n = 46$), injected into soft tissue ($n = 24$), or epidurally ($n = 7$) they were specifically asked to report flushing or menstrual irregularities during a mean follow-up period of 6 weeks. Of the 77 women in the study, 39 reported menstrual disorders. The onset of menstruation was later than expected in ten women and earlier in 16 women. There was reduced loss of blood and/or a shorter duration of menstruation in four women and increased loss of blood and/or a longer duration of menstruation in 18. Also, 22 women had flushing. Menstrual disorders occurred significantly less often in women who were taking oral contraceptives.

Immunologic

Since the glucocorticoids have immunosuppressive and anti-inflammatory properties, one would not expect allergic reactions to be a problem, except when excipients act as allergens. Nevertheless, allergic reactions to glucocorticoids themselves have been reported (SEDA-21, 419) (250). Urticaria after glucocorticoid treatment has been explained as a reaction of the mesenchyme. Also, an increase in eosinophilic leukocytes (which normally are diminished by glucocorticoids) has been reported as a first reaction to treatment with glucocorticoids.

© 2006 Elsevier B.V. All rights reserved.

Class I immune reactions

Anaphylactic shock has been described after intranasal hydrocortisone acetate, intramuscular methylprednisolone (SEDA-21, 419) (251), intravenous methylprednisolone (SEDA-22, 448) (252), intramuscular dexamethasone (SEDA-22, 448) (253), and intra-articular methylprednisolone (SEDA-22, 449) (254). A life-threatening anaphylactic-like reaction to intravenous hydrocortisone has been described in patients with asthma (255). Acute laryngeal obstruction has been described for the first time after the intravenous administration of hydrocortisone (SEDA-22, 449) (256). There is some reason to believe that sodium succinate esters are more likely to cause hypersensitivity reactions (SEDA-17, 449), but unconjugated glucocorticoids can definitely produce allergy in some cases (SEDA-16, 452).

- A 64-year-old woman with a history of bronchial asthma developed increasing shortness of breath after an upper respiratory tract infection (257). Her medication included inhaled salbutamol as necessary, theophylline 300 mg bd, and aspirin 325 mg/day. She was given nebulized salbutamol and ipratropium and hydrocortisone 200 mg intravenously. Within 30 minutes, she developed a generalized rash, fever (38.3°C), and respiratory distress. She was promptly intubated and mechanical ventilation was started. No further doses of glucocorticoid were given. Skin testing with various parenteral formulations of glucocorticoids produced a 5 mm wheal at the site of hydrocortisone and methylprednisolone injections. She was subsequently given a challenge dose of triamcinolone using a metered-dose inhaler with no reaction, and was therefore continued on this medication.
- An anaphylactoid reaction (angioedema, generalized urticaria, worsening bronchospasm, and marked hypotension) occurred in a 35-year-old man with multiple sclerosis who became allergic to methylprednisolone (dose not stated) after starting treatment with interferon beta-1b (258). He had previously been treated with different courses of methylprednisolone. Clinicians should be aware that the complexity of the effects of interferon beta-1b on the immune system can lead to unexpected outcomes. It is uncertain whether the sequence of events here was due to an effect of interferon beta-1b or to coincidence.
- A 17-year-old boy, with an 11-year history of asthma, had anaphylaxis with respiratory distress shortly after he received intravenous methylprednisolone for an exacerbation of asthma while taking a tapering course of oral prednisone 15 mg/day (259). He had been glucocorticoid-dependent for at least 1 year. He reported having received intravenous glucocorticoids previously. He was treated with inhaled salbutamol and then intravenous methylprednisolone 125 mg over 15–30 seconds, and 3–4 minutes later became flushed and dyspneic, and developed diffuse urticarial lesions on his trunk and face and an undetectable blood pressure. He was treated with adrenaline, but required intubation. Sinus bradycardia developed and then asystole. He was successfully resuscitated and a 10–15 seconds period of generalized tonic-clonic activity was treated with diazepam. He remained unresponsive to stimulation for 30 minutes. However, he awoke 1 hour after his respiratory arrest and was extubated and discharged the following day taking a tapering dosage of prednisone.
- An anaphylactoid reaction occurred in a 68-year-old woman after treatment with intravenous methylprednisolone for asthma. She had developed urticaria with methylprednisolone 1 year earlier, but the reaction had been thought to be related to the solvent in the formulation (260).
- Forty minutes after a first dose of prednisone 25 mg, a 17-year-old girl with a history of aspirin intolerance had generalized flushing, hives, hypogastric pain, and abdominal cramps, followed by vomiting and diarrhea (261). She lost consciousness and developed arterial hypotension. She responded to intravenous diphenhydramine and hydrocortisone. Intradermal skin tests were positive for prednisone and negative for methylprednisolone and hydrocortisone. An oral challenge test with prednisone led to flushing, nausea, dizziness, tachycardia, and hypotension and responded to intravenous diphenhydramine and hydrocortisone. Challenge tests with intravenous methylprednisolone and hydrocortisone were negative.
- A 30-year-old man with recurrent atopic eczema of the head and neck, generalized xerosis, keratosis pilaris of the arms, and a history of dyshidrosis was initially treated with prednisolone-21-acetate ointment (262). His skin eruption became worse. He was given oral prednisolone 25 mg, and 5 hours after the first dose developed intense generalized pruritus with erythema and swelling of the face. After 24 hours there was generalized erythema with disseminated partly follicular papules. There was an eosinophilia (1.1×10^9/l). Total IgE was not raised. Patch tests showed delayed reactions to hydrocortisone 1%, prednisolone 1%, prednisolone-21-acetate ointment, and prednisolone 2.5%. Prick and intradermal tests with methylprednisolone succinate, hydrocortisone succinate, betamethasone, and triamcinolone acetonide in concentrations up to 1 : 10 were negative at 15 minutes. However, 4 hours after intradermal testing, generalized pruritus developed and 24 hours later there was a disseminated partly follicular eczematous reaction with involvement of the flexural areas. Biopsy of the eruptions caused by prednisolone and of the positive skin reaction to methylprednisolone succinate showed superficial dermatitis with a perivascular infiltration consisting predominantly of CD4+ cells and some eosinophils. Immunofluorescence showed increased expression of HLA-DR molecules on the CD4+ and CD8+ cells. During the exanthema caused by prednisolone, interleukin-5 (14 pg/ml), interleukin-6 (38 pg/ml), and interleukin-10 (26 pg/ml) were detected in the blood; 2 months after recovery these cytokines were not detectable.

The authors of the last report commented that generalized delayed type hypersensitivity to systemic administration of a glucocorticoid is rare. Despite the potent immunosuppressive effect of glucocorticoids on immunocompetent cells, the clinical features, the skin biopsy specimen, and the positive delayed skin test reactions strongly suggested an immunological mechanism: T cells were clearly involved and the high concentrations of

© 2006 Elsevier B.V. All rights reserved.

interleukins 5, 6, and 10 were consistent with a T helper type 2 reaction. The raised concentrations of interleukin-5 were probably responsible for the blood and tissue eosinophilia.

Budesonide has been marketed in oral form for intestinal inflammatory disease. An non-IgE-mediated anaphylactic reaction has been associated with oral budesonide (263).

- A 32-year-old woman with Crohn's disease, who had taken prednisone 20 mg/day and azathioprine 150 mg/day, switched to budesonide 9 mg/day because of weight gain, and 5 minutes after the first capsule her tongue and throat swelled, accompanied by wheeziness and diarrhea. She was given clemastine and recovered after 4 ays. Intracutaneous tests with diluted budesonide suggested a non-IgE-mediated reaction. She had a previous history of a similar reaction to mesalazine. One year later her tongue and throat swelled after intravenous dexamethasone.

Urticaria with angioedema has been described in a patient taking deflazacort (264).

- A 64-year-old woman with allergic alveolitis caused by parakeet feathers improved with intravenous methylprednisolone, and was given oral deflazacort 60 mg/day, to be reduced progressively. After 30 days she developed generalized itchy blotches and lip edema. At that time she was mistakenly taking deflazacort in a dose of 120 mg/day. She was given an antihistamine, without any improvement. Deflazacort was then replaced by prednisolone and her symptoms disappeared immediately. Skin tests (a prick test and an epicutaneous test) were positive with deflazacort. Oral provocation with deflazacort 30 mg was positive, with the immediate appearance of the same symptoms as in the initial episode.

Vasculitis

Exacerbation of giant cell arteritis, with clinical signs of an evolving vertebrobasilar stroke, has been attributed to prednisolone (265).

- A 64-year-old man with giant cell arteritis was given prednisolone 60 mg/day. Within 5 days he developed double vision and agitation and became drowsy and confused. A cranial MRI scan showed recent cerebral lesions and a Doppler scan showed high-resistant blood flow in both vertebral arteries. He had an episode of complete loss of vision and was given dexamethasone and intravenous heparin followed by warfarin. He gradually improved over the next few weeks but was left with cognitive and memory deficits.

Immunosuppression

Glucocorticoids inhibit the formation of antibodies. Of 111 consecutive heart transplant recipients taking oral prednisone (mean 13.8 months), 57% developed hypogammaglobulinemia (IgG below 7 g/l) (266). Those with severe hypogammaglobulinemia (IgG below 3.5 g/l) were at increassed risk of opportunistic infections compared with those with IgG concentrations over 3.5 g/l (55 versus 5%, OR = 23). Parenteral glucocorticoid pulse therapy was associated with a significantly increased risk of severe hypogammaglobulinemia (OR = 15).

With long-term treatment, IgG subclass deficiencies can become marked (267). There is suppression of the antigen–antibody reaction, and since this reaction itself normally results in liberation of kinins, the latter is also suppressed. Failure of kinin liberation leads in turn to inhibition of invasion of sensitized leukocytes and reduced production and maturation of phagocytes. Undoubtedly, it is true that using minimal effective doses will avoid the most serious consequences, but the problem cannot be fully circumvented, since the anti-inflammatory effects themselves involve some inhibition of the migration of leukocytes and phagocytosis.

Dexamethasone significantly affected the antibody response of preterm infants with chronic lung disease to immunization against *Haemophilus influenzae* (268). Serum samples were obtained before and after immunization from an unselected cohort of 59 preterm infants (30 boys; gestational age 175–208 days). *Haemophilus influenzae* antibodies were measured using ELISA. IgG antibody concentrations in 16 infants who received no dexamethasone were 0.16 and 4.63 microgram/ml before and after immunization respectively. The corresponding values for those who received dexamethasone were 0.10 and 0.51 microgram/ml.

Infection risk

The consequence of this interference with immune responses can be multiplication of bacteria and an increased risk of bacterial intoxication when infection does occur; hence, the frequency and severity of clinical infections tend to increase during glucocorticoid therapy. Aggravation of existing tuberculosis and reactivation of completely quiescent cases of this infection are classic consequences demanding prophylactic measures; atypical mycobacteria have also caused tissue infections (SEDA-17, 449). Other bacterial infections, some severe and proceeding to sepsis, have followed glucocorticoid treatment. There is little evidence that glucocorticoids, even in high dosages and early in the course of infection, significantly alter the ultimate outcome (269). Use of glucocorticoids in the treatment of septic shock is not recommended in the absence of adrenal suppression.

It has been suggested that there are some differences between drugs. The use of fluticasone nasal spray to control polyp recurrence after functional endoscopic sphenoethmoidectomy should be viewed with caution, as it has been said to be associated with a high incidence of severe postoperative infection compared with beclomethasone (SEDA-21, 375) (270).

Acute generalized exanthematous pustulosis due to a glucocorticoid has been reported (SEDA-21, 416) (271).

Bacterial infections

Infections with *Clostridium difficile*, *Pseudomonas aeruginosa*, and *Listeria monocytogenes* (SEDA-22, 450) (272) have occasionally been precipitated or aggravated by glucocorticoids, as has tuberculous peritonitis (SEDA-20, 377) (273).

The cumulative and mean daily dosages of glucocorticoids in patients with systemic lupus erythematosus,

© 2006 Elsevier B.V. All rights reserved.

inflammatory myopathy, overlap syndrome, or mixed connective tissue disease were the most important risk factors for the development of tuberculosis, according to a study conducted in Korea (274). Records were analysed from 269 patients who had been hospitalized during a 5-year period. In 21 patients active tuberculosis developed after a mean duration of 27 months from diagnosis of their rheumatic disease, an incidence rate of 20 cases per 1000 patient-years. The mean cumulative and daily dosages of prednisolone during the follow-up period were 31 594 and 25 mg respectively in patients who developed tuberculosis, compared with 17 043 and 18 mg in patients who did not. Glucocorticoid pulse therapy was a risk factor for the development of tuberculosis.

- A 43-year-old woman developed cavitary lung tuberculosis after she received methotrexate and glucocorticoid pulse therapy for rheumatoid arthritis (275).

The authors commented that the onset of the lung infection appeared to be closely related to methotrexate and glucocorticoid pulse therapy, because of the interval between drug administration and the onset of tuberculosis, and the lack of other risk factors for opportunistic infections.

In a retrospective study, the use of glucocorticoids during *Pneumocystis jiroveci* pneumonia (mean total dose methylprednisolone 420 mg, mean treatment duration 12 days) did not increase the risk of development or relapse of tuberculosis or other AIDS-related diseases (SEDA-20, 377) (276). The study included 129 patients (72 who took glucocorticoids and 57 who did not) who were followed up at 6, 12, 18, and 24 months of glucocorticoid therapy. The rates of infections were similar in both groups, and the cumulative rate of tuberculosis at 2 years was 12–13%.

Mycobacterium avium septic arthritis has been reported in two patients with pre-existing rheumatic disease (scleroderma and polymyositis) who were taking prednisolone and azathioprine; the infection was in the left shoulder in one patient and in the knee in the other (277).

The use of glucocorticoids in patients with hematological diseases is a factor that facilitates the occurrence of *Legionella pneumophila* pneumonia, and 10 episodes of this infection were possibly related to glucocorticoids in a series of 67 cases of Legionnaires' disease diagnosed in a single institution during 2.5 years (278).

Viral infections

Infections such as chickenpox can have serious consequences, including death, in patients taking systemic glucocorticoids (SEDA-19, 378) (SEDA-20, 377) (279,280). It has been suggested that *Varicella zoster* immunoglobulin should be given to patients in contact with chickenpox if they have taken glucocorticoids in dosages over 0.5 mg/kg/day during the preceding 3 months, in the context of near-fatal chickenpox in a child receiving prednisolone (SEDA-20, 377) (281). Smallpox vaccination has in the past resulted in vaccinia gangrenosum in patients taking glucocorticoids, and the current type of *Varicella* vaccine is much more likely to produce rashes in children who are already taking glucocorticoids than in controls (SEDA-16, 452).

Herpes simplex virus encephalitis after myxedema coma has been described in an 81-year-old man treated with hydrocortisone (100 mg 8-hourly) and levothyroxine (282). In renal transplantation, two cases of death from *Herpes simplex* as a result of glucocorticoid treatment are on record (SED-8, 827) (SEDA-17, 449).

Fungal and yeast infections

Fungal and yeast infections (including cases of fulminant fungal pericarditis, mucormycosis, *Aspergillus fumigatus* infection, and cutaneous alternariosis) can be precipitated or aggravated by glucocorticoid treatment (SEDA-17, 449) (SEDA-18, 390) (SEDA-20, 377) (SEDA-21, 418) (SEDA-22, 449) (283–286).

Primary esophageal histoplasmosis must be considered in patients who have a history of gastroesophageal reflux disease and are immunosuppressed by long-term glucocorticoids (SEDA-22, 450) (287). Oropharyngeal candidiasis is a well-described adverse effect of inhaled glucocorticoids. However, few cases of esophageal candidiasis have been reported (SEDA-22, 179).

Invasive pulmonary aspergillosis with cerebromeningeal involvement has been described after short-term intravenous administration of methylprednisolone (SEDA-22, 449) (288). Of 473 HIV-infected children, 7 (1.5%) developed invasive aspergillosis during the study period (1987–95) (SEDA-22, 449) (289). Sustained neutropenia or glucocorticoid therapy as predisposing factors for invasive aspergillosis were found in only two patients.

- Fatal pulmonary infection with *Aspergillus fumigatus* and *Nocardia asteroides* has been described in a patient who took prednisone 1 mg/kg/day for 1 month for bronchiolitis obliterans (290).
- Fatal *Aspergillus* myocarditis, probably related to short-term administration of glucocorticoids, has been described in a 58-year-old man, who had an acute exacerbation of his chronic obstructive pulmonary disease and received oxygen, bronchodilators, omeprazole, co-amoxiclav, and intravenous methylprednisolone 40 mg 8-hourly; he died 5 days later and postmortem examination showed a fungal myocarditis (291).
- Fatal aspergillosis with a thyroid gland abscess occurred in a 74-year-old man after treatment with prednisolone for polymyalgia rheumatica (292).

Scedosporium apiospermum infection occurred in the left forearm of an 81-year-old man who was taking chronic oral prednisone (increased to 40 mg/day 1 month before presentation) for lung fibrosis (293).

Cutaneous alternariosis (infection with *Alternaria alternata*) has been described in a 78-year-old farmer with idiopathic pulmonary fibrosis taking oral prednisone 20 mg/day (294).

The effect of dexamethasone has been assessed in a retrospective chart review study in neonates weighing less than 1200 g, both with ($n = 65$) and without ($n = 269$) *Candida* sepsis; dexamethasone therapy and prolonged antibiotic therapy were associated with *Candida* infection (295).

© 2006 Elsevier B.V. All rights reserved.

Helminth infections

Strongyloidiasis (SEDA-20, 377) (SEDA-21, 419) (SEDA-22, 449) (296–298) has been precipitated or aggravated by glucocorticoids.

Protozoal infections

Toxoplasmosis has been precipitated by glucocorticoids (299,300).

Pneumocystis jiroveci pneumonia has been precipitated or aggravated by glucocorticoids (SEDA-20, 377) (SEDA-22, 450) (272,301,302). There is some concern about the use of glucocorticoids as adjunctive therapy in patients with AIDS who develop *Pneumocystis jiroveci* pneumonia. The immunosuppressant properties of glucocorticoids have been reported to enhance the risk of tuberculosis and other AIDS-related diseases (for example Kaposi's sarcoma or cytomegalovirus infection).

Amebic dysentery has been precipitated by glucocorticoids (303).

Death

Mortality associated with glucocorticoid has been retrospectively studied in 556 patients with chronic obstructive pulmonary disease admitted to a rehabilitation center (304). Median survival was 38 months and 280 patients died during follow-up. On multivariate analysis, oral glucocorticoid use at a prednisone equivalent of 10 mg/day without inhaled glucocorticoid was associated with an increased risk of death (RR = 2.34; 95% CI = 1.24, 4.44), and 15 mg/day increased the risk further (RR = 4.03; 95% CI = 1.99, 8.15). The risk of death was not increased in those using 5 mg/day or when patients used any oral dose in combination with inhaled glucocorticoids.

Long-Term Effects

Drug withdrawal

Suppression of adrenocortical function is one of the consequences of repeated administration of glucocorticoids; after termination of treatment a withdrawal syndrome can occur. In many cases this is unpleasant rather than acutely dangerous; in such instances the patients may have headache, nausea, dizziness, anorexia, weakness, emotional changes, lethargy, and perhaps fever; in some cases severe mental disorders occur and there are repeated reports of benign intracranial hypertension (305). The glucocorticoid withdrawal syndrome also seems to underlie the "glucocorticoid pseudorheumatism" that can occur when the drugs are withdrawn in rheumatic patients.

Withdrawal symptoms disappear if the glucocorticoid is resumed, but as a rule they will in any case vanish spontaneously within a few days. More serious consequences can ensue, however, in certain types of cases and if adrenal cortical atrophy is severe. In patients treated with corticoids for the nephrotic syndrome and apparently cured, the syndrome is particularly likely to relapse on withdrawal of therapy if the adrenal cortex is atrophic (SEDA-3, 305). In some cases, acute adrenocortical insufficiency after glucocorticoid treatment has actually proved fatal. It is advisable to withdraw long-term glucocorticoid therapy gradually so that the cortex has sufficient opportunity to recover. Table 5 lists methods of withdrawing prednisolone after long-term therapy in different circumstances (306).

Table 5 Suggested methods of withdrawing prednisolone

Circumstances	Change in daily dose
The problem has resolved and treatment has been given for only a few weeks	Reduce by 2.5 mg every 3 or 4 days down to 7.5 mg/day; then reduce more slowly, for example by 2.5 mg every week, fortnight, or month
There is uncertainty about disease resolution and/or therapy has been given for many weeks	Reduce by 2.5 mg every fortnight or month down to 7.5 mg/day then reduce by 1 mg every month
Symptoms of the disease are likely to recur on withdrawal (for example rheumatoid arthritis)	Reduce by 1 mg every month

Anorexia nervosa has been precipitated by withdrawal of oral prednisolone for asthma (SEDA-21, 414) (307).

A case of papilledema as a manifestation of raised intracranial pressure has been reported following withdrawal of topical glucocorticoids (SEDA-3, 305).

Panniculitis, which causes erythematous, firm, warm subcutaneous nodules, can occur within 2 weeks of withdrawal of large doses of glucocorticoids, but case reports confirm that resolution without scarring is the rule and that reintroduction of glucocorticoids is not necessary for improvement (308).

Churg–Strauss syndrome has come into prominence with the introduction of the leukotriene receptor antagonists, because they allow glucocorticoid-dependent asthmatics to discontinue their oral prednisolone. Five patients developed Churg–Strauss syndrome when their oral glucocorticoids were withdrawn (309). The duration of oral glucocorticoid therapy was 3–216 months and the dosage of prednisolone was 2.5–25.5 mg/day. The diagnosis of Churg–Strauss syndrome was made from 6 to 83 months after withdrawal of the oral glucocorticoids. These case reports support the hypothesis that it is the withdrawal of glucocorticoids that unmasks the underlying systemic vasculitis in these patients with asthma, rather than an effect of the new therapeutic agents that permits the reduction (and withdrawal) of prednisolone. Case-control studies are needed to determine the respective roles of the new therapeutic agents, prednisolone withdrawal, or other factors in the emergence of Churg–Strauss syndrome in these asthmatic patients

Tumorigenicity

Direct tumor-inducing effects of the glucocorticoids are not known, but the particular risk that malignancies in patients undergoing immunosuppression with these or other drugs will spread more rapidly is a well-recognized problem.

- Progressive endometrial carcinoma associated with azathioprine and prednisone therapy has been reported (310).

© 2006 Elsevier B.V. All rights reserved.

- Rapid progression of Kaposi's sarcoma 10 weeks after combined treatment with glucocorticoids and cyclophosphamide has been described; marked improvement of the skin lesions was noted after discontinuation of prednisone therapy (311).

Patients (mean age 39 years, $n = 1862$) who underwent 1924 renal transplantations from March 1995 to May 1997 were followed for 3–150 months. They received one of the following regimens: prednisolone plus azathioprine (group 1; $n = 100$); prednisolone plus azathioprine plus ciclosporin (group 2; $n = 1464$); and the same therapy as group 2 plus either muromonab-CD3 or antithymocyte globulin as induction or antirejection therapy (group 3; $n = 298$). The mean time to appearance of neoplasia after renal transplantation was 48 months. Malignancies developed earlier in group 3 patients (mean time to appearance 31 months) than in group 2 (39 months) and in group 1 (90 months). Seven of the patients who developed malignancies had also received pulse methylprednisolone for acute rejection. The authors concluded that the treatment of acute rejection with pulsed methylprednisolone and the use of muromonab-CD3 and antithymocyte globulin may lead to an increased incidence of malignancies after renal transplantation. They recommended that strategies be implemented for the early detection of malignancy (312)

In seven patients, accelerated growth of Kaposi's sarcoma lesions during glucocorticoid therapy suggested that glucocorticoids can alter the biological behavior of this malignant disease (313). Hydrocortisone accelerates the growth of cell lines derived from Kaposi's sarcoma cells cultured in vitro and this may partially explain these findings. Reports continue to point to the reversibility of the condition when glucocorticoids are withdrawn (314).

Kaposi's sarcoma has been associated with prednisolone therapy in two elderly women (315).

- An 84-year-old woman with polymyalgia rheumatica and a 79-year-old woman with undifferentiated connective tissue disease and leukocytoclastic vasculitis were given prednisolone 20 mg/day with subsequent dosage reductions. The first patient developed a raised purpuric rash and lymphedema of the left leg within 5 months and the second developed large purple nodules on the soles of her feet and the backs of her hands accompanied by periorbital and peripheral edema. Skin biopsies showed Kaposi's sarcoma, and both patients had raised IgG antibody titers to human herpesvirus-8.

Prior infection with herpesvirus-8 is a requisite for the development of Kaposi's sarcoma. The question arises as to how glucocorticoid treatment alone can lead to the emergence of this malignancy. In vitro evidence supports the hypothesis that glucocorticoids have a direct role in stimulating tumor development and the activation of herpesvirus-8.

A possible relation between systemic glucocorticoid use and a risk of esophageal cancer has been described in a population-based study in Denmark, in which the prescriptions database and the Danish cancer registry were linked (316). There was an increase in the number of cases observed ($n = 36$) compared with the number expected ($n = 19$), with a standardized incidence ratio of 1.92 (95% CI = 1.34, 2.65).

Second-Generation Effects

Pregnancy

In a statement, the American Academy of Pediatrics and the Canadian Paediatric Society did not recommend the routine use of systemic dexamethasone for the prevention or treatment of chronic lung disease in infants with very low birthweights, because it does not reduce overall mortality and is associated with impaired growth and neurodevelopment delay (317,318).

In an analysis of 595 preterm infants born at 26–32 weeks gestation during a randomized controlled trial for the prevention of lung disease, glucocorticoids given to women at risk of preterm delivery promoted fetal lung maturation, reduced the incidence of respiratory distress syndrome, and reduced neonatal morbidity and mortality (319). Dexamethasone was given as either two doses of 12 mg 24 hours apart or four doses of 6 mg every 6 hours. Mortality was 9.2% after three or more courses, compared with 4.8% after one or two courses. This association was not explained by other factors (maternal or other common preterm morbidities).

The effects of glucocorticoids on uterine activity and preterm labor in high-order multiple gestations have been retrospectively reviewed (SEDA-20, 377) (320). In 15 women with triplet or quadruplet pregnancies, 17 out of 57 courses of betamethasone were associated with episodes of significant contractions requiring tocolytic intervention; 11 of these episodes were associated with cervical change and four resulted in premature delivery. The authors did not recommend the use of glucocorticoids if patients have more than 3.5 contractions per hour.

Prenatal glucocorticoid therapy to enhance fetal lung maturation reduces neonatal morbidity and mortality. However, adverse effects of serial courses of betamethasone on mother and fetus can occur.

Endocrine

Maternal hyperadrenalism occurred after five courses of betamethasone to enhance fetal lung maturation (321).

- A 26-year-old woman was given intravenous salbutamol 0.3 mg/hour for preterm labor, and intramuscular betamethasone 12 mg/day for 2 days. Daily oral tocolysis (salbutamol 2 mg every 6 hours plus nicardipine 50 mg every 12 hours) and betamethasone every week were continued at home for 3 weeks. The mother developed amyotrophy, acne on the face and trunk, moon face, hirsutism with whiskers, and thin skin. Free urinary cortisol was less than 5 micrograms/day (reference range 25–90), plasma cortisol was less than 10 ng/ml (100–200), and the salivary cortisol was less than 0.6 ng/ml (2.3–4.7). One hour after intramuscular tetracosactide 250 micrograms, her plasma cortisol was 102 ng/ml (reference range over 210) and the salivary cortisol was 3.1 ng/ml (13–25), indicating no adrenocortical response. She was given hydrocortisone 20 mg/day, and 2 months later adrenocortical insufficiency persisted, with a plasma cortisol of

© 2006 Elsevier B.V. All rights reserved.

152 ng/ml after corticotropin stimulation. One year later, she still required hydrocortisone 10 mg/day.

Hyperadrenalism has never otherwise been reported after the sequential use of glucocorticoids for fetal lung maturation.

A study in 10 women has been conducted to determine whether betamethasone administered at risk of preterm delivery causes adrenal suppression (322). After adrenal stimulation with corticotropin 1 microgram at 24–25 weeks, each woman received two intramuscular doses of betamethasone 12 mg 24 hours apart; 1 week later, another corticotropin test was followed by another two doses of betamethasone; a third corticotropin stimulation test was carried out 1 week later. All the women had normal baseline and stimulated cortisol concentrations during the first corticotropin stimulation test. Mean baseline serum cortisol concentrations fell with each corticotropin stimulation test (from 700 nmol/l (254 micrograms/l) before betamethasone to 120 nmol/l (43 micrograms/l) 1 week after the second course of betamethasone). The mean stimulated cortisol concentrations also fell significantly, from 910 nmol/l (330 micrograms/l) to 326 nmol/l (118 micrograms/l). There was evidence of adrenal suppression in four patients after the first course of betamethasone and in seven patients after the second course. There was no evidence of Addisonian crisis antepartum or intrapartum.

Musculoskeletal

Osteonecrosis of the femoral head can occur with glucocorticoids in nonpregnant individuals, but has not previously been reported in pregnancy (323).

- A 37-year-old white woman was given betamethasone, two doses of 12 mg over a day, at 24 weeks of a twin pregnancy, because of a history of growth restriction in her first pregnancy. At 25 weeks Doppler of the umbilical vessels suggested a reduction in end-diastolic flow in one twin. Betamethasone was prescribed again and was repeated weekly to a total of six courses because of the high risk of preterm delivery. At 30 weeks she complained of pain in the right hip exacerbated by weight bearing, which increased over the following 7 days until standing was impossible. An MRI scan showed avascular necrosis of the femoral head.

Infection risk

The use of betamethasone for the treatment of premature rupture of membranes during pregnancy is associated with an increased prevalence of maternal and neonatal infections. Two reports have described the risk of infections associated with the use of glucocorticoids during pregnancy. Of 374 patients with preterm premature rupture of membranes, 99 received a single course of glucocorticoids, 72 received multiple courses, and 203 were not treated with glucocorticoids (324). Only multiple courses of betamethasone increased the incidence of early-onset neonatal sepsis, chorioamnionitis, and endometritis in mothers. A single course of glucocorticoid was not significantly associated with any maternal or neonatal infectious complications. The incidence of maternal infections in 37 patients who received three or more courses of betamethasone (median 6, range 3–10) because of the risk of preterm delivery has been evaluated, with 70 healthy pregnant women as controls (325). Of those treated with betamethasone, 65% developed infectious diseases compared with 18% of controls. Symptomatic lower urinary tract infections (35 versus 2.7%) and serious bacterial infections (24 versus 0%) were more frequent in treated mothers. Eight of nine serious infections occurred in patients exposed to five or more courses of glucocorticoids.

Singleton pregnancies delivered at 24–34 weeks after antenatal betamethasone exposure have been prospectively analysed, in order to study the incidence of perinatal infection (326). There were 453 patients, 267 of whom took a single course of betamethasone (two doses of 12 mg in 24 hours), and 186 of whom took a multiple course (more than two doses in the 24 hours after the initial course). Multiple courses were significantly associated with early-onset neonatal sepsis (OR = 5.0; 95% CI = 1.0, 23), neonatal death (OR = 2.9; CI = 1.3, 6.9), chorioamnionitis (OR = 10; CI = 2.1, 65), and endometritis (OR = 3.6; CI = 1.7, 8.1). Respiratory distress and intraventricular hemorrhage were similar in the two groups. Although the study was non-randomized the results suggest an increased risk of neonatal infection and death after multiple courses of dexamethasone during pregnancy.

In a retrospective study in 609 mothers and their 713 infants who were treated with 1–12 courses of antenatal glucocorticoids, data from 369 singleton preterm infants born at 34 weeks or later, 210 multiple gestations, and 134 infants delivered at 35 weeks or later were analysed (327). The incidence of respiratory distress syndrome was 45% for single courses and 35% for multiple courses of glucocorticoids (OR = 0.44; 95% CI = 0.25, 0.79). The multiple-course group also had significantly less cases of patent ductus arteriosus (20 versus 13%). The incidences of death before discharge and other neonatal morbidities were similar. The multiple-course group had a significant reduction of 0.46 cm in head circumference at birth when adjusted for gestational age and pre-eclampsia. The two groups had similar birthweights. Infants born at more than 35 weeks, multiple-gestation infants, and infants who were born more than 7 days after the last dose of glucocorticoid had similar outcomes, regardless of the number of courses they had received. Mothers treated with multiple courses compared with a single course had a significantly higher incidence of postpartum endometritis, even though they had a lower incidence of prolonged rupture of membranes (24 versus 33%) and similar cesarean delivery rates. In conclusion, antenatal exposure to multiple courses of glucocorticoids compared with a single course resulted in a significant reduction in the incidence of respiratory distress syndrome in singleton preterm infants delivered within a week of the last glucocorticoid dose. This was associated with a reduction in head circumference at birth and an increased incidence of maternal endometritis. Whether the potential benefits of repeated therapy outweigh the risks will ultimately be determined in randomized controlled trials.

Teratogenicity

Teratogenic effects of glucocorticoids, which have been demonstrated in animal experiments since 1950, have not generally been confirmed in man. The question whether a

© 2006 Elsevier B.V. All rights reserved.

disease that has had to be treated with glucocorticoids in pregnancy or the glucocorticoid treatment itself may have caused congenital anomalies reported anecdotally usually cannot be answered in any individual case. Dexamethasone, for instance, given in a suppressive dosage, seems to have been therapeutically effective in endocrine abnormal pregnancy with congenital adrenogenital syndrome (328); how is one to distinguish cause and effect here? Cleft lip and palate, seen in animal studies, have not been encountered more often in the offspring of glucocorticoid-treated women than in those of untreated women. In several small series of patients in whom glucocorticoids were used before and during pregnancy, no congenital abnormalities were seen on follow-up, but material on which to base a firm judgement is lacking. Certainly, the evidence to date does not suggest that on teratological grounds one should hesitate to administer glucocorticoids for therapeutic reasons during pregnancy (SEDA-3, 306).

However, first trimester in utero exposure to a glucocorticoid was associated with a small risk of major neonatal malformations, according to the results of a Canadian meta-analysis (329). Six cohort studies and one case-control study were analysed, and the results showed that women who had taken long-term glucocorticoid therapy during pregnancy were more likely to have a baby with a major malformation than women who had not (OR = 2.46; 95% CI = 1.41, 4.29).

Glucocorticoids have been used in cases of hyperemesis gravidarum when standard antiemetics are ineffective. In an observational comparison of women with complicated hyperemesis gravidarum and weight loss, over 5% of prepregnant weight treated with ($n = 30$) or without ($n = 25$) glucocorticoids, gestational evolution and singleton birthweights were not different in the two groups (330).

A hydatidiform mole during pregnancy may have been due to the glucocorticoids used in an immunosuppressive regimen (331).

- A 33-year-old woman took immunosuppressive therapy after renal transplantation: ciclosporin (dosage adjusted to achieve blood concentrations of 120–160 ng/ml), azathioprine 1 mg/kg (frequency of administration not stated), and methylprednisolone 40 mg/day from day 1 after transplantation, tapered weekly by 4–8 mg/day. Because of rejection symptoms at weeks 1, 4, and 7, she received three cycles of intravenous methylprednisolone 250 mg/day, each cycle lasting 5–7 days; she also received a bolus dose of methylprednisolone 500 mg on day 0. Pregnancy was diagnosed on day 12 after transplantation (9 weeks after conception). At week 6 after transplantation she had a missed abortion. Curettage was performed and a partial hydatidiform mole was detected. She was discharged at week 10 and immunosuppressive therapy was tapered.

The teratogenic effects of prednisone have been evaluated in a placebo-controlled study in 372 women and a meta-analysis (332). There was no statistical difference in the rate of major anomalies between the glucocorticoid-exposed women and the controls. The meta-analysis included 10 studies (six cohort and four case-control studies), with data from 535 exposed and 50 845 nonexposed women. The odds ratios for major malformations were 1.5 (95% CI = 0.8, 2.6) for the cohort studies and 3.4 (CI = 2.0, 5.7) for the case-control studies. The results suggest that although prednisone does not represent a major teratogenic risk in humans in therapeutic doses, it does increase the risk of oral cleft defects by an order of 3.4-fold.

Fetotoxicity

The effect of prolonged antenatal betamethasone (three or more weekly administrations) has been studied in 414 fetuses (333). Multidose betamethasone was not associated with higher risks of antenatal maternal fever, chorioamnionitis, reduced birthweight, neonatal adrenal suppression, neonatal sepsis, or neonatal death.

The effects of antenatal dexamethasone on birthweight have been studied in 961 infants and matched controls (334). Dexamethasone-treated infants had significantly lower birthweights (after adjustment for week of gestation). The average differences from controls were 12 g at 24–26 weeks, 63 g at 27–29 weeks, 161 g at 30–32 weeks, and 80 g at 33–34 weeks. In the case of preterm rupture of membranes, the data were not conclusive.

Betamethasone, two doses of 12 mg a day apart, in 40 pregnant women (27–34 weeks) caused important changes in fetal physiology (335). Fetal breathing (the number of breathing episodes and the total breathing time in 30 minutes) fell by 83% and fetal limb and trunk movements fell by 53% and 49% respectively. These changes were transient and returned to the range of normality 96 hours after administration. There were no changes in Doppler velocimetry of the umbilical and middle cerebral arteries. Awareness of these effects may prevent unnecessary iatrogenic delivery of preterm infants who present abnormal biophysical profile scores 2 days after glucocorticoid exposure.

Retardation of intrauterine growth by glucocorticoids has been reported not only in animals but also in man. In a 1990 case from France, dwarfism (as well as Cushing's syndrome) was recorded in a child whose mother had received high-dose glucocorticoids during pregnancy.

It has been suggested that the risk of stillbirth may be increased by glucocorticoid treatment; the figures are suggestive, but the possibility that the disorder that led to the use of the glucocorticoid was itself responsible for the less favorable outcome cannot be excluded (336).

Prevention of the respiratory distress syndrome in anticipated prematurity has become a widely accepted (though not uncontroversial) indication for glucocorticoids in late pregnancy, the compound most often used being dexamethasone. The timing of such treatment in late pregnancy seems to be of crucial importance (SEDA-3, 306); the possible adverse effects on the mother and child are still being discussed. The issue has been extensively reviewed (SEDA-17, 445). A meta-analysis of 15 trials, involving 1780 patients treated with glucocorticoids and 1780 controls, has shown a lower risk of the syndrome, and a substantial reduction in neonatal mortality (OR = 0.60; 95% CI = 0.48, 0.76),

© 2006 Elsevier B.V. All rights reserved.

without a higher risk of infection in the mother or maternal pulmonary edema (SEDA-20, 377) (337). In the mother, labor can be delayed by such glucocorticoid therapy (SEDA-3, 306); the combination of this treatment with sympathomimetic drugs may put the mother at risk of fluid retention with pulmonary edema (SED-12, 990), although it is not clear whether this problem only occurs when both drugs are used.

As far as the child is concerned, there may be only moderate adrenal suppression (338), although in some cases substitution treatment with glucocorticoids can be necessary in such babies; short-term treatment with betamethasone shortly before birth generally does not inhibit the infant's adrenal capacity to react to corticotropin (339). A single case of a leukemoid reaction in a preterm infant has been observed, after the mother was given betamethasone shortly before delivery (SEDA-3, 306).

On the other hand, there are many reports of hypertension (340), and electrocardiographic and other studies have often confirmed the presence of a disproportionately serious and bilateral hypertrophic obstructive cardiomyopathy, which unless it proves fatal is, in general, reversible once the glucocorticoids are withdrawn (SEDA-18, 386). Although the issue is confounded by the possibility that infants with bronchopulmonary dysplasia may be innately hypertensive, there seems no doubt as to the effect.

Most babies treated with glucocorticoids for lung dysplasia also show an appreciable rise in blood urea nitrogen, due almost entirely to an increase in structural protein catabolism (341). Serious gastrointestinal complications can occur. In one typical series of premature neonates treated in this way there were three such instances (perforated duodenal ulcer, perforated gastric ulcer, and upper gastrointestinal hemorrhage, the last two proving fatal) (342); the symptoms are apparently not masked by the glucocorticoid, as one would expect in adults. Treated infants also tend to have a low pH, which is unusual in premature babies (SEDA-18, 445).

Clearly, the duration of such treatment after delivery should be as brief as possible, but there is no reason for such concern as would lead to withholding therapy; one Dutch study with a 10-year follow-up detected no problems with exposed children's intellectual, motor, or social functioning compared with controls (114).

A meta-analysis, including 15 controlled trials and involving more than 1400 women, has shown that antenatal glucocorticoids in women with ruptured membranes may be beneficial in reducing the risks of neonatal death (RR = 0.68; 95% CI = 0.43, 1.07) and respiratory distress syndrome (RR = 0.56; CI = 0.46, 0.70), with no increase in the risk of infection in either the mother (RR = 0.88; CI = 0.61, 1.20) or baby (RR = 1.05; CI = 0.66, 1.68) (343).

A reduction in fetal response to vibroacoustic stimulation (vibroacoustic startle reflex) has been reported during 48 hours after the administration to pregnant women of two doses of betamethasone (12 mg 2 days apart) (344). The authors recommended that this test should not be used to evaluate well-being in fetuses exposed to glucocorticoids.

Susceptibility Factors

Genetic factors

Significant differences in the pharmacokinetics of methylprednisolone have been described in black and white renal transplant patients. Black patients had a slower clearance rate and a lower apparent volume of distribution. They had higher cortisol concentrations throughout the day, with higher nadir concentrations. Some of them had glucocorticoid-associated diabetes, and no white patients did. Further studies are needed to define the differences between the races (SEDA-20, 377) (345).

Age

Children

Inhaled glucocorticoids are recommended as first-line therapy for persistent asthma in children, to reduce both asthma symptoms and inflammatory markers. Treatment should be begun early in the course of the disease, because inhaled glucocorticoids can preserve airway function and prevent airway remodelling and subsequent irreversible airway obstruction (346). Because asthma is a chronic disease requiring long-term treatment, it is very important to balance the safety and efficacy of inhaled glucocorticoids to achieve optimal long-term results. Major safety concerns in children are the potential adverse effects on growth, adrenal function, and bone mass. Overall, the benefits of inhaled glucocorticoids clearly outweigh their potential adverse effects and the risks of poor asthma control. However, high doses of inhaled glucocorticoids in children are still of concern (347). It is of utmost importance to use the lowest effective dose, to limit systemic availability by selecting drugs with high first-pass hepatic inactivation, and to instruct patients on proper inhalation technique. Moreover, the use of adjuvant asthma medications acting by different mechanisms can help to reduce inhaled glucocorticoid dosages (346,347). These add-on therapies include leukotriene modifiers, long-acting beta$_2$-agonists, cromoglicate and nedocromil, and in selected cases theophylline. These agents should be added to, but should not in any case replace, inhaled glucocorticoid therapy (346,347).

The use of postnatal glucocorticoids in very premature infants is controversial; although dexamethasone reduces bronchopulmonary dysplasia, it has been associated with severe adverse effects (348). In 220 infants with a birthweight of 501–1000 g randomized to placebo or dexamethasone (0.15 mg/kg/day for 3 days and tapering over a period of 7 days) the relative risk of death or chronic lung disease compared with controls was 0.9 (95% CI = 0.8–1.1) at 36 weeks of gestational age (304). Infants treated with dexamethasone were less likely to need supplementary oxygen. Dexamethasone was associated with increased risks of hypertension (RR = 7.4; 95% CI = 2.7, 20.2), hyperglycemia (RR = 2.0; 95% CI = 1.1, 3.6), spontaneous gastrointestinal perforation (13 versus 4%), lower weight, and a smaller head circumference.

Elderly people

Prolonged use of glucocorticoids in elderly people can exacerbate diabetes, hypertension, congestive heart failure, and osteoporosis, or cause depression. In a retrospective,

© 2006 Elsevier B.V. All rights reserved.

controlled study, the risks of high-dose intravenous or oral glucocorticoid therapy were assessed in 55 patients with Crohn's disease who were over the age of 50 years (350). They had a higher risk of developing hypertension, hypokalemia, and changes in mental state.

Hepatic disease

In patients with acute hepatitis and active hepatitis, protein binding of the glucocorticoids will be reduced and peak concentrations of administered glucocorticoids increased. Conversion of prednisone to prednisolone has been reported to be impaired in chronic active liver disease (351). However, although plasma prednisolone concentrations were more predictable after the administration of prednisolone than of prednisone to a group of healthy subjects (352), there was no difference in patients with chronic active hepatitis. There was also impaired elimination of prednisolone in these patients. In a review of the pharmacokinetics of prednisone and prednisolone it was concluded that fear of inadequate conversion of prednisone into prednisolone was not justified (353). Patients with hepatic disease suffer adrenal suppression more readily (91).

Other features of the patient

Menopause

Significant differences in the pharmacokinetics of prednisolone amongst menopausal women have been described (SEDA-21, 419) (354). The postmenopausal women had reduced unbound clearance (30%), reduced total clearance, and an increased half-life. Similar results are seen in the postmenopausal women who took estrogen or estrogen–progestogen therapy.

Protein binding

The association between low serum albumin concentrations and complications of prednisone has been long recognized, and it is an elementary pharmacokinetic principle that concentrations of unbound drug in plasma (the fraction that can reach the tissues) will be increased when binding of a drug to serum albumin is reduced (355).

Systemic lupus erythematosus

In 539 patients with systemic lupus erythematosus, organ damage was associated with glucocorticoid therapy compared with controls (356). Oral prednisone 10 mg/day for 10 years (cumulative dose 36.6 g) was significantly associated with osteoporotic fractures (RR = 2.5; 95% CI = 1.7, 3.7), symptomatic coronary artery disease (RR = 1.7; CI = 1.1, 2.5), and cataracts (RR = 1.7; CI = 1.4, 2.5). Avascular necrosis was associated with high-dose prednisone (at least 60 mg/day for at least 2 months; RR = 1.2; CI = 1.1, 1.4). Intravenous pulses of methylprednisolone (1000 mg for 1–3 days) were associated with a small increase in the risk of osteoporotic fractures (RR = 1.3; CI = 1.0, 1.8).

Drug Administration

Drug contamination

Unregulated Chinese herbal products adulterated with glucocorticoids have been detected (357). Dexamethasone was present in eight of 11 Chinese herbal creams analysed by UK dermatologists. The creams contained dexamethasone in concentrations inappropriate for use on the face or in children (64–1500 micrograms/g). The cream with the highest concentration of dexamethasone was prescribed to treat facial eczema in a 4-month-old baby. In all cases, it had been assumed that the creams did not contain glucocorticoids. The authors were concerned that these patients received both unlabelled and unlicensed topical glucocorticoids. They wrote that "greater regulation and restriction needs to be imposed on herbalists, and continuous monitoring of side effects of these medications is necessary."

Drug dosage regimens

Daily or alternate-day administration

The unwanted effects of the glucocorticoids can be reduced to some extent by altering the dosage routine, for example by giving them on alternate days or giving the total daily dose every morning.

Because of circadian variation in endogenous glucocorticoid secretion, the pituitary–adrenal axis is suppressed more easily in the night than during the day (358). Thus, administration of the total dose as a single dose in the morning is preferable to twice daily dosing or administration in the evening alone.

Alternate-day therapy (giving twice the daily dose on alternate days) can in some cases maintain the therapeutic efficacy of oral glucocorticoids, while reducing their adverse effects (359–361).

Use in fixed combinations

Fixed combinations of oral glucocorticoids with nonsteroidal anti-inflammatory analgesics or broncholytic drugs that have to be given repeatedly during the day are undesirable, since their pattern of administration is determined in part by the demands of the other components; the glucocorticoid is thus likely to be given in such a way that it alters the circadian rhythm of endogenous glucocorticoids.

Pulse or megadose therapy

Extremely large intravenous doses of glucocorticoids given at longer intervals can sometimes be effective when a patient does not respond to conventional high doses. Systemic lupus erythematosus, various rheumatic diseases, and the treatment of renal graft rejection are indications for this type of use (SEDA-6, 331). High doses of glucocorticoids also have an antiemetic effect in patients with cancers.

No adverse effects are to be expected after a single injection of a high dose of a glucocorticoid, but some serious complications have been observed with repeated use, including both infections and the known direct adverse effects of glucocorticoids. Cases of ventricular dysrhythmias and atrial fibrillation have been reported (SEDA-18, 391). With pulse therapy, the nature of the injected glucocorticoid seems to be important; for

© 2006 Elsevier B.V. All rights reserved.

example, hydrocortisone, which is more rapidly metabolized, seems to be better tolerated than dexamethasone (SEDA-6, 331).

Drug administration route

Most knowledge of the adverse effects of glucocorticoids has been acquired in connection with their use as oral products. However, various other routes of administration have been developed, sometimes specifically in the hope of securing a local therapeutic effect while avoiding systemic adverse reactions. Although experience has shown that the latter cannot be eliminated in this way, they can be diminished in some cases. In other cases, new problems arise. Administration by inhalation is covered in the monograph on inhaled glucocorticoids.

Topical administration to the skin

The percutaneous absorption of high-potency topical glucocorticoids has been documented, but hypothalamic–pituitary–adrenal axis suppression, leading to clinically significant adrenal insufficiency or Cushing's syndrome, is infrequent. Two patients developed adrenal suppression after the unregulated use of betamethasone dipropionate 0.05% ointment (about 80 g/week) or clobetasol 0.05% ointment (up to 100 g/week), obtained without prescription to treat psoriasis (362).

Although glucocorticoids are used to treat eczema, they can sometimes exacerbate it (363).

- A 74-year-old man developed worsening eczema 24 hours after he applied clobetasol (Decloban) to treat chronic eczema of his external ear. Twelve years earlier he had noted exacerbation of a cutaneous lesion after he had applied a topical glucocorticoid. He had also had generalized erythema after an intra-articular injection of paramethasone. Patch tests to a series of glucocorticoids were positive for all drugs except flupametasone, fluocortine, and tixocortol. In addition, intradermal tests were positive to hydrocortisone and prednisolone, despite negative patch tests.

The authors commented that most glucocorticoid-sensitized patients react to several of the same group and less frequently of different groups. No case of hypersensitivity to glucocorticoids of all four classes has previously been reported.

- Chronic lichenified eczema has been attributed to prolonged use of topical methylprednisolone aceponate and budesonide (strength and duration of therapy not stated) in a 26-year-old woman (364). Patch tests were positive for methylprednisolone aceponate and budesonide cream, but negative for all other topical glucocorticoids.

The effects of exposure to topical glucocorticoids during pregnancy have been evaluated in a population-based follow-up study in 363 primigravida exposed to topical glucocorticoids during pregnancy and 9263 controls who received no prescriptions at all (365). The prevalence of malformations was 2.9% among 170 infants exposed to glucocorticoids during the first trimester and 3.6% among the controls. There were no increases in the risks of low birthweight, malformations, or preterm delivery in the offspring of women who were exposed to topical glucocorticoids during pregnancy.

Topical administration to the eye

Glucocorticoids that have been used for local ophthalmic treatment include medrysone, fluorometholone, tetrahydroxytriamcinolone, and clobetasone. Loteprednol etabonate 0.5% increases intraocular pressure less than dexamethasone. Studies on animal models of uveitis and two randomized double-masked trials showed that loteprednol etabonate 0.5% was less potent than dexamethasone, prednisolone acetate 1%, or fluorometholone, which may partly explain the improved toxicity profile of loteprednol etabonate (366).

Clinicians should not prescribe glucocorticoid-containing eye-drops unless they have performed a slit-lamp examination with tonometry, have assurance of appropriate follow-up, and understand the differential diagnosis, evaluation, and treatment. Unless clearly indicated, prescribing volumes larger than 5 ml or providing refillable prescriptions should be avoided. It should be stressed that excessive use of glucocorticoids can result in corneal Herpes infection and mycosis.

Since glucocorticoids reduce the immunological defences of the body to most types of infection, their use in the eyes should be monitored carefully. When long-term use is necessary, even with oral or inhalation therapy, eye examination should be performed every 6 months. The ophthalmological follow-up of patients using topical glucocorticoids should include tonometry at least twice a year, careful slit-lamp examination for early signs of herpetic or fungal keratitis and for changes in the equatorial and posterior subcapsular portions of the lens, examination of pupillary size and lid position, and staining of the cornea to detect possible punctate keratitis. Blood glucose concentrations should be checked if there are symptoms that suggest hyperglycemia.

Sensory systems

Ocular adverse effects of local or systemic administration of glucocorticoids include cataracts, glaucoma, papilledema, pseudotumor cerebri, activation of corneal infections, superficial keratitis, ptosis, pupillary dilatation, conjunctival palpebral petechiae, uveitis, and scleromalacia. Topical ocular application and facial application can cause high glucocorticoid concentrations in the anterior compartment of the eye. Serious visual loss can occur owing to the development of cataract in patients using glucocorticoid creams.

Glucocorticoid creams applied topically to the skin are routinely used in the treatment of many skin disorders, and their use on the face in severe atopic eczema is relatively common. Three patients developed advanced glaucoma while using topical facial glucocorticoids. Two other patients developed ocular hypertension secondary to topical facial glucocorticoids (367).

The use of a combination of a glucocorticoid with an antimicrobial drug is illogical and should generally be avoided because of the possibility of the emergence of resistant bacterial strains. It would be highly preferable if prescriptions for these drugs were issued by

© 2006 Elsevier B.V. All rights reserved.

ophthalmologists only, at least in those parts of the world where adequate medical services are available.

Three vision-threatening complications have been described due to the indiscriminate use of glucocorticoid-containing eyedrops (368).

- A 31-year-old man noted a blind spot in his right eye. He had worn contact lenses for 10 years to correct his myopia. He had applied Tobradex ointment (tobramycin 0.3% and dexamethasone 0.1%) to each eye every evening for the past 4 years because of irritation due to contact lenses, and continuous refills of this prescription were obtained through an acquaintance who was employed in a pharmacy. With spectacle correction his visual acuity was 20/25 in each eye. The intraocular pressure was 52 mmHg in his right eye and 37 mmHg in his left eye. The optic discs showed glaucomatous cupping in each eye. Automated visual field testing showed superior and inferior arcuate defects typical of glaucoma in both eyes. Slit-lamp biomicroscopy showed mild papillary conjunctivitis bilaterally due to contact lenses. The antibiotic + glucocorticoid ointment was withdrawn and his bilateral glucocorticoid-induced open-angle glaucoma was treated with antiglaucomatous drugs.
- A 15-year-old boy felt a foreign body sensation in his right eye after he had been raking hay. His local physician prescribed a suspension of tobramycin 0.3% + dexamethasone 0.1% tds, but 6 days later referred him for evaluation of a suspected fungal keratitis. He had a corneal epithelial defect with an underlying dense inflammatory infiltrate. Corneal scrapings contained fungal hyphae and *Fusarium* species was identified. Natamycin 5% was administered topically every hour, the infection resolved, and his visual acuity returned to 20/20 despite a dense corneal scar.
- A 56-year-old woman had bilateral primary open-angle glaucoma without visual field loss, which was well controlled with a long-term topical beta-blocker in each eye. She underwent a left dacryocystorhinostomy for nasolacrimal duct obstruction, but developed persistent tearing and irritation of the left eye several months postoperatively. A suspension of tobramycin 0.3% + dexamethasone 0.1% was prescribed, which she continued to use as needed for 6 months. Pain and reduced vision persisted in her left eye. Corrected visual acuity was 20/20 in her right eye and 20/60 in her left eye. The intraocular pressures were 18 mmHg in her right eye and 68 mmHg in her left eye. Automated visual field testing showed a normal field in her right eye, but only a central island and a crescent of temporal visual field in her left eye. External examination showed persistent nasolacrimal duct obstruction on the left side with mild conjunctival injection. The diagnosis was primary open-angle glaucoma in both eyes, which was exacerbated by topically applied glucocorticoids in her left eye. The antibiotic + glucocorticoid suspension was withdrawn, and a topical ocular hypotensive therapeutic regimen was initiated in her left eye.

Susceptibility factors

Local and systemic adverse effects of ophthalmic glucocorticoids occur in children more often, more severely, and more rapidly than in adults, for unknown reasons. It could be that children have relatively immature chamber angles, giving rise to a rapidly increasing intraocular pressure (369).

Glaucoma has been reported after the use of a glucocorticoid ointment in a young boy (369).

- A 6-year-old boy underwent a resection of levator palpebrae superioris for congenital blepharoptosis. Postoperatively, an ointment containing 0.1% dexamethasone and neomycin (Maxitrol) was applied to the operated eyelid three times a day to reduce lid edema. Four days later the surgical correction was satisfactory and there were no symptoms, but the intraocular pressure was raised to 44 mmHg in the operated eye, although normal in the other eye. The glucocorticoid was withdrawn and topical ocular hypotensive agents were prescribed. The intraocular pressure returned to normal the next day, and the antiglaucoma treatments were maintained for 1 week and tapered over the next 2 weeks. Subsequent follow-up confirmed normal intraocular pressure and no glaucomatous damage.

The ocular hypertensive response in this case could have been due to systemic absorption of glucocorticoid through the skin of the eyelid, especially when there was a surgical wound. Alternatively, a sufficient amount of ointment could have seeped over the eyelid margins, causing the rise in intraocular pressure, similar to the application of eye-drops, as has been reported in another child, who also had Cushing's syndrome, a rare result of ophthalmic glucocorticoids (370).

- An 11-year-old boy with iridocyclitis developed Cushing's syndrome, a posterior subcapsular cataract, and increased intraocular pressure in both eyes after the topical administration of prednisolone acetate 1% eyedrops bilaterally for 6 months. The Cushing's syndrome was aggravated when periocular methylprednisolone acetate was started while bilateral posterior subtenon injections of 80 mg of suspension were continued every 6 weeks for 6 months. He had not used systemic glucocorticoids before.

Topical administration to the nose

The local application of glucocorticoids for seasonal or perennial rhinitis often results in systemic adverse effects. The use of nasal sprays containing a glucocorticoid that has specific topical activity (such as beclomethasone dipropionate or flunisolide) seems to reduce the systemic adverse effects, but they can nevertheless occur, even to the extent of suppression of basal adrenal function in children (371). Local adverse effects include *Candida* infection, nasal stinging, epistaxis, throat irritation (372), and, exceptionally, anosmia (373).

Nervous system

Benign intracranial hypertension with nasal glucocorticoids has been reported (374).

- A 13-year-old boy with Crohn's disease in remission, who had taken fluticasone aqueous nasal spray 50 micrograms to each nostril od regularly for 5 days, gave a 10-day history of head and back pain. He had a

© 2006 Elsevier B.V. All rights reserved.

right sixth nerve palsy with bilateral swelling of his optic discs. An unenhanced computer tomogram was normal and magnetic resonance imaging excluded cavernous sinus thrombosis. The cerebrospinal fluid was clear with no cells, and protein and glucose concentrations were normal.

Although there was no clear temporal relation between the onset of the symptoms and the regular use of fluticasone, the authors proposed that the fluticasone was responsible, because the symptoms resolved after drug withdrawal. The association remains unproven but it does highlight the possibility of an association.

Sensory systems

Nasal budesonide or beclomethasone 100 micrograms bd for 3–9 months had no effect on the eyes in 26 patients who had undergone endoscopic sinus surgery (375). Ophthalmologic examination, tonometry, visual field testing, and biomicroscopic studies showed no evidence of ocular hypertension or posterior subcapsular cataract.

Ear, nose, and throat

The use of intranasal glucocorticoids in the treatment of allergic and vasomotor rhinitis in Sweden has doubled over a period of 5 years, and the number of reported cases of nasal septum perforation increased over the same time (376). The most common risk factor in 32 patients with nasal septum perforation (21 women, 11 men) was glucocorticoid treatment. Information from the Swedish Drug Agency showed that 38 cases of glucocorticoid-induced perforation had been reported over 10 years. The number of adverse effects per million Defined Daily Doses averaged 0.21. The risk of perforation was greatest during the first 12 months of treatment and most cases were in young women.

Endocrine

Aqueous nasal triamcinolone spray 220 or 440 micrograms od for the treatment of allergic rhinitis reportedly had no measurable adverse effects on adrenocortical function in 80 children (aged 6–12 years) in a placebo-controlled, double-blind study (377). Plasma triamcinolone concentrations measured over 6 hours fell rapidly and there was little or no accumulation during 6 weeks.

There have been reports of Cushing's syndrome after prolonged use of intranasal betamethasone 0.1% for chronic catarrh in two boys (378) and from an interaction of nasal fluticasone with ritonavir (379).

- A 30-year-old man who was using an intranasal formulation of fluticasone (therapeutic indication not stated), developed Cushing's syndrome about 5 months after starting ritonavir 600 mg bd, zidovudine, and lamivudine for HIV infection. His plasma cortisol concentrations were undetectable, his corticotrophin was low (under 2 pmol/l), and his 24-hours urinary cortisol excretion was under 30 nmol/l. Further investigations were consistent with secondary adrenal failure or with glucocorticoid use. He admitted to having used a topical glucocorticoid cream for 2 months. However, 6 weeks after he stopped using this cream, his plasma cortisol concentrations were still undetectable. It was then established that he had used nasal fluticasone propionate 200 micrograms/day for about 1 year before starting ritonavir. Ritonavir was replaced by nevirapine, and he continued to use fluticasone nasal spray. Three weeks later, his plasma cortisol concentration had increased to 290 nmol/l. Ritonavir was then added and his plasma cortisol concentration fell rapidly. Ritonavir was stopped again and his cortisol concentration normalized and his Cushingoid facies improved.

The authors thought it likely that inhibition of cytochrome P-450 by ritonavir increased the systemic availability of fluticasone and thus caused Cushing's syndrome in this patient.

Intralesional injection

Intralesional triamcinolone acetonide has been used extensively for the treatment of hypertrophic and keloid scars. Complications are few, usually being local skin color changes, prominent vascular markings, or subcutaneous atrophy. Cushing's syndrome after intralesional administration of triamcinolone acetate has been described in two adults and two children (aged 10 years and 21 months) after treatment of hypertrophic burn scars with intralesional triamcinolone acetonide (SEDA-21, 419) (350). These two children may have had a form of hypersensitivity to triamcinolone acetonide, as Cushing's syndrome was not the result of overdosage.

- Acute anaphylaxis occurred in an 18-year-old man after the third course of intradermal injections of triamcinolone suspension ("Kenalog" 10 mg per treatment) for alopecia areata (380). Subsequent rechallenge with intradermal triamcinolone 1 ml resulted in the same anaphylactic reaction as before and his serum IgE concentration was increased.

Immediate hypersensitivity reactions to paramethasone acetate, causing widespread eruptions, have been described in at least four cases. Delayed allergic reactions are less common.

- A woman had received intralesional paramethasone and other topical glucocorticoids several times for alopecia between the ages of 7 and 18 years (381). When she was 30 she was again treated with intralesional paramethasone for a relapse of alopecia. She developed pruritus after the first intralesional injection and erythema, edema, and vesicles 6–8 hours later. A biopsy showed spongiform lymphocytic folliculitis with spongiosis and exocytosis in the sweat gland ducts and in the pilosebaceous unit. She was treated with triamcinolone cream and her skin lesions resolved. Patch tests were positive for paramethasone, with cross-reactivity to tixocortol pivalate, hydrocortisone, and hydrocortisone butyrate.

Intraspinal injection

Intrathecal

The effects of intrathecal administration, both wanted and unwanted, are still much debated (382). The question as to whether oral glucocorticoid therapy should be preferred to intrathecal injections is raised by the harmful effects that have sometimes occurred after the latter,

© 2006 Elsevier B.V. All rights reserved.

although some of these may have been caused by irritative substances in the injection fluid (SEDA-6, 331). The same local glucocorticoid concentrations can probably be attained with fewer problems with oral administration. Epidural injection of glucocorticoids seems to be safer than intrathecal injection, but injection of high doses can cause the same systemic adverse effects as seen with oral treatment. Facial flushing and erythema after lumbar epidural glucocorticoid administration have been reported (SEDA-20, 378) (383).

Glucocorticoids given intrathecally can cause a rise in cerebrospinal fluid protein and carry the risk of arachnoiditis (SED-8, 820). Chemical meningitis has been reported after two intrathecal injections of methylprednisolone acetate (384) and after lumbar facet joint block (SEDA-17, 450). Intraspinal injections of hydrocortisone for multiple sclerosis apparently led in one case to a cauda equina syndrome, with subsequent ulceromutilating acropathy (SEDA-17, 450). Intra-discal injections of triamcinolone acetonide in a number of French cases led to disk or epidural calcification, sometimes symptomless (SEDA-17, 450).

Postlumbar puncture syndrome with abducent nerve palsy followed the use of intrathecal prednisolone for the treatment of low back pain and sciatica (385).

- A 38-year-old woman received intrathecal prednisolone 3 ml (strength not stated) and 1 day later developed a postural headache, nausea, and dizziness. She was treated with intravenous fluids and analgesics. Eight days later she suddenly developed a complete palsy of the right abducent nerve. An MRI brain scan showed contrast meningeal enhancement typical of postlumbar puncture syndrome. She was treated with oral glucocorticoids and blood patching was performed. Her headache began to resolve a week later. Four months later she had almost completely recovered function of her abducent nerve and a repeat MRI scan was normal.

Epidural

The indications, rationale, techniques, alternatives, contraindications, complications, and efficacy of lumbar and caudal epidural glucocorticoid injections have been reviewed (SEDA-21, 420) (386).

Bilateral posterior subcapsular cataracts have been reported after treatment with epidural methylprednisolone for low back pain secondary to degenerative joint disease and disk protrusion (387).

- A 42-year-old man had received 15 epidural injections of methylprednisolone 80 mg over 10 years. About 6 weeks after his last injection, he developed progressively worsening cloudy vision. He had bilateral posterior subcapsular cataracts and subsequently underwent bilateral cataract removal.

The authors commented that it is possible that multiple epidural glucocorticoid injections had contributed to cataract formation. The patient also had several other risk factors for cataracts (cigarette smoking, alcohol consumption, exposure to ultraviolet radiation, low socioeconomic class, and low intake of antioxidant vitamins). However, the role of these other risk factors was speculative.

Symptoms consistent with complex regional pain syndrome have been reported after a cervical epidural glucocorticoid injection (SEDA-22, 451) (388).

Spinal epidural lipomatosis secondary to exogenous administration of glucocorticoids is a rare condition that has been reported almost exclusively in association with systemic treatment. However, local epidural administration has also been implicated (389).

One case of *Staphylococcus aureus* meningitis, a rare complication of epidural analgesia, has been published. The same patient developed a cauda equina syndrome of uncertain etiology, although neural ischemia as a result of meningitis secondary to immunosuppression was possible (SEDA-21, 420) (390). A unique case of transient profound paralysis after epidural glucocorticoid injection (acute paraplegia) has now been reported (SEDA-22, 451) (391). Diplopia associated with the peridural or intrathecal infiltration of prednisolone have not been previously reported (SEDA-22, 451) (392).

Of 31 patients who received 1 ml (40 mg) of methylprednisolone epidurally at the end of microdiscectomy, three developed epidural abscesses (393). These results were compared with a historical series of 400 patients not taking glucocorticoids, who had no deep infection. Although the data were limited, epidural glucocorticoids after discectomy should not be recommended.

Cervical epidural glucocorticoid injection is often used for the treatment of cervical radiculopathy. Subjective patient satisfaction has been reported, but controlled trials have not yet delineated the effectiveness of this procedure. Three cases of severe pain consistent with nerve injury have been reported immediately after cervical epidural glucocorticoid injection, bringing into question the benefit–harm balance of this technique (394).

Intra-articular and periarticular administration

Local injections of glucocorticoids into and around the joints can have a dramatic therapeutic effect, but the catabolic effect can have serious consequences, including adverse effects on joint structure (395) and on local tendons, subcutaneous atrophy, and possibly osteonecrosis. Provided the state of the joint is carefully inspected before any new injection is given, and the interval between the injections is not less than 4 weeks, the risk seems to be small enough to justify treatment in invalidating cases (SEDA-3, 307).

Neuropsychiatric effects of glucocorticoids, like hallucinations, can result from intra-articular administration (SEDA-22, 444) (396).

An acute adrenal crisis occurred in a woman who received an intra-articular glucocorticoid for pseudogout of the knee (397).

- An 87-year-old woman received intra-articular betamethasone (Diprophos) 7 mg on three occasions for painful knee joints over 6 months. Six weeks after the last injection she developed diffuse pain and contractures in the legs, fatigue, nausea, abdominal pain, and weight loss of 6 kg. Both knee joints were tender but there was no effusion. Her serum sodium concentration was 123 mmol/l, serum osmolality 254 mosmol/kg, urine sodium 136 mmol/l, and urinary osmolality

© 2006 Elsevier B.V. All rights reserved.

373 mosmol/kg. The syndrome of inappropriate antidiuretic hormone secretion was diagnosed, but despite treatment she remained drowsy and hyponatremic. About a week later, she developed hypotension and symptoms of an acute abdomen. Further investigations showed that her basal cortisol concentration was low (36 nmol/l) but it increased to 481 nmol/l after a short tetracosactide test, consistent with acute adrenal crisis. She recovered rapidly after treatment with oral hydrocortisone, but still required glucocorticoid substitution several months later.

An erythema multiforme-like eruption has been reported after intra-articular triamcinolone in the right knee, with cross-sensitivity to budesonide (398).

- A 70-year-old man had received three intra-articular injections of triamcinolone (dose not stated) into the same knee over 3 months without any allergic reactions. However, 12–24 hours after the last injection he developed pruritus and erythema at the injection site. This eruption was treated with topical budesonide, but within the next few hours, acute eczema developed. The lesions spread to his legs and abdomen, and were erythematous, edematous, and resembled erythema multiforme. He was treated with boric acid solution dressings, emollients, and oral antihistamines. His lesions gradually resolved and did not recur during 8 months of follow-up. A month after the lesions had resolved, he underwent patch testing, which was positive to triamcinolone 1% and budesonide 1% in petrolatum, but negative to other glucocorticoids.

Hiccups have been reported after intra-articular administration (399).

- A 38-year-old man had an intra-articular injection of betamethasone dipropionate (dose not stated) into his right ankle, and the day after had hiccups that lasted for 24 hours and then resolved without treatment. Some months later, because of persistent arthritis, he received a further injection of betamethasone dipropionate into his right ankle. Once again, he had hiccups the following day. On this occasion, the hiccups resolved after 2 weeks, following treatment with levomepromazine.

Anaphylaxis occurred in two women after intra-articular administration of paramethasone plus mepivacaine 2% (400).

- A 44-year-old woman developed generalized pruritus 10 minutes after intra-articular paramethasone and mepivacaine and 30 minutes later developed generalized urticaria, tachycardia, and dyspnea. She received emergency treatment and her condition initially improved. However, her symptoms recurred after 6 hours and she was treated again and then discharged taking oral dexchlorpheniramine. She had a history of allergic contact dermatitis due to nickel sulfate sensitization, and 7 years before had had generalized urticaria and dyspnea after intra-articular administration of a glucocorticoid.
- A 31-year-old woman developed generalized pruritus and urticaria, facial edema, and dyspnea 2 hours after the intra-articular administration of paramethasone and mepivacaine. She was treated with an intramuscular glucocorticoid and antihistamines, with worsening of her symptoms. She received intravenous fluids and dexchlorpheniramine, but her symptoms recurred after 1 hour, when she was given subcutaneous adrenaline, intravenous fluids and dexchlorpheniramine. She was later discharged taking oral diphenhydramine. She had a history of a systemic reaction after the administration of a glucocorticoid and a local anesthetic.

Skin prick tests were positive for isolated paramethasone in both patients, but negative for mepivacaine. There has only been one previous report of anaphylaxis in association with paramethasone.

Osteomyelitis after three glucocorticoid injections for tennis elbow has been reported; the second injection was given 3 months after the first and the third 2 days later (401). This case illustrates the need for vigilance, even after common procedures, and that exacerbation of symptoms after local glucocorticoid injections should prompt the doctor to review the diagnosis and consider the need for further investigation.

Inadvertent intra-arterial injection

Particularly when injecting glucocorticoids locally, for example to relieve arthritis of the wrist, accidental injection into an artery is possible. Severe local ischemia can result (SEDA-17, 450).

Intracapsular injection

The use of implants for augmentation of the breast can lead to capsular contracture. Patients with intractable capsular contracture are treated with intracapsular injection of triamcinolone. Major complications included three cases of major atrophy requiring surgical correction. This problem appeared to have been eliminated by reduction of the dose of triamcinolone from 50 to 25 mg. There was one implant puncture (SEDA-19, 379) (402).

Rectal administration

Systemic absorption of glucocorticoids can occur after rectal administration.

- A 48-year-old woman developed avascular necrosis 9 months after she had completed a 3-month course of hydrocortisone 100 mg retention enemas once or twice daily for ulcerative proctitis (403). An MRI scan showed multiple bony infarcts in her distal femora, proximal tibiae, and posterior proximal right fibular head, extending from the diaphysis to the epiphysis, consistent with avascular necrosis.
- Cushing's syndrome occurred in a 65-year-old woman with ulcerative colitis who received a daily betamethasone enema (404).

The authors of the second report reported the pharmacokinetics of betamethasone after rectal dosing, with plasma concentrations of betamethasone high enough to cause Cushing's syndrome. Suppression of the hypothalamic–pituitary–adrenal axis disappeared after the dosage schedule was changed from daily to three times a week. These findings suggest that a considerable amount of betamethasone is absorbed after rectal dosing.

Occupational exposure

Occupational exposure to glucocorticoids can cause adverse effects. Facial plethora has been found in workers manufacturing synthetic glucocorticoids, some of them having grossly abnormal responses to tetracosactide.

- A 58-year-old woman, who had been involved in the manufacturing of glucocorticoid creams and ointments for over 10 years, developed occupational contact sensitization to topical glucocorticoids (405). Patch tests were positive to hydrocortisone, hydrocortisone butyrate, and tixocortol pivalate. Intradermal tests were positive to hydrocortisone succinate, methylprednisolone, and prednisolone. An oral challenge with betamethasone 0.75 mg, 2.5 mg, and 8 mg on three consecutive days resulted in no adverse reactions.

It has been recommended that all workers manufacturing potent glucocorticoids should be screened regularly for glucocorticoid overdosage and should be moved regularly to units processing other drugs (406).

Drug overdose

High doses of glucocorticoids in patients with cancers can increase the risk of metastases, for example in breast cancer; this has been attributed in some cases to immunosuppression (407). These hormones should therefore only be used in patients with those types of tumors for which they are known to improve the efficacy of the cancer treatment.

A curious reaction to intravenous high-dose dexamethasone, used as an antiemetic agent in cancer chemotherapy or for other purposes, is sudden severe itching, burning, and constrictive pain in the perineal region, which has been described in several published reports (SEDA-11, 336) (408).

Drug–Drug Interactions

Albendazole

Dexamethasone reduced the clearance of albendazole and increased its half-life; plasma concentrations almost doubled (SEDA-22, 450) (409).

Amiodarone

Budesonide for collagenous colitis caused Cushing's syndrome in a patient with chronic renal insufficiency taking amiodarone for paroxysmal atrial fibrillation (410).

- An 81-year-old man with persistent diarrhea was given oral budesonide 9 mg/day, following unsuccessful treatment with mesalazine and prednisone. He was also taking amiodarone 100 mg/day. His diarrhea resolved within 6 weeks, and attempts to reduce the dosage of bzudesonide resulted in recurrent diarrhea. After 11 months he developed Cushing's syndrome, which persisted despite a reduction in dosage to 3 mg/day. His mild diarrhea recurred and the dosage of budesonide was increased to 6 mg/day with worsening of Cushing's syndrome; the dosage was reduced to 3 mg/day. Four weeks later amiodarone was withdrawn. The symptoms of Cushing's syndrome resolved within 4 weeks.

The authors suggested that the development of Cushing's syndrome and its persistence at a low dosage of budesonide was caused by inhibition of the metabolism of budesonide by amiodarone.

Anticoagulants

Intravenous methylprednisolone (1 g/day for 3 days) has been reported to inhibit the metabolism of oral anticoagulants (acenocoumarol and fluindione) in 10 patients, increasing the INR by 8 (range 5–20) (411).

Glucocorticoids can also alter the response to anticoagulants. A raised tolerance to heparin has been reported and a fall in fibrinolytic activity has been seen during glucocorticoid treatment (SED-8, 816). The entire clotting mechanism and particularly the prothrombin time should therefore be checked periodically in patients taking glucocorticoids concomitantly with anticoagulants, particularly if the glucocorticoid dose is changed. In addition there is an increased risk of gastric bleeding in patients taking both glucocorticoids and anticoagulants.

Antifungal azoles

Itraconazole 200 mg/day markedly increased plasma methylprednisolone concentrations and reduced morning plasma cortisol concentrations by over 80% in 10 healthy volunteers (412). The C_{max}, AUC, and half-life of methylprednisolone were increased 1.9, 3.9, and 2.4 times respectively.

Itraconazole 200 mg/day orally for 4 days markedly reduced the clearance and increased the half-life of intravenous methylprednisolone from 2.1 to 4.8 hours in a double-blind, randomized, two-phase, crossover study in nine healthy volunteers (SEDA-23, 430) (413). The volume of distribution was not affected. The mean morning plasma cortisol concentration during the itraconazole phase, measured 24 hours after methylprednisolone, was only 9% of that during the placebo phase (11 versus 117 ng/ml).

The authors of these two reports recommended that care be taken when methylprednisolone is prescribed in combination with itraconazole or other potent inhibitors of CYP3A4.

Itraconazole, given orally increased oral prednisolone concentrations by only 24% (414) but increased intravenous dexamethasone concentrations 3.3-fold and oral dexamethasone 3.7-fold (415).

In another study, ketoconazole was given orally as 200 mg od for 4 days, following a single oral dose of budesonide 3 mg either at the same time as ketoconazole or 12 hours before (416). Ketoconazole increased budesonide concentrations (C_{max} and AUC) 6.8- to 7.6-fold when the two drugs were co-administered; with a 12-hour separation, budesonide concentrations increased only 1.7- to 2.1-fold.

Calcium channel blockers

Methylprednisolone concentrations increased with the co-administration of diltiazem (2.6-fold) and mibefradil (3.8-fold) (417).

© 2006 Elsevier B.V. All rights reserved.

Ciclosporin

Glucocorticoids cause additive immunosuppression when they are given with other immunosuppressants, such as ciclosporin (SEDA-22, 451) (418).

Clarithromycin

Clarithromycin inhibits CYP3A4, which is responsible for the metabolic clearance of prednisolone, the biologically active metabolite of prednisone. Clarithromycin (500 mg bd for 2 days) reduced the clearance of methylprednisolone by 65% and significantly increased its plasma concentrations; clarithromycin did not influence the clearance or plasma concentrations of prednisone (419). Acute mania has been reported to be related to inhibition of the metabolic clearance of prednisone by clarithromycin (SEDA-22, 444) (420).

Cyclophosphamide

The effect of prednisone 1 mg/kg on the pharmacokinetics of cyclophosphamide and its initial metabolites 4-hydroxycyclophosphamide and aldophosphamide (the acyclic tautomer of 4-hydroxycyclophosphamide) has been studied between the first and sixth cycles in seven patients (two men) with systemic vasculitis receiving intravenous cyclophosphamide 0.6 g/m^2 as a 1-hour intravenous infusion every 3 weeks for six cycles (421). Prednisone reduced the clearance of cyclophosphamide from 5.8 to 4.0 l/hour, reducing the amount of initial metabolites formed. Although the clinical significance of this interaction is unclear, 4-hydroxycyclophosphamide and aldophosphamide are probably responsible for the cytotoxic activity of cyclophosphamide, and increased cyclophosphamide dosages should be considered in patients taking prednisone.

Diuretics

Glucocorticoids with mineralocorticoid activity potentiate potassium loss when they are given with potassium-wasting diuretics (422).

Grapefruit juice

Methylprednisolone concentrations increased with the coadministration of grapefruit juice (1.75-fold) (423).

Leukotriene receptor antagonists

In a probable pharmacodynamic interaction, severe peripheral edema followed treatment with montelukast and prednisone for asthma (424).

- A 23-year-old man, with a history of asthma, house dust mite allergy, and rhinoconjunctivitis, presented with acute respiratory symptoms. He was given oral cetirizine, inhaled salmeterol, and fluticasone propionate, and oral prednisone 40 mg/day for 1 week and 20 mg/day for 1 week. His asthma recurred when prednisone was withdrawn and he took oral prednisone 60 mg/day for 1 week and 40 mg/day for 1 week. He also took montelukast 10 mg/day. He then developed severe peripheral edema with a gain in weight of 13 kg. Prednisone was withdrawn and his edema resolved. Montelukast was continued.

The author commented that the patient had tolerated prednisone without montelukast and montelukast without prednisone. However, he had severe edema when both drugs were used together. Montelukast may have potentiated glucocorticoid-induced renal tubular sodium and fluid retention. Both have been associated with edema.

Oral contraceptives

Oral contraceptives increased budesonide concentrations by only 22%, but prednisolone concentrations increased by 131%, suggesting a clinically important interaction (425).

Phenobarbital

Phenobarbital increases the metabolism of glucocorticoids, reducing the half-life by some 50% (426).

Phenytoin

Phenytoin increases the metabolism of glucocorticoids, reducing the half-life by some 50% (426).

Rifampicin

Rifampicin and other drugs that induce liver enzymes increase the metabolism of glucocorticoids (427), sufficient to reduce their therapeutic effects, for example in asthma (428).

Salicylates

Glucocorticoids reduce the plasma concentrations of salicylates (429). If they are given with aspirin or other anti-inflammatory drugs, there may be an additive effect on the gastric wall, leading to an increased risk of bleeding and ulceration (430–432).

Corticosteroids—glucocorticoids, inhaled

See also Corticosteroids—glucocorticoids *and* Inhaler propellants

General Information

Treatment with inhaled glucocorticoids reduces the need for oral glucocorticoids in the treatment of severe asthma. The compounds used for inhalation have high local activity and low systemic availability when delivered to the lung. However, if sufficient amounts of glucocorticoids reach the bronchioles be absorbed, systemic effects will occur. Furthermore, a proportion of the dose intended for inhalation is actually swallowed and is absorbed from the gastrointestinal tract. The consequence is that if sufficiently high doses are used, enough drug will be absorbed from the respiratory and gastrointestinal surfaces to result in systemic effects.

Systemic availability of inhaled glucocorticoids can be reduced in two ways. First, by using esters that reduced local absorption; in the case of beclomethasone the dipropionate is used. Secondly, by using glucocorticoids that are extensively metabolized in the liver after absorption from the gut, such as fluticasone and budesonide. These strategies can be combined: fluticasone is given as the ester fluticasone propionate.

When a patient switches from oral or parenteral therapy to inhalation therapy, the systemic effect is reduced, just as if the dose of systemic glucocorticoid is reduced, and precautions should be taken to avoid withdrawal symptoms.

Systemic availability of inhaled glucocorticoids

The systemic availability of an inhaled glucocorticoid represents the additive and complex combination of pulmonary and gastrointestinal drug absorption. Absorption is influenced by many factors, including delivery device, the use of a spacer, the particle size of the inhaled drug, and the absorption and metabolism of the swallowed drug (1).

In healthy volunteers, high doses of both budesonide and fluticasone were readily absorbed after inhalation from a metered-dose aerosol (2). Fluticasone is extensively metabolized by the liver, so measurable concentrations of parent drug in the systemic circulation reflect efficient absorption across the lung. Lower doses of these inhaled glucocorticoids also result in some systemic absorption, reflected in effects on the hypothalamic–pituitary–adrenal axis (3).

© 2006 Elsevier B.V. All rights reserved.

The extent of absorption of inhaled glucocorticoids tends to be less in asthmatic subjects than in healthy volunteers. In a study of fluticasone (500 micrograms via a dry powder device) in asthmatic patients with a wide range of severity, there was a highly significant linear correlation between lung function (expressed as percentage predicted FEV_1) and the absolute magnitude of adrenal suppression (4). In 11 patients with moderately severe asthma (mean FEV_1 54% predicted), who took fluticasone 1000 micrograms/day via a metered-dose inhaler with a spacer, the systemic availability of fluticasone was significantly less (10%) than in 13 healthy controls (21%). The plasma fluticasone concentrations (expressed as AUC) correlated positively with gas transfer (5). In contrast, there was no difference in plasma concentrations of fluticasone and budesonide between 15 mild asthmatics (mean FEV_1 81% predicted) and healthy volunteers after inhalation of 1000 micrograms of either drug with single or repeated dosing (6). Taken together, these studies suggest that patients with severe asthma are protected from the systemic adverse effects of high doses of inhaled glucocorticoids, owing to airways obstruction and reduced lung availability. However, as their lung function improves with continued use of the inhaled glucocorticoids, it is likely that the lung availability of inhaled glucocorticoid will increase. This likely outcome is a compelling argument for reducing the dose of inhaled glucocorticoids to a lowest dose that maintains optimal control of asthma and optimal lung function.

Plasma concentrations have been measured in 13 healthy subjects and eight patients with mild asthma using inhaled fluticasone propionate 1000 micrograms bd via Diskus or pressurized metered-dose inhaler and of budesonide 1000 micrograms bd daily via Turbuhaler for 7 days. Twenty-four-hour plasma cortisol concentrations were determined to assess the systemic activity of fluticasone propionate and budesonide. At steady state, the systemic availability of budesonide via Turbuhaler (39%) was significantly higher than that of fluticasone propionate via Diskus (13%) or inhaler (21%). Fluticasone propionate had a larger distribution volume and slower rates of absorption and clearance. Despite a significantly higher pulmonary availability of budesonide via Turbuhaler, plasma cortisol suppression was less than that of fluticasone propionate via inhaler and similar to that of fluticasone propionate via Diskus. There were no differences between healthy subjects and patients with mild asthma in subgroup analyses. However, this study had some limitations as the doses of fluticasone propionate and budesonide were not equipotent, fluticasone being twice as potent as budesonide (7).

The effects of fluticasone 1500 micrograms/day and budesonide 1600 micrograms/day, both by dry powder inhalation, on three systemic markers (urinary concentrations of total cortisol metabolites, morning serum cortisol, and osteocalcin concentrations) have been investigated in 46 healthy and 31 asthmatic subjects (8). Urinary total cortisol metabolite concentrations represented the most sensitive marker of the systemic effects of inhaled glucocorticoids, and were lower in healthy subjects treated with fluticasone than in asthmatic patients, suggesting greater systemic availability of fluticasone in healthy subjects. A similar correlation was not found for budesonide. Fluticasone impaired the hypothalamic–pituitary–adrenal axis more than budesonide, while budesonide significantly lowered serum osteocalcin concentrations, which reflect osteoblastic activity. The authors suggested that different inhaled glucocorticoids have different effects on the hypothalamic–pituitary–adrenal axis and bone metabolism. This study also had its limitations given that the fluticasone and budesonide doses were not equipotent (9).

The safety and efficacy of fluticasone, beclomethasone dipropionate, and budesonide have been compared in a randomized trial in 133 patients with chronic severe asthma who required at least 1750 micrograms/day of beclomethasone/budesonide (10). The patients were randomized to their regular beclomethasone/budesonide or to fluticasone at about half the dose for 6 months. The patients who used fluticasone had a better safety profile, especially with regard to adrenocortical function and bone turnover, while maintaining asthma control. There were significant increases in morning serum cortisol concentrations, the urine cortisol:creatinine ratio, serum osteocalcin, and the serum (deoxy)-pyridinoline:creatinine ratio only with fluticasone, suggesting less suppression of the hypothalamic–pituitary–adrenal axis. The 2:1 potency ratio for clinical efficacy of fluticasone and budesonide/beclomethasone seems to be maintained even at doses of 2000 micrograms/day or higher.

Since many patients with allergic asthma also have rhinitis, they may be taking both inhaled glucocorticoids for their asthma and intranasal formulations for their hay fever. The total systemic availability of glucocorticoids has been studied after the addition of intranasal therapy in patients already taking inhaled glucocorticoids (11) in 12 moderately severe asthmatic subjects (mean FEV_1 84% predicted), who were randomized in a placebo-controlled, two-way, crossover comparison of inhaled fluticasone (880 micrograms bd) plus intranasal fluticasone (200 micrograms od), inhaled triamcinolone (800 micrograms bd) plus intranasal triamcinolone (220 micrograms od), and respective placebos. Both the inhaled glucocorticoids caused significant suppression of adrenocorticoid activity, although the addition of intranasal formulations did not produce further significant suppression. There were more individual subjects with abnormally low cortisol values when intranasal fluticasone was added. These findings suggest that the dose of intranasal glucocorticoids should be taken into account (particularly if used in the long term) when considering the systemic availability of glucocorticoids used in the treatment of asthma and hay fever.

The concept of the L:T ratio in inhalation therapy is a useful one, where L represents the local or lung availability of an inhaled drug and T the total systemic availability. This ratio will be affected by differences in first-pass metabolism. Another important variable that determines the L:T ratio is the inhalation device. The L:T ratio for budesonide is 0.66–0.85, depending on the method of inhalation (12).

Another way of describing the L:T ratio concept is that of "pulmonary targeting." Drug properties that improve pulmonary targeting include slow absorption from the lungs, low oral systemic availability, and rapid systemic clearance.

© 2006 Elsevier B.V. All rights reserved.

Differences in delivery devices can also produce differences in pulmonary targeting by altering the dose of drug deposited in the lungs. Allowing for both drug and inhaler differences, the relative potencies of the commonly used drugs are as follows: fluticasone propionate > budesonide = beclomethasone dipropionate > triamcinolone acetonide = flunisolide. Potency differences can be overcome by giving a larger dose of the less potent drug. However, comparisons between glucocorticoids must measure the systemic effects as well as the lung effect of each dose (13).

Inhalation devices

The importance of the inhalation device has been shown in studies of beclomethasone. Pressurized metered-dose inhalers containing chlorofluorocarbons produce relatively large particles that deposit less than 10% of the delivered dose in the lungs, primarily in the large airways, more than 90% being deposited in the oropharynx. A hydrofluoroalkane beclomethasone multidose aerosol (Qvar 3M Pharmaceuticals) delivers a smaller particle size. More than 50% is deposited in the lungs in animal and mechanical models. This has been confirmed using radiolabelled Qvar in patients with asthma and in healthy volunteers. In these subjects, 50–60% of the dose is deposited throughout the airways and about 30% in the oropharynx. The breath-activated Autohaler provides lung deposition equivalent to an optimally used Qvar inhaler, by automatically delivering drug early in the inhalation. Neither of these devices is improved by the addition of a spacer (14).

Both inhaled and swallowed fractions cause significant systemic activity, the degree of which depends on the inhaler device used. In one study, systemic activity was greater using a dry power inhaler (52%) than a pressurized metered-dose inhaler with a large volume spacer (28%) (15). It was recommended that when high-dose beclomethasone is used, a pressurized metered-dose inhaler with a large volume spacer would help in limiting potential adverse effects.

The systemic availability of inhaled budesonide has been measured in 15 healthy volunteers, using an open crossover design. Each subject was given three treatments, intravenous budesonide 0.5 mg, inhaled budesonide (from a metered-dose inhaler with a Nebuhaler) 1 mg (200 micrograms × 5) plus oral charcoal, and inhaled budesonide 1 mg without oral charcoal. The treatment order was randomized. The mean systemic availability of inhaled budesonide compared with intravenous budesonide was 36% with charcoal and 35% without charcoal, indicating that the absorption of budesonide from the gastrointestinal tract did not contribute to its systemic availability. Pulmonary deposition was 36% with charcoal and 34% without. When the inhaler was used incorrectly, that is, the canister was shaken only before the first of the five inhalations, systemic availability fell by 50%. This shows that the performance of each inhaler is very dependent on proper use (16).

The available studies suggest that fluticasone is more effective than beclomethasone, triamcinolone, or budesonide. However, budesonide delivered by Turbuhaler has equivalent efficacy to fluticasone delivered by metered-dose inhaler or Diskhaler, and is more effective than beclomethasone. When comparative safety is considered, budesonide and triamcinolone delivered by metered-dose inhaler have less systemic activity than fluticasone. Beclomethasone and fluticasone delivered by metered-dose inhaler are equivalent. Budesonide delivered by Turbuhaler has less systemic activity than fluticasone delivered by Diskhaler (17).

The equivalence of inhaled glucocorticoids based on equipotent (cortisol suppression) effects has been studied by the Asthma Clinical Research Network (ACRN). Six different inhaled glucocorticoids and matched placebos (beclomethasone chlorofluorocarbon, budesonide dry powder inhaler, fluticasone dry powder inhaler, fluticasone chlorofluorocarbon metered-dose inhaler, flunisolide chlorofluorocarbon, and triamcinolone chlorofluorocarbon) were compared by measuring their systemic effects (18). Glucocorticoid-naïve patients with asthma ($n = 156$) were enrolled at six centers and a one-week doubling dose design was used for each of the six inhaled glucocorticoids and matched placebos to a total of four doses. The best outcome variable for the reliable assessment of a systemic effect was the 12-hour AUC of the hourly overnight plasma cortisol measurements from 8 p.m. to 8 a.m. Microgram comparisons of the glucocorticoids could only be performed at 10% cortisol suppression, because fluticasone did not cause higher suppression. The following equipotent doses (that is, doses producing equal systemic cortisol suppression) were found: flunisolide 936 micrograms; triamcinolone 787 micrograms; beclomethasone 548 micrograms; fluticasone dry powder: 445 micrograms; budesonide 268 micrograms; and fluticasone metered-dose inhaler 111 micrograms. The ranking of systemic effects was very similar to that found earlier in a large meta-analysis (19).

Dry powder inhaler and pressurized metered-dose inhaler for administration of low-dose budesonide (400 micrograms/day) have been compared (20). Only the dry powder caused suppression of the hypothalamic–pituitary–adrenal axis. As effective inhaled glucocorticoid therapy is expected to cause detectable reductions in the physiological secretion of cortisol (1), low-dose budesonide by pressurized metered-dose inhaler is probably not effective. In another study, budesonide inhalation suspension, developed for nebulization to meet the specific needs of infants and young children, did not cause significant suppression of hypothalamic–pituitary–adrenal axis function (basal plasma cortisol concentrations and corticotropin test) in doses from 0.25 to 1.0 mg (21). However, inhaled fluticasone propionate by pressurized metered-dose inhaler with a spacer in 62 children resulted in abnormal morning cortisol concentrations in 36% (17 using a low dose of 176 micrograms/day; 43 using a high dose, over 880 micrograms/day) (22).

In a randomized, double-blind study, adult asthmatic patients took budesonide 800 micrograms/day over 12 weeks either by Easyhaler ($n = 103$) or by Turbuhaler ($n = 58$) dry powder inhaler. The Easyhaler was equivalent to the Turbuhaler with regard to safety and efficacy, but was more acceptable to the patients (23).

Therapeutic studies

Budesonide

Inhaled budesonide has been studied in the management of moderately severe, acute asthma in children (24). After treatment with nebulized terbutaline, 11 children were randomly allocated to receive one dose of either budesonide 1600 micrograms by Turbuhaler or prednisolone 2 mg/kg. There was no significant difference in the improvement of the pulmonary index score or peak expiratory flow rate. Children treated with budesonide had an earlier clinical response than those given prednisolone. Prednisolone caused a fall in serum cortisol concentration. The authors concluded that children with moderately severe asthma attacks could be effectively treated with a short-term course of inhaled budesonide, starting with a high dose and reducing over the following week.

In 81 patients with acute asthma, mean age 38 years, inhaled budesonide 1600 micrograms bd via Turbuhaler was compared with oral prednisolone (40 mg on day 1, reducing to 5 mg by day 7) in a randomized, double-blind, parallel-group design (25). The mean increase in FEV_1 from baseline to day 7 was 17% with budesonide and 18% with prednisolone. Mean values of morning peak expiratory flow rate increased from day 1 to day 7 by 67 l/second with budesonide and by 57 l/second with prednisolone. There were no statistically significant differences between the groups in either symptoms or the number of doses of rescue medication. The authors concluded that high-dose inhaled budesonide may be a substitute for oral therapy in the treatment of an acute attack of asthma.

The effect of supplementary inhaled budesonide in acute asthma has been evaluated in a randomized, double-blind comparison with standard treatment in 44 children aged 6 months to 18 years with a moderate to severe exacerbation of asthma (26). Prednisone 1 mg/kg orally and nebulized salbutamol (0.15 mg/kg) every 30 minutes for three doses and then every hour for 4 hours were given to all children. In addition, each child was given 2 mg of nebulized budesonide or nebulized isotonic saline. There was a more rapid discharge rate in the budesonide group. There were no adverse effects. The authors concluded that nebulized budesonide may be an effective adjunct to oral prednisone in the management of moderate to severe exacerbations of asthma.

Fluticasone

Inhaled fluticasone 500 micrograms bd from a pressurized metered-dose inhaler for 6 months has been compared with placebo in a randomized, double-blind trial in 280 patients with COPD, aged 50–75 years (27). There was no significant difference in the number of patients who suffered one or more exacerbations. Moderate or severe exacerbations occurred significantly more often with placebo than with fluticasone. Diary-card scores, morning peak expiratory flow rate, clinic FEV_1, FVC, and mid-expiratory flow all improved significantly with fluticasone. Scores for median daily cough and sputum volume were significantly lower with fluticasone than with placebo. At the end of treatment, patients using fluticasone had increased their 6-minute walking distance significantly more than those using placebo. Fluticasone propionate was tolerated, as well as placebo, with few adverse effects and no clinically important effect on mean serum cortisol concentration. The authors suggested that inhaled glucocorticoids may have an important place in the long-term management of patients with COPD.

Local adverse effects

The local adverse effects of inhaled glucocorticoids have been studied in a prospective, cross-sectional, cohort study in 639 asthmatic children using beclomethasone (721 micrograms/day) or budesonide (835 micrograms/day) for at least one month (28). The local adverse effects included cough (40%), thirst (22%), hoarseness (14%), dysphonia (11%), oral candidiasis (11%), perioral dermatitis (2.9%), and tongue hypertrophy (0.1%). A spacer doubled the incidence of coughing.

Potent glucocorticoids in high local doses increase the risk of local infection and even promote atrophy of the bronchial mucosa. The latter effect has not proved clinically important, but there is an increased incidence of oropharyngeal candidiasis. The incidence varies depending on the population studied and the criteria used to make the diagnosis; candidiasis can affect 13–71% of patients, the highest incidence being seen with doses up to 0.8 mg. Candidiasis rarely requires treatment or withdrawal of the drug. Local measures, such as gargling immediately after inhalation of the aerosol, and the use of a large-volume spacer are effective in reducing the incidence of this complication. However, candidiasis can result in dysphonia.

A local myopathy caused by inhaled glucocorticoids can also cause dysphonia. However, patients with asthma have more dysphonia and vocal fold pathology than healthy controls and inhaled glucocorticoids can improve the voice in some patients (SEDA-21, 188).

In some patients, the propellant used in certain aerosols can cause acute bronchoconstriction (SEDA-6, 332).

Organs and Systems

Sensory systems

Cataract

In a population-based cross-sectional study of vision and common eye diseases in 3654 people, 49–97 years of age, inhaled glucocorticoid use was reported by 370 subjects, of whom 164 reported current use and 206 previous use. Subjects who reported using inhaled glucocorticoids had a higher prevalence of nuclear cataracts (OR = 1.5; CI = 1.2, 1.9) and posterior subcapsular cataracts (OR = 1.9; CI = 1.3, 2.8). The highest prevalence (27%) was in patients whose lifetime dose was more than 2000 mg (relative prevalence 5.5) (SEDA-22, 187).

In 3677 patients undergoing cataract extraction over 2 years compared with a matched control group of 21 868 people, the patients were more likely to undergo cataract extraction if they had used inhaled glucocorticoids for more than 3 years (OR = 3.06; CI = 1.53, 6.13). This risk was not significant in patients who used low to medium doses (1000 micrograms/day or less) when the OR was 1.63 (CI = 0.85, 3.13) after 2 years. The OR was

© 2006 Elsevier B.V. All rights reserved.

higher in patients using average daily doses of beclomethasone dipropionate or budesonide (over 1000 micrograms) (OR = 3.40; CI = 1.49, 7.76) after more than 2 years of treatment (29).

In a nested case-control analysis based on a retrospective, observational, cohort study, 103 289 asthmatic patients using inhaled glucocorticoids were identified from the UK General Practice Database and were compared with 98 527 asthmatic patients with no history of glucocorticoid use (30). There was a slightly increased risk of cataract in those who used inhaled glucocorticoids (RR = 1.3; 95% CI = 1.1, 1.5). The relative risk of cataract was 2.0 in oral glucocorticoid users relative to glucocorticoid non-users (95% CI = 1.5, 2.2). The risk ratio increased with extensive use of inhaled glucocorticoids, but not with moderate use. The association of extensive use with cataract was most pronounced in those aged 70 years and over, and there was no effect in those aged under 40. The increased risk of cataract in patients aged 70 years and over persisted after controlling for cataract risk factors, such as smoking, diabetes mellitus, hypertension, and sex.

In another study, treatment for 2 years with fluticasone propionate (500 micrograms bd) had no significant effect on ophthalmic parameters (glaucoma and posterior subcapsular cataracts) (31). Slit lamp examinations were carried out in 157 asthmatic children treated with inhaled budesonide at a mean daily dose of 504 (range 189–1322) micrograms for 3–6 years (mean 4.4 years). Posterior subcapsular cataract due to budesonide was not detected (32).

Glaucoma

A case-control study compared 9793 patients with open-angle glaucoma or ocular hypertension to 38 325 randomly selected controls (33). There was no association between the use of inhaled or intranasal glucocorticoids and the risk of open-angle glaucoma or ocular hypertension. In patients who were currently using high doses, there was a small but significant increase in risk (OR = 1.44; CI = 1.01, 2.06).

Endocrine

Hypothalamic–pituitary–adrenal axis function provides one of the most sensitive markers of the systemic activity of inhaled glucocorticoids (34), and suppression can be used as a surrogate marker for adverse effects of inhaled glucocorticoids in other tissues.

The different methods of assessing hypothalamic–pituitary–adrenal axis activity in patients using inhaled glucocorticoids have been compared (35). The AUC of serum cortisol concentrations was the most reliable method. There were significant positive correlations between AUC and the 8 a.m. serum and salivary cortisol concentrations. The authors favored the non-invasive method of salivary concentration measurement. However, 24-hour urine collection is not recommended, as it correlated only moderately well. This finding is consistent with the results of other studies. Urinary free-cortisol estimation based on immunoassay after inhaled glucocorticoids may be an unreliable surrogate marker of adrenal suppression, and studies using this method should be interpreted with caution (36).

In a randomized, placebo-controlled study, the activity of the hypothalamic–pituitary–adrenal axis was assessed at baseline and after 21 days by determining 22-hour time-integrated serum cortisol concentrations, 24-hour urinary cortisol (corrected for creatinine), and morning salivary cortisol concentrations in 153 patients with mild to moderate asthma, randomly assigned to either inhaled flunisolide (500 or 1000 micrograms bd), inhaled fluticasone (110, 220, 330, or 440 micrograms bd), oral prednisone (7.5 mg/day), or placebo (19). Flunisolide and fluticasone caused dose-dependent suppression of the hypothalamic–pituitary–adrenal axis, and fluticasone was significantly more potent. However, the lowest fluticasone dose (110 micrograms/day) had no effect. These findings are consistent with those of a previous meta-analysis, which showed that fluticasone caused a greater dose-related suppression of the hypothalamic–pituitary–adrenal axis than other inhaled glucocorticoids (37). Fluticasone is more lipophilic than flunisolide and therefore has a larger volume of distribution and a longer half-life (34), but it is not clear how this might be associated with the larger effect described here.

The effect of fluticasone aqueous nasal spray on the hypothalamic–pituitary–adrenal axis has been compared with that of oral prednisone and placebo, using a 6-hour tetracosactide infusion test in a 4-week, randomized, double-blind, placebo-controlled study in 105 adults with allergic rhinitis randomly assigned to receive fluticasone 200 micrograms od, fluticasone 400 micrograms bd, oral prednisone 7.5 mg od, oral prednisone 15 mg od, or placebo (38). Fluticasone 400 micrograms bd and both doses of prednisone caused a significant reduction in the morning plasma cortisol concentration. The two fluticasone treatments produced no significant change in the hypothalamic–pituitary–adrenal axis response to co-syntropin. This contrasted with oral prednisone 7.5 or 15 mg od, which significantly reduced both plasma cortisol concentrations after co-syntropin and 24-hour urinary cortisol excretion.

A review of the literature from 1 January 1966 to 31 July 1998 identified 27 studies in which the effects of inhaled glucocorticoids on adrenal function were measured. A meta-regression of adrenal suppression in these 27 studies showed that adrenal suppression occurred with high doses of inhaled glucocorticoids (above 1500 micrograms/day; 750 micrograms/day for fluticasone propionate). However, there is a considerable degree of interindividual susceptibility. Meta-analysis showed significantly greater potency for dose-related adrenal suppression with fluticasone propionate compared with beclomethasone dipropionate, budesonide, or triamcinolone acetonide. Prednisolone and fluticasone propionate were approximately equivalent in a dose ratio of 10:1 (19).

Adrenal suppression by inhaled glucocorticoids in children

Inhaled glucocorticoids are being prescribed more and more in younger children at an earlier stage of their disease and for longer periods; children with severe asthma are also treated with larger doses than licensed.

© 2006 Elsevier B.V. All rights reserved.

Therefore, considerations of their systemic effects are of importance. Symptomatic adrenal insufficiency has been reported in children after various regimens of inhaled glucocorticoids.

- Four boys 4–8 years old with symptomatic adrenal insufficiency had all used consistent high doses of fluticasone propionate 1000–1500 micrograms/day over extended periods (16 months to 5 years) (39). They presented with acute hypoglycemia secondary to iatrogenic adrenal suppression, with abnormal corticotropin tests, although none had Cushingoid features.
- A 33-year-old man and three children (two girls, one boy, 7–9 years) presented with symptomatic adrenal insufficiency (40). All three children had seizures because of hypoglycemia, and the man had a low blood pressure, nausea, and fatigue. In all cases, corticotropin tests were abnormal, showing adrenal insufficiency. The children had used fluticasone propionate 500–2000 micrograms/day and the man had recently switched from fluticasone propionate 1000–2000 micrograms/day to budesonide dry powder inhaler 800 micrograms/day. Only one of the children had used oral glucocorticoids in the previous year.
- A 21-month-old boy had a hypoglycemia-induced seizure in the setting of adrenal suppression (41). He had been given increasing doses of budesonide up to 2000 micrograms qds and oral glucocorticoids until the age of 15 months.
- A 32-month-old girl developed hypoglycemic seizures (42). She had been given fluticasone propionate 440–880 micrograms/day and up to 5 months before the incident oral glucocorticoids.
- Two girls aged 11 and 16 years, one boy aged 12 years, and one woman aged 54 years developed hypothalamic–pituitary–adrenal axis suppression during treatment with inhaled fluticasone propionate 220–880 micrograms bd for long-term control of asthma; however, two of the patients also took oral prednisone or prednisolone (43). Because of poor growth, an 8-year-old girl's asthma medication was changed from budesonide to fluticasone propionate 250 micrograms/day (44). However, 5 months later she had developed a round face. Her early morning cortisol concentration was less than 30 nmol/l (reference range 140–720) and her growth had been no more than 0.5 cm during the past 5 months. Fluticasone propionate was discontinued. After 1 month, her Cushingoid features had resolved and her fasting morning cortisol concentration was 310 nmol/l.
- A 32-year-old woman's asthma regimen was changed from budesonide to fluticasone propionate 500 micrograms/day and salmeterol (44). Eight months later, she was evaluated because of excessive bodyweight gain; her serum cortisol concentration was 16 nmol/l. Fluticasone propionate was replaced with nedocromil and 1 month later her serum cortisol concentration had normalized.

In addition to these case reports, there has been a survey of symptomatic adrenal suppression associated with inhaled glucocorticoids in the UK (45). Only 24% of the questionnaires were returned (709 responses), and there were 28 cases of symptomatic adrenal suppression reported in children and five in adults (including the 10 cases discussed above). The children presented mostly with hypoglycemia and coma, whereas the adults mainly had lethargy and nausea. No obvious precipitating cause was found in 65% of the cases. In four children, diagnosis was delayed by 3 months to 2 years. All but three patients had been treated with fluticasone propionate alone, but at high daily doses (children 500–2000 micrograms, adults 1000–2000 micrograms). One child had used both fluticasone propionate and budesonide, and one adult and one child used beclomethasone dipropionate.

A series of cases has illustrated the unexpected occurrence of symptomatic adrenal insufficiency in eight asthmatic children using inhaled glucocorticoids (46). The authors concluded that therapeutic doses of inhaled glucocorticoids can provoke paradoxical symptoms of adrenal insufficiency. Very high doses (calculated according to body surface area) may partly explain marked suppression of the hypothalamic–pituitary–adrenal axis. The need to taper inhaled glucocorticoid doses and to recognize the possibility of life-threatening acute adrenal insufficiency is of utmost importance.

In a double-blind, randomized pilot study of the efficacy and adverse effects of inhaled fluticasone in 25 newborn preterm infants who required mechanical ventilation for treatment of respiratory distress syndrome, the infants were randomized to receive inhaled fluticasone 1000 micrograms/day or placebo (47). The hypothalamic–pituitary–adrenal axis was assessed by the response to corticotropin-releasing factor. All basal and post-stimulation plasma corticotropin and serum cortisol concentrations were significantly less with inhaled fluticasone than placebo. Cumulative high-dose inhaled glucocorticoids caused moderately severe suppression of both the pituitary and the adrenal glands. This systemic activity is probably associated with pulmonary vascular absorption that avoids hepatic first-pass metabolism.

Chronic inhalation of beclomethasone dipropionate (up to 1000 micrograms/day) can produce adrenal suppression in some children. This effect is reduced by the attachment of a large volume spacer to the aerosol (SEDA-21, 188). Budesonide inhaled from the Turbuhaler, at doses of 800 or 1600 micrograms/day), did not produce any statistically significant suppression of the hypothalamic–pituitary–adrenal axis compared with placebo. The reduction was significant only after 3200 micrograms/day of budesonide when suppression equivalent to 10 mg/day oral prednisone was seen (48). Fluticasone propionate powder, 500 micrograms bd, given using a Diskhaler, for 104 weeks caused only minimal changes in the hypothalamic–pituitary–adrenal axis (31). Inhaled fluticasone propionate 400 micrograms/day for 8 weeks did not cause adrenal suppression in asthmatic children. In children, the benefit/risk ratio generally decreases at doses above 400 micrograms/day of fluticasone propionate (49). Hypothalamic–pituitary–adrenal axis suppression has been reported with inhaled fluticasone propionate at doses in excess of 1000 micrograms/day (SEDA-21, 188).

Different inhaled glucocorticoids have been compared for their suppressing effects on the hypothalamic–pituitary–adrenal axis (18). In a large meta-analysis, budesonide or beclomethasone dipropionate in doses of over 1500 micrograms/day was associated with adrenal

© 2006 Elsevier B.V. All rights reserved.

suppression in adults (19). In children, fluticasone propionate 200 micrograms/day or budesonide 400 micrograms/day caused detectable adrenal gland suppression (50). For interpretation of the different studies, it is very important to distinguish between detectable indicators for systemic drug action (that is, reduced morning cortisol) and true suppression of the hypothalamic–pituitary–adrenal axis, as determined by adrenal function tests (standard-dose or low-dose corticotropin test), which are more predictive of possible systemic adverse effects (1).

The fact that fluticasone propionate is involved in the vast majority of the published cases should be discussed further. The systemic concentration of an inhaled glucocorticoid depends on the absorbed fraction of the drug in the gut and in the lung. Swallowed fluticasone propionate is almost completely metabolized in the liver by CYP3A4 (first-pass effect over 99.9%) before reaching the systemic circulation; however, its metabolic clearance can be altered in patients with low CYP3A4 expression and activity (51). Pulmonary absorbed fluticasone propionate is very potent; because of its pronounced lipophilicity, it binds with higher affinity to glucocorticoid receptors and has a larger distribution volume and a longer half-life than other inhaled glucocorticoids (52). These characteristics give it the potential of accumulating with multiple doses.

Other factors that determine the absorbed fraction of inhaled glucocorticoids include the age of the child, as lung deposition of inhaled drugs increases with age (53). Therefore, the minimum effective dose may fall as the child becomes older. Moreover, it is reasonable to hypothesize that systemic absorption will increase once asthma control is established (54). Furthermore, patient adherence and inhaler technique are two factors that can have a large influence on the amount of glucocorticoid inhaled and absorbed.

However, the most important factor is the dose. The safety and efficacy of fluticasone propionate in children in daily doses of 100–200 micrograms have been demonstrated in many studies (55). The doses in the case reports of symptomatic adrenal suppression have to be considered as being excessively high. These reports reflect excessive dosing of inhaled glucocorticoids, and in some cases a residual effect of previous oral glucocorticoid treatment cannot be excluded. The use of excessive doses is empirical and not supported by the literature. All inhaled glucocorticoids have a flat dose–response curve (56). Extensive clinical experience with inhaled glucocorticoids over the past 20 years has suggested that the risk of adrenal insufficiency with inhaled glucocorticoids alone is very low when recommended doses are used (57). To avoid symptomatic adrenal suppression, the lowest effective dose should always be used. Before automatically increasing the dose in refractory patients, the diagnosis should be reconsidered. Furthermore, a reduction in the dosage of inhaled glucocorticoid can also be achieved with the addition of adjuvant therapies, such as leukotriene receptor antagonists and long-acting β_2-adrenoceptor agonists (58).

Monitoring children using inhaled glucocorticoids has been discussed (1). Children using low to moderate doses of inhaled glucocorticoids (up to 200 micrograms of fluticasone propionate or budesonide) do not require routine hypothalamic–pituitary–adrenal axis measurement. In children using consistently higher doses (up to 400 micrograms of fluticasone propionate or budesonide) or using glucocorticoids by other routes, morning plasma cortisol should be monitored periodically because of the increased risk of clinically significant adrenal suppression. If cortisol concentrations are below 276 μmol/l (100 ng/ml), functional testing of the hypothalamic–pituitary–adrenal axis should be considered.

Metabolism

Impaired diabetic control has been reported with high doses of inhaled glucocorticoids.

- A 67-year-old man with asthma and non-insulin-dependent diabetes mellitus, taking glibenclamide 5 mg/day and metformin 1700 mg/day, had glycated hemoglobin concentrations of 7.0–7.3% (59). For asthma, he used nebulized ipratropium bromide 0.5 mg and salbutamol 5 mg qds. He was given inhaled fluticasone propionate 2000 micrograms/day by metered-dose inhaler through a Volumatic spacer device, with beneficial effect. In the third week he developed persistent glycosuria and the dose of fluticasone was reduced stepwise to 500 micrograms/day. He was then rechallenged by increasing his daily dose of fluticasone from 500 to 1000 micrograms. Within a week he had glycosuria, which again resolved on reduction of the dose of fluticasone. His glycated hemoglobin concentration rose to 7.8% after 1000 micrograms/day and to 8.2% after 2000 micrograms/day.
- Deterioration in glucose control occurred in a 64-year-old man with non-insulin-dependent diabetes mellitus (60). High doses of both fluticasone (2000 micrograms/day) and budesonide (2000 micrograms/day) had produced glycosuria despite treatment with glibenclamide and metformin 1700 mg/day. On reducing the dose of budesonide, there was a commensurate fall in glycosylated hemoglobin and glycosuria. There was no glycosuria at a daily maintenance dose of 800 micrograms and the glycosylated hemoglobin fell from 8.2 to 7.2%.

The association between inhaled glucocorticoids and the risk of diabetes mellitus in elderly people (over 65 years) has been investigated in two Canadian studies. In a nested case-control study of the association between current use of inhaled glucocorticoids and the risk of using antidiabetic drugs among 21 645 subjects the risk of diabetes was not statistically significant (61). Moreover, there was no statistically significant increase in risk among users of high-dose beclomethasone compared with non-users. In a retrospective population-based cohort study using administrative databases, the association between oral and inhaled glucocorticoid use and the onset of diabetes mellitus in the elderly was quantified (62). Users of proton pump inhibitors ($n = 53\ 845$) were the controls. Relative to controls, oral glucocorticoid users ($n = 31\ 864$) were more likely to develop diabetes mellitus, but there was no association between the use of inhaled glucocorticoids ($n = 38\ 441$) and diabetes mellitus. These results suggest that the use of inhaled glucocorticoids in elderly people does not significantly increase the risk of diabetes mellitus.

Skin

Reduced skin thickness

Skin thickness (measured with ultrasound) was not significantly different from controls in patients taking low-dose beclomethasone dipropionate (200–800 micrograms/day). There was a reduction in skin thickness of 15–19% in patients using high dose beclomethasone dipropionate (1000–2500 micrograms/day), and 28–33% in patients using long-term oral prednisolone (5–20 mg/day). Bruising occurred in 12% of controls, 33% of patients using low-dose beclomethasone dipropionate, 48% of patients using high-dose beclomethasone dipropionate, and 80% of patients using oral prednisolone (63). Other workers have concluded that patients using beclomethasone dipropionate who report bruising are older (61 versus 52 years), take higher daily doses (1388 versus 1067 micrograms), and have been on treatment longer (55 versus 43 months) (64). The number of bruises seems to be inversely related to the concentration of urinary cortisol (SEDA-21, 188). In children using budesonide (189–1322 micrograms/day) for 3–6 years, there was no increase in bruising (32).

The effect of long-term inhaled glucocorticoids (800–1000 micrograms/day of either budesonide or beclomethasone) on skin collagen synthesis and thickness has been prospectively investigated in 27 consecutive new asthmatic patients (65). Asthma was treated with a moderate dosage of inhaled glucocorticoids. Skin thickness was measured before treatment and at 3 and 6 months using ultrasound on the abdomen and the upper right arm. Suction blisters were induced on the abdominal skin using a disposable suction blister device. Blister fluid was collected and kept frozen for radioimmunoassay of PINP and PIIINP. Skin punch biopsies were taken from the abdominal wall for the determination of skin hydroxyproline. After 1–2 years, 20 subjects attended for a further measurement of skin thickness. Control data were obtained in 14 healthy women who were followed for 6 months. PINP and PIIINP concentrations in blister fluid were followed in eight male volunteers for 1 year. There was no significant change in abdominal skin thickness after 6 months of inhaled glucocorticoids. In the upper arm there was a small, significant reduction from 1.64 to 1.50 mm after 6 months. After 1–2 years the skin thickness in the abdomen and upper arm was unchanged in 14 subjects who had used only inhaled glucocorticoids, but in six patients who had taken supplementary oral glucocorticoids for one to several weeks there was thinning of the skin in the upper arm but not the abdomen. The procollagen propeptides were markedly reduced in blister fluid at 3 and 6 months. There was no significant change in skin collagen expressed as hydroxyproline. Thus, despite evidence of a reduction in collagen synthesis, skin thickness and collagen did not change, possibly because the degradation and turnover of collagen slowed down. However, in the six patients who subsequently used oral glucocorticoids, skin thickness decreased.

Bruising

Since the original observation of the association between high-dose glucocorticoids and purpura and dermal thinning, easy bruising of the skin has become recognized as a systemic adverse effect of inhaled glucocorticoids (63). In a double-blind crossover study 69 asthmatic subjects received either the usual dose of beclomethasone dipropionate or fluticasone (at half the dose of beclomethasone) both for 4 months (66). The frequency and severity of skin bruising were assessed by questionnaire, and the numbers of bruises were assessed by direct examination. The dose of fluticasone was selected on the basis of previous studies that showed that it had comparable efficacy when given in half the dose of beclomethasone. This dose of fluticasone had comparable efficacy with respect to the control of asthma, but there was no skin bruising. These findings suggest that the systemic availability of equieffective doses of fluticasone is less than that of beclomethasone.

Contact allergy

Nasal glucocorticoids and inhaled glucocorticoids can have adverse effects on the nose and mouth, including pruritus, burning, dryness, erythema, edema, dry cough, and odynophagia; less commonly, they can cause eczema and urticaria, particularly on the face. Contact dermatitis to glucocorticoids can be facilitated by impaired epithelial barriers, and has been found in 4.7% of patients receiving topical hydrocortisone (67). Inhaled glucocorticoids can cause hypersensitivity reactions, especially in patients with chronic eczema who have been sensitized to local glucocorticoids.

Tixocortol pivalate is a marker for glucocorticoid contact allergy, as a positive patch test suggests established contact allergy to hydrocortisone, prednisolone, and their derivatives (68). A literature search via Medline from 1966 to May 2000 revealed only one patient hypersensitive to tixocortol pivalate and budesonide in a pilot study in 34 patients (10 with asthma, 13 with rhinitis, 11 with both) (69). From case reports, the prevalence of glucocorticoid-induced contact allergy has been estimated at 2.9–5%.

Based on these observations it has been concluded that patients who use inhaled glucocorticoids and develop unprecedented skin reactions during therapy should be tested for glucocorticoid-related contact allergy (70). Switching from one of the four main glucocorticoid groups to another might prove successful in these cases.

Two cases of perioral dermatitis have been associated with the use of inhaled glucocorticoids (71).

- A 38-year-old woman who had used inhaled beclomethasone daily (dosage not stated) during the winter for the past 5 years for mild asthma, developed a perioral rash with numerous small pustules and papules. She stopped using beclomethasone and was treated with oral erythromycin and topical tretinoin. Her rash resolved within 4 weeks. One year later, she restarted beclomethasone and her rash reappeared after 2 weeks. There was no recurrence of her perioral dermatitis during subsequent treatment with monthly intramuscular injections of betamethasone.
- A 46-year-old woman, who had used inhaled budesonide (dosage not stated) for 8 years for vasomotor rhinitis, developed a recurrent perioral rash, which responded to treatment with oral erythromycin 1 g/day for 6 weeks. One year later, she had a recurrence, which resolved with oral erythromycin. She continued to use inhaled budesonide.

As cross-reactivity within glucocorticoid groups may be clinically relevant, skin patch testing has been proposed in cases of suspected glucocorticoid allergy, to identify the substances that can be safely administered (72). The prevalence of glucocorticoid allergy has been studied by skin patch testing in 30 patients using inhaled or intranasal glucocorticoids (73). Four patients had a positive patch test (three allergic reactions and one irritant reaction). Eight different glucocorticoids were used, but allergic reactions occurred only with budesonide. The authors therefore suggested that budesonide is more likely to cause contact hypersensitivity, but also referred to the possible relevance of allergic or irritant reactions to preservatives.

Contact allergy to glucocorticoids is not rare in patients with atopic dermatitis. In patients with known contact allergy to budesonide, allergic skin reactions can also occur when inhaled forms of the drug are used, as shown by a randomized, double-blind, placebo-controlled study in 15 non-asthmatic patients with budesonide hypersensitivity on patch testing (74). In four of seven patients who used inhaled budesonide, there was reactivation of the 6-week-old patch test sites and they had new distant skin lesions. No flare-up reactions were observed in the other 11 patients (three had used inhaled budesonide and eight placebo for 1 week). None of the patients developed respiratory symptoms; spirometry and peak expiratory flow rates remained normal.

Musculoskeletal

Bone

Studies of the effects of inhaled glucocorticoids have used biochemical markers of bone function and imaging techniques to assess bone mineral density. Some of the biochemical markers are summarized in Table 1. Initial, short-term studies caused concern about the effect of inhaled glucocorticoids on bone metabolism. Beclomethasone dipropionate 2000 micrograms/day reduced serum osteocalcin concentrations at 1 and 2 weeks, and they returned to normal at 1 and 2 weeks after withdrawal. Nebulized budesonide (2000 micrograms bd) produced a similar increase in FEV_1 to oral prednisolone 30 mg/day given over 5 days. Serum osteocalcin was significantly higher: 2.3 (0.9–3.7) ng/ml with budesonide compared with 0.6 (0–1.2) ng/ml with prednisolone. The 24-hour urinary calcium to creatinine ratio was significantly lower in patients treated with nebulized budesonide (SEDA-22, 183). After 4 weeks on beclomethasone dipropionate or budesonide 800 micrograms/day, there were significant but paradoxical changes in osteocalcin and PICP (both markers of bone formation). Osteocalcin concentrations fell, but PICP concentrations rose. Patients on beclomethasone dipropionate 800 micrograms/day followed for 30 months showed no change in markers of resorption (ICTP) or formation (PICP) (SEDA-22, 183).

While biochemical markers of bone metabolism may be sensitive to the effects of glucocorticoids in the short term, the relation between changes in these markers and intermediate measures, such as bone mineral density, and the more important clinical outcomes of fractures, is unknown. In a random stratified sample of 3222 women in the perimenopausal age range (47–56 years), including 119 women with asthma, bone mineral density was measured to determine whether asthma was a risk factor of osteoporosis and to investigate the effect of inhaled glucocorticoids (75). The subjects had predominantly adult-onset asthma, as the age at diagnosis was over 40 years. There were 26 patients who were treated mainly with inhaled glucocorticoids (average daily dose 1000 micrograms). The asthmatic women in this general perimenopausal population had slightly reduced spinal and femoral neck bone mineral density compared with non-asthmatic women. These differences were more prominent in women who were not taking hormone replacement therapy. The reduction in bone mineral density may be due to glucocorticoids, and hormone replacement therapy appears to be protective against bone loss in asthmatics as well as healthy subjects. Cross-sectional studies such as this provide information about association but do not imply causality, for which longitudinal studies are required. Studies of the effects of inhaled glucocorticoids on markers of bone mineral density have provided conflicting data (76).

Table 1 Biochemical markers of bone mineral density

Bone formation	Bone resorption
Blood	*Blood*
Alkaline phosphatase (bone-specific)	Acid phosphatase (acid-resistant)
Osteocalcin	Type I collagen carboxy-terminal telopeptide (ICTP)
Procollagen type I carboxy-terminal propeptide (PICP)	*Urine*
Procollagen type I amino-terminal propeptide (PINP)	Calcium
Procollagen type III amino-terminal propeptide (PIIINP)	Hydroxyproline
	Cross-linked peptides (pyridinium and deoxypyridinoline)

Effects on bone mineral density

Bone mineral density has been measured in a 3-year prospective study in 109 premenopausal asthmatic women, aged 18–45 years, all of whom used inhaled triamcinolone acetonide (77). They were grouped according to their inhaled glucocorticoid use at base line (no glucocorticoids and triamcinolone less than 800 micrograms/day or more than 800 micrograms/day). Therapy with triamcinolone was associated with a dose-related fall in bone mineral density at the hip overall and the trochanter. There was no effect at the femoral neck or the spine. None of the measured serum or urinary markers of bone turnover predicted the degree of bone loss. The dose-related loss of bone mineral density was suggested to be clinically related to prolonged treatment with inhaled glucocorticoids, and periodic bone mineral density assessment in patients taking high-dose inhaled glucocorticoids was proposed.

The effect of beclomethasone on bone mineral density has been examined over 1 year in 36 premenopausal and

© 2006 Elsevier B.V. All rights reserved.

early postmenopausal women with asthma using inhaled glucocorticoids (beclomethasone at a mean dose of 542 micrograms/day) compared with 45 healthy matched controls (78). In early postmenopausal asthmatic women using beclomethasone, bone mineral density was significantly lower than in the controls, but not in premenopausal asthmatic women using inhaled beclomethasone. Serum osteocalcin concentrations were lower in the early postmenopausal asthmatic women using inhaled glucocorticoids than in the healthy controls, suggesting reduced bone formation, which leads to more pronounced bone loss. Ovarian hormones were suggested to offset the bone-depleting effects of inhaled beclomethasone in premenopausal women by maintaining or stimulating osteoblastic function.

There were significant reductions in bone mineral density in the lumbar spine and femur in 32 asthmatic women taking long-term inhaled beclomethasone (750–1500 micrograms/day) compared with 26 healthy controls (79). Control subjects and asthmatic patients were matched for age, sex, menopausal status, body-mass index, calcium intake, and physical activity. Loss of bone mass was more pronounced in the postmenopausal women. The authors identified several risk factors for accelerated bone loss in the lumbar spine, including postmenopausal status, low body-mass index, long duration of disease, long-term inhaled glucocorticoid therapy, and higher average daily and cumulative inhaled glucocorticoid doses.

The effects of inhaled budesonide 800 micrograms/day and fluticasone 400 micrograms/day on bone metabolism, morning cortisol concentrations, and clinical parameters have been studied in eight asthmatic patients (80). There were no changes in serum and bone alkaline phosphatase, osteocalcin, carboxyterminal propeptide of type 1 procollagen, and urinary calcium and deoxypyridinoline concentrations over 6 months. The authors concluded that fluticasone is as effective as twice the dose of budesonide in controlling asthmatic symptoms, without adverse effects on bone metabolism.

In a prospective comparison of the changes in bone mineral density in adults with mild asthma, 374 subjects with mild asthma (mean FEV_1 86% predicted; mean age 35 years; 55% women) were randomized to receive inhaled budesonide, inhaled beclomethasone, or non-glucocorticoid treatment (the control group) for 2 years (81). Bone mineral density was measured blind after 6, 12, and 24 months. The median daily doses of budesonide (87 subjects) and beclomethasone (74 subjects) were 389 and 499 micrograms respectively. The mean changes in bone density over 2 years in the budesonide, beclomethasone, and control groups were 0.1, –0.4, and 0.4% in the lumbar spine and –0.9, –0.9, and –0.4% in the neck of the femur. The mean daily dose of inhaled glucocorticoid was related to the reduction in bone mineral density only in the lumbar spine. Low to moderate doses of inhaled glucocorticoids caused little change in bone mineral density over 2 years and provided better asthma control.

In a retrospective cohort comparison of patients using inhaled glucocorticoids or bronchodilators with controls, there was an increased risk of fractures, particularly at the hip and spine, in those using inhaled glucocorticoids. There were no differences in relative fracture risks with different drugs, for example fluticasone, budesonide, beclomethasone (82). In an earlier retrospective study, there was a dose-dependent increase in bone fracture risk with oral glucocorticoids (83).

The effects of inhaled glucocorticoids on bone mineral density (measured using dual X-ray absorptiometry of the spine and hip) and biochemical parameters were followed over 18 months. Mean serum osteocalcin concentrations were significantly lower in patients taking beclomethasone dipropionate or budesonide at doses of 800 micrograms/day and more. However, bone mineral density of the lumbar spine and hip was not affected. The normal advancement of bone mineral density expected in growing children was not affected by inhaled glucocorticoids taken for 7–16 months (SEDA-22, 184).

Treatment with beclomethasone dipropionate 1500 micrograms/day for 6 weeks significantly reduced markers of bone formation (osteocalcin and PICP), whereas fluticasone propionate 750 micrograms/day had no effect. Neither drug affected biochemical markers of bone resorption. There was no significant change in bone density (SEDA-22, 183).

Effects on bone mineral density in children

A cross-sectional study in children (84) showed no significant difference in total and anteroposterior spine bone mineral density between children with asthma treated with long-term budesonide (200–800 micrograms for at least 6 months; $n = 52$) and asthmatic children who had never used inhaled glucocorticoids ($n = 22$). These results are in agreement with those of a larger cross-sectional study of the effects of long-term treatment (3–6 years, mean 4.5 years) with inhaled budesonide on total bone mineral density in children with asthma ($n = 157$). The results provided evidence that long-term treatment with inhaled glucocorticoids in moderate dosages is unlikely to affect bone mineral density adversely in children with asthma (85). However, a study of the association of clinical risk factors and bone density with fractures in 324 prepubertal children, of whom 32 had a fracture, suggested that for total fracture risk bone mineral density may be less important than clinical risk factors (86). In a multivariate model incorporating age, weight, height, breast-feeding history, sports participation, and the use of inhaled glucocorticoids, these factors accounted for 10% of the variability in the risk of fracture. Surprisingly, bone mineral density in the lumbar spine, femoral neck, and total body bone did not differ between those with and without fractures.

In a small cross-sectional study, bone mineral density was studied in 20 prepubertal asthmatic patients treated with moderate to high doses of inhaled glucocorticoids (under 400 micrograms/day beclomethasone or budesonide or over 200 micrograms/day fluticasone) (87). Volumetric trabecular bone mineral density of the lumbar spine and distal radius were measured using dual energy X-ray absorptiometry and were within the reference ranges.

Bone mineral density (measured by dual X-ray absorptiometry) did not change significantly in asthmatic children treated for 3–6 years with a mean daily dose of 504 micrograms (189–1322 micrograms) budesonide (85).

© 2006 Elsevier B.V. All rights reserved.

In 23 children, randomized to either fluticasone 100 micrograms bd or beclomethasone 200 micrograms bd for 20 months, there was a significant increase in bone mineral density in the lumbar spine with time, following the normal growth pattern (88).

Comparisons with placebo

More data on the effect of inhaled glucocorticoids on bone mineral density in adults have been generated by the large randomized, multicenter, double-blind, placebo-controlled EUROSCOPE (European Respiratory Society Study on Chronic Obstructive Pulmonary Disease) study of 912 patients with chronic obstructive pulmonary disease randomly assigned to treatment for 3 years with budesonide 800 micrograms/day or placebo (89). There were no significant differences in bone mineral density at L2–4 vertebrae, the femoral neck, trochanter, or Ward's triangle; nor did the fracture rate between budesonide-treated and placebo-treated patients differ. These findings are in contrast to recent data from the Lung Health Study, which showed that triamcinolone 1200 micrograms/day for 4 years was associated with a statistically significant 2% reduction in bone mineral density in the femoral neck compared with placebo (90).

Comparisons of glucocorticoids

In a 12-month, multicenter comparison of fluticasone propionate 250–500 micrograms/day with beclomethasone dipropionate 500–1000 micrograms/day, the two drugs had an equal therapeutic effect. Fluticasone propionate treatment resulted in a higher bone mineral density (assessed at the hip) and higher serum osteocalcin concentrations.

In a prospective randomized comparison of the effects of fluticasone propionate 1000 micrograms/day and budesonide 1600 micrograms/day, over 1 year, bone mineral density measured in the spine was normal at the start of the study and increased slightly with time in both groups, as did serum osteocalcin concentration.

Fluticasone propionate 1000 micrograms/day or beclomethasone dipropionate 2000 micrograms/day taken for 2 years caused no change in biochemical markers of bone metabolism. Bone mineral density, measured by dual X-ray absorptiometry or single-photon absorptiometry, showed no consistent change. However, when bone mineral density was measured using quantitative computed tomography of the lumbar spine, beclomethasone dipropionate was associated with a small fall in bone mineral density, which stabilized by 24 months. It is doubtful that a small fall in bone density seen only on quantitative computed tomography is clinically relevant (SEDA-22, 184).

The efficacy and safety of fluticasone 750 micrograms/day and beclomethasone 1500 micrograms/day delivered by a spacer device have been compared in 30 asthmatic children in a 12-week, randomized, double-blind, crossover study (91). All of the children had persistent asthma requiring 1000–2000 micrograms/day of inhaled glucocorticoids before the trial. There was no significant difference in efficacy, as judged by daytime and nighttime symptom scores and PEFR. There was a minimal reduction in serum cortisol in both groups. Both groups had identical height gain velocities. At the doses used in this trial, the authors were unable to show a safety advantage of fluticasone over beclomethasone, as assessed by cortisol concentrations.

In a 1-year prospective, randomized, open comparison of inhaled fluticasone 500 micrograms bd with budesonide 800 micrograms bd delivered by metered-dose inhaler and large volume spacer, bone mineral density was measured in 29 patients in the lumbar spine and femoral neck (92). Bone mineral density in the spine increased slightly in both groups over the 12 months. Serum osteocalcin concentrations increased from baseline in both treatment groups (fluticasone +17%, budesonide +14%). The percentage change from baseline in bone mineral density of the spine correlated with the increase in serum osteocalcin. Mean serum cortisol concentrations remained in the reference range after both inhaled glucocorticoids.

It can be hypothesized that different glucocorticoids have different systemic effects, and therefore different effects on bone metabolism. An alternative hypothesis is that these effects are dose dependent (58), support for which comes from a population-based case-control study of 16 341 older patients with hip fractures (mean age 79 years) and 29 889 controls; recent use of an inhaled glucocorticoid was associated with a small dose-dependent increase in the risk of hip fracture (93).

Comparisons with other drugs

Bone mineral density was measured after 7.4 months in 49 asthmatic children, 38 of whom took inhaled beclomethasone, average daily dose 276 micrograms, and 11 sodium cromoglicate, average daily dose 30 mg (94). Children who had used beclomethasone had grown as much as those who used sodium cromoglicate. Trabecular and cortical bone mineral density in the proximal forearm and lumbar spine increased to the same extent in both groups.

The effects of fluticasone 50 micrograms bd or sodium cromoglicate 20 mg qds on growth over 12 months have been studied in 122 asthmatic children aged 4–10 years (95). The mean height velocity was 6 cm/year with fluticasone and 6.5 cm/year with sodium cromoglicate. There was no significant treatment difference in the mean 24-hour urinary-free cortisol concentrations at 6 or 12 months. Mean predicted peak expiratory flow rate improved over 1 year in both groups, but to a greater extent with fluticasone. The authors concluded that growth was normal in mildly asthmatic children using fluticasone (50 micrograms bd) for 1 year. Fluticasone was more effective than sodium cromoglicate, with fewer withdrawals and greater improvement in lung function.

Dose relation

Current evidence suggests that the changes in bone mineral density in asthmatic patients who take inhaled glucocorticoids occur within the high therapeutic range of doses. In patients with mild asthma who are well maintained on low doses of inhaled glucocorticoids, the benefits derived from good control of the asthma appear to

© 2006 Elsevier B.V. All rights reserved.

outweigh any concerns about minor changes in bone mineral density. The picture is less clear in patients with other risk factors, such as estrogen deficiency and advancing years.

No adverse effect on bone has been shown with beclomethasone dipropionate or budesonide at doses less than 1000 micrograms/day or fluticasone propionate less than 500 micrograms/day. Most patients obtain a good therapeutic response at these doses. Higher doses may be required in some patients. Aerosols delivering doses of beclomethasone dipropionate 250 and 500 micrograms, budesonide 400 micrograms and fluticasone propionate 250 and 500 micrograms should be reserved for patients in whom the requirement for a high dose has been demonstrated in an adequate trial of therapy.

In an uncontrolled study, 56 women with asthma taking long-term inhaled glucocorticoids had bone mineral density measurements of the lumbar spine and hip (96). Women who had taken more than three short courses of systemic glucocorticoids per year over the preceding 3 years were excluded. Data on duration of use and dose of inhaled glucocorticoids were obtained from the patients' medical records. Doses of inhaled glucocorticoids were arbitrarily classified as low (under 500 micrograms/day), medium (500–1000 micrograms/day), and high (over 1000 micrograms/day). More than half the women (61%) had reduced bone mineral density at either the hip or lumbar spine. Amongst the postmenopausal women in the study, 17% of those aged under 65 years had osteoporosis compared with 43% of those aged over 65 years. These figures exceeded those from a national sample of estrogen-deficient women, in which 5.7% under the age of 65 and 29% over the age of 65 years had osteoporosis. Bone mineral density loss increased with higher doses of inhaled glucocorticoids, from 5% in the low-dose group to 50% in the high-dose group. Whilst this is a potentially important finding in women at risk of osteoporosis because of the menopause, there are some aspects of the design of the study that limit the applicability of the findings. There was no appropriate age- and ethnicity-matched control group, and the contribution of nasal glucocorticoids was not accurately assessed.

In a large cross-sectional study, patients aged 20–40 years with asthma who had taken inhaled glucocorticoids for a median of 6 years were studied (97). Patients were excluded if they had taken a course of oral or parenteral glucocorticoids in the past 6 months or more than two courses ever, or if they had had more than 10 inhalers of nasal glucocorticoids or more than 10 prescriptions of a dermal glucocorticoid. Computerized records of general practices were used to identify patients for the study. Bone mineral density was measured at the lumbar spine (L2–L4) and the left femur (neck, Ward's triangle, trochanter). The cumulative dose of inhaled glucocorticoid was expressed as a product of the mean daily dose and time (mg days). This information was obtained from a patient questionnaire and validated against general practice computer and paper records. More than half of the patients (119/196) were women and the median cumulative dose of inhaled glucocorticoid was 876 mg (range 88–4380 mg). There was a significant inverse relation between the cumulative dose of inhaled glucocorticoid and bone mineral density at the spine and hip in both men and women. A doubling of cumulative dose was associated with a 0.16 times SD reduction in bone mineral density. Extrapolation from cross-sectional data such as these requires confirmation in longitudinal studies, since bone loss with oral glucocorticoids is more rapid in the first 12–24 months of therapy.

Bone mineral density has been measured at 3-year intervals in 51 patients taking inhaled glucocorticoids for asthma (98). The patients were divided into a high-dose group taking over 800 micrograms/day of beclomethasone or budesonide ($n = 28$, mean dose 983 micrograms/day) and a control group taking no inhaled glucocorticoid or less than 500 micrograms/day ($n = 23$, mean dose 309 micrograms/day). Whilst there were statistically significant reductions in bone markers, such as serum calcium and phosphorus and osteocalcin, over the 3-year period in each group, there was no significant reduction in bone mineral density in either group of asthmatic patients. Although the change in bone mineral density in the high-dose group was small over the 3-year period and not statistically significant, there was a correlation between bone loss and the daily dose of inhaled glucocorticoids. There was no significant correlation between the changes in bone density and either the initial bone density or biomarkers of bone turnover for the level of physical activity. This longitudinal study has shown the unreliability of biomarkers of bone turnover in predicting changes in bone density (and presumably relevant clinical outcomes, such as risk of fracture) and shows the need for measurement of bone mineral density in asthmatic patients who are deemed to be at risk of bone loss. Such patients include those taking oral glucocorticoids, perimenopausal women not taking hormone replacement therapy, and patients who need high doses of inhaled glucocorticoids. Whilst patients in this study did not have significant changes in bone mineral density over 3 years, the effects of higher doses remain uncertain, so it would be prudent to measure bone mineral density in patients who need higher doses.

Time course

The time course of changes in bone mineral density with inhaled glucocorticoids has yet to be determined. Longitudinal studies will be required to determine whether bone loss is most rapid in the first 12–24 months after initiating inhaled glucocorticoid therapy, as is the case with oral glucocorticoids (99) and whether the risk of fracture falls towards baseline after withdrawal of treatment, as was suggested by the GPRD (General Practice Research Database) study (87).

In older women with asthma, who have an increased risk of osteoporosis, there was no significant change in bone mineral density after 1 year of treatment with beclomethasone dipropionate 1000 micrograms/day (100).

Bone mineral density, bone turnover markers, and adrenal glucocorticoid hormones have been measured in 53 patients (34 women, 19 men) with chronic bronchial asthma who took either inhaled beclomethasone or budesonide in doses of at least 1500 micrograms/day for at

© 2006 Elsevier B.V. All rights reserved.

least 12 months (101). The patients were divided into those who had taken oral glucocorticoids for more than 1 month and those who had not. Bone mineral density was measured at the lumbar spine and the proximal femur. The values were about one standard deviation lower in men and women taking oral glucocorticoids or very high doses of inhaled glucocorticoids. The reduction in bone mineral density was enough to a double the risk of fracture at these sites. There was suppression of both endogenous glucocorticoid and adrenal androgen production in all subjects. Adrenal androgen suppression may increase the susceptibility of postmenopausal women treated with an oral glucocorticoid to bone loss.

Risk of fracture

Although studies in which biochemical markers of bone turnover are measured for periods of 1–2 months do not predict the development of bone thinning, osteoporosis, or fracture, they can be useful in comparing the potential effects on bone of different glucocorticoids. Studies of bone mineral density over longer time periods relate more directly to osteoporosis and fracture risk.

Whilst there have been several studies of the effects of inhaled glucocorticoids on bone mineral density, there are few data on the effects of inhaled glucocorticoids on the risk of fracture. In a retrospective cohort study the risk of fracture was established by examining the General Practice Research Database (GPRD), which is run by the Medicines Control Agency in the UK (87). Users of inhaled glucocorticoids were defined as permanently registered patients aged 18 years or more who received one or more prescriptions for inhaled glucocorticoids during the time from enrolment in the GPRD until the end of data collection. Patients who received a prescription for oral glucocorticoids for a period of 6 months before to 91 days after the last prescription for an inhaled glucocorticoid were excluded. There were two comparison groups: a bronchodilator group, which included adults who received prescriptions for non-systemic glucocorticoids and bronchodilators, and a second control group who received non-systemic glucocorticoids but never inhaled systemic glucocorticoids or bronchodilators. The database included over 440 000 patients and all patients who had fractures were identified from their medical records during the follow-up period, which was 91 days after the last prescription for an inhaled glucocorticoid. The relative rates of non-vertebral, hip, and vertebral fractures during inhaled glucocorticoid treatment compared with controls were 1.15 (95% CI = 1.10, 1.20), 1.22 (CI = 1.04, 1.43), and 1.51 (CI = 1.22, 1.85) respectively. There were no differences between inhaled glucocorticoids and bronchodilators (non-vertebral fracture relative rate = 1). The authors concluded that users of inhaled glucocorticoids may have an increased risk of fracture, particularly at the hip and spine, but that this excess risk may be related more to the underlying respiratory disease than to the inhaled glucocorticoids.

There were no major differences between the three groups in baseline fracture history. About 1% in each cohort recorded a history of non-vertebral fractures in the year before baseline. During the follow-up, the incidence of non-vertebral fractures was 1.4 fractures per 100 persons with inhaled glucocorticoids, 1.4 with bronchodilators, and 1.1 in the control group. Comparing inhaled glucocorticoid users with a control group, there was a dose response for hip and vertebral fractures. For a standardized daily dose of under 300 micrograms/day of budesonide, hip fracture was 0.95, rising to 1.06 at doses of 300–700 micrograms/day and 1.77 at doses of 700 micrograms/day or more. There was no consistent trend in the rate of fractures amongst users of inhaled glucocorticoid compared with bronchodilators.

This is a noteworthy study because it has examined the most important clinical outcome of change in bone mineral density: the risk of fracture. The results point to an increased risk of fracture, especially at the hip and the vertebral bodies, amongst patients who use inhaled glucocorticoids as well as those using bronchodilators, when compared with patients not using these drugs. Fracture risk tended to fall after withdrawal of inhaled glucocorticoids or bronchodilators. These findings suggest that low-dose inhaled glucocorticoids are not associated with an increased risk of fracture and that patients with chronic respiratory disease who use any inhaled therapy are at risk compared with a control population. There were no differences in fracture risk between the various types of bronchodilators, suggesting that the underlying lung disease itself was the basis of risk rather than any particular type of bronchodilator. The authors noted that 1.9% of patients were using doses of budesonide equivalents of over 1500 micrograms/day and that the possibility of a more pronounced increased fracture risk at these high doses cannot be excluded. The age- and sex-specific incidence of fracture in the control group was similar to that of the general population in the GPRD.

Estimates of the important outcome of bone fracture have shown a small increased risk with inhaled glucocorticoids, but this may well be a feature of the disease rather than the therapy, because comparisons with treatment with bronchodilator drugs show no difference between risk factors in patients taking glucocorticoids or bronchodilators.

Prevention of osteoporosis with bisphosphonates

The effect of high-dose inhaled glucocorticoids and antiresorptive therapy with sodium etidronate has been studied for 18 months in 38 Chinese patients (24 men and 14 premenopausal women aged 30–50 years), of whom 28 were asthmatics who had already been treated for at least 12 months with high-dose inhaled glucocorticoids (beclomethasone or budesonide over 1.5 mg/day), and 10 healthy controls (102). The patients were randomly allocated to (1) no supplement, (2) a calcium supplement 1000 mg/day, or (3) cyclical sodium etidronate 400 mg/day for 14 days followed by calcium 1000 mg/day for 76 days. All three groups continued to take inhaled glucocorticoids. Bone mineral density was measured at the lumbar spine and hip. Bone mineral density in the group one patients fell by about 1% over 18 months and rose by about 1.5% in the healthy controls, neither change being significant. In groups 2 and 3 bone mineral density rose significantly at 12 and 18 months by 2 and 3% respectively. Serum osteocalcin concentrations fell significantly in all three groups of asthmatic patients but not in the controls. There were no significant changes in serum

© 2006 Elsevier B.V. All rights reserved.

alkaline phosphatase or parathyroid hormone. In the patients taking calcium, with or without etidronate, mean serum calcium increased. The authors suggested that calcium supplementation and cyclical etidronate work by reducing bone resorption, and hence reduced bone turnover, rather than by increasing bone formation. This is consistent with the fall in serum osteocalcin.

The efficacy of clodronate in treating glucocorticoid-induced bone loss in asthmatic subjects has been evaluated in a double-blind study in 74 adults (41 women and 33 men, mean age 57 years) with a long history (mean 8.1 years) of oral and inhaled glucocorticoid use, randomized to clodronate 800, 1600, or 2400 mg/day or placebo (103). There was no increase in bone mineral density with placebo or clodronate 800 mg/day, but a significant dose-related increase with clodronate 1600 and 2400 mg/day. The most common adverse effect was gastric irritation in the patients who took the highest dose of clodronate.

Growth

Oral glucocorticoids inhibit growth by blunting pulsatile growth hormone secretion, by decreasing insulin-like growth factor-1 activity, and by directly inhibiting collagen synthesis (104). Although inhalation reduces systemic exposure, concerns have been raised regarding the potential effects on growth and final height in children, especially when inhaled glucocorticoids are used for long periods.

Uninterrupted administration of moderate-dose inhaled glucocorticoids (for example 400 micrograms/day of budesonide equivalents) has been associated with a suppressed growth rate in some children with asthma. Budesonide reduced the growth by 1 and 1.4 cm over 7 and 12 months, respectively (105). Consequently, in the USA, a class label warning for inhaled glucocorticoids about growth retardation in children was introduced in 1998, when the FDA decided to alter the class labeling for all inhaled and nasal glucocorticoids in children, to indicate that the use of recommended doses might be associated with a reduction in growth velocity (19). However, the available studies suggest that in children, the major advantages of adequate asthma control with inhaled glucocorticoids outweigh any potential adverse effects on growth.

However, results from trials in asthmatic children can be flawed by confounding variables. Severe asthma can itself have a negative effect on growth and adversely affect adult height, as with any chronic disease. Even in well-controlled asthma, children typically show retardation in pubertal growth spurt and attain normal adult height later. As growth in children is non-linear over time, trials over short periods are likely to capture short-term effects of inhaled glucocorticoids rather than the long-term outcome. Furthermore, the growth-retarding effect of inhaled glucocorticoids is more pronounced at the start of treatment.

Long-term studies have suggested that a temporary short-term or medium-term reduction in growth velocity is normally compensated for later on, and individuals attain normal adult height (106,107). The effects of inhaled glucocorticoids on growth rate over weeks and months are dose-dependent, and dose-response curves of pulmonary and adverse systemic effects differ widely, so that individual titration of the inhaled glucocorticoid dose according to the severity of the disease is strongly recommended, and the lowest dose of inhaled glucocorticoids that controls the disease should always be preferred. In conclusion, accumulating evidence shows that children with asthma, even when treated with inhaled glucocorticoids for years, attain normal adult height. However, close growth monitoring during inhaled glucocorticoid therapy is recommended, as idiosyncratic responses can occur, probably owing to individual glucocorticoid receptor polymorphism (108).

A two-part review was published in 2002, addressing the difficulties of assessing the effects of asthma therapy on childhood growth and reviewing the published literature based on the authors' recommendations (109,110). In the first part (109), a simple classification system for growth studies was developed:

- comparisons with placebo (type 1 studies);
- comparisons with non-steroidal asthma therapy (type 2 studies);
- comparisons with another inhaled glucocorticoid (type 3 studies);
- comparisons with "real life" asthma therapy (type 4 studies).

In the context of these different study types, the authors also discussed the choice of end-point, key trial design issues, the selection and numbers of subjects in the active and control groups, the duration of assessments, and methods for measuring height and data analysis. They also elaborated specific recommendations regarding study duration, age/sexual maturity of the patients, exclusion criteria for height and growth velocity, permitted therapy during the study, the protocol for height measurement, the numbers of patients for adequate statistical power, and methods for statistical analysis (109).

In the second part, they selected 18 growth studies that included minimal criteria, such as selected control group, measured height by stadiometry, and at least a 12-month duration; they compared the design attributes of these studies with the described recommendations (110). Of the 18 selected studies, 17 were susceptible to one or more important confounding factors; nevertheless, the outcomes of all 18 studies were considered to be consistent. In summary, impaired growth velocity was found with budesonide and beclomethasone dipropionate compared with placebo, non-steroidal treatment, and fluticasone propionate during 1–2 years of therapy, but none of the inhaled glucocorticoids appeared to affect final height (110). Growth in children treated with low-dose fluticasone propionate (up to 200 micrograms/day) for 1 year is similar to growth in those treated with placebo or non-steroidal therapy. Standard pediatric doses of inhaled glucocorticoids (less than 800 micrograms of budesonide and less than 400 micrograms of budesonide or fluticasone) are considered not to affect growth adversely (57,111). The risk of growth suppression depends on the dose, the administration regimen, and the delivery device.

An important confounding factor is the influence of non-adherence to inhaled glucocorticoid treatment (112). Sensitive and reliable measures of adherence

© 2006 Elsevier B.V. All rights reserved.

should be applied when evaluating long-term effects on height.

The time of dosing can influence the effect of inhaled glucocorticoids on growth suppression in the prepubertal child, since growth hormone secretion is generally confined to nighttime. Therefore, once-daily morning dosing could be advantageous (113).

For clinical practice, the lowest effective dose should be achieved, and all children using inhaled glucocorticoids should have their growth measured every 6 months, as this is a sensitive method of detecting significant systemic effects (57,113).

These results apply to children over 4 years of age; for younger children only assumptions can be entertained and age-specific studies are needed (113).

Dose relation

Lumbar spine bone mineral density has been assessed in 76 prepubertal asthmatics (mean age 7.7 years, 26 girls) using glucocorticoids (114). After stratification for dose and route of administration, the children who used over 800 micrograms/day of inhaled glucocorticoids, with or without intermittent oral glucocorticoids, had a significant lower weight-adjusted bone density than children who used 400–800 micrograms/day of inhaled glucocorticoids (mean difference –0.05 g/cm^2; 95% CI = –0.02, –0.09). Bone mass was similar in children who did not use inhaled glucocorticoids and those who used 400–800 micrograms/day.

The authors of a review concluded, from short-term and intermediate-term growth studies, that there are no clinically significant adverse effects on growth with inhaled glucocorticoids at normal pediatric doses (100–200 micrograms/day budesonide equivalents), but that growth retardation can occur with all inhaled glucocorticoids at higher doses (115). Individual idiosyncratic adverse reactions are rare. Long-term studies and studies that have examined the effect on final adult height have been consistent in showing significantly reduced growth rates during the first months and up to 2 years of treatment with inhaled glucocorticoids. However, children treated with inhaled glucocorticoids attain their predicted adult height to the same extent as their healthy peers. It is important to note that changes in growth rate during the first year of inhaled glucocorticoid treatment cannot be used to predict final adult height.

Growth velocity measured over a 12-month period in prepubertal children with asthma was reduced by prior treatment with inhaled glucocorticoids for an average of 2.7 years. However, measurement of biochemical markers (Table 1) gave conflicting results. Osteocalcin concentrations were reduced, but alkaline phosphatase did not change. PINP and PIIINP were reduced, but PICP increased. ICTP, a marker for collagen I degradation, fell.

Comparisons of glucocorticoids

Fluticasone propionate 400 micrograms/day or budesonide 800 micrograms/day were administered for 20 weeks to children with moderate to severe asthma aged 4–12 years. Fluticasone propionate was superior to budesonide in improving peak expiratory flow and comparable in controlling symptoms. Growth was reduced with budesonide treatment compared with fluticasone propionate treatment mean difference, 6.2 mm (CI = 2.9, 9.6). There was no difference in serum cortisol suppression (116).

Comparisons with other drugs

Beclomethasone dipropionate 400 micrograms/day and salmeterol 50 micrograms bd were compared in asthmatic children treated for 12 months. Beclomethasone dipropionate treatment resulted in better overall asthma control. Over 12 months, linear growth was 3.96 cm/year in the children using beclomethasone dipropionate, compared with 5.40 cm/year in those who used salmeterol and 5.04 cm/year in a placebo group (SEDA-22, 186).

The long-term effects of inhaled glucocorticoids on growth in children have been recently assessed. In the so-called CaAMP Study (117), children aged 5–12 years with mild to moderate asthma were randomized to budesonide 200 micrograms bd (n = 311), nedocromil 8 mg bd (n = 312), or placebo (n = 418). At the end of the 4–6 year treatment period, the mean increase in height in the budesonide group was 1.1 cm less than in the placebo group. The difference between budesonide and placebo in the rate of growth was evident primarily within the first year but did not increase thereafter, and all the groups had similar growth velocity by the end of the treatment period.

Comparisons with oral glucocorticoids

A meta-analysis of 21 studies in which 810 asthmatic children were treated with oral prednisolone (8 trials) and/or beclomethasone dipropionate, dosage range 200–900 micrograms/day (12 trials) has been reported. Significant suppression of growth occurred with oral glucocorticoids but not with beclomethasone dipropionate (118).

Reversibility

Growth data obtained in 50 children who used beclomethasone dipropionate over 7 months suggested that any growth suppression is temporary and that growth velocity recovers during continuing treatment. Growth velocity fell most in the first 6 weeks of treatment, from 0.140 to 0.073 mm/week (0.067 mm/week; 95% CI = 0.015, 0.120). There were similar reductions at 12 and 18 weeks. After this, growth velocity increased to rates seen before treatment began: 0.138 mm/week at 24 weeks and 0.120 mm/week at 30 weeks (119).

Long-term use of beclomethasone dipropionate 400–600 micrograms/day was reported to delay the onset of puberty. However, subsequent catch-up growth was unaffected and subjects reached their normal predicted adult height (120).

Children taking budesonide (mean daily dose 412 micrograms, range 110–877 micrograms) for periods of 3–13 years have been followed to adulthood to determine their final height (107). These 142 budesonide-treated children were compared with 18 control patients with asthma who had never taken inhaled glucocorticoids

© 2006 Elsevier B.V. All rights reserved.

and 51 healthy siblings of the patients in the budesonide group. These children, who had taken long-term inhaled glucocorticoids, attained normal adult height. There was no evidence of a dose–response relation between the mean daily dose of budesonide, the cumulative dose, or the duration of treatment with budesonide and the difference between the measured and target adult heights.

These studies are important, because several previous reports of growth during a period of 1 year after beginning treatment with inhaled glucocorticoids (in daily doses of about 400 micrograms of budesonide) identified growth retardation of about 1.5 cm. The mechanism for the termination after 1 year of the effects on growth is uncertain.

Immunologic

Hypersensitivity to inhaled glucocorticoids is rare.

- An asthmatic patient using inhaled budesonide and salbutamol developed an acute asthma attack. Despite emergency treatment the patient deteriorated, requiring endotracheal intubation and assisted ventilation, and there was no improvement until the glucocorticoid was withdrawn, after which there was steady improvement. Skin prick tests with prednisolone, sodium hemisuccinate, and 6-methylprednisolone-sodium hemisuccinate were positive. Thirty minutes after intradermal 6-methylprednisolone-sodium hemisuccinate 4 mg, the patient developed a dry cough, dyspnea, and wheezing and a 17% fall in FEV_1.
- A 37-year-old woman who was pregnant developed Churg–Strauss syndrome after withdrawal of her usual high-dose inhaled glucocorticoid therapy (drug not stated) that she had used for 3 years for bronchial asthma (121).

The authors of the second report commented that activated eosinophils and their cytotoxic products, such as eosinophil catatonic protein, may play a part in the pathogenesis of Churg–Strauss syndrome. Measuring serum concentrations of eosinophil catatonic protein may be useful in monitoring disease activity, since concentrations were increased before treatment and normalized afterwards.

Infection risk

Inhaled or topical immunosuppressive and anti-inflammatory glucocorticoids increase the risk of oral candidiasis (122). Patients who harbor oral *Candida* before they use inhaled glucocorticoids may have an increased risk. The location and degree of oral candidiasis seems to be related to dosage, administration frequency, and inhalation technique. Preventive measures include using a spacer, lowering the dosage, and rinsing the mouth after use.

Invasive aspergillosis occurred after high-dose inhaled fluticasone (440 micrograms qds) and zafirlukast 20 mg/day in a 44-year old man with moderately severe asthma; this is the first report of invasive pulmonary aspergillosis associated with an inhaled glucocorticoid (123).

Second-Generation Effects

Teratogenicity

Congenital malformations that may be associated with inhaled budesonide in pregnancy have been evaluated using the Swedish Medical Birth Registry (124). Of 2014 infants whose mothers started to use inhaled budesonide in early pregnancy, 75 (3.7%) had a congenital malformation; the corresponding rate among all infants born in 1995–97 was 3.5%. Five infants had chromosomal anomalies that were unlikely to have been caused by drugs. This study did not identify teratogenic properties of inhaled budesonide.

Drug–Drug Interactions

Itraconazole

Interactions with other drugs can increase plasma concentrations of inhaled glucocorticoids. Itraconazole, a potent inhibitor of CYP3A4, markedly increased plasma concentrations of inhaled budesonide (125).

Ritonavir

Ritonavir, a potent inhibitor of CYP3A4, caused Cushing's syndrome in a patient using fluticasone propionate 1000 micrograms/day (126).

Corticosteroids—glucocorticoids, topical

See also Glucocorticosteroids

The local adverse effects of topical glucocorticoids (1,2) are listed in Table 1. They include transient local erythema, calcinosis cutis, cramps (due to injection of crystals into a vessel), amaurosis (a dubious report), depigmentation, skin atrophy, and skin necrosis (3,4). The systemic adverse effects of topical glucocorticoids (5–8), which are those to be expected from systemic use, are also listed in Table 1.

Table 1 Local adverse effects of topical glucocorticoids

Effects on the pilosebaceous unit
Perioral dermatitis (SEDA-5, 151)
Steroid rosacea or rosacea-like dermatitis; cannot be differentiated from perioral dermatitis and can be identical
Steroid acne
Exacerbation of pre-existing rosacea
Hypertrichosis of the face
Atrophic changes
Cigarette-paper wrinkling of the skin
Telangiectasia (SEDA-6, 153)
Petechiae, ecchymoses
Striae rubrae distensae, mainly in the inguinal and axillary region (occlusion effect)
Susceptibility of the skin to minor trauma
Fragile skin in surgery
Delayed wound healing
Worsening of existing ulceration
Photosensitivity of atrophic skin
Effects on the immune system
Aggravation of pre-existing folliculitis
Development of extensive, but unrecognized dermatophytic infections ("tinea incognito")
Perpetuation of masked infections with *Candida albicans*
Conversion of scabies into the Norwegian type
Widespread lesions of molluscum contagiosum
"Galloping" impetigo
(Possibly) exacerbation or dissemination of viral skin infections
Generalized pustular psoriasis
Generalized urticaria
Spreading of malignant skin lesions
Suppression of pruritus
Allergic contact dermatitis* (SEDA-15, 139)
Ocular effects
Ocular hypertension
Open-angle glaucoma (9)
Uveitis
Posterior subcapsular cataracts (9)
Nasal effects
Nasal septal perforation (steroid aerosols)
Skin lesions
Acne
Hirsutism
Ecchymoses
Milia
Granuloma gluteale infantum
Pseudocicatrices stellaires spontanées
Eczema craquelatum after withdrawal
Elastoidosis cutanée nodulaire à cystes et à comedones Favre-Raacouchot
Erythrosis interfollicularis colli
Cutis punctata linearis colli or "stippled skin"
Effects on skin color
Hypopigmentation
Hyperpigmentation
Striae
Miscellaneous effects
Tachyphylaxis to the vasoconstrictor effect of topical glucocorticoids
Systemic adverse effects of topical administration
Cushing's syndrome
Suppression of the hypothalamic–pituitary–adrenal axis
Growth retardation (SEDA-6, 151)
Hyperglycemia
Benign intracranial hypertension after withdrawal
Subcapsular cataract
Pancreatitis
Bony avascular necrosis (9)
Psychiatric symptoms
Fluid retention
Hypertension (SEDA-7, 167)

*Cross-allergy between glucocorticoids is infrequent (10–12).

Corticosteroids—mineralocorticoids

General Information

Aldosterone is the principal physiological salt-retaining mineralocorticoid, but it is unsuitable for routine medical use since it is rapidly inactivated when given orally. Desoxycorticosterone (DCA, DOCA, desoxycortone) was used for a long time, but it had to be taken sublingually (or implanted or injected) to avoid inactivation during passage through the liver. Overdosage of desoxycorticosterone, leading to hypertensive encephalopathy and permanent brain damage, has been described (SED-8, 820).

The approximate potency of various mineralocorticoids relative to cortisone is shown in Table 1.

Fludrocortisone is the compound that is most often used at present for long-term mineralocorticoid treatment. The dose of fludrocortisone needed in chronic adrenocortical insufficiency varies very widely, from 0.05 to 1.0 mg/day. In salt-losing forms of the congenital adrenogenital syndrome up to 0.2 mg/day may be needed. In doses appropriate to the individual's needs, adverse reactions to the glucocorticoid effects of fludrocortisone rarely prove problematic; the main problem is to adjust the dosage (as well as salt intake) to these needs, since the adverse effects that can be experienced mainly reflect relative overdosage; if high doses are to be used, meticulous monitoring is required.

Table 1 Approximate potency of various mineralocorticoids relative to cortisone

Compound	Route of administration	Mineralocorticoid effect	Glucocorticoid effect
Cortisone	Oral	1	1
Desoxycorticosterone	Sublingual	50	Negligible
Fludrocortisone	Oral	150	10–20
Aldosterone	Injected	500	None

Organs and Systems

Cardiovascular

Edema, hypertension, and cardiac hypertrophy can occur with fludrocortisone (1). Hypertension is the most common reason for reducing the dosage.

Fluid retention due to mineralocorticoid effects can cause cardiac failure (1).

- Congestive heart failure occurred in a 47-year-old woman after she had taken fludrocortisone 100 micrograms/day for 2 weeks for Addison's disease (2). Ten months later, fludrocortisone 25 micrograms/day was restarted, and the dosage was increased to 100 micrograms/day over 2 months. At follow-up after 4 months she was well, without fluid retention or electrolyte abnormalities.

Electrolyte balance

Hypokalemia due to fludrocortisone can cause muscle weakness (3).

Drug–Drug Interactions

Phenytoin

In two patients with adrenal insufficiency, phenytoin increased fludrocortisone dosage requirements (4).

Potassium-sparing diuretics

Potassium-sparing diuretics, such as prorenoate and spironolactone, can prevent the potassium-losing effects of fludrocortisone (5).

Corticotrophins (corticotropin and tetracosactide)

General Information

The adrenocorticotrophic hormone ACTH (corticotropin) stimulates the adrenal cortex to secrete the glucocorticoids hydrocortisone (cortisol) and corticosterone, the mineralocorticoid aldosterone, and a number of weakly androgenic substances, as well as a small amount of testosterone. Aldosterone synthesis is also regulated by renin and angiotensin.

This monograph should be read in conjunction with the monograph on glucocorticoids. It is not always clear which adverse effects are specific to corticotrophins and which simply result from the secretion of the glucocorticoids that they induce; conversely, almost any adverse effect associated with glucocorticoids can in principle also occur with corticotrophins.

Structures and nomenclature

Natural ACTH (corticotropin) is a polypeptide consisting of 39 amino acids. Its hormonal activity is related to the first 24 amino acids in a sequence that is found in both animal and human pituitary glands. The differing sequences of the remaining 15 amino acids in animals can lead to antibody formation and hence to allergic reactions when animal hormones are injected into humans. From 1970 onwards, therefore, even highly purified corticotropin preparations of animal origin were largely displaced by the so-called "synthetic ACTH" or "synthetic corticotropin," better known by its generic name of tetracosactide (rINN), which contains only the first 24 amino acids, hence avoiding much of the antigenicity of the complete molecule. Collectively, corticotropin and tetracosactide are known as the corticotrophins.

Since the development of tetracosactide, other modifications to the corticotropin molecule have been made, and some clinical work has been done with products containing fewer than 24 amino acids, for example 1–18. However, none has proved more usable than tetracosactide. The replacement of some naturally occurring amino acids by others may intensify or prolong the effect of the polypeptide.

Production and elimination

Fluctuations in the rates of secretion of glucocorticoids from the adrenal cortex are determined by variations in the rate of release of corticotropin from the anterior pituitary, and this in turn is controlled by the hypothalamic corticotropin-releasing hormone (CRH). Since release of CRH is affected by circulating glucocorticoid concentrations, a negative-feedback control operates to keep the system in balance. It follows from this that if glucocorticoids are administered exogenously they will operate through this feedback to suppress adrenal function.

The mode of inactivation and excretion of corticotropin is still almost completely unknown; its biological half-life has been variously assessed as several minutes or several hours.

Uses

Corticotrophins can be used diagnostically to investigate adrenocortical insufficiency. Corticotropin has also been used therapeutically in most of the conditions for which systemic glucocorticoids are indicated, although such use is now fairly limited. However, corticotropin is used in certain neurological disorders, such as infantile spasms and multiple sclerosis. The main indications for corticotropin and tetracosactide are thus diagnostic rather than therapeutic; for the latter purpose they are being increasingly replaced by CRH.

General adverse effects

Corticotrophins share all the adverse effects of glucocorticoids, including impaired immunity, but they do not depress adrenocortical function. In addition, the melanocyte-stimulating hormone (MSH) sequence in the corticotropin molecule can result in hyperpigmentation, and induction of androgen secretion can lead to virilization. Corticotrophins also have additional unwanted effects of their own, such as myoclonic encephalopathy and adrenal hemorrhage. Hypersensitivity reactions occur occasionally, but have become less frequent since older preparations of animal origin were phased out. Tumor-inducing effects have not been observed.

Organs and Systems

Cardiovascular

Corticotropin has been reported to cause enlargement of cardiac tumors in tuberous sclerosis (1).

- A female infant with tuberous sclerosis had multiple large cardiac tumors in the left and right ventricles. Corticotropin was given (dose not stated; once a day for 2 weeks, tapering over 3 months) at 4 months for infantile spasms. At 6 months a heart murmur was detected. Echocardiography showed pronounced enlargement of the tumors in both ventricles and a small tumor extending from the upper portion of the interventricular septum into the left ventricular outflow tract. An electrocardiogram showed 2–3 mm ST segment depression in leads I, aVL, and V4-6. Gated single photon emission CT showed low perfusion at the lateral and inferior regions of the left ventricle, indicating myocardial ischemia.

© 2006 Elsevier B.V. All rights reserved.

Corticotropin was withdrawn and 3 months later the patient was asymptomatic. An echocardiogram showed that the tumors had reduced in size, and there was concomitant improvement in the electrocardiogram.

There is a risk of myocardial hypertrophy in children on prolonged treatment with ACTH (2), an effect that could reflect increased androgen secretion and thus be more likely to occur than with glucocorticoids.

Hypertension, with or without simultaneous hypertrophic myopathy, is a common feature of adrenal stimulation that seems to be common with depot tetracosactide but not simple tetracosactide (3). During treatment for infantile spasms, hypertension occurred more often in those treated with high doses (SEDA-19, 374) (4), and changes in cardiac function, such as left ventricular shortening fraction, can occur early and sometimes before systolic hypertension (SEDA-19, 374) (5).

Respiratory

Corticotropin and to a lesser extent tetracosactide can cause asthma in sensitive subjects (6). The question as to whether tetracosactide or glucocorticoids should be preferred for the treatment of chronic asthmatic bronchitis has been discussed mainly with respect to adverse effects, particularly adverse endocrine effects and effects on growth. An earlier belief that corticotropin might be more effective in children has not been confirmed.

Nervous system

In 138 Japanese patients with West syndrome treated with low-dose tetracosactide, the initial effects on seizures and long-term outcome were not related to dose (daily dose 0.005–0.032 mg/kg, 0.2–1.28 IU/kg; total dose 0.1–0.87 mg/kg, 4–35 IU/kg) (7). There were moderate or severe adverse effects in 30% of the patients. There was slight loss of brain volume on CT/MRI scans in 64% of the patients, moderate loss in 23%, and severe loss in 4%. The severity of adverse effects correlated with the total dose of corticotropin, and the severity of brain volume loss due to corticotropin correlated well with the daily and total doses. The authors recommended a reduction in the dose of corticotropin in order to avoid serious adverse effects.

Brain shrinkage has been described as a possible adverse effect of corticotropin treatment of infantile spasms, and this has been confirmed using magnetic resonance imaging (SEDA-20, 368) (8,9). Changes in midline structures (volume reductions in the pons, corpus callosum, and cerebellum) seem to show that the beneficial effect of corticotropin in infantile spasms could be due to a direct effect on the brainstem. Cerebral shrinkage and subdural hematoma occurred after the administration of high doses of corticotropin for West syndrome (total dose 4.5–6.75 mg) and subdural hematoma occurred in two children (aged 2 and 5 months) during the administration of low doses of tetracosactide (0.01 mg/kg/day; total dose 0.24–0.26 mg) (10).

Drowsiness, hypotonia, and irritability were observed in 37% of infants given corticotropin in a randomized comparison of corticotropin with vigabatrin in the treatment of infantile spasms (SEDA-22, 442) (11).

Myoclonic encephalopathy appears to be a specific, if rare, complication of corticotropin, not seen with the glucocorticoids (12).

Sensory systems

Bilateral subcapsular cataracts and glaucoma have been reported as possible risks (13), but they presumably reflect glucocorticoid effects.

Bilateral macular degeneration has been described with tetracosactide (13), but presumably reflects glucocorticoid effects.

Central serous retinopathy has been linked to the therapeutic use of corticotrophins or glucocorticoids or to endogenous corticotropin hypersecretion. Bilateral central serous retinopathy has been reported in a woman treated with tetracosactide intramuscularly (SEDA-22, 442) (14).

Psychological, psychiatric

Mood changes continue to be reported in association with corticotropin (15). Emotional instability or psychotic tendencies can be aggravated, while euphoria, insomnia, and personality changes such as hypomania and depression can be precipitated, sometimes even with psychotic manifestations. Although it seems reasonable to assume that one is dealing here mainly with an effect of the glucocorticoids secreted in response to corticotropin, it should be recalled that segments of the corticotropin molecule themselves have effects on brain function and could conceivably play a role.

Endocrine

Corticotropin can promote the development of a more or less pronounced Cushingoid state. Corticotropin also increases the metabolic clearance rate of cortisol, aldosterone, and desoxycorticosterone (SEDA-1, 282).

Prolonged stimulation by corticotropin leads to adrenocortical cell hyperplasia and an increase in the size and weight of the adrenal glands; massive enlargement can be demonstrated by computerized tomography as well as clinical examination (16).

Acute adrenal hemorrhage, either unilateral (17) or bilateral (18), has been observed repeatedly after corticotropin administration, and causes an acute abdominal crisis. Although it is usually seen in children, hemorrhage can also occur in adults (SEDA-17, 451).

Even a single dose of corticotropin can cause inhibition of thyrotrophic hormone secretion (19), although the effect is brief. Conversely, thyroid hormones increase the sensitivity of adrenocortical cells in vitro to corticotropin (20) and hyperthyroidism increases sensitivity to corticotropin (21,22).

Corticotropin suppresses the growth hormone response to hypoglycemia (23).

Androgen secretion due to corticotropin can cause virilization in women (24).

Fluid balance

Corticotropin affects mineral and fluid balance in varying degrees, as would be expected from its effect on mineralocorticoid secretion.

© 2006 Elsevier B.V. All rights reserved.

Hematologic

Marked leukocytosis has been described, despite the absence of infection, in a patient treated with tetracosactide (SED-12, 980); the effect may well have been due to glucocorticoid secretion rather than to tetracosactide itself.

Gastrointestinal

A relative indication for corticotropin is the occasional gastrointestinal intolerance that occurs with oral glucocorticoids. In these cases, however, only the local effects of the glucocorticoids can be avoided, and not their systemic effects on the gastrointestinal tract (25).

Urinary tract

Renal calcinosis can develop as a result of hypercalciuria and is a major concern in the treatment of infantile spasms with corticotropin. In 16 infants, corticotropin, often associated with anticonvulsants, results in increased urinary excretion of calcium and phosphate, with increased parathormone serum concentrations and in some cases generalized aminoaciduria (26). This makes it imperative that the dose of corticotropin and the duration of treatment be kept to the minimum required to ensure efficacy. In one case in which calcified stones were removed surgically, recurrence was apparently prevented, despite the presence of a Cushingoid state, by long-term chlorothiazide (27).

Skin

Allergic skin reactions, for example urticaria, can occur. Since the first 13 amino acids in the corticotropin peptide are the same as in MSH, treatment with corticotropin can occasionally cause hyperpigmentation. The shorter peptide chain in tetracosactide can even cause rather more pronounced melanocyte-stimulatory effects. Long-term treatment with depot tetracosactide has itself caused melanoderma (SED-12, 980) and, in one series of 41 patients, there was hyperpigmentation in 3 of them (SEDA-1, 281).

Immunologic

Although the incidence of severe allergic reactions to natural corticotropin of animal origin fell as progressively purer products were introduced, the problem remained for a small minority of patients. Exact figures are difficult to cite, but hypersensitivity reactions have sometimes even been described in patients with no history of corticotropin treatment, presumably sensitized by other animal material. Hypersensitivity to corticotropin generally causes only dizziness, nausea and vomiting, or cutaneous hypersensitivity reactions, but in several instances shock with circulatory failure has been observed (28). In a number of patients who were allergic to porcine corticotropin, no such problems were observed when tetracosactide was given. This suggests that the absence of most of the antigenic part of the original molecule reduces the risk of hypersensitivity reactions. However, the smaller synthetic molecule can still stimulate the formation of antibodies in some individuals (SEDA-12, 979) (29).

However, allergic reactions and anaphylactic shock have been observed during treatment with tetracosactide and have even proved fatal. Local reactions have even been seen after the administration of small doses for intracutaneous testing. In the early years of tetracosactide use, the frequency of local and general reactions to a long-acting acetylated tetracosactide was estimated at as little as one in 30 000 (SED-12, 979), but it is doubtful whether this figure can be supported today, unless one interprets it as referring only to major calamities. Indeed, subclinical immune reactions to both natural and tetracosactide appear to be fairly common during long-term treatment of patients with asthma, with an incidence of intradermal reactions of about 50%, a prevalence of IgE antibodies that is significantly higher than in controls, and a high incidence of low-titer agglutinating antibodies to corticotropin. The antibodies can result in a gradual loss of effect.

Infection risk

Pneumonia due to *Pneumocystis jiroveci* (formerly *Pneumocystis carinii*) has been attributed to high-dose corticotropin (30).

- An infant girl was given corticotropin 80 U/day for infantile spasms. After 5 weeks she became increasingly lethargic, with reduced oral intake, cough, an increased respiratory rate (50 breaths/minute), and a fever of 38.6°C. Investigations were consistent with pneumonia and she was given intravenous ceftriaxone. She initially improved, but 36 hours later her respiratory distress worsened and she required intubation and mechanical ventilation. The diagnosis of *P. jiroveci* pneumonia was confirmed and she was given intravenous co-trimoxazole and glucocorticoids. Her respiratory distress resolved and she was extubated 10 days later. Immunological testing after the withdrawal of corticotropin did not show any abnormalities that could have predisposed her to *P. jiroveci* pneumonia.

The authors commented that a transient immunodeficiency related to corticotrophin may have predisposed to the development of *P. jiroveci* pneumonia.

Long-Term Effects

Drug withdrawal

Relative adrenocortical insufficiency can follow withdrawal of corticotropin treatment (presumably because the cortex has adapted itself to a constant high level of stimulation) and can persist for some months. Glucocorticoid substitution has to be provided during this period. The risk of this effect can be reduced by keeping the dose of corticotropin as low as possible.

Second-Generation Effects

Pregnancy

There are no firm data on the use of corticotropin in pregnancy; both glucocorticoid and androgenic effects might be expected to affect the fetus.

© 2006 Elsevier B.V. All rights reserved.

Susceptibility Factors

Age

Although it has been stated in reviews that treatment with corticotropin inhibits growth much less than glucocorticoid treatment does, the growth hormone response to stimuli is reduced, and since growth hormone secretion is impaired during corticotropin treatment, claims for the greater safety of this therapy in children with asthma must be treated with reservations.

Other features of the patient

Susceptibility factors for adverse effects are as for glucocorticoids. In addition, patients with a known allergic tendency should preferably not receive these substances, unless sufficient supervision is possible to cope with unexpected allergic reactions, at least until tolerance has been demonstrated.

Drug–Drug Interactions

Coumarin anticoagulants

In 10 of 14 patients taking dicoumarol or phenindione who also took corticotropin for 4–9 days, there was a small increase in the effects of the anticoagulants (31). One patient taking ethyl biscoumacetate developed bleeding after taking corticotropin 20 mg/day for 3 days (32). However, in contrast, reduced efficacy of ethyl biscoumacetate has been described (33).

Corynebacterium parvum

General Information

Inactivated *Corynebacterium parvum* has been tried as an adjuvant in patients with cancer and in the treatment of malignant pleural effusions. Fever and chills were frequent, with sustained fever and chest or abdominal pain in several patients (1,2).

Coumarin

General Information

The plant lactone coumarin (not to be confused with coumarin anticoagulants) is a constituent of some plants, including:

- *Alyxia lucida*
- *Dalea tuberculata*
- *Dipteryx odorata*
- *Dipteryx oppositofolia*
- *Levisticum officinale*
- *Melilotus officinalis*
- *Scabiosa comosa.*

Organs and Systems

Hematologic

Coumarin is devoid of anticoagulant activity, but the molding of sweet clover can give it hemorrhagic potential by transforming coumarin to the anticoagulant dicoumarol. This transformation could explain a case of abnormal clotting function and mild bleeding after the drinking of an herbal tea prepared from tonka beans, sweet clover, and several other ingredients. Unfortunately, this possibility was not investigated, as the reporting physician was not aware of the exact phytochemistry and pharmacology of coumarin-yielding plants.

Liver

Coumarin has hepatotoxic potential in man, when taken in daily doses of 25–100 mg (1). Bile-duct carcinomas have been reported to occur in rats fed coumarin, but the correctness of this diagnosis has been seriously criticized.

Coumarin anticoagulants

General Information

The coumarins were first discovered in Wisconsin, when bleeding in cattle was found to be due to the consumption of bruised sweet clover in the 1920s (1). The causative agent, dicoumarol, was isolated in 1940, and a range of related compounds was then synthesized, the most popular of which proved to be warfarin (named after the Wisconsin Alumni Research Foundation). Other coumarins that have been used are acenocoumarol (nicoumalone), bishydroxycoumarin, dicoumarol, ethyl biscoumacetate, and phenprocoumon.

The coumarins act as competitive inhibitors of vitamin K epoxide reductase, which is responsible for regenerating reduced vitamin K from vitamin K epoxide after it has been consumed as a co-factor in the synthesis of coagulation factors II, VII, IX, and X.

Uses

The main use of the coumarins is in the treatment and prevention of thromboembolic disease, including deep vein thrombosis, pulmonary embolism, and cerebral embolism from cardiac and other sources.

Protein C, another vitamin K-dependent serine protease zymogen in plasma, is a regulatory protein that, when activated, limits the activity of two activated procoagulant co-factors, factors Va and VIIIa. Heterozygotes for hereditary isolated protein C deficiency tend to develop a thrombotic disease which has been successfully treated with long-term coumarins (2,3). Apparently, the

© 2006 Elsevier B.V. All rights reserved.

balance between the activities of protein C and the procoagulant factors (II, VII, IX, and X), which is disturbed in protein C-deficient patients, is restored during long-term treatment with coumarins.

Non-anticoagulant uses

Warfarin reduces calcium deposition in spontaneously degenerated bioprosthetic valves (4).

Both direct and indirect antitumor actions of anticoagulants have been postulated on the basis of experimental findings in animals (5). Warfarin given alone or in combination with cytostatic drugs reduces the size of fibrosarcomas in animals (5,6) and of osteosarcomas in man (7), and consequently prolongs survival times in both. The Cooperative Studies Program of the Veterans Administration Medical Research Service suggests that, among patients with various tumors, those with small-cell carcinoma of the lung had a significantly longer survival (about 4 years instead of 2) when warfarin was added to standard treatment (8). There were no differences in survival between warfarin-treated and control groups for advanced non-small-cell lung cancers, colorectal, head and neck, and prostate cancers (9). However, the contention that cancer morbidity and/or mortality is reduced in anticoagulated patients is not substantiated by the results of a retrospective study of 378 patients who had been taking anticoagulants for about 10 years on average (10).

It has been suggested that warfarin may have a specific effect on tumor-cell growth via the inhibition of protein synthesis (11). Another explanation of the effect of the drug is a reduction in the co-adherence of tumor cells, which renders them more vulnerable to the actions of defence mechanisms. The reduction in co-adherence is thought to be caused by an inhibitory action of anticoagulants on the fibrin network that is vital for tumor cell growth. This hypothesis, which is supported by dose dependence of the inhibitory effect of both heparin and warfarin (12), has been studied in a controlled randomized trial of the use of streptokinase after surgery for tumors of the large bowel (6).

Supercoumarins

Resistance to warfarin emerged soon after its original use as a poison for rodents. Second-generation anticoagulants, termed "superwarfarins," were subsequently developed and are sold as rodenticides for pest control. These include agents such as brodifacoum and difenacoum, which typically have much longer half-lives than warfarin. There have been several published case reports of accidental or intentional poisoning due to these drugs (13,14), which can result in prolonged coagulopathy (15,16).

In 10 762 children aged 6 years and under who unintentionally took single doses of brodifacoum, there were no deaths or major adverse effects, although 67 reported evidence of coagulopathy (17). There were minor and moderate adverse effects in 38 and 54 children, respectively. About half of the children received some form of gastrointestinal decontamination, which had no effect on the distribution of outcomes but caused adverse effects in 42 patients.

Ingestion of a small amount of a superwarfarin does not require specific therapy (18,19). However, if the coagulopathy due to a superwarfarin is severe, large doses of vitamin K may be required (15). Recombinant activated factor VII has been successfully used to treat superwarfarin poisoning (20).

When cases of unexplained acquired coagulopathy and selective deficiency of vitamin K-dependent clotting factors occur in patients in the absence of liver disease or inhibitors, physicians should consider the possibility of superwarfarin poisoning as a cause.

General adverse effects

The major adverse effect of the coumarins is hemorrhage and, exceptionally, hemorrhagic skin necrosis. Administration during pregnancy can cause an embryopathy. Allergic reactions are extremely rare. Tumor-inducing effects have not been reported.

Organs and Systems

Cardiovascular

Vasodilatory effects on the coronary arteries, peripheral veins, and capillaries, with purple toes as one of the most obvious consequences (21,22), have been reported. Sensations of cold may be due to increased loss of body heat caused by peripheral vasodilatation (23).

Cholesterol embolization, which promptly improves after the drug is withdrawn (24), may explain the purple-toe phenomenon.

Nervous system

Apart from cerebral hemorrhage, coumarins have no direct adverse effects on the nervous system.

Endocrine

An antithyroid effect of bishydroxycoumarin has been suspected (25).

Metabolism

Dicoumarol has been reported to have a uricosuric effect (26).

Hematologic

Hemorrhage

Bleeding is the major complication of coumarin anticoagulants. The annual incidence of major bleeding among 4060 patients in the AFFIRM trial, who were followed for an average of 3.5 years, was about 2% per year (27).

Dose-dependency

The intensity and stability of treatment, in addition to the beneficial effect of the coumarins, determine the rate and severity of bleeding complications. The average annual frequencies of fatal, major, and major and minor bleeding during warfarin therapy were 0.6, 3.0, and 9.6% respectively (28). The relationship between the intensity of anticoagulant therapy and the risk of bleeding is very strong, both in patients with deep vein thrombosis tissue and in those with mechanical heart valves. In randomized trials for these indications, the incidence of major bleeding in patients randomly assessed to less intense warfarin therapy (targeted INR 2.0–3.0) has been less than half the incidence found in patients randomly assigned to more

© 2006 Elsevier B.V. All rights reserved.

intense anticoagulation (INR more than 3) (29). The bleeding risk increases dramatically when the INR is higher than 4.0 (30), especially the risk of intracranial hemorrhage. Less intense warfarin therapy has been used in patients with non-rheumatic atrial fibrillation, with only a very slight increase in major bleeding compared with placebo. In such patients, an INR of 2.5 (range 2.0–3.0) minimizes both hemorrhage and thromboembolism (31).

Time-dependency
Although bleeding can occur at any time, if the effective dose of drug increases, whether because of a change in dose or an interaction, most studies have reported higher frequencies of bleeding soon after the start of treatment. In one study the incidence of major bleeding fell from 3.0% per month during the first month of outpatient warfarin therapy to 0.8% per month during the rest of the first year of therapy and to 0.3% per month thereafter (32). Increased variation in anticoagulant effect, as reflected by time-dependent variation in the INR is associated with an increased frequency of hemorrhage independent of the mean INR (33,34).

Susceptibility factors
Important susceptibility factors include age, endogenous coagulation defects, thrombocytopenia, hypertension, cerebrovascular disease, thyroid disease, renal insufficiency, liver disease, tumors, cerebrovascular disease, alcoholism, a history of gastrointestinal bleeding (peptic ulcer disease alone without past bleeding is not associated with an increased risk of bleeding), and an inability to adhere to the regimen.

Management
The management of coumarin toxicity depends on the INR and whether there is bleeding.

- INR more than 0.5 over the target but under 5.0: reduce the dose
- INR 5.0–8.0: withhold the drug and restart once the INR is below 5.0
- INR over 8.0 and no bleeding: withhold the drug and restart once the INR is below 5.0
- INR over 8.0 with bleeding: withhold the drug and give vitamin K_1 (phytomenadione) 0.5 mg intravenously or 5 mg orally
- INR over 8.0 with life-threatening hemorrhage: withhold the drug and give a prothrombin complex concentrate (such as Beriplex-P/N or Prothromplex-T) 50 U/kg (35); if this is not available, give fresh frozen plasma 15 ml/kg.

If rapid and complete reversal is required (for example before a procedure such as a liver biopsy), vitamin K_1 (phytomenadione) 5–10 mg can be given slowly (1 mg/minute).

Other effects
Blood and plasma viscosity fall by 5–10% during the administration of coumarins in healthy volunteers and in patients with coronary artery disease (36). This may also explain, at least partly, the antianginal effect of coumarins. The mechanism might be related to changes in the protein composition of the plasma.

A reversible increase in white cell count has been reported with long-term use of acenocoumarol (37).

Hemolytic anemia thought to be related to warfarin has been reported (38).

Gastrointestinal

Gastrointestinal complications due to coumarins are limited to hemorrhage.

Liver

Only a few cases of hepatic injury have been documented in patients taking coumarins. In some of them, rechallenge caused a relapse (39). The usual presentation was with a cholestatic illness, beginning about 10 days after the coumarin anticoagulant was started, sometimes associated with eosinophilia. In Switzerland, oral anticoagulants were involved in only 11 of 674 reports of drug-induced liver disease collected during 1981–95. Seven cases were due to phenprocoumon and three to acenocoumarol. The severity ranged from asymptomatic rises in liver enzymes to cholestatic hepatitis. The interval between administration and onset of symptoms varied from 2 days to several weeks or months (40).

Subacute liver failure necessitating orthotopic liver transplantation has been reported with phenprocoumon (41).

- A 39-year-old woman developed idiopathic thrombosis of the posterior tibial vein. Oral contraceptives and resistance to activated protein C were identified as risk factors. After initial treatment with intravenous heparin, she was given phenprocoumon and the oral contraceptive was withdrawn. After 4 months she developed subacute liver failure and phenprocoumon was withdrawn immediately. Autoimmune disease, viral hepatitis, toxic causes, and Budd–Chiari syndrome were excluded. Despite symptomatic treatment, she deteriorated further and orthotopic liver transplantation was performed. Histopathology of the explanted liver further excluded ischemic liver cell necrosis and Budd–Chiari syndrome.

Urinary tract

In one case, multisystem abnormalities, including renal insufficiency, were caused by cholesterol embolization. Withdrawal of the anticoagulant resulted in dramatically improved renal function (24).

Skin

Maculopapular rashes with cross-sensitivity between coumarin derivates have been reported (42). Non-pruritic purpuric skin eruptions, histologically presenting as vasculitis and reappearing on rechallenge with warfarin or acenocoumarol, have been described (43).

Skin necrosis
Skin necrosis is a rare but serious complication of oral anticoagulation, seen typically during induction of therapy and occurring in about 0.01–0.1% of patients (44). It is conceivable that this condition is more common than is generally recognized, because many formes frustes can occur, presenting as painful cellulitis without hemorrhagic necrosis. Severe skin necrosis in a patient taking an oral

© 2006 Elsevier B.V. All rights reserved.

anticoagulant was first described in 1943, but not documented in a series of patients until 11 years later (45). The morbidity of this complication is high and, despite treatment, about 50% of patients ultimately require surgical intervention and in some cases skin grafting.

There is convincing evidence that skin necrosis occurs exclusively in patients with excessively severe initial coumarin-induced hypocoagulability (46). As a rule, excessive doses have been given, resulting in severe and rapid reductions in the concentrations of factor VII and protein C (47,48).

Time-course

Familiarity with the clinical and histological pictures is essential, because the earliest signs and symptoms must be recognized if necrosis is to be prevented. The lesion does not usually occur before the second day of treatment or after the second week of treatment has started; most commonly it appears between the third and fifth day (49,50). There are occasionally exceptions to this rule; warfarin-induced skin necrosis can occur several days after discontinuation of warfarin (51) and some cases have been reported during long-term treatment (52,53). However, as a general rule, when skin necrosis occurs after 10 days of warfarin therapy, another cause must be sought.

Presentation

The lesion often appears symmetrically or at a pair of unrelated sites, with a predilection for parts of the body rich in fatty tissue, such as the breasts, abdomen, buttocks, thighs, and calves (54). Feet and toes are seldom affected, male genitalia only rarely (45,55,56), and the vagina and uterus very exceptionally (57).

The lesion begins with an evanescent, painful, slightly raised, more or less clearly demarcated erythematous patch. Histological examination at this stage reveals slight round-cell perivascular infiltration of the corium, edema, and swelling of the capillary endothelium, particularly at the cutis/subcutis boundary (the dermovascular loop), with fibrin thrombi in the small venules. Patches of necrotic fatty tissue, slight polymorphonuclear perivascular infiltration, and patchy interstitial edema as well as bleeding are present at this stage. Very soon, petechiae appear and become confluent within 24 hours, forming purple ecchymotic lesions surrounded by a sharply defined zone of hyperemia. During the next 24 hours, thrombotic occlusion of the veins causes infarction with necrosis of the skin, subcutaneous fat, and sometimes also of deeper anatomical structures. Hemorrhagic blisters characterize the onset of irreversible necrosis of the skin. Laboratory investigation may reveal diffuse intravascular coagulation and even hemolytic anemia (58).

Mechanism

The pathogenesis is still not completely elucidated, but data suggest that transient protein C deficiency may be causative.

Hemorrhagic skin necrosis has been described with all coumarins and indanediones. During the initial phase of oral anticoagulant treatment with these agents, the plasma concentration of protein C falls rapidly in parallel with factor VII. The half-lives of protein C and factor VII are much shorter than those of factors II, IX, and X, and during this initial phase of oral anticoagulation, there is therefore a striking imbalance between procoagulant factors (factors IX, X, and II) and anticoagulant vitamin K-dependent factors (protein C).

Susceptibility factors

Probably because of the sites of predilection, women account for about 80% of cases (49).

Patients with hereditary protein C deficiency (59,60) or acquired functional protein C deficiency (61) are particularly susceptible to the development of hemorrhagic skin necrosis. However, skin necrosis has also been reported in patients with deficiency of protein S (a co-factor for protein C), in patients at high thrombogenic risk linked to a constitutional antithrombin III deficit, and in patients with antiphospholipid antibodies associated with systemic lupus erythematosus (62,63).

Prevention

Prevention of coumarin-induced skin necrosis can be achieved by avoiding initial overshooting of the coumarin effect. A primary cautious initial dosage is mandatory (60), especially in elderly people, who require a smaller dose than younger age groups (one-third less on average) (64). Secondly, adequate patient surveillance is essential. The development of full-blown skin necrosis can usually be prevented by the administration, at the first signs of a developing lesion, of vitamin K_1 (46). If the lesions progress, the oral anticoagulant should preferably be withdrawn.

Prevention of recurrence of coumarin necrosis in patients with protein C deficiency, if treatment is necessary, could consist of transient simultaneous infusion of fresh frozen plasma (leading to a constant concentration of protein C) and heparin both before and at the first time of administration of an oral anticoagulant, associated or not with protein C concentrate (65,66).

Musculoskeletal

Preliminary results that suggested coumarin-associated reduction in bone density have not been confirmed. In a study from the Osteoporotic Fractures Research Group, 6201 postmenopausal women who were either users ($n = 149$) or non-users of warfarin were assessed for fractures and bone mineral density. Over 2 years, the two groups had similar age-adjusted heel and hip bone mineral density measurements. During an average of 3.5 years, non-traumatic, non-vertebral fractures occurred in 10% of warfarin users and 9.3% of non-users (67).

However, bones that fracture during oral anticoagulant therapy require more time to form adequate amounts of callus. This may be explained by an anticoagulant-induced increase in the size of fracture hematoma. However, the observation that warfarin inhibits calcification inside artificial hearts implanted in calves adds to the body of evidence indicating that coumarin depresses not only coagulation factors, but also other (Gla)-containing proteins, for example osteocalcin, a shortage of which may also delay skeletal calcification (68). Osteocalcin is a non-collagenous bone matrix protein containing gamma-carboxyglutamic acid, the synthesis of which is vitamin K-dependent. During oral

© 2006 Elsevier B.V. All rights reserved.

anticoagulation with phenprocoumon, osteocalcin concentrations were lower than in control subjects, whereas the proportion of non-carboxylated osteocalcin was significantly higher than in healthy subjects (69). Since osteocalcin concentrations reflect bone formation, but not bone resorption activity, the reduced serum total osteocalcin concentrations during oral anticoagulation do not necessarily imply that bone loss occurs in these patients. However, reduced bone formation and impaired gamma-carboxylation of osteocalcin in patients treated with phenprocoumon can be clinically important in circumstances such as fracture healing or when there is pre-existing bone disease. It has been suggested that vitamin D regulates the synthesis of vitamin K-dependent bone protein, but no significant effect of the duration of phenprocoumon therapy on parathormone and vitamin D concentrations has been observed (69).

Immunologic

Skin-test reactivity, that is induration and tissue factor generation by monocytes, is reduced by therapeutic doses of oral anticoagulants, but lymphocyte transformation activity is not. This constitutes the rationale for the use of oral anticoagulants in the treatment of immune diseases characterized by fibrin deposition, such as allograft rejection and lupus nephritis (70).

Second-Generation Effects

Pregnancy

Antithrombotic treatment during pregnancy carries a well-established and substantial risk for both mother and fetus (71). The mother has an increased chance of abortion and of perinatal bleeding complications.

Contraceptive counselling must be given to all women who need anticoagulants. Recommendations for the use of anticoagulants during pregnancy have been reassessed in various publications (72–75). In cases of previous venous thrombosis and/or pulmonary embolism, two reasonable approaches are possible. One can either use low-dose heparin throughout pregnancy followed by an oral anticoagulant postpartum for 4–6 weeks, or one can choose to initiate clinical surveillance combined with periodic venous non-invasive tests followed by an oral anticoagulant postpartum for 4–6 weeks. If venous thrombosis occurs, heparin should be used until term, withdrawn immediately before delivery, and then both heparin and an oral anticoagulant can be started postpartum. When pregnancy is planned in patients who are taking long-term oral anticoagulants, the physician should either replace the oral anticoagulant with heparin before conception is attempted, or perform frequent pregnancy tests and substitute oral anticoagulant for heparin when pregnancy is achieved.

In patients with artificial heart valves, management in pregnancy is problematic, because the efficacy of heparin has not been established. Two approaches have been recommended. One can use heparin in a therapeutic dosage throughout pregnancy or use heparin until the 13th week, followed by an oral anticoagulant until the middle of the third trimester, and then heparin until delivery.

Teratogenicity

Vitamin K antagonists, including hydroxycoumarin derivatives and indan-1,3-dione-derived drugs, can be teratogenic and can also induce bleeding in the fetus (71,72,76–79). Adverse fetal outcomes occur in about one-third of pregnancies after either oral anticoagulants or heparin (77). This surprisingly high figure, which is often quoted, should be tempered by the consideration that these data are largely (if not exclusively) derived from women with heart valves taking relatively large doses of warfarin in order to maintain the INR at around 4. Some have suggested that the risk of fetal embryopathy is lower in women taking lower doses for prophylaxis or treatment of deep venous thrombosis (80).

The pattern of teratogenicity of congeners of the vitamin K antagonist group is generally known as warfarin embryopathy, also referred to as the fetal-warfarin syndrome and Conradi–Hünermann syndrome, although the latter term also covers an identical hereditary disorder. The pattern is now considered to represent a specific group of malformations occurring in some fetuses exposed to a vitamin K antagonist during the first trimester, with a critical period during the sixth to twelfth weeks of gestation. The minimal criteria for the diagnosis include either nasal hypoplasia or stippled epiphyses. In severe cases the forehead is bossed and the nose is sunken, with deep grooves between the alae nasi and the tip of the nose; other skeletal deformities can also be present. Half the affected children have upper airway obstruction, secondary to underdeveloped cartilage. Radiography shows stippling (caused by abnormal focal calcification of the epiphyseal regions), preferentially in the axial skeleton, for example the proximal femur, and in the calcanei. Children with milder defects can show catch-up growth, and stippling can disappear after the first year of life; however, in severe cases the nose remains small and sunken. It is questionable whether mental retardation is part of the syndrome, since it has only been observed in cases of exposure for at least two trimesters.

The belief that the incidence of the overt syndrome is of the order of 5% seems to have been confirmed by a review of 186 studies: among 1325 pregnant women who took anticoagulant drugs, 970 were allocated to warfarin and the incidence of warfarin embryopathy was 4.6% (81). However, in a prospective survey of 72 pregnant women with cardiac valve prostheses, the incidence of coumarin embryopathy was 25% in the 12 pregnancies in which heparin was not substituted for acenocoumarol until after the 7th week, and 30% in the 37 pregnancies in which acenocoumarol was given throughout pregnancy. There were no signs of coumarin embryopathy when acenocoumarol was withdrawn from the sixth to the twelfth weeks of gestation and the women were treated instead with heparin (82).

Oral anticoagulation may cause warfarin embryopathy by inhibiting post-translational carboxylation of proteins needed in the normal ossification process. Intensity of treatment appears to be of importance, since there were no cases of warfarin embryopathy in 44 consecutive children of 42 mothers exposed in the first trimester, but who had prothrombin times prolonged by 40–60% (83,84). Experiments in rats in which highly intensive long-term

© 2006 Elsevier B.V. All rights reserved.

anticoagulant therapy produced excessive mineralization disorders favor this causal relation (85).

Another possible adverse reaction is the occurrence of central nervous system anomalies in fetuses exposed to vitamin K antagonists at any time during pregnancy. The anomalies may result from fetal intracerebral hemorrhage with scarring. There are two patterns: one consists of dorsal midline dysplasia, expressed as agenesis of the corpus callosum, Dandy-Walker malformation, midline cerebral atrophy, or possible encephalocele; the other consists of ventral midline dysplasia, characterized by optic atrophy. The patients are never completely normal on follow-up, and the resulting personal and social burdens are considerable. According to a review (81), there were central nervous system anomalies in 26 (2.7%) of 970 pregnancies in which warfarin was used. Neonates can also have hemorrhagic complications if a pregnant mother takes an oral anticoagulant near term. The neonatal liver is immature, and concentrations of vitamin K-dependent coagulation factors are low. Although maternal warfarin concentrations are in the therapeutic range, bleeding can occur in neonates. Warfarin in particular should be avoided beyond 36 weeks of gestation (86).

Other consequences of oral anticoagulation during pregnancy are spontaneous abortion, stillbirth, and premature birth (87).

Lactation

In contrast to heparin, coumarins are secreted into the breast milk, but it has long been known that prothrombin activity in the plasma of neonates whose mothers take coumarins is not significantly reduced (88–90) and that warfarin does not have anticoagulant effects in breast-fed infants when given to nursing mothers (89,91). These conclusions are subject to the reservation that in some of the studies the dose of anticoagulant was low (89). Acenocoumarol-treated breastfeeding mothers can as a rule safely breastfeed their infants (92,93); nevertheless, it is prudent to check the infant's prothrombin time in such cases.

There are differences between infants in their sensitivity to coumarins. Some experts therefore recommended weekly oral administration of 1 mg of vitamin K_1 to the child if the mother is taking a coumarin and breastfeeding (94).

Susceptibility Factors

Genetic factors

There is a strong association between CYP2C9 variant alleles and warfarin dosage requirements (95), and the CYP2C9*2 and CYP2C9*3 variant alleles, which are associated with reduced enzyme activity, have been associated with significant reductions in mean warfarin dosage requirements (96). The possession of a variant allele may also be associated with an increased risk of adverse effects (97). The CYP2C9 genotype is also relevant to acenocoumarol (98). Other polymorphisms, such as those that affect CYP3A4 or CYP1A2, may also be important (96). The molecular basis of warfarin resistance is unclear but could be due to unusually high CYP2C9 activity (pharmacokinetic resistance) or to abnormal activity of vitamin K epoxide reductase (pharmacodynamic resistance) (96).

There is also a rare ala-10 mutation in the propeptide of factor IX, which leads to an increased risk of bleeding when starting anticoagulation with coumarin anticoagulants (99,100).

Age

Age is generally considered as an important susceptibility factor for bleeding during oral anticoagulant treatment (101). The frequency of bleeding was higher in elderly patients in four of five cohort studies of warfarin-related bleeding, published over a 10-year period (29,33). In one study (30), age was the only significant independent risk factor for subdural hemorrhage, apart from the intensity of anticoagulation, whereas age was only of borderline significance for intracerebral hemorrhage. Various explanations could account for the effect of age: co-medication, co-morbidity, increased sensitivity to warfarin, and impaired vascular integrity. Elderly patients, especially those with moderate hypertension, cerebral thrombosis, or a latent gastrointestinal ulcer, should be supervised closely (102).

Other features of the patient

Susceptibility factors for bleeding with oral anticoagulants, apart from age, include (29):

- endogenous coagulation defects
- thrombocytopenia
- hypertension
- cerebrovascular disease
- thyroid disease
- renal insufficiency
- liver disease
- tumors
- cerebrovascular disease
- alcoholism
- a history of gastrointestinal bleeding (peptic ulcer disease alone without past bleeding is not associated with an increased risk of bleeding)
- an inability to adhere to the regimen.

Patients with hypothyroidism and hyperthyroidism should all be carefully monitored because the response is greatly reduced in hypothyroidism and greatly enhanced in hyperthyroidism (103). The increased warfarin sensitivity is said to be related to increased degradation of clotting factors. When the thyroid disease is treated, the susceptibility of these patients to coumarins gradually normalizes.

Since vitamin K is one of the vitamins whose absorption is significantly affected by diarrhea, a raised INR and bleeding can occur during episodes of diarrhea (104). Therefore, patients who have diarrhea or reduced food intake should have their INR evaluated more often and their anticoagulant doses adjusted appropriately.

For oral anticoagulant prophylaxis, the overall number of bleeding patients with organic lesions exceeds 50%. Most have prothrombin times within the usual target range. It is therefore clear that all cases of major (or recurrent mild) internal hemorrhagic complications should be investigated for possible underlying organic disease. In one study, patients with hemorrhagic complications, despite a

© 2006 Elsevier B.V. All rights reserved.

prothrombin time within the target range, were more likely to have an underlying pathological lesion as a direct cause of bleeding than patients whose bleeding occurred when the prothrombin time was above the target range (105).

Drug–Drug Interactions

General

Commonly prescribed drugs can potentiate or antagonize the anticoagulant effect of coumarin drugs in several ways:

- by interfering with the absorption of the drug
- by inhibiting intestinal bacterial production and absorption of vitamin K_2
- by inhibiting the absorption of vitamin K_1 present in food
- by altering the binding of the coumarins to plasma proteins
- by altering the metabolism of the drug by liver microsomes.

Competition for metabolic pathways (for example cytochrome P_{450} isozymes) could lead to an increase in the anticoagulant effect, and/or the pharmacological effects of a drug whose active metabolites are produced by the same metabolic pathway. Hence, any patient taking an oral anticoagulant who has another drug added to or withdrawn from the regimen must have prothrombin time carefully monitored to avoid important changes in the intensity of treatment.

The information on interactions given in Table 1 is mainly based on well-documented prospective studies and, in a few instances, on anecdotal reports. A given interaction may hold for one but not for another coumarin congener.

Alcohol

Alcoholics can drink ethanol in amounts large enough (200 g) to inhibit warfarin clearance as an acute effect. However, daily consumption of ethanol for a period of 3 weeks in the form of wine taken with meals in moderate amounts (28 g/day) or even in liberal amounts (56 g/day) had no effect on the hypoprothrombinemia induced by warfarin (256).

Although long-term alcohol can induce some cytochrome P_{450} isozymes, such as CYP1A1, CYP1A2 (257), CYP2B1, and CYP2E1 (258), these effects are not relevant to the coumarins, which are mostly metabolized by CYP2C9.

A report of ethanol potentiation of aspirin-induced prolongation of bleeding time (259) is of importance, in view of a putative increase, due to alcohol intake, of the hemorrhagic risk accompanying outpatient oral anticoagulation.

Co-amoxiclav

In a case-control study in 300 previously stable outpatients taking phenprocoumon or acenocoumarol with INR values of 6.0 or more and 302 matched controls with INR values within the target range, potentially interacting drugs were predominantly antibacterial drugs (260). A course of co-amoxiclav was associated with a small increase in risk (OR = 2.4; 95% CI = 1.0, 5.5). Of 87 potentially interacting drugs, 45 were not used during the 4-week study and only 15 drugs were used by at least 10 patients. The authors concluded that unless no therapeutic alternative is available, co-amoxiclav should be avoided in patients taking coumarins. If no therapeutic alternative is available, increased monitoring of INR values is warranted to prevent overanticoagulation and potential bleeding complications.

Co-trimoxazole

In a case-control study in 300 previously stable outpatients taking phenprocoumon or acenocoumarol, with INR values of 6 or more, and 302 matched controls with INR values within the target range, potentially interacting drugs were predominantly antibacterial drugs (260). A course of co-trimoxazole was associated with a large increase in the risk of excess anticoagulation (adjusted OR = 24; 95% CI = 2.8, 209). Of 87 potentially interacting drugs 45 were not used during the 4-week study and only 15 drugs were used by at least 10 patients. The authors concluded that unless no therapeutic alternative is available, co-trimoxazole should be avoided in patients taking coumarins. If no therapeutic alternative is available, increased monitoring of INR values is warranted to prevent overanticoagulation and potential bleeding complications.

Danshen

- Potentiation of the effect of warfarin by danshen (the root of *Salvia miltiorrhiza*), a widely used traditional Chinese herbal medicine, particularly for cardiovascular complaints, has been described in a 62-year-old man with a mechanical mitral valve prosthesis (159).

Fluoroquinolones

A series of cases of coagulopathy due to an interaction of warfarin with ciprofloxacin has been extracted from the FDA's Spontaneous Reporting System database, including all cases reported from 1987 to 1997, combined with two of the author's own cases (261). Soon after the introduction of ciprofloxacin in 1987, hemorrhagic events from hypoprothrombinemia were reported in patients taking warfarin. However, several prospective studies of combining ciprofloxacin and other fluoroquinolones with warfarin failed to show a significant change in INR (Table 2). Although it is impossible to estimate the frequency of the ciprofloxacin/warfarin interaction from these or other descriptive data, it can be concluded that potentiation of anticoagulant effect by ciprofloxacin occurs most often in older patients and those taking multiple medications.

Methylprednisolone

Potentiation of the effects of vitamin K antagonists by high-dose intravenous methylprednisolone has been prospectively studied in 10 consecutive patients and 5 controls after the observation of a sharp increase in the International Normalized Ratio (INR) in a patient taking oral anticoagulation after concomitant administration of methylprednisolone (1 g/day for 3 days) (262). The mean INR was 2.8 (range 2.0–3.8) at baseline and increased to 8.0 (5.3–20). The maximum increase in INR occurred after a mean of 93 (29–156) hours. The coumarins taken by these patients were fluindione in eight and acenocoumarol in two. The prothrombin time in the controls

Table 1 Important drug–drug interactions with coumarin anticoagulants

Drug	Effect on anticoagulant response	Mechanism	Comment
Acetylsalicylic acid and other salicylates	Potentiation (106,107) (at doses over 1.5 g/day) even with topical application (108)	Unknown	Avoid concurrent use: can also impair platelet aggregation and cause peptic erosion and ulceration
Allopurinol	Potentiation (109)	Inhibition of microsomal enzymes (110)	Adjust dosage
Aminoglutethimide	Reduction possible (111)	Unknown	Adjust dosage
Aminoglycoside antibiotics	Potentiation possible (112)	Reduced availability of vitamin K (113)	Monitor INR
Amiodarone	Potentiation (114–117)	Reduced warfarin and acenocoumarol clearances (114,117)	Adjust dosage
Anabolic steroids and androgens (C17-alkylated)	Potentiation (118)	Unknown	Adjust dosage
Antacids containing magnesium	Potentiation possible (119) (only documented for dicoumarol)	Increased absorption (119)	Of no practical importance
Azapropazone	Potentiation (120)	Displacement from binding sites on plasma proteins (121); inhibition of metabolism causes peptic ulceration	Avoid concurrent use
Azathioprine	Reduction (122,123)	Unknown	
Azithromycin	Potentiation (124)	Inhibition of microsomal enzymes possible	Monitor INR or avoid concurrent use
Barbiturates	Reduction (125)	Induction of microsomal enzymes (126)	Adjust dosage
Benziodarone	Potentiation (127)	Unknown	Adjust dosage
Bezafibrate	Potentiation (128,129)	Unknown	Adjust dosage
Carbamazepine	Reduction (130,131)	Induction of microsomal enzymes (131)	Adjust dosage
Carbimazole	Reduction (132)	Decreased catabolism of vitamin K-dependent clotting	Adjust dosage
Cetirizine	Potentiation (133)	Unknown	Anecdotal
Cephalosporins	Potentiation possible (134,135)	Inhibition of hepatic vitamin K metabolism (136)	Monitor INR
Chloral hydrate and related compounds	Minor potentiation during initial phase of anticoagulation therapy, not during maintenance therapy (108,137)	Displacement from binding sites on plasma proteins	Usually of no practical importance
Chloramphenicol	Potentiation (138,139) even with ocular administration (140)	Unknown	Adjust dosage Monitor INR
Chlortalidone	Pseudoreduction	Hemoconcentration (141)	No practical importance
Colestyramine	Reduction (142,143)	Reduced absorption and interruption of enterohepatic circulation (142,143)	Adjust dosage: separate dosage of these two drugs by a long time interval
Cimetidine	Potentiation (144); not documented for phenprocoumon (145)	Stereoselective inhibition of warfarin metabolism (146)	Adjust dosage
Ciprofloxacin	Potentiation possible (147,148)	Unknown	Monitor INR
Cisapride	Potentiation (149)	Inhibition of microsomal enzymes possible	Monitor INR
Clarithromycin	Potentiation (150–152)	Inhibition of microsomal enzymes possible	Monitor INR or avoid concurrent use
Clofibrate	Potentiation (153)	Unknown	Adjust dosage
Co-trimoxazole	Potentiation (154,155)	Unknown	Adjust dosage
Cyclophosphamide	Reduction possible (156)	Unknown	Anecdotal
Ciclosporin	Reduction possible (157)	Unknown	Adjust dosage
Danazol	Potentiation (158)		
Danshen	Potentiation (159)	Unknown	Anecdotal
Dicloxacillin	Reduction (160)	Unknown	Monitor INR
Diflunisal	Potentiation possible (161)	Can impair platelet aggregation and cause peptic ulceration	Avoid concurrent use

© 2006 Elsevier B.V. All rights reserved.

Drug	Effect on anticoagulant response	Mechanism	Comment
Disulfiram	Potentiation (162,163)	Inhibition of microsomal enzymes (162)	Adjust dosage
Erythromycin	Potentiation possible (164,165)	Reduced warfarin clearance (166)	Monitor INR
Etacrynic acid	Potentiation possible (167)	Unknown	Anecdotal
Fenofibrate	Potentiation (168)	Displacement from binding sites on plasma proteins	Adjust dosage Monitor INR
Floctafenine	Minor potentiation (169)	Unknown	Monitor INR
Fluconazole	Potentiation possible (170–172)	Unknown	Monitor INR
Fluorouracil	Potentiation possible (173)	Unknown	Monitor INR
Fluoxetine	Potentiation (174)	Unknown	Adjust dosage or avoid concurrent use
Flurbiprofen	Potentiation possible (175,176)	Unknown	Monitor INR
Fluvastatin	Potentiation possible (177)	Unknown	Monitor INR
Furosemide	Reduction (178)	Hemoconcentration	Monitor INR
Ginseng	Reduction (179)	Unknown	Anecdotal
Glucagon	Potentiation (180)	Unknown	Avoid concurrent use
Glucocorticoids	Ambiguous (181,182)		No practical importance
Glutethimide	Reduction (183)	Induction of microsomal enzymes (183)	Adjust dosage
Griseofulvin	Reduction (184)	Unknown	Adjust dosage
Haloperidol	Reduction possible (185)	Unknown	Anecdotal
Indometacin	Potentiation possible (186)	Unknown	Monitor INR
Isoniazid	Potentiation possible (187)	Unknown	Anecdotal
Itraconazole	Potentiation possible (188)	Unknown	Monitor INR
Ketoconazole	Potentiation possible (189)	Unknown	Monitor INR
Lovastatin	Potentiation possible (190)	Unknown	Monitor INR
Mefenamic acid	Potentiation possible (191)	Fibrinolysis	No clinical importance
Mercaptopurine	Reduction (192)	Unknown	Adjust dosage
Mesalazine	Reduction (193,194)	Unknown	Monitor INR
Metronidazole	Potentiation (195)	Stereoselective inhibition of metabolism (warfarin) (195)	Adjust dosage
Miconazole	Potentiation possible (196–198) even with topical application (197,199,200)	Inhibition of metabolism (201)	Avoid concurrent use or contraindicated
Nafcillin	Reduction possible (202,203)	Unknown	Anecdotal
Nalidixic acid	Potentiation possible (204,205)	Unknown	Anecdotal
Norfloxacin	Potentiation (147)	Unknown	Monitor INR
Nutritional formulations	Reduction (206)	Increased availability of vitamin K (206)	Adjust dosage
Ofloxacin	Potentiation (207)	Unknown	Monitor INR
Omeprazole	Potentiation (208)	Unknown	Monitor INR
Oral contraceptives	Ambiguous (209,210)	Unknown	No practical importance
Paracetamol	Potentiation during long-term administration (211,212)	Unknown	Use paracetamol for limited periods Monitor INR
Phenylbutazone	Potentiation (213)	Displacement from binding sites on plasma proteins; stereoselective inhibition of metabolism (warfarin); causes peptic ulceration (214,215)	Avoid concurrent use
Phenytoin	Reduction (216); warfarin may give potentiation (217,218)	Unknown	Adjust dosage
Piracetam	Potentiation possible (219)	Unknown	Anecdotal
Piroxicam	Potentiation (220)	Unknown	Monitor INR
Pravastatin	Potentiation (221)	Unknown	Monitor INR
Proguanil	Potentiation (222)	Unknown	Monitor INR
Propafenone	Potentiation (223)	Unknown	Monitor INR
Propranolol	Potentiation (224)	Inhibition of metabolism	Monitor INR
Quinidine	Potentiation possible (225,226)	Pharmacodynamic interaction	Monitor INR

Table 1 Continued

Drug	Effect on anticoagulant response	Mechanism	Comment
Ranitidine	Possible potentiation at high dosages (227)	Unknown	Monitor INR if high dosage
Rifampicin	Reduction (228)	Induction of microsomal enzymes (229,230)	Adjust dosage
Ritonavir	Reduction (231)	Unknown	Monitor INR
Saquinavir	Potentiation (232)	Inhibition of microsomal enzymes	Monitor INR
Simvastatin	Potentiation (233,234)	Unknown	Adjust dosage Monitor INR
Spironolactone	Pseudoreduction (235)	Hemoconcentration	No practical importance
Sucralfate	Reduction possible (236,237)		Anecdotal
Sulfinpyrazone	Potentiation possible (238–241) (not documented with phenprocoumon) (240)	Inhibition of microsomal enzymes (242)	Adjust dosage
Sulfonamides	Potentiation possible (243,244)	Unknown	Anecdotal
Sulindac	Potentiation possible (245,246)	Unknown	Monitor INR
Tamoxifen	Potentiation possible (247,248)	Unknown	Adjust dosage
Tetracyclines	Potentiation possible (139,154)	Reduced availability of vitamin K (113)	Monitor INR
Thiouracils	Reduction	Reduced catabolism of vitamin K-dependent clotting factors	Adjust dosage
Thyroid hormones	Potentiation (148,249)	Increased catabolism of vitamin K-dependent clotting factors (132)	Adjust dosage
Tramadol	Potentiation possible (250,251)	Inhibition of microsomal enzymes	Monitor INR
Ubidecarone	Reduction (252)	Unknown	Adjust dosage
Vitamin E	Potentiation possible (253)	Unknown	Anecdotal
Zafirlukast	Potentiation possible (254)	Unknown	Monitor INR
Zileuton (255)	Potentiation	Unknown	Adjust dosage Monitor INR

Table 2 Prospective interaction studies of fluoroquinolones with warfarin

Study design	N	Source of subjects	Drug	Coagulation effect	Reference
Single arm	9	Warfarin clinic	Ciprofloxacin	None	(264)
Single arm	16	Warfarin clinic	Ciprofloxacin	*R*-warfarin	(265)
Placebo-controlled[a]	36	Warfarin clinic	Ciprofloxacin	*R*-warfarin	(266)
Randomized crossover[b]	6	Healthy volunteers	Enoxacin	*R*-warfarin	(267)
Randomized crossover[c]	10	Healthy volunteers	Ofloxacin	None	(268)
Single arm	7	Healthy volunteers	Ofloxacin	None	(269)
Single arm	10	Healthy volunteers	Temafloxacin	None	(270)

[a]Randomized, double-blind, placebo-controlled study
[b]Randomized, double-blind, placebo-controlled, multicenter study
[c]Randomized, two-way, crossover study

remained stable. A similar rise in INR was described in two patients with multiple sclerosis taking warfarin (263).

The mechanism of the interaction of methylprednisolone with oral anticoagulants has not been elucidated, but it might be due to inhibition of anticoagulant catabolism. In the three patients in whom the authors assayed fluindione concentrations, these increased in parallel with the INR. The administration of high-dose methylprednisolone to patients taking oral anticoagulants is not rare; daily monitoring of INR or even reducing the anticoagulant dose before administering methylprednisolone is advised.

Miconazole

Interactions between coumarins and miconazole have been reported, although the mechanism of the interaction is not known. There have been two separate reports of potentiation of the anticoagulant effect of acenocoumarol by non-systemic administration of miconazole. Three patients taking long-term acenocoumarol who used miconazole gel for oral candidiasis had significant rises in INR (197). In two other patients vaginal miconazole potentiated the anticoagulant effect of acenocoumarol (198).

NSAIDs

The COX-2 selective non-steroidal anti-inflammatory drug celecoxib did not alter the pharmacokinetics or the hypoprothrombinemic effect of warfarin in 24 healthy subjects (30). However, there have been at least two reports of increased INR in patients taking stable warfarin therapy and celecoxib (31,101).

Another COX-2-selective non-steroidal anti-inflammatory drug, rofecoxib, increased plasma concentrations of the biologically less active isomer, *R*(+) warfarin, which accounted for an approximately 8% increase in INR at steady state in healthy volunteers (33).

Standard monitoring of INR in patients taking warfarin should be performed when therapy with celecoxib or rofecoxib is begun or changed.

Paracetamol

In a prospective, case-control study, designed to determine causes of INRs over 6.0 in an outpatient anticoagulant unit, there was a clear dose-dependent association between the use of paracetamol (acetaminophen) and having an INR greater than 6.0 (212). The authors studied 93 patients with INRs over 6.0 (cases) and 196 patients with INRs of 1.7–3.3 (controls) during warfarin therapy. The likelihood of an INR greater than 6.0 increased from an odds ratio of 3.5 for doses of 2275–4549 mg per week, to 6.9 for doses of 4550–9099 mg per week, to a 10-fold increase at a dose of over 9100 mg per week.

Paracetamol also potentiates the effects of acenocoumarol (211) and although a study with phenprocoumon showed no interaction (271), the study was too small and not well designed to detect an effect of the sort that has been shown in case-control studies.

Ribavirin

Inhibition of the effect of warfarin by ribavirin has been described.

- In a 61-year-old man, who was taking long-term warfarin after a heart valve replacement, the dose of warfarin had to be increased by 40% after the introduction of ribavirin for chronic hepatitis C; the inhibition of the effect of warfarin was reproduced on rechallenge (272).

The mechanism of this effect was not clear.

Ritonavir

Inhibition of the effect of acenocoumarol by ritonavir has been described.

- A 46-year-old man with two prosthetic heart valves taking acenocoumarol started to take ritonavir 600 mg/day. Despite a progressive increase in the dose of acenocoumarol to three times the original dose, it was impossible to achieve a therapeutic INR, and the ritonavir was withdrawn (273).

The authors proposed that ritonavir had induced CYP1A2, CYP1A4, and CYP2C9/19 activity, leading to increased metabolism, at least of acenocoumarol. However, this effect was the opposite of what was expected, since ritonavir is a potent inhibitor of most hepatic isoenzymes.

Salicylates

Salicylates can interact with warfarin in different ways. They displace warfarin from albumin binding sites, and this can result in a transient increase in anticoagulant activity, which is usually clinically unimportant. They can also cause peptic ulceration and reduce platelet aggregation, making bleeding more likely and slower to stop when it occurs.

There was a rise in INR from 2.8 to 12 when a topical pain-relieving gel containing methylsalicylate was applied to the knees of a 22-year-old white woman taking stable warfarin anticoagulation (274).

Other similar cases have been reported (275).

Food–Drug Interactions

Cranberry juice

Cranberry juice has been reported to enhance the action of warfarin (276).

- After a chest infection, a man in his 70s had a poor appetite for 2 weeks and ate next to nothing, taking only cranberry juice as well as his regular drugs (digoxin, phenytoin, and warfarin) (277). Six weeks later his international normalised ratio was over 50, having previously been stable. He died of gastrointestinal and pericardial haemorrhage. He had not taken any over-the-counter preparations or herbal medicines, and he had been taking his drugs correctly.

The Committee on Safety of Medicines has received several other reports through the yellow card reporting scheme about a possible interaction between warfarin and cranberry juice. In one case, this effect was suggested to have been due to contamination with salicylic acid, which displaces warfarin from protein binding sites (278).

Smoking

Cigarette smoking altered the clearance and apparent volume of distribution of warfarin, although the net effect on anticoagulant activity was negligible both in volunteers (279) and patients (280).

Monitoring Therapy

There are no clear guidelines about how often the INR should be measured in patients taking coumarins. However, it should be done quite frequently at the start of therapy when the risk of bleeding is higher (32). Monitoring anticoagulant therapy is greatly improved by the use of anticoagulation clinics or anticoagulation management services in which the management is conducted by registered nurses, pharmacists, or physicians using dosage adjustment protocols developed by experts in the field (281).

COX-2 inhibitors

See also Individual agents

General Information

The cyclo-oxygenase (COX) that is responsible for prostaglandin synthesis exists in two isoforms, COX-1 and COX-2, which differ in their structure, regulation, expression, and function. COX-1 is expressed normally in a constant amount in almost all body tissues and produces prostaglandins important for the maintenance of normal homeostasis. In particular, among other important functions, they help to protect the gastrointestinal mucosa against ulceration and regulate renal function and platelet activity. COX-1 appears to be largely unaffected by inflammatory stimuli. In contrast, the COX-2 isoform is constitutively expressed only in the brain, in bone (associated with osteoblast activity), in the female reproductive tract (associated with both the ovulatory cycle and implantation of fertilized ova), and in the kidney, where it may play an important role in regulating renal function. In many other cells COX-2 is expressed at very low levels or is undetectable, but it is readily induced by inflammatory cytokines, mitogens, and endotoxins. Therefore, prostaglandins generated by COX-2 mediate pain and inflammation in many tissues and probably also have a role in renal, brain, and reproductive physiology, and in tissue repair (1–4).

Traditional NSAIDs inhibit both COX-1 and COX-2, providing benefit at sites of inflammation, but at the cost of potential adverse effects related to COX-1 inhibition, particularly in areas such as the gastrointestinal mucosa, platelets, and the kidney. The development of a drug that inhibits only COX-2 would offer the promise of relieving pain and inflammation without some, if not all, of these adverse effects. However, the concept that selective inhibition of COX-2 is only a positive event and inhibition of COX-1 a bad one may be simplistic, as it is flawed by many experimental data that have also implicated COX-2 as an integral component in the maintenance of physiological homeostasis (3). In particular, COX-2 may reduce inflammation by generating anti-inflammatory prostanoids (5); COX-2, like COX-1, may be present in normal gastric mucosa (6,7) and can play a physiological role there in defense mechanisms (8,9), and there is evidence that prostaglandins derived from COX-2 may be important in the healing of gastric ulcers (9–12). Furthermore, COX-2 inhibition alone may be insufficient to resolve inflammation and pain (13), suggesting that COX-1 inhibition may play a role in reducing inflammation as well (14). Although the relevance of these experimental observations to the possible beneficial role of COX-2 activity is uncertain, they cannot be simply dismissed.

Nearly all of the traditional NSAIDs are predominantly COX-1-selective. In fact, only two of them, meloxicam and nimesulide (1,2), have been shown to have some COX-2 selectivity in humans. Two other NSAIDs, etodolac and nabumetone, may be COX-2 preferential inhibitors, but the evidence is less convincing than for meloxicam or nimesulide. Unfortunately, despite their wide use, clinical and epidemiological evidence that supports the claim of better tolerability of these preferential inhibitors with respect to other NSAIDs, is scanty and even controversial (1,4). Furthermore, for both meloxicam and nimesulide there are data consistent with reduced COX-2 selectivity at high doses, those usually used in clinical practice. These considerations have prompted research for more selective COX-2 inhibitors, and three compounds, celecoxib, parecoxib, and rofecoxib, have become available. These compounds are much more selective than previous preferential inhibitors and they have no effect on COX-1 (COX-1 sparing drugs) over the whole range of doses used and concentrations achieved in clinical use. In particular, they have been shown in humans to spare gastric COX-1 to a much greater extent than traditional NSAIDs.

© 2006 Elsevier B.V. All rights reserved.

Is there convincing evidence that COX-2-selective NSAIDs offer a distinct therapeutic advantage over non-selective ones? To prove the usefulness of these compounds, clinical studies should show:

- whether the COX-2 selective inhibitors are as effective as older NSAIDs in the relief of pain and/or inflammation;
- whether in the effective dosage range there is evidence of less damage to the mucosa of the upper gastrointestinal tract than with conventional NSAIDs;
- whether there are any effects on platelet in effective doses;
- whether unexpected adverse drug reactions compromise the safety of these compounds.

As far as the last of these criteria is concerned, the finding that rofecoxib increases the risk of cardiovascular disease (heart attacks and strokes) during long-term therapy has led to a reappraisal of the role of the COX-2 inhibitors. Furthermore, both rofecoxib and valdecoxib have been withdrawn by their manufacturers, the former because of its adverse cardiovascular effects and the latter because of an increased risk of cardiovascular events after coronary artery bypass surgery and reports of potentially fatal skin reactions.

Clinical studies

Both celecoxib and rofecoxib have been evaluated in large randomized trials lasting from weeks to 1 year, for the relief of the signs and symptoms of osteoarthritis or rheumatoid arthritis in adults (1,15–21). In all of these studies both compounds have been shown to be more effective than placebo and at least as effective as traditional NSAIDs (that is ibuprofen, diclofenac, nabumetone, naproxen). However, there is less information about their efficacy as analgesics. A few randomized, double-blind trials have shown that both compounds are more effective than placebo; rofecoxib was as effective as non-selective NSAIDs (ibuprofen, naproxen) in relieving the pain of osteoarthritis or after dental surgery, but celecoxib was less effective (22–26). Rofecoxib was also analgesic in patients with primary dysmenorrhea (27). However, there are no published data on the usefulness of COX-2-selective NSAIDs in other types of acute pain, such as that related to acute gout, migraine, cancer, or biliary or ureteric colic.

General adverse effects

Although the scientific literature has been flooded by articles and reviews on the use of selective COX-2 inhibitors (coxibs), the safe prescribing and use of these compounds is controversial (28–31).

COX-2 selectivity may be a double-edged sword. Because the cardiovascular risk outweighs the gastrointestinal risk in adults with rheumatoid arthritis or osteoarthritis, the harm would outweigh the benefits in most clinical settings. This means that the total number of serious adverse events would be increased by COX-2-selective NSAIDs compared with non-selective NSAIDs. COX-2 selectivity, which is an appealing theoretical concept, might be a clinical failure (30).

Much information on celecoxib and rofecoxib has come from two large pivotal randomized clinical trials, the Celecoxib Long-term Arthritis Safety Study (CLASS) and Vioxx Gastrointestinal Outcomes Research (VIGOR) studies, in which the efficacy and safety of the two coxibs and various non-selective NSAIDs were compared (32,33).

Summary

The COX-2-selective inhibitors are as efficacious as traditional NSAIDs in treating inflammation and pain due to osteoarticular diseases. However, there are questions to be addressed before COX-2-selective inhibitors can be considered to be definitely safer than traditional NSAIDs (4). Among these questions the most important relate to the possibility that COX-2 inhibitors may cause complicated ulceration in some subgroup of patients and may retard ulcer healing in others. Therefore, whether the COX-2 inhibitors in place of non-selective NSAIDs will prove to be cost-effective by reducing ulcer-related morbidity remains to be demonstrated. Moreover, it is likely that such drugs can cause the same renal problems as traditional NSAIDs do. Finally, the effect of COX-2 inhibitors on the incidence of vascular disease will need strict scrutiny, since vascular disease is a commoner cause of death than ulcer perforation or bleeding and since some of them clearly increase the long-term risk of heart attacks and strokes. Only their continuing use and postmarketing surveillance studies will demonstrate their strengths and weaknesses with respect to non-selective NSAIDs.

Organs and Systems

Cardiovascular

Prothrombotic effects

COX-2 inhibitors inhibit the synthesis of prostacyclin in the vascular wall but not platelet thromboxane production. They could therefore theoretically increase the risk of cardiovascular events by shifting the hemostatic balance toward a prothrombotic state. However, it is not clear that theory has much impact on reality.

Information about this topic comes from the two large studies, CLASS and VIGOR, from a pooled cardiovascular safety analysis using individual patient data derived from all rofecoxib phase IIb to V trials conducted by the manufacturer that lasted at least 2 weeks, and from the adverse events reporting system in the USA (34). As a result of these and other studies the COX-2 inhibitors, rofecoxib and valdecoxib, have been voluntarily withdrawn from the market by their manufacturers, and other COX-2 inhibitors are under scrutiny.

In VIGOR, rofecoxib 50 mg/day was associated with a higher rate of non-fatal myocardial infarction (0.4%) than the non-selective COX-2 inhibitor naproxen 500 mg bd (0.1%) (RR = 0.2; CI = 0.1, 0.7) (33). In CLASS there was no difference in the rates of myocardial infarction in patients taking celecoxib (0.5%) and those taking ibuprofen or diclofenac (0.4%). However, the protocols of the two studies differed substantially with respect to the use of aspirin. In VIGOR, the patients were not allowed to take aspirin or any other antiplatelet drug, while in

© 2006 Elsevier B.V. All rights reserved.

CLASS one-fifth of the patients took aspirin. A re-analysis of CLASS for cardiovascular thromboembolic events, including myocardial infarction, stroke, cardiovascular deaths, and peripheral events, showed no significant increase with celecoxib versus NSAIDs (35).

The results of VIGOR might be explained by a significant prothrombotic effect of rofecoxib and/or an antithrombotic effect of naproxen, which may have a significant antiplatelet effect. To clarify this, the annualized myocardial infarction rates in both VIGOR and CLASS were compared with those found in placebo-treated patients with similar cardiac risk factors enrolled in three meta-analyses of four aspirin primary prevention trials (34,36). The analysis showed 0.24 and 0.30% increases over placebo in cardiovascular events for rofecoxib and celecoxib respectively, suggesting a prothrombotic potential of both COX-2 inhibitors. However, these results have been heavily criticized (37–43), because of many potential pitfalls in the comparisons of patient populations in different trials. The results from a recently reported pooled analysis of individual patient data combined across rofecoxib phase IIb to phase V trials seem to be more reliable (44). Cardiovascular events were assessed across 23 studies. Comparisons were made between patients taking rofecoxib and those taking placebo, naproxen, or other non-selective NSAIDs (diclofenac, ibuprofen, and nabumetone). The major outcome measure was the combined end-point used by the Anti-platelet Trialist Collaboration, which includes cardiovascular death, hemorrhagic death, death of unknown cause, non-fatal myocardial infarction, and non-fatal stroke. More than 28 000 patients, representing more than 14 000 patient-years at risk, were analysed. The relative risk for an end-point was 0.84 (95% CI = 0.51, 1.38) when comparing rofecoxib with placebo; 0.79 (95% CI = 0.40, 1.55) when comparing rofecoxib with non-selective NSAIDs; and 1.69 (95% CI = 1.07, 2.69) when comparing rofecoxib with naproxen. These data provide no evidence for an excess of cardiovascular events for rofecoxib relative to either placebo or the non-selective NSAIDs that were studied. Instead, the difference between rofecoxib and naproxen showed that naproxen was associated with a reduced risk of cardiovascular events.

The cardiovascular results in VIGOR may have occurred simply by chance, given the low number of events, or because naproxen may have a cardioprotective effect similar to that of aspirin, or because rofecoxib 50 mg/day could have prothrombotic effects, especially in the absence of concomitant COX-1 inhibition in patients at increased risk of cardiovascular thromboembolic events. Because there was no untreated group in VIGOR, we do not know whether this finding suggests a protective effect of naproxen or a harmful effect of rofecoxib. All three explanations are plausible, and they are not mutually exclusive.

It has been suggested that the increase in thrombotic cardiovascular events in rofecoxib-treated patients probably represents the antiplatelet effect of naproxen (34,45,46). Naproxen has a long pharmacodynamic half-life and inhibits platelet aggregation by 88% for up to 8 hours (47).

In VIGOR (30,33), the incidence of confirmed thrombotic cardiovascular events was 0.6% higher with rofecoxib than with naproxen (RR = 2.4; 95% CI = 3.9, 4.0).

Some data may help to answer the important question of whether the relative difference in the incidence of myocardial infarction in VIGOR was due to a harmful effect of rofecoxib or a beneficial effect of naproxen. Although contrasting data have been published (48), the hypothesis that naproxen has a cardioprotective effect has gained wider support (49). Only one of the four most recently published studies negated a potential cardioprotective effect of naproxen.

However, an analysis of FDA data suggested an increase in serious cardiac events with celecoxib (30). The incidence of serious cardiac adverse events (myocardial infarction, combined anginal events, and atrial dysrhythmias) was 0.6% higher with celecoxib than with other NSAIDs (RR = 1.55; CI = 1.04, 2.30). The reasons for these inconsistencies are not clear.

In an 11-year observational study in new users of non-selective, non-aspirin NSAIDs (n = 181 441) and an equal number of non-users there was no evidence of a protective effect of naproxen (50). During 532 634 person-years of follow-up there were 6382 cases of serious coronary heart disease (11.9 per 1000 person-years). Multivariate-adjusted rate ratios for current and former use of non-aspirin NSAIDs were 1.05 (95% CI = 0.97, 1.14) and 1.02 (0.97, 1.08) respectively. Rate ratios for ibuprofen, naproxen, and other NSAIDs were 1.15 (1.02, 1.28), 0.95 (0.82, 1.09), and 1.03 (0.92, 1.16) respectively. There was no protection in long-term users with uninterrupted use; the rate ratio among current users with more than 60 days of continuous use was 1.05 (0.91, 1.21). When naproxen was directly compared with ibuprofen, the rate ratio in current users was 0.83 (0.69, 0.98). This study therefore seems to have shown no cardioprotective effect of naproxen. However, the study had a number of important limitations, including: lack of information about some important confounders (smoking, obesity), possible exposure misclassification, and lack of information about over-the-counter use of aspirin.

Opposite evidence has emerged from three case-control studies from the USA, Canada, and the UK, which showed that the rates of myocardial infarction in patients taking naproxen were lower than in patients not taking any NSAIDs (51,52) and those taking other NSAIDs (53).

In the first study, 4425 patients hospitalized with acute myocardial infarction who used NSAIDs were compared with 17 700 controls in a large health-care database in the USA (51). Multivariate models were constructed to control for potential confounders. A quarter of the cases and controls had also filled a prescription for an NSAID in the 6 months before the study. Overall, the NSAID users had the same risk of acute myocardial infarction as non-users, but naproxen users had a significantly lower risk of acute myocardial infarction compared with those who were not taking NSAIDs (adjusted OR = 0.84; 95% CI = 0.72, 0.98). The cardioprotective effect of naproxen was very modest compared with aspirin (a 44% reduction in the risk of acute myocardial infarction in the Physician Health Study (54)).

The second study was a case-control study sponsored by Merck & Co (the manufacturers of celecoxib), in which the risk of acute thromboembolic cardiovascular events among 16 937 patients aged 40–75 years with rheumatoid arthritis using naproxen was examined using the British General Practice Research Database (52). Each patient with a first

© 2006 Elsevier B.V. All rights reserved.

thromboembolic event ($n = 809$: 435 myocardial infarctions, 347 strokes, 27 sudden deaths) was matched with four controls. The results suggested that patients with rheumatoid arthritis who currently use naproxen have a significantly lower risk of thromboembolic events relative to those who have not used naproxen in the past year (RR = 0.61; 0.39, 0.94). However, the risk was not lower with previous use of naproxen, suggesting that any effect of naproxen is likely to be short-lived. Moreover, the significantly lower risk of myocardial infarction with current naproxen was not found when myocardial infractions were analysed separately (RR = 0.57; 0.3, 1.06). There was no protective effect for thromboembolic events with current use of non-naproxen NSAIDs.

The third study was also sponsored by Merck & Co and was designed to examine the association between the use of naproxen and other non-selective NSAIDs and hospitalization for acute myocardial infarction (53). In a database of 14 163 patients aged 65 years or older who were hospitalized for acute myocardial infarction and an equal number of age-matched controls, concurrent exposure to naproxen had a protective effect against myocardial infarction compared with the other non-selective non-aspirin NSAIDs (RR = 0.79; CI = 0.63, 0.99). This effect was present only with concurrent naproxen exposure and was stronger in long-term users. However, this study also had several limitations: some important risk factors, such as smoking and obesity, could not be assessed, patients who died of myocardial infarction before reaching the hospital were not included, and there was uncertainty about concurrent use of over-the-counter drugs, especially aspirin.

In conclusion, although these three studies suggest that patients who take naproxen have a lower incidence of myocardial infarction than those who take other NSAIDs or who do not take NSAIDs, the data do not provide definitive evidence that naproxen is cardioprotective. The data therefore raise a cautionary flag about the risk of severe cardiovascular events with COX-2 inhibitors and again call for more studies.

Hypertension

The shift in hemostatic balance toward a prothrombotic state might not be the only mechanism by which COX-2 inhibitors could increase the risk of cardiovascular adverse effects. In fact, non-selective NSAIDs can raise blood pressure and antagonize the hypotensive effect of antihypertensive medications to an extent that may increase hypertension-related morbidity (55,56). The problem is clinically relevant, as arthritis and hypertension are common co-morbid conditions in elderly people, requiring concurrent therapy.

Information on the effect of COX-2-selective inhibitors on arterial blood pressure is scanty. In VIGOR, more patients developed hypertension with rofecoxib than naproxen. For rofecoxib, the mean increase in blood pressure was 4.6/1.7 mmHg compared with a 1.0/0.1 mmHg increase with naproxen (34). Previous work has shown that a 2 mmHg reduction in diastolic blood pressure can result in about a 40% reduction in the rate of stroke and a 25% reduction in the rate of myocardial infarction (57). The effect of celecoxib on blood pressure was evaluated in a post hoc analysis using the safety database generated during the celecoxib clinical development program in more than 13 000 subjects (58). The incidence of hypertension after celecoxib was greater than that after placebo but similar to that after non-selective NSAIDs. Hypertension and exacerbation of pre-existing hypertension occurred, respectively, in 0.8 and 0.6% of patients. Furthermore, there was no evidence of interactions between celecoxib and other antihypertensive drugs.

The safety profiles of celecoxib (200 mg/day) and rofecoxib (25 mg/day) have recently been compared in a 6-week, randomized, parallel-group, double-blind trial in 810 patients with osteoarthritis aged 65 years or over taking antihypertensive drugs (59). The primary endpoints were edema and changes in systolic and diastolic blood pressures, measured at baseline and after 1, 2, and 6 weeks. Systolic blood pressure rose significantly in 17% of rofecoxib-treated patients ($n = 399$) compared with 11% of celecoxib-treated patients ($n = 411$), a statistically significant difference, at any time in the study. Diastolic blood pressure rose in 2.3% of rofecoxib-treated patients compared with 1.5% of celecoxib-treated patients, a non-significant difference. At week 6, the change from baseline in mean systolic blood pressure was +2.6 mmHg for rofecoxib compared with –0.5 mmHg for celecoxib, a highly significant difference. Nearly twice as many rofecoxib-treated than celecoxib-treated patients had edema. Despite some limitations, this study provides some evidence that COX-2-selective inhibitors may differ in their ability to alter arterial blood pressure.

Cardiac dysrhythmias

There have been reports of celecoxib-associated torsade de pointes in three patients who had never had any complaints before celecoxib administration; the dysrhythmia did not recur after the drug was withdrawn (60). However, all three patients had cardiac abnormalities that might have predisposed them to the development of torsade de pointes, and the follow-up period was too short to evaluate possible spontaneous recurrence. The hypothesis that celecoxib is dysrhythmogenic requires confirmation.

Respiratory

Most people tolerate aspirin well, but not patients with asthma, of whom there is a subgroup in whom aspirin precipitates asthmatic attacks (61,62). This is a distinct clinical syndrome, called aspirin-induced asthma, which affects about 10% of adults with asthma (63). Aspirin-induced asthma is usually accompanied by naso-ocular symptoms and can be triggered not only by aspirin, but by several NSAIDs, a fact that makes immunological cross-reactivity most unlikely. The propensity of an NSAID to precipitate an attack of asthma is probably related to inhibition of COX (63). There is evidence that potent inhibitors of COX-1 (such as ibuprofen, indometacin, and naproxen) are more likely to precipitate bronchoconstriction than NSAIDs that inhibit COX-2 preferentially (such as meloxicam and nimesulide) (64,65). A widely accepted hypothesis is that in patients with asthma and aspirin intolerance, NSAID-induced COX inhibition results in increased products from the 5-lipoxygenase pathway, the leukotrienes, which are both potent bronchoconstrictors and also inducers of

© 2006 Elsevier B.V. All rights reserved.

mucous hypersecretion and airway edema. The leukotrienes implicated in aspirin intolerance are cysteinyl leukotrienes (61,63), but leukotriene release is probably not the only pathogenic mechanism.

The hypothesis that in aspirin-induced asthma the attacks are triggered by inhibition of COX-1 and not COX-2 has been tested in three small studies, two of which were double-blind and placebo-controlled (66–68). In the first study (66) 12 patients with aspirin-induced asthma were challenged with increasing doses of rofecoxib (1.25–25 mg/day for 5 days); no patients had any adverse symptoms, and biochemical markers that reflect intolerance to aspirin in asthma (urinary leukotriene E4 and 9α-11β-PGF-2) were unchanged.

In the second study, 60 aspirin-sensitive asthmatics were challenged with oral rofecoxib (12.5 and 25 mg/day for 2 days) (67). There were no signs or symptoms of asthma in any patient and no reductions in FEV_1.

In the third study, 27 patients with stable chronic asthma in whom inhalation of lysine aspirin caused a 20% fall in FEV_1 were challenged with increasing doses of oral celecoxib (from 10 to 200 mg/day); they do not develop bronchoconstriction or other extrapulmonary reactions (68).

So, is the safety of COX-2 inhibitors in patients with aspirin-induced asthma sufficiently well documented? Avoidance of NSAIDs is crucial in patients with asthma who have aspirin sensitivity, and hitherto two alternative analgesic options have been available: paracetamol and non-acetylated salicylates. Paracetamol is a generally safe substitute; however, it is a weak COX inhibitor and, albeit very rarely, patients who are sensitive to aspirin have an adverse reaction to high-dose paracetamol (69). Choline magnesium salicylate and salicylic acid are also weak COX inhibitors and should therefore be used with care in these patients. The results of the above-mentioned studies suggest that rofecoxib and celecoxib can be taken safely by patients with aspirin-induced asthma. However, this conclusion must be treated with caution, as only a few patients were studied and this does not exclude COX-2 inhibitors from participating in other types of reactions, including immune recognition after prior treatment.

Nervous system

Aseptic meningitis is a rare complication of NSAID therapy. Five serious cases of aseptic meningitis associated with rofecoxib have been reported (70).

- A 55-year-old woman who had taken rofecoxib for 1 month reported numbness and tingling on the left side of the tongue and left hand (71). The association between paresthesia and rofecoxib was supported by the time-course of the reaction and resolution after withdrawal.

Because this patient was using other medications (paroxetine, zolpidem, and sumatriptan), which can have a similar effect, this report requires confirmation.

Hematologic

Platelets have only the COX-1 isoform for generating thromboxane to precipitate platelet aggregation. Therefore, selective COX-2 inhibitors have no effect on platelet aggregation or bleeding time (3,72). On the other hand, COX-2 plays a role in the production of endothelial PGI2. In vitro studies have shown that COX-2 expression is up-regulated in endothelial cells by laminar shear stress (73). Furthermore, selective COX-2 inhibitors reduce systemic PGI-2 production in healthy volunteers (74). The clinical implications of these observations are unknown. In theory, COX-2 selective NSAIDs might increase the risk of thromboembolic cardiovascular events because of preferential inhibition of endothelial prostacyclin synthesis without corresponding inhibition of platelet thromboxane synthesis, but no reliable data are available on the occurrence of cardiovascular events in patients treated with COX-2 selective or non-selective NSAIDs.

Gastrointestinal

Gastric damage

Evidence that the COX-2 selective agents cause less damage to the gastrointestinal mucosa than traditional NSAIDs is still limited. Gastrointestinal tolerability has been evaluated by measuring the frequency and severity of gastrointestinal adverse effects during randomized comparative efficacy trials, by performing microbleeding or endoscopic studies, and by evaluating the incidence of severe ulcer complications. Evidence from efficacy trials suggests an incidence of unwanted gastrointestinal effects (dyspepsia, epigastric abdominal pain, nausea, or diarrhea) similar to that caused by the traditional NSAIDs (1,15–17,20,75). The withdrawal rate from clinical trials because of unwanted effects (gastrointestinal or as a whole) was also similar, the only exception being one study in which fewer patients with rheumatoid arthritis stopped taking celecoxib than stopped taking diclofenac (16). However, the clinical importance of the frequency and severity of symptoms is uncertain. In fact, it is well known that symptoms do not necessarily predict the presence of mucosal damage, and it is still unclear if patients who have dyspeptic symptoms associated with NSAIDs are at greater or lesser risk of serious gastrointestinal complications (SEDA-15, 92) (SEDA-17, 103), the crucial question in evaluating these drugs.

In endoscopic comparisons of the new compounds with placebo or older NSAIDs, in both healthy volunteers and patients with rheumatoid arthritis or osteoarthritis, endoscopically observed lesions (erosions, ulcers) in the stomach and duodenum were undoubtedly fewer with the two COX-2-selective compounds than with non-selective NSAIDs (16,75–78) and were similar to those found with placebo (1).

However, the clinical significance of endoscopically detected erosions and ulcers is debatable (SEDA-14, 79) (SEDA-20, 97), as there is much controversy about whether endoscopic ulcers are surrogates for clinical outcomes such as perforation, obstruction, and gastrointestinal bleeding (78). Thus, although endoscopic studies are an important step in the evaluation of COX-2-selective inhibitors, large-scale, prospective, randomized outcome studies are necessary before we can definitively determine if these drugs will indeed represent significantly safer alternatives to the older NSAIDs. Unfortunately, these prospective comparative complication trials are difficult to perform, as the absolute rate of serious gastrointestinal complications (perforation, obstruction, and bleeding) is

© 2006 Elsevier B.V. All rights reserved.

low (about 2% per year) (78) and so a large number of patients must be studied.

Suggestions for improved gastrointestinal safety of COX-2-selective inhibitors have come from two studies, which addressed the problem of sample size by pooling published and unpublished randomized, double-blind trials of varying design and duration, comparing celecoxib, rofecoxib, non-selective NSAIDs (diclofenac, ibuprofen, nabumetone), and placebo in patients with osteoarthritis and/or rheumatoid arthritis.

In the first study the results of eight studies were pooled (79). The sample size of 5435 patients was large enough to detect even small differences in rates of complicated ulcers (perforation, symptomatic ulcers, and bleeding ulcers). Over 12 months complicated ulcers occurred at a rate of 1.33 per 100 patient-years with rofecoxib and 2.60 per 100 patient-years with non-selective NSAIDs. The analysis of confirmed upper gastrointestinal perforations, symptomatic ulcers, and upper gastrointestinal bleeding showed a relative risk (RR) with rofecoxib versus NSAIDs of 0.51 (95% CI = 0.26, 1.00). The difference between rofecoxib and the usual NSAIDs in the incidence of perforation, symptomatic ulcers, and bleeding ulcers became statistically significant as early as 6 weeks and remained so up to 12 months. However, this study has some limitations: first, it was not a prospective analysis or a properly conducted meta-analysis; secondly, there were only enough patient-years of exposure to compare rofecoxib with pooled traditional NSAIDs rather than individual drugs; thirdly, the confidence intervals were wide and compatible with no difference between the two treatment groups; fourthly, the time to exposure with any selective drug or placebo was too short to give a good prediction of actual complication rates with typical use.

In the second analysis, data from 14 studies of the efficacy of celecoxib in osteoarthritis or rheumatoid arthritis in 11 007 patients were pooled (80,81). Gastrointestinal complications (bleeding, obstruction, or perforation) occurred in 0.2% of the patients per year of exposure to celecoxib and in 1.7% per year of exposure to traditional NSAIDs. The absolute risk reduction was 1.5% (CI = 0.4, 2.6). This study, too, had some limitations. In fact, ulcer complication was not the specified end-point of the studies that were pooled, and about 15% of celecoxib-treated patients took a dose below that indicated for arthritis.

Assuming that a COX-2-selective inhibitor will prevent complicated ulcers in 50% of patients, it has been calculated that the NNT for avoiding one complicated ulcer each year in low-risk patients with rheumatoid arthritis (that is with a 0.4% risk of ulcer complications) is 500. On the other hand, in patients at higher risk (that is a 5% risk for ulcer complications) the NNT is 40 (82). It is therefore of paramount importance that studies currently under way confirm the same benefit from COX-2-selective agents in patients with a high risk of ulcer complications (that is aged 75 years or older, with a prior history of ulcer and gastrointestinal tract bleeding, taking low-dose aspirin for cardiovascular disease).

Two large trials have addressed the efficacy of COX-2 selective inhibitors and the associated risk of gastrointestinal complications: the CLASS and the VIGOR trial (32,33).

The CLASS consisted of two separate studies, in which celecoxib was compared with ibuprofen and diclofenac; the results obtained from the two traditional NSAIDs were pooled for analysis. Overall, 3987 patients with osteoarthritis and rheumatoid arthritis took celecoxib (400 mg bd), 1985 patients took ibuprofen (800 mg tds), and 1996 took diclofenac (75 mg bd). The study lasted 13 months, but only the data from 6 months of follow-up were published initially.

There was no statistically significant difference between the two groups in the incidence of the primary end-point of complicated ulcers (upper gastrointestinal bleeding, ulcer perforation, gastric outlet obstruction); the annualized incidence of complicated ulcers in patients taking celecoxib was 0.76% (11 events per 1441 patient-years) versus an incidence of 1.45% (20 events per 1384 patient-years) in patients taking the non-selective NSAIDs, a non-significant difference. However, for the composite end-point of upper gastrointestinal ulcer complications plus symptomatic gastroduodenal ulcers, celecoxib was significantly better tolerated than traditional NSAIDs; the annualized incidence was 2.08% (30 events per 1441 patient-years) with celecoxib versus 3.54% (49 events per 1384 patient-years) for patients taking traditional NSAIDs, significantly different.

The lack of difference in the rate of ulcer complications between the two treatments appeared to be a function of the higher-than-expected rate of complicated ulcers in those taking celecoxib compared with previous studies (81). Further analysis showed that this increase in complications was likely to be attributable to concurrent low-dose aspirin; the annualized incidence of upper gastrointestinal tract ulcer complications and of symptomatic gastroduodenal ulcers in patients not taking low-dose aspirin was significantly lower with celecoxib than with non-selective NSAIDs (0.44% or 5 events per 1143 patient-years versus 1.27% or 14 events per 1101 patient-years respectively). In patients taking aspirin, the annualized incidence of upper gastrointestinal complications and symptomatic ulcers were not significantly different (4.7% or 14 events per 298 patient-years in patients taking celecoxib versus 6.0% or 17 events per 283 patient-years in those taking traditional NSAIDs).

Moreover, the overall incidence of gastrointestinal symptoms in patients taking celecoxib was only slightly lower than that of patients taking the traditional NSAIDs, as was the rate of withdrawal due to gastrointestinal intolerance in both users and non-users of low-dose aspirin.

This subgroup analysis shows what might be called "competing co-morbidity"; that is, in the subgoup of patients taking aspirin as prophylaxis against ischemic heart disease, the gastrointestinal safety advantage of celecoxib over traditional NSAIDs was almost totally wiped out by the use of aspirin (83).

Despite that, the authors of CLASS concluded by stating that celecoxib caused fewer symptomatic ulcers and ulcer complications than ibuprofen or diclofenac at 6 months.

However, these conclusions were not only contradicted by the published data (32), but were also called into question by subsequent information on the trial available to the FDA (84,85). As was first

© 2006 Elsevier B.V. All rights reserved.

described on the FDA website, the published account of CLASS differed from the original protocol in many respects (in primary outcomes, statistical analysis, and trial duration). In particular, the published article represented selective reporting of the combined analysis of only the first 6 months of two separate protocols of longer duration: the first a 12-month comparison of celecoxib with diclofenac and the other a 16-month comparison of celecoxib with ibuprofen. The unpublished data show that by week 65 celecoxib was associated with a similar number of ulcer complications as diclofenac and ibuprofen and that the relative risks of both complicated ulcers and all serious gastrointestinal adverse events were higher at 12–16 months than they were at 6 months, suggesting an increased risk of serious adverse events with celecoxib long-term therapy.

Serious criticism was therefore aimed at the authors on the grounds of design, data analysis, and misleading presentation of the results. They were charged with having published and circulated overoptimistic short-term pooled data from different protocols, and of omitting disappointing long-term data. They replied to these criticisms, but their explanations were not considered to be convincing (86–88). Furthermore, Pharmacia, the manufacturers of celecoxib, continue to present inappropriately pooled short-term results from different protocols performed in different continents with different comparator drugs for the SUCCESS 1 trial, the successor to CLASS (86–88).

In the VIGOR study, 8076 patients with rheumatoid arthritis were randomly assigned to receive rofecoxib 50 mg/day or naproxen 500 mg bd. The primary endpoint was a confirmed clinical upper gastrointestinal event (gastroduodenal perforation or obstruction, upper gastrointestinal bleeding, and symptomatic gastroduodenal ulcer).

Overall, confirmed upper gastrointestinal events occurred in 177 patients, 56 with rofecoxib ($n = 4047$), and 121 in those taking naproxen ($n = 4029$). In 53 of these patients (16 taking rofecoxib and 37 taking naproxen) the event was complicated. That means that during a median follow-up of 9.0 months, there were 2.1 confirmed gastrointestinal events per 100 patient-years with rofecoxib compared with 4.5 per 100 patient-years with naproxen (RR = 0.5; 95% CI = 0.2, 0.8). The respective rates of complicated ulcers (perforation, obstruction, and bleeding) were 0.6 per 100 patient-years and 1.4 per 100 patient-years (RR = 0.4; 95% CI = 0.2, 0.8).

It is also worth noting that the most common adverse events that led to withdrawal of treatment, excluding the primary gastrointestinal end-points, were dyspepsia, abdominal pain, epigastric discomfort, nausea, and heartburn and that significantly fewer patients discontinued treatment as a result of any one of these five upper gastrointestinal symptoms in the rofecoxib group (3.5%) than in the naproxen group (4.9%).

Problems have also occurred in interpreting the results of VIGOR (33). There were significantly fewer upper gastrointestinal adverse events with rofecoxib compared with naproxen, but an unexpected substantial excess of serious cardiovascular events, making the overall safety of rofecoxib uncertain. When the complete data from VIGOR were presented and all serious adverse events were included (not just gastrointestinal events) the patients who took naproxen had fewer overall serious events: 9.3% of the patients who took rofecoxib had a serious adverse event, compared with 7.8% of those who took naproxen (RR = 0.81; 95% CI = 0.62, 0.97).

The reasons for the discrepancy between celecoxib and rofecoxib in the frequency of upper gastrointestinal complications are not clear, but some hypotheses have been proposed. First, aspirin was used concomitantly with celecoxib (20% of patients) in CLASS but not in VIGOR, increasing the risk of gastrointestinal damage. Secondly, diclofenac (which has greater COX-2 selectivity than naproxen) was used as a comparator in CLASS. Thirdly, the dosages of celecoxib were too high and at the doses studied in CLASS celecoxib might not have had true selectivity for COX-2. Finally, the selectivity of celecoxib for COX-2 is probably lower than that of rofecoxib. Therefore, given major differences in study design and data analysis between the two trials, a valid comparison of the two coxibs is not possible from these data alone; a head-to-head comparison in a large outcome study is needed (89).

Two recently published articles have helped to clarify this point: a systematic review of randomized clinical trials on the upper gastrointestinal safety of celecoxib (90) and a population-based retrospective cohort comparison of the rate of upper gastrointestinal hemorrhages in over 40 000 NSAID-naïve elderly users of non-selective NSAIDs, celecoxib, or rofecoxib with the rate in 100 000 patients who had not been exposed to NSAIDs (91).

In the systematic review, all published and unpublished randomized clinical trials that compared at least 12 weeks of celecoxib treatment with placebo or a traditional NSAID (diclofenac, ibuprofen, naproxen) were analysed. Nine of 17 trials fulfilled the inclusion criteria (a total of 15 187 patients). Withdrawals because of drug-related gastrointestinal adverse effects, ulcers detected at endoscopy, and complicated ulcers were used as measures of gastrointestinal tolerability. Compared with those taking non-selective NSAIDs, the patients who took celecoxib had a lower rate of withdrawals because of adverse gastrointestinal effects at 12 weeks (3.2 versus 6.2%), but there was no significant difference between celecoxib and NSAIDs in the incidence of withdrawals for all adverse events. The incidence of ulcers detected at routine endoscopy at 12 weeks was also lower in patients who took celecoxib compared with those who took non-selective NSAIDs (6.2 versus 23%). In four trials that provided information on the incidence of ulcers detected by endoscopy according to whether or not patients were taking concomitant aspirin up to 325 mg/day, the benefit provided by celecoxib was greater in patients not taking aspirin. The incidences of ulcers were as follows:

- celecoxib alone 6.2%;
- celecoxib + aspirin 12%;
- non-selective NSAID alone 25%;
- non-selective NSAID + aspirin 26%.

© 2006 Elsevier B.V. All rights reserved.

However, these results must be treated with great caution, as the total number of patients who took prophylactic aspirin was small (150 taking celecoxib and 140 taking non-selective NSAIDs) and the largest number of patients came from a single trial (CLASS).

The same warning applies to evaluation of the incidence of complicated ulcers (bleeds, perforation, and obstructions). The incidence of these serious events with celecoxib was 2.7% (11 events) versus 5% (20 events) in patients taking diclofenac or ibuprofen, a non-significant difference.

This meta-analysis has provided further evidence that celecoxib has better upper gastrointestinal tolerability that some traditional NSAIDs when withdrawal from trials due to drug-related adverse effects or ulceration detected during routine endoscopy are used as measures of tolerability. However, not all ulcers detected by endoscopy progress to a serious event, and many probably heal spontaneously; the clinical relevance of this measure is therefore controversial. On the other hand, there is a consensus that ulcer complications, the prime cause of concern with NSAIDs, should be the primary end-point of outcome studies aimed at evaluating the gastrointestinal toxicity of NSAIDs. Unfortunately, this consensus is counterbalanced by the problems of doing such studies, as they need to be very large to achieve even marginal power and there are also problems in evaluating the clinical outcomes (89).

Another study that deserves attention was an observational study of upper gastrointestinal hemorrhage in over 40 000 elderly patients taking COX-2-selective drugs (celecoxib, rofecoxib) or non-selective NSAIDs with and without misoprostol, compared with 100 000 non-NSAID users (91). Of about 1.3 million potential subjects aged 65 years and over, 364 686 (28%) were given an NSAID during the study period (about 1 year). From the total elderly population, the authors identified 5391 users of non-selective NSAIDs, 5087 users of diclofenac plus misoprostol, 14 583 users of rofecoxib, 18 908 users of celecoxib, and 100 000 controls. Most of the users of non-selective NSAIDs were taking naproxen (32%), ibuprofen (23%), or diclofenac (20%). During over 55 000 person-years of follow-up, there were 187 hospitalizations for upper gastrointestinal hemorrhage. Relative to the non-users, there was a significantly greater risk of upper gastrointestinal hemorrhage in the patients who took non-selective NSAIDs (adjusted risk ratio 4.0; 95% CI = 2.3, 6.9), diclofenac plus misoprostol (3.0; 1.7, 5.6), or rofecoxib (1.9; 1.3, 2.6), but not celecoxib (1.0; 0.7, 1.6). There were also significant differences in the risks of upper gastrointestinal hemorrhage. Relative to celecoxib users, there was a higher risk of hospitalization for upper gastrointestinal hemorrhage, not only among users of non-selective NSAIDs and diclofenac plus misoprostol but also among users of rofecoxib.

This study has provided further evidence that the risk of upper gastrointestinal hemorrhage with COX-2 inhibitors is significantly lower than with conventional NSAIDs, whether or not they are taken with misoprostol. The apparently greater risk of gastrointestinal hemorrhage with rofecoxib than with celecoxib needs confirmation, as the study had some limitations, of which the most important were the low absolute number of events in the study group and the retrospective design.

What are the implications of these data on the use of the coxibs? Overall they suggest that COX-2 selective inhibitors are less likely to cause upper gastrointestinal damage than some traditional NSAIDs. This advantage is measured by a lower number of events that represent a composite end-point of gastrointestinal toxicity, such as endoscopically detected symptomatic ulcers and serious ulcer complications (perforation, obstruction, bleeding). However, this may not be true in all patients, especially in those who simultaneously take aspirin. This question is of major clinical importance, as many patients with osteoarthritis or rheumatoid arthritis use low-dose aspirin for cardiovascular prophylaxis. We do not know whether gastrointestinal safety is preserved with the use of such combinations, nor whether a proton pump inhibitor should be added in this situation. Furthermore, the data on which of the coxibs has better gastrointestinal tolerability are inconclusive. Large outcome studies will be necessary to solve these questions.

A final consideration is worthwhile. To focus attention only on gastrointestinal events may provide an incomplete picture of the benefit/harm profile of the COX-2 inhibitors. Meta-analysis of mortality and morbidity outcomes from CLASS and VIGOR has suggested that total mortality was higher with coxibs than with non-selective NSAIDs, although the difference was not statistically significant (30). Moreover, if one takes into account the incidence of serious adverse events (including death, admission to hospital, and any life-threatening event or events leading to serious disability) as a combined measure of harm, the incidence was significantly higher with COX-2 selective compounds than with other NSAIDs, and complicated gastrointestinal ulcers accounted for only a small proportion of total serious adverse events. Non-gastrointestinal serious adverse events call for more attention.

Two other aspects of gastrointestinal toxicity have yet to be studied. First, the use of COX-2 inhibitors in patients with inflammatory bowel disease, in whom it is likely that COX-2 activity is upregulated (92) and in whom traditional NSAIDs may exacerbate the disease. Experimental colitis has been induced both in COX-2-deficient mice and in rats treated with COX-2-selective inhibitors (93). However, in healthy volunteers, rofecoxib did not alter intestinal permeability, in contrast to indometacin, which increased it (94). Studies in patients with inflammatory bowel disease are necessary before considering COX-2 selective inhibitors to be safe in these patients (95).

Secondly, a possible beneficial role of COX-2 on the stomach should also be taken into account. In mice, COX-2 is expressed at the borders of gastric ulcers and has been implicated as a critical factor in promoting repair (11). Whether these experimental data have any clinical relevance is unknown, but this issue raises the possibility that individuals with pre-existing peptic ulcers who take COX-2 selective drugs may be at risk of delayed ulcer healing and potential complications. This issue may be of particular concern in patients with ulcers due to *Helicobacter pylori* infection.

© 2006 Elsevier B.V. All rights reserved.

In conclusion, clinical trials have shown that COX-2-selective NSAIDs seem to be less toxic to the gastrointestinal mucosa than traditional ones. However, life-threatening ulcer complications have been reported in patients taking both celecoxib (81,96,97) and rofecoxib (79). The FDA and other regulatory authorities require that drug information sheets for celecoxib and rofecoxib carry gastrointestinal ulcer warnings similar to those for older NSAIDs.

Large bowel damage

Little is known about the effects of COX-2 inhibitors on the colon, although animal evidence suggests that they can worsen or precipitate acute colitis. Features similar to those seen in cases of ischemic colitis have been reported in a patient taking rofecoxib (98).

- A 52-year-old woman with a colostomy for a tumor of the sigmoid colon developed low back pain that radiated to the legs. A bone scan showed no evidence of tumor. She was given rofecoxib 25 mg/day and 4 days later noticed bloody diarrhea from the colostomy. At colonoscopy a large portion of the transverse colon was seen to be hemorrhagic, with nodularity, a superficial exudate, and mucosal edema, with a well-demarcated transition to normal areas. Despite extensive investigations, no plausible cause of the bloody diarrhea and colitis were found, except the possible involvement of rofecoxib. She stopped taking it and was given intravenous fluids. After 4 days the colostomy stopped oozing blood; colonoscopy showed no evidence of hemorrhage and the mucosa was regenerative. Bleeding did not recur.

Pancreas

Two case reports have suggested a potential association between the sulfonamide group in celecoxib and the development of acute pancreatitis (99,100). The cause of acute pancreatitis in patients taking celecoxib is speculative, but sulfonamides are known to cause pancreatitis, and one of these patients reported an allergy to sulfa medication. Thus, the reaction might have been allergic in nature.

Urinary tract

Kidneys

Renal dysfunction after therapy with COX-2 inhibitors is not unexpected. COX-2 is expressed in the normal human kidney, especially in endothelial and smooth muscle cells of the vasculature and glomerular epithelial cells. Angiotensin II and endothelin induce and upregulate COX-2 and prostaglandin synthesis. Furthermore, it seems reasonable to hypothesize that intrarenal dependence on COX-2-synthesized prostaglandins increases in heart failure, liver failure, volume depletion, and chronic renal disease (101). It is thought that in healthy kidneys COX-2 plays an important role in the balance of water and electrolytes, and its activity is upregulated in patients with reduced left ventricular filling pressure, to help maximize renal blood flow.

As experience with COX-2-selective inhibitors accumulates, it appears that the pattern of nephrotoxicity is similar to that of traditional NSAIDs (102,103). Non-selective NSAIDs can cause hemodynamically mediated acute renal insufficiency in predisposed patients and can cause sodium and water retention, causing peripheral edema and hypertension. Efficacy trials have shown a similar incidence of pedal edema, renal adverse effects, and hypertension with COX-2 selective and non-selective NSAIDs (18,75).

- A 43-year-old woman with rheumatoid arthritis developed dizziness having taken celecoxib 200 mg/day for 2 weeks. At the start of treatment she had normal renal function (104). Her serum creatinine was 670 μmol/l (7.4 mg/dl) and blood urea nitrogen 30 mmol/l (90 mg/dl). Creatinine clearance was 16 ml/minute. Urinalysis was normal and casts were not present. Urinary chemical analysis showed a sodium concentration of 18 mmol/l, a fractional excretion of sodium of 0.3, and a renal failure index of 0.493, consistent with prerenal acute renal insufficiency. Celecoxib was withdrawn. Although her renal function then improved, her serum creatinine was still abnormal (4.7 mg/dl) 1 month later.

In a randomized comparison of celecoxib and diclofenac plus omeprazole, renal adverse events, including hypertension, peripheral edema, and renal insufficiency, were common and similar in the two groups (105). They occurred in the 24% of the patients who took celecoxib and in 31% of those who took diclofenac plus omeprazole. Among patients with renal impairment at baseline, 51% of those who took celecoxib and 41% of those who took diclofenac plus omeprazole had renal adverse events. Careful monitoring of renal function in patients taking COX-2 inhibitors or traditional NSAIDs is mandatory, especially in high-risk subjects (for example those with pre-existing renal disease, diabetes, or heart failure).

Two studies in healthy volunteers have shown that the effects of COX-2 inhibitors on renal function are similar to those of traditional non-selective NSAIDs (106,107). The first was a short-term crossover study on renal function in healthy elderly subjects treated with rofecoxib and naproxen. Although there was a greater fall in glomerular filtration rate with naproxen, reductions in the urinary excretion of sodium, prostaglandin E-2, and 6-keto-prostaglandin F-1α were similar with the two compounds (106). In the second study in elderly people taking a low-salt diet, rofecoxib and indometacin significantly lowered the glomerular filtration to a similar extent (107).

However, these data are limited and must be interpreted with caution, since NSAIDs have significant toxic effects on the kidney only in patients at risk (that is those with volume depletion, heart failure, cirrhosis, intrinsic renal disease, and hypercalcemia), in whom the secretion of vasodilator prostaglandins is increased in an attempt to counteract the effect of increased renal vasoconstrictors, such as angiotensin II.

The incidence of adverse effects related to renal function in CLASS and VIGOR was low and similar (0.9% with celecoxib and 1.2% with rofecoxib). The incidence of increased creatinine and urea nitrogen concentrations was slightly lower in patients taking celecoxib than in those taking ibuprofen or diclofenac. Similar results have been documented in two other clinical trials. The

© 2006 Elsevier B.V. All rights reserved.

first compared celecoxib with diclofenac in long-term management of rheumatoid arthritis in 430 patients (16). There were only small increases in serum creatinine concentration (from 93 μmol/l at baseline to 96 μmol/l at the final visit) and serum urea concentration (from 6.0 to 6.4 mmol/l). There was a similar increase in patients taking diclofenac. The second trial, in 1149 patients, compared celecoxib with naproxen; serum creatinine concentrations were not affected by either celecoxib or naproxen (75). However, data from these clinical trials must be interpreted with caution, as patients at major risk of renal adverse events were likely to be excluded.

In contrast, published case reports and case series have provided more insight into the potential nephrotoxicity associated with COX-2-selective inhibitors. Taken together, these case reports suggest that COX-2 inhibitors, like non-selective NSAIDs, produce similar and consistent renal adverse effects in patients with one or more risk factors that induce prostaglandin-dependent renal function (that is patients with renal and cardiovascular disease and taking a number of culprit medications, such as diuretics and ACE inhibitors). Acute renal insufficiency, disturbances in volume status (edema, heart failure), metabolic acidosis, hyperkalemia, and hyponatremia have been commonly described. The duration of treatment with COX-2 inhibitors before the development of clinically recognized renal impairment ranged from a few days to 3–4 weeks. Withdrawal of COX-2 inhibitors and supportive therapy most often resulted in resolution of renal dysfunction, but in some patients hemodialysis was required (102,108–112).

The renal safety of rofecoxib and celecoxib has been studied using the database of spontaneous reports of adverse drug reactions in the WHO Monitoring Center in Uppsala (113). Disproportionality in the association between COX-2 selective inhibitors and renal-related adverse drug reactions was evaluated using a Bayesian confidence propagation neural network method, in which a statistical parameter (the information component: IC) was calculated for each drug-reaction combination. In this method an IC value significantly greater than 0 implies that the association of a drug-reaction pair is stronger than background; the higher the IC value, the more the combination stands out from the background. As with non-selective NSAIDs, both COX-2 selective inhibitors were associated with renal-related adverse drug reactions. IC values were significantly different for the following comparisons: water retention, abnormal renal function, renal insufficiency, cardiac failure, and hypertension. However, the adverse renal impact of rofecoxib was significantly greater than that of celecoxib. Renal-related events for rofecoxib were two- to four-fold higher than for celecoxib and the severity of these reported adverse reactions was also more serious. Studies based on spontaneous reports have many limitations and their results must therefore be confirmed by additional epidemiological studies that can provide more accurate information on incidence rates and risk factors.

Rare reports of acute reversible renal impairment have been recorded in patients with predisposing factors (109).

Whether selective COX-2 inhibitors can cause the other types of renal toxicity that are associated with non-selective NSAIDs (that is acute interstitial nephritis, nephrotic syndrome with or without renal insufficiency) is not known.

Bladder

The use of NSAIDs to treat and prevent bladder spasms has been documented in clinical trials (114) and their role in relaxing bladder smooth muscle has experimental support (115). Three elderly patients who used rofecoxib or celecoxib developed acute but reversible urinary retention (116). Each had co-morbidities likely to cause bladder dysfunction, and the administration of a COX-2 inhibitor may have caused further relaxation of the detrusor muscle, resulting in urinary retention.

Skin

There have been reports of maculopapular rash (117) and severe erythema multiforme (toxic epidermal necrolysis) (118) with celecoxib. Three patients developed erythema multiforme while taking rofecoxib (119). All were well documented, and oral rechallenge with rofecoxib, positive in two of them, confirmed the role of rofecoxib in the pathogenesis of this adverse reaction.

- Swelling and wrinkling of the palms soon after exposure to water occurred in an 18-year-old-woman taking rofecoxib for mixed connective tissue disease (120). The swelling followed exposure for 1 to a few minutes to water at any temperature. The swelling developed rapidly and was accompanied by symptoms of mild pain and discomfort. Over the following 2 hours, the palms would return to normal. Because of the temporal correlation with the use of rofecoxib, it was withdrawn, and 3 weeks later her symptoms had almost completely resolved.

The authors speculated that this phenomenon might have been due to increased salt content of the skin caused by the rofecoxib, resulting in increased water-binding capacity of keratin.

Musculoskeletal

An in vitro experiment on cartilage explants from patients with osteoarthritis showed upregulation of COX-2 activity, which may be linked to cartilage repair (121). If this is true, long-term use of COX-2 inhibitor NSAIDs could have harmful effect on joints. Preliminary data suggest that these drugs are efficacious in osteoarthritis, at least in the short term.

Reproductive system

Many reproductive processes (ovulation, fertilization, implantation, decidualization, and parturition) depend on prostaglandin ligand–receptor interactions. It is therefore not surprising that selective COX-2 inhibition has a negative local effect on ovulation, resulting in delayed follicular rupture and infertility, without affecting peripheral hormonal cyclicity (122,123).

© 2006 Elsevier B.V. All rights reserved.

There have been several case reports that non-selective NSAIDs (diclofenac, naproxen, piroxicam) can cause infertility, attributed to "luteinized unruptured ovarian follicles" syndrome (124–126). Now the syndrome has been documented in a double-blind, randomized, placebo-controlled study, in which women were assessed over two menstrual cycles while taking rofecoxib (123). Women who are trying to become pregnant should avoid taking any NSAIDs if possible, and those who need one for a chronic rheumatic disorder should be aware of possible infertility; in such cases further investigation is not required, as withdrawal of the drug restores fertility.

Immunologic

There is considerable difficulty and controversy in identifying and classifying allergic reactions to NSAIDs, for many reasons (127). First, the difficulty in making a definite diagnosis in patients who have these reactions without provocative challenge with the suspected drug and other NSAIDs. Secondly, reactions are characterized by a large spectrum of target organ responses to NSAIDs, and the same drug can cause different types of reactions in different organs in the same or different individuals. Thirdly, a patient can have a similar reaction to a structurally different NSAID. Finally, reports of these reactions include different, often imprecise, terms, making interpretation difficult. It is worth evaluating the safety of new coxibs in patients who cannot tolerate non-selective NSAIDs.

Anaphylaxis due to celecoxib has been described (SEDA 26, 121). Life-threatening anaphylaxis, with urticaria, angioedema, and bronchospasm, has also been described 30 minutes after a dose of celecoxib for arthritis of the hip (128).

Allergic vasculitis has been reported in association with various NSAIDs, and has been attributed to celecoxib (129,130), including one case with a fatal outcome (131).

Whether allergic reactions to celecoxib occur more often in patients who report a previous reaction to sulfonamides, and should therefore be contraindicated in such patients, is still unknown (132).

Angioedema has been attributed to rofecoxib (SEDA-26, 121).

- A 60-year-old man developed angioedema after taking two doses of rofecoxib 12.5 mg 18 and 12 hours before (133). Despite intensive treatment he developed pulmonary hemorrhagic edema and died a day later. He had fibrotic lung disease, which may have predisposed him to the lethal event.

The tolerability of rofecoxib in patients with cutaneous allergic and pseudoallergic adverse reactions to non-selective NSAIDs has been confirmed in a study in 139 patients with NSAID-induced adverse reactions: 60 with urticaria alone (43%), 34 with angioedema (25%), 34 with angioedema plus urticaria (2.9%), and 2 with Stevens–Johnson syndrome (1.4%) (134). They all underwent a single-blind, placebo-controlled oral challenge with increasing doses of rofecoxib, and 138 of them tolerated it without adverse reactions. Only one had mild urticaria on the arms. Rofecoxib may be a useful alternative in patients with NSAID hypersensitivity.

Anaphylaxis

Among the anaphylactic reactions to NSAIDs that result in different types of reaction (urticaria, angioedema, asthma, or hypotension), there have been very few reports of anaphylactic shock. However, anaphylaxis has been described in patients taking celecoxib (135,136) or rofecoxib (137). Rofecoxib caused anaphylaxis in a patient who had had a similar reaction to diclofenac, suggesting that COX-2 inhibitors may be not safe in all individuals who have adverse reactions to non-selective COX inhibitors. It also suggests that different mechanisms may be involved in patients with asthma and in those with anaphylactoid reactions to NSAIDs.

Sulfonamide-like allergic adverse reactions

Concerns that COX-2 inhibitors may be associated with an increased risk of allergic reactions in patients with a history of sulfonamide hypersensitivity arise from the molecular structures of these compounds (SEDA-24, 119) (138).

A sulfur component is necessary for the receptor binding of both celecoxib and rofecoxib, but their structures differ and they have different potentials for causing allergic reactions. Consequently, celecoxib is thought to be contraindicated in patients with a history of allergy to sulfonamides. The available data on the immunological tolerability profile of celecoxib and rofecoxib are scanty but merit attention.

Sulfonamide-like adverse drug reactions seem to occur more frequently with celecoxib than with rofecoxib, according to a report from Sweden (139). The investigators identified a profile of 19 typical sulfonamide-like adverse reactions from published papers and the WHO Adverse Drug Reactions database from 1968 to 2000, and compared this profile with reported adverse drug reactions associated with celecoxib and rofecoxib. The WHO database contained 11 514 reports about celecoxib describing 21 292 suspected adverse drug reactions and 10 200 reports about rofecoxib describing 18 585 suspected drug reactions. The relative reporting rate of sulfonamide-like adverse drug reactions was almost twice as high for celecoxib as for rofecoxib (RR = 1.8; 95% CI = 1.6, 1.9) for all reports and for reports that listed a COX-2 inhibitor as the only suspected drug. The reporting rate for 15 of the 19 sulfonamide-like adverse drug reactions was higher for celecoxib than for rofecoxib, with significant differences for rash (RR = 2.3; CI = 2.0, 2.6), urticaria (RR = 2.0; CI = 1.6, 24), Stevens–Johnson syndrome (RR = 3.6; CI = 1.4, 12), and photosensitivity (RR = 2.4; CI = 1.5, 4.0). Fatal adverse drug reactions fitting the typical sulfonamide profile also occurred more often with celecoxib than with rofecoxib (1.8; CI = 0.9, 4.0).

Even though serious sulfonamide reactions are rare, their clinical impact warrants close monitoring as more data become available, and physicians should be aware of possible sulfonamide allergy when prescribing COX-2 inhibitors, in particular celecoxib.

There have been single case reports of sulfonamide-like allergic reactions in patients taking celecoxib; in two cases sulfonamide allergy was ignored and was discovered only after an adverse reaction to celecoxib (140) or rofecoxib (141) had occurred.

Urticaria and angioedema

Of 110 patients with a history of urticaria and angioedema triggered by one or more non-selective NSAIDs, who were submitted to 184 single-blind, placebo-controlled oral challenges with the suspected NSAID, patients with a positive challenge underwent further oral challenge with various COX-2 inhibitors (celecoxib and rofecoxib, and also nimesulide and meloxicam, which are relatively selective COX-2 inhibitors) (142). The maximal challenge doses were celecoxib 200 mg, rofecoxib 25 mg, meloxicam 15 mg, and nimesulide 100 mg. Reactions (expressed as a percentage of tested patients with a positive test) varied among the COX-2 inhibitors: 33% (10/30) for celecoxib, 21% (16/75) for nimesulide, 17% (8/46) for meloxicam, and 3% (1/33) for rofecoxib. This suggests that the degree of cross-reactivity of COX-2 inhibitors was related to the degree of in vitro COX-1 inhibition, since meloxicam, nimesulide, and celecoxib inhibit COX-1 to a similar extent (143). The results also suggested that the most selective COX-2 inhibitor (rofecoxib) might be relatively safe in a patient with NSAID-induced urticaria/angioedema.

In another study, 34 patients with a history of urticaria and/or angioedema after ingestion of at least two chemically unrelated non-selective NSAIDs, 22 of whom also had chronic urticaria, all underwent a single-blind, placebo-controlled oral tolerance test with rofecoxib (12 and 25 mg 1 hour apart) (144). Rofecoxib caused urticaria and/or angioedema in 6/34 patients (18%), with no difference between patients with or without a history of chronic urticaria.

There was even better tolerability of rofecoxib in another study in 33 patients with documented urticaria/angioedema after ingestion of two different NSAIDs (145). The patients underwent provocative tests with increasing doses of rofecoxib (from 6.25 to 25 mg); at the end of the challenge all tolerated rofecoxib 25 mg.

Other single case reports have supported the evidence of better tolerability of COX-2-selective inhibitors (in particular rofecoxib) in patients with a history of urticaria/angioedema (64,146). However, contrasting data have shown cross-reactivity of celecoxib with other NSAIDs and between celecoxib and rofecoxib (147).

Why are COX-2-selective drugs better tolerated? The mechanisms underlying intolerance to chemically unrelated NSAIDs are unknown, but it has been hypothesized that intolerant patients may have exaggerated sensitivity to the effects of leukotrienes, which are more active than histamine in inducing wheal and flare reactions. Blockade of both COX-1 and COX-2 by non-selective NSAIDs increases the production of leukotrienes by the lipoxygenase pathway, whereas COX-2-selective agents do not increase the production of LTB_4 or cysteinyl LTS. However, this may not be the only pathogenic mechanism, as some drugs probably trigger histamine release from mast cells and basophils non-specifically, and others may trigger immunological cross-reactivity. Overall, the above-mentioned studies and clinical experience suggest that urticaria and angioedema can occur with COX-2 inhibitors, albeit with a lower frequency than with non-selective NSAIDs.

Second-Generation Effects

Fetotoxicity

A single case report supports the hypothesis that a COX-2-selective NSAID might have the efficacy of indometacin as a tocolytic agent without its adverse effects in the fetus (148).

Drug–Drug Interactions

Lithium

A possible interaction of rofecoxib with lithium has been reported (149).

- A 73-year-old man with manic-depressive illness, who had taken lithium for 40 years, underwent coronary bypass surgery and was given long-term warfarin. He developed signs of lithium intoxication (confusion, irritability, tremor, and gait disturbance) after having taken rofecoxib 12.5 mg/day for 9 days for arthritis. Rofecoxib had been chosen in order to avoid a possible drug interaction with warfarin. Lithium and rofecoxib were withdrawn and the signs resolved within 1 week. His serum lithium concentration was 1.5 mmol/l and his serum creatinine 1430 μmol/l.

Both lithium and rofecoxib have been associated with nephrotoxicity, and it is likely that lithium intoxication was caused by concomitant administration of rofecoxib, causing a reversible reduction in renal function.

Propofol

A single perioperative dose of parecoxib did not alter the disposition or the clinical effects of a bolus of propofol (150).

Sex hormones

Rofecoxib did not cause any clinically important changes in ethinylestradiol and norethindrone pharmacokinetics in 18 subjects (151).

Cremophor

General Information

Cremophor is a non-ionic solubilizer and emulsifier that is made by reacting ethylene oxide with castor oil (1). It is a pale yellow oily liquid consisting of a mixture of components, primarily polyethylene glycol conjugates. Fatty acid esters of polyethyleneglycol are also present, as well as hydrophilic polyethylene glycols and ethoxylated glycerol. It is present in intravenous formulations of the anticancer drugs teniposide and paclitaxel. The paclitaxel formulation consists of 6 mg/ml in 50% ethanol and 50% Cremophor. Thus, a patient receiving paclitaxel in the widely used dose of 175 mg/m^2 will also receive about 14 ml/m^2 of Cremophor.

Anaphylactoid reactions can occur after the intravenous administration of Cremophor (SEDA-22, 526) when it is used as a diluent of alfadolone/afaxolone (SED-11, 211) (2), ciclosporin (3), paclitaxel (4), propanidid (SED-11, 211) (5,6), teniposide (7), and vitamin K (8,9). Cardiorespiratory arrest after intravenous miconazole has been attributed to the histamine-releasing properties of Cremophor (10).

In a study of the effects of Cremophor after 74 cycles of doxorubicin in Cremophor in 39 patients, there were no major hypersensitivity reactions to Cremophor, and no patients had their infusion discontinued or modified (11). Adverse effects that were considered to be potentially related to Cremophor were cutaneous (pruritus, flushing, or rashes), hypotension or dizziness, and headache. Because of the subjective nature of some of these symptoms, they were classified as grade 1 (mild and not requiring treatment or interfering with function), grade 2 (moderate, causing some impairment of function but not requiring hospitalization), or grade 3 (severe, requiring hospitalization or causing significant interference with function). No grade 2 or 3 toxicity was recorded at the first three doses. One patient at level 4A had grade 2 dizziness, one patient at level 5 had grade 2 rash, one patient at level 5 had grade 3 headache and grade 3 pruritus, and one patient at level 6 had grade 3 hypotension and grade 3 rash. In no patient did these symptoms occur with doxorubicin alone, confirming their relation to Cremophor. These symptoms began several hours to days after Cremophor and persisted for 1–2 weeks, with the exception of the patient at level 5, whose pruritus gradually resolved over 3 months after discontinuing Cremophor.

Organs and Systems

Hematologic

The hematological toxicity of Cremophor has been evaluated after 74 cycles of doxorubicin in Cremophor in 39 patients (11). The principal effect was neutropenia. The incidence of grade 4 neutropenia increased with increasing doses of Cremophor from 1 to 60 ml/m^2. Grade 4 neutropenia occurred in zero of three patients at 1 ml/m^2, one of four patients at 7.5 ml/m^2, four of six patients at 15 ml/m^2, and 11 of 16 patients at 30 ml/m^2. When the dose of doxorubicin was reduced, grade 4 neutropenia occurred in one of six patients at 45 ml/m^2 and two of four patients at 60 ml/m^2. Febrile neutropenia occurred in one patient at 15 ml/m^2, three patients at 30 ml/m^2, one patient at 45 ml/m^2, and one patient at 60 ml/m^2. There was one death from neutropenic sepsis at 30 ml/m^2.

Cromoglicate sodium

General Information

Cromoglicate disodium salt (cromoglicate sodium) is available as a powder for inhalation. Each capsule contains 20 mg. The usual dose is 1 capsule inhaled four times daily. It is also dispensed in a multidose-pressurized aerosol delivering 1 or 5 mg per actuation. A 1.0% nebulizer solution (20 mg dissolved in 2 ml of distilled water) is also available. It is nebulized over 15 minutes and has the same effect as 20 mg given as a powder (1). Cromoglicate is taken regularly in chronic asthma and when it is effective it improves symptoms and lung function and reduces the need for bronchodilators. It has a steroid-sparing effect and should be tried before inhaled steroids are used,

© 2006 Elsevier B.V. All rights reserved.

especially in children. It is a prophylactic drug and is not effective in acute asthma.

A liquid form is also available for use in rhinitis and ocular conditions. When applied topically to the eye cromoglicate is effective in the treatment of vernal keratoconjunctivitis (vernal catarrh, spring catarrh), allergic conjunctivitis, and hay fever.

Cromoglicate inhibits mast-cell degranulation and histamine release induced by phospholipase A2, but does not interfere with the interaction of antigen and reaginic antibodies. Evidence is accumulating that it has an important stabilizing action on leukocytes, apart from mast cells, such as neutrophils, eosinophils, and monocytes, and that it also affects nerve reflexes in the lung (2).

The overall incidence of adverse effects was about 2% when using inhaled cromoglicate (3). Most of the observed adverse effects are mild and transient and do not require withdrawal of therapy. Adverse effects such as laryngeal edema, swollen parotid glands, bronchospasm, joint swelling, nausea, cough, headache, nasal congestion, rash, and urticaria have been reported in only one in 10 000 patients (SEDA-12, 142). The American Academy of Allergy and Immunology reported two 10-year safety reports involving 424 and 85 patients. These emphasized the safety of long-term treatment with cromoglicate. The only serious adverse effects were three cases of pulmonary infiltration and eosinophilia (SEDA-6, 171). In another series of 375 patients, only eight experienced adverse reactions; these included dermatitis with pruritus, myositis, and gastroenteritis (SEDA-4, 120).

While no systemic or severe adverse reactions have been attributed to ocular cromoglicate even after as long as 8 months of therapy, transient local stinging and burning have been reported in 13–77% of patients who used the original formulation of this drug, which contained 2-phenylethyl alcohol as a preservative. These effects regressed during continued treatment and can vary greatly depending on both the individual and the underlying disease. Ocular cromoglicate without 2-phenylethyl alcohol has been reported to be more effective than formulations that contain this preservative; stinging, leading to increased lacrimation, dilutes the drug and reduces the time for which it is retained in the conjunctival sac. The desired topical effects of cromoglicate are therefore reduced if it is formulated with 2-phenylethyl alcohol.

Organs and Systems

Cardiovascular

- A woman developed peripheral eosinophilia and pericarditis with cardiac tamponade after using cromoglicate (SEDA-4, 120). Cellular and humoral sensitivity to cromoglicate were demonstrated and she recovered following pericardiocentesis.

Respiratory

Initial bronchospasm, seen in some patients, is thought to be due to the irritant effect of the dry powder. This can be prevented by prior inhalation of a beta$_2$-adrenoceptor agonist. In one case, a severe asthmatic reaction occurred and was thought to be reflexogenic in origin (SEDA-4, 120). Inhalation of nebulized cromoglicate by asthmatic children causes a reduction in forced mid-expiratory flow rate equivalent to that seen with distilled water (SEDA-17, 205). Bronchospasm and breathlessness as a result of hypersensitivity are rare, but do occur.

Rarely, a hypersensitivity reaction can cause bronchospasm or aggravation of existing asthma and a progressive fall in FEV_1, resulting in dyspnea (4).

Three cases of pulmonary infiltration with eosinophilia were reported among a total of 509 patients treated with cromoglicate (SEDA-6, 171).

- A 7-year-old asthmatic child, sensitive to timothy grass, used inhaled cromoglicate for 1 week and developed cyanosis, hypotension, and cardiopulmonary arrest. IgE involvement was demonstrated by passive transfer of the patient's serum to the mother (5).

Ear, nose, throat

Intranasal use of cromoglicate can cause sneezing and nasal congestion. There is nasal irritation in 35% of patients, swollen sore eyes in 17%, and a sore throat in 21%. The sensitive nasal mucosa can be susceptible to irritation by any nasal spray (6).

Nervous system

Most investigators have referred to headaches, but no clear relation to cromoglicate has been seen in any study. Dizziness has been reported, but may be connected with hyperventilation during the inhalation of the powder.

Sensory systems

The irritant effect of cromoglicate can cause lacrimation and inflammatory changes in the eye.

An allergic reaction to cromoglicate eye drops has been reported. After application of the eye-drops intense itching, burning, redness, and severe swelling of both conjunctivae developed immediately. Skin prick tests and conjunctival provocation with pure cromoglicate were positive. Circulating IgE-specific antibodies to cromoglicate were demonstrated by RAST (7).

Gastrointestinal

Nausea can occur. Esophagitis following inhalation of cromoglicate has been reported. It was much improved by prophylactic antacids given before each inhalation (SEDA-5, 169). In a patient with lactose intolerance, cromoglicate disodium capsules with lactose produced nausea, bloating, and flatulence. Lactose-free formulations produced no such symptoms (SEDA-13, 135).

Liver

Minor abnormalities of liver function have been described when cromoglicate is used orally for ulcerative colitis (8).

- A 45-year-old woman developed liver disease, vasculitis, and peripheral eosinophilia (SEDA-4, 120). Liver

© 2006 Elsevier B.V. All rights reserved.

biopsy showed inflammatory changes with infiltration of eosinophils. Withdrawal of the drug markedly improved the symptoms.

Skin

Skin reactions including dermatitis with pruritus have been reported in patients using cromoglicate. Urticaria or maculopapular rashes occur rarely.

Musculoskeletal

Bone mineral density was measured after 7.4 months in 49 asthmatic children, 38 of whom took inhaled beclomethasone, average daily dose 276 μg, and 11 sodium cromoglicate, average daily dose 30 mg. Children who had used beclomethasone had grown as much as those who used sodium cromoglicate. Trabecular and cortical bone mineral density in the proximal forearm and lumbar spine increased to the same extent in both groups.

The effects of fluticasone 50 μg bd or cromoglicate 20 mg qds on growth over 12 months have been studied in 122 asthmatic children aged 4–10 years (9). The mean height velocity was 6 cm/year with fluticasone and 6.5 cm/year with sodium cromoglicate. There was no significant treatment difference in the mean 24-hour urinary free cortisol concentrations at 6 or 12 months. Mean predicted peak expiratory flow rate improved over 1 year in both groups, but to a greater extent with fluticasone. Fluticasone was more effective than sodium cromoglicate, with fewer withdrawals and greater improvement in lung function.

Immunologic

Immunological reactions to cromoglicate can involve the pericardium, the lung, the eye, the nasal mucosa, the skin, the joints, and the liver. Rarely, a hypersensitivity reaction can cause fever (4). A survey of the world literature up to 1982 found 13 cases of facial rash, urticaria, and/or generalized dermatitis, and one of nasal congestion. In 19 patients there was bronchospasm and/or pulmonary edema, eventually culminating in shock. Four cases of eosinophilic or granulomatous pulmonary infiltration, one of liver disease and vasculitis, one of pericarditis, and three of polymyositis were reported.

IgE and/or specifically reactive lymphocytes do not mediate many of the adverse reactions to cromoglicate, which mimic allergic processes of the immediate or delayed type. These reactions fulfilled the criteria that characterize pseudo-allergic reactions (3,10). There is a much higher incidence of such adverse reactions when cromoglicate is used orally in the treatment of food allergy, as high as 29% of cases treated (3,10).

The US Food and Drug Administration has issued a report (SEDA-7, 1) on a suspected case of cromoglicate-induced lupus-like syndrome. Treatment with cromoglicate for 6 months resulted in arthritis, positive LE cells, and a positive antinuclear factor. After withdrawal of cromoglicate, the signs and symptoms regressed. Although this does not prove cause and effect, the report suggests a similarity between lupus-like syndrome and some of the adverse reactions that were listed earlier in the US data sheet (SEDA-3, 48).

Second-Generation Effects

Teratogenicity

Cromoglicate probably does not reach the fetus after inhalation, as systemic blood concentrations are extremely low (11). Animal testing did not show any teratogenic effects.

A critical review of drug therapy for allergic rhinitis during pregnancy has been published (12). Mast cell stabilizers are not teratogenic and can be considered as excellent first-line choices to treat allergic conjunctivitis and rhinitis. However, any recommendation should be accompanied by informed consent.

Drug Administration

Drug administration route

No systemic or severe adverse reactions have been attributed to ocular sodium cromoglicate, even after as long as 8 months of therapy. However, transient local stinging and burning were reported in 13–77% of patients who used the original formulation of this drug, which contained 2-phenylethyl alcohol as a preservative. These effects regressed during continued treatment and varied greatly depending on the individual and the underlying disease. Ocular sodium cromoglicate without 2-phenylethyl alcohol has been reported to be more effective; stinging, leading to increased lacrimation, dilutes the drug and reduces the time it is retained in the conjunctival sac. The desired topical effects of sodium cromoglicate are therefore reduced if it is formulated with 2-phenylethyl alcohol.

Crotetamide

General Information

Crotetamide is a mixture in equal parts by weight of cropropamide and crotethamide. It has similar actions to doxapram hydrochloride and has been used as a respiratory stimulant in man as well as illicitly in racehorses. When crotetamide was given intravenously, the incidence of adverse effects was 25% (1–3).

Organs and Systems

Nervous system

Flushing, paresthesia, headache, restlessness, muscle twitching, tremor, and dyspnea have been ascribed to crotetamide. Convulsions have been reported but are rare.

Crystalloids

General Information

Potassium and sodium salts are given intravenously in solutions to replace body fluids and electrolytes. Adverse effects are rare and usually limited to the effects of overtransfusion.

Microwave heating of crystalloid fluids has been recommended as a method of correcting hypothermia during resuscitation. Severe full-thickness burns and venous thrombosis occurred after infusion of over-heated crystalloid fluid in the management of a ruptured aortic aneurysm in a 75-year-old man (1). Measuring the temperature of the fluid before starting the infusion is necessary to avoid this complication.

Organs and Systems

Nervous system

Central pontine myelinolysis has been reported in patients given intravenous saline (2). Pontine and extrapontine myelinolysis are generally considered to be linked with rapid correction of severe hyponatremia, for example in the treatment of hyponatremia in patients with so-called hyperosmolar non-ketoacidotic hyperglycemia reference. Neurological deterioration is likely to result. It is not certain what rate of sodium repletion is safe. The best data available suggest that correction should not exceed 12 mmol/l per day, although more rapid correction may be safe. The duration of treatment also seems to be important: 12 mmol/l per day may be excessive if continued for more than 2 or 3 days.

Accurate control of the serum sodium is a major difficulty in the setting of severe hyponatremia. The administration of an amount of hypertonic saline calculated to raise the sodium to mildly hyponatremic concentrations can result in serum sodium in the normonatremic or even hypernatremic range. The serum sodium should not be allowed to raise more that 12 mmol/l over the first 24 hours, and even less over each subsequent 24-hour period. It is clear that an amount of saline calculated to raise the serum sodium by a given amount affects individuals differently. This makes frequent monitoring of serum sodium mandatory.

Gastrointestinal

Gastric and upper small bowel necrosis have been described after oral ingestion of massive amounts of concentrated saline (1 kg of sodium chloride in 660 ml of water) as an emetic.

Second-Generation Effects

Pregnancy

The value of intravenous crystalloid administration in preventing hypotension developing during spinal anesthesia in parturition has been questioned (3). Moreover, the association between increasing crystalloid volume and reducing postpartum colloid osmotic pressure raises concerns about the risks of maternal and fetal pulmonary edema. In a comparative study of the dose–response effects of crystalloid fluids before spinal anesthesia, all groups had a fall in mean arterial blood pressure and systemic vascular resistance index, measured using non-invasive thoracic impedance monitoring (3). The extent of the fall did not differ according to the volume given. There were no differences in neonatal colloid osmotic pressure with varying preload. No apparent benefit is to be gained in healthy parturients by giving crystalloid in volumes up to 30 ml/kg.

Cucurbitaceae

See also Herbal medicines

General Information

The genera in the family of Cucurbitaceae (Table 1) include cucumbers, gourds, and melons.

Bryonia alba

Bryonia alba (white bryony) contains toxic triterpenoids called cucurbitacins.

Adverse effects

Cucurbitacins are drastic laxatives and emetics and can cause the symptoms of food poisoning (1).

Citrullus colocynthis

The dried pulp of the fruit of *Citrullus colocynthis* (colocynth) is a drastic laxative, which contains toxic cucurbitacins.

Table 1 The genera of Cucurbitaceae

Apodanthera (apodanthera)
Benincasa (benincasa)
Brandegea (starvine)
Bryonia (bryony)
Cayaponia (melonleaf)
Citrullus (watermelon)
Coccinia (coccinia)
Ctenolepis (ctenolepis)
Cucumis (melon)
Cucumeropsis (cucumeropsis)
Cucurbita (gourd)
Cyclanthera (cyclanthera)
Doyerea (doyeria)
Ecballium (squirting cucumber)
Echinocystis (echinocystis)
Echinopepon (balsam apple)
Fevillea (fevillea)
Hodgsonia (hodgsonia)
Ibervillea (globeberry)
Lagenaria (lagenaria)
Luffa (luffa)
Marah (manroot)
Melothria (melothria)
Momordica (momordica)
Psiguria (pygmymelon)
Sechium (sechium)
Sicana (sicana)
Sicyos (burr cucumber)
Sicyosperma (sicyosperma)
Telfairia (telfairia)
Thladiantha (thladiantha)
Trichosanthes (trichosanthes)
Tumamoca (tumamoca)

Adverse effects

A man experienced vomiting, colicky pain, and bloody diarrhea after self-medication with *C. colocynthis* (2). Hemorrhagic colitis secondary to ingestion of colocynth has been reported (2). In three cases of toxic acute colitis 8–12 hours after ingestion of colocynth for ritual purposes, the prominent clinical feature was dysenteric diarrhea; colonoscopic changes included congestion and hyperemia of the mucosa with abundant exudates but no ulceration or pseudopolyp formation; there was rapid recovery within 3–6 days, with normal endoscopy at day 14 (3).

Ecballium elaterium

Ecballium elaterium (squirting cucumber) contains toxic cucurbitacins, which are violent purgatives. It is used in the Mediterranean as a purgative and in treating sinusitis.

Adverse effects

Intranasal use of *E. elaterium* has been associated with Quincke's edema (4) and with fatal cardiac and renal failure (5).

A report from a poisons unit in Israel included 13 patients who had used the juice of the squirting cucumber, either orally or topically, for unreported reasons (6). They subsequently had edema of the pharynx, dyspnea, drooling, dysphagia, vomiting, and conjunctivitis. With symptomatic treatment they recovered within a few days.

In a retrospective chart analysis in a Greek ENT department 42 patients with allergic reactions to *E. elaterium*, including upper airway edema, were identified (7). Treatment with glucocorticoids and antihistamines resulted in full recovery in all cases.

Momordica charantia

Oral formulations of *Momordica charantia* (karela fruit, bitter melon) have hypoglycemic activity in non-insulin dependent diabetes mellitus (8,9), and can interfere with conventional treatment with diet and chlorpropamide (10). In 15 patients aged 52–65 years a soft extract of *M. charantia* plus half doses of metformin or glibenclamide or both in combination caused hypoglycemia greater than that caused by full doses during treatment for 7 days (11). Subcutaneous injection of a principle obtained from the fruit may lower blood glucose concentrations in juvenile diabetes.

Adverse effects

Metabolism

M. charantia can cause hypoglycemic coma and convulsions in children (12).

Drug interactions

M. charantia inhibits P glycoprotein in vitro and drug interactions can therefore be expected (13).

Sechium edule

The tuber of *Sechium edule* (chayote) is valued as a potent diuretic by Latin American populations. Its use as a decoction by a pregnant woman suffering from pedal edema may have been the cause of a severe case of hypokalemia (14).

Cuprammonium cellulose

General Information

Cuprammonium cellulose is a constituent of some dialysis membranes (1).

Organs and Systems

Immunologic

Anaphylaxis as an adverse effect of hemodialysis has been analysed from records of about 260 000 courses of dialysis treatment, at three centers. There were 21 severe reactions over the 10.5-year period of the survey, all highly suggestive of anaphylaxis (2). Reactions occurred within minutes of initiating dialysis and were characterized by cardiopulmonary, mucocutaneous, and/or gastrointestinal tract symptoms. Four respiratory arrests occurred and there was one death. When the individual histories and treatments were analysed, there was strong evidence that hollow-fiber dialysers made of cuprammonium cellulose were responsible. No obvious factors could be found to identify predisposed patients; suboptimal rinsing of the cuprammonium cellulose hollow-fiber dialysers before use may have been responsible for some of the reactions. Repeated dialysis anaphylaxis in one patient has been reported (3).

Cupressaceae

See also Herbal medicines

General Information

The genera in the family of Cupressaceae (Table 1) include cedar, cypress, and juniper.

Juniperus communis

Extracts of *Juniperus communis* and other species are used in cosmetics, as hair conditioners, and in fragrances (1). The volatile oil distilled from the berries of *Juniperus communis* (juniper) can act as a gastrointestinal irritant. It is said that excessive doses can cause renal damage, and use during pregnancy is discouraged because of a fear that this might also stimulate the uterus.

Table 1 The genera of Cupressaceae

Callitris (cypress pine)
Calocedrus (incense cedar)
Chamaecyparis (cedar)
Cupressus (cypress)
Cupressocyparis
Juniperus (juniper)

Cyanoacrylates

General Information

Cyanoacrylate (Histoacryl) is a tissue adhesive used in duraplasty. The sites at which it is used should be carefully chosen. Cyanoacrylates are also in use for embolization of arteriovenous malformations in the brain. The risk of this procedure is the creation of pulmonary emboli after acrylate glue injection, particularly when delivery systems without flow arrest are used in high-flow vascular brain lesions. Techniques using acetic acid to delay polymerization time and "sandwich" techniques, in which glue is pushed with dextrose, appear to be more likely to cause this complication (1).

Organs and Systems

Immunologic

Infection can develop in the frontal area and at the lateral base of the skull after the use of cyanoacrylates, even after a symptom-free interval of several years; the lesions can be characterized by infected granular nodules, chronic sinusitis, or otogenic meningitis (2).

References

1. Pelz DM, Lownie SP, Fox AJ, Hutton LC. Symptomatic pulmonary complications from liquid acrylate embolization of brain arteriovenous malformations. AJNR Am J Neuroradiol 1995;16(1):19–26.

Cycadaceae

See also Herbal medicines

General Information

The family of Cycadaceae contains the single genus *Cycas*.

Cycas circinalis

The seeds of *Cycas circinalis* (false sago palm, queen sago) contain the non-protein amino acid beta-*N*-methylamino-L-alanine, which is similar to the neurotoxic amino acid beta-*N*-oxalylamino-L-alanine. Monkeys fed this amino acid develop a syndrome that closely resembles the disease that is known by the Chamorros of Guam as lytico-bodig, a complex of amyotrophic lateral sclerosis parkinsonism dementia that occurs in Guam, where the seeds of *C. circinalis* are a traditional staple of the indigenous diet (1). Consumption of flying foxes may also generate sufficiently high cumulative doses of *Cycas* neurotoxins, since the flying foxes forage on cycad seeds (2). The risk may be increased by the use of poultices prepared from cycad seeds as a topical cure for skin lesions in Eastern Irian Jaya (New Guinea), Indonesia.

Adverse effects

In a retrospective chart review at the Poison Control Center in Taiwan from 1990 to 2001 there were 21 cases of *Cycas* seed poisoning (3). The patients had taken 1–30 seeds for cosmetic use (5%), as edible food (70%), or for health promotion (10%), cancer prevention (10%), and gastrointestinal discomfort (5%). All had eaten the seeds after washing and cooking them. The time from ingestion to the onset of symptoms ranged from 30 minutes to 7 hours (mean 2.8 hours). All the patients except one presented with gastrointestinal disturbances, and 90% sought medical care at the emergency department. Severe vomiting was the most striking symptom. There was no respiratory depression. Within 24 hours all had recovered. Six patients had blood cyanide or thiocyanate concentrations measured, and although they were higher than normal, they did not reach the toxic range.

Cyclandelate

General Information

The spasmolytic action of cyclandelate, an ester of mandelic acid, was described as early as 1959, but only in later years have its properties been more fully investigated. It appears to act as a calcium channel blocker in smooth muscle and platelets, this effect being partly due to inhibition of phosphodiesterases. It also produces increased deformability of erythrocytes, the mechanism of which is so far unknown, although phosphodiesterase inhibition may again be responsible. Cyclandelate also reduces the activity of the rate-limiting enzyme in the biosynthesis of cholesterol (HMG-CoA), and its "antidiabetic" properties may be due to inhibition of aldose reductase.

© 2006 Elsevier B.V. All rights reserved.

Cyclandelate is mainly given to elderly patients with mild to moderate cognitive impairment; it is also used in the prophylaxis of migraine. Its efficacy is not impressive (SEDA-21, 215) (1).

Major adverse effects have not been reported with dosages of 1.6 g/day. Gastrointestinal upset, flushing, and tingling are rare and minor complaints. Even elderly patients apparently tolerate 3.2 g/day without problems (SEDA-9, 189).

Reference

1. Diener HC, Krupp P, Schmitt T, Steitz G, Milde K, Freytag S. Cyclandelate in the prophylaxis of migraine: a placebo-controlled study. Cephalalgia 2001;21(1):66–70.

Cyclazocine

General Information

Cyclazocine is an agonist at OP_2 (κ) opioid receptors and it is its affinity for these receptors that is thought to account for disruption of the normal sleep pattern, urination, and sustained arousal that it causes (1). Visual disturbances and racing thoughts have also been reported and are subject to tolerance (2).

Long-Term Effects

Drug withdrawal

Abrupt withdrawal resulted in a classical withdrawal syndrome, but without drug-seeking behavior (2). Adverse effects could be minimized by gradual increments in daily dosage over 3 weeks.

References

1. Pickworth WB, Neidert GL, Kay DC. Cyclazocine-induced sleep disruptions in nondependent addicts. Prog Neuropsychopharmacol Biol Psychiatry 1986;10(1):77–85.

Cyclizine

See also Antihistamines

General Information

Cyclizine is a first-generation antihistamine, a piperazine derivative, with sedative and antimuscarinic activity, although its sedative effects are not marked.

Organs and Systems

Nervous system

Four cases of dystonic reactions caused by single doses of cyclizine have been reported (1–4).

Long-Term Effects

Drug abuse

Abuse of cyclizine in teenagers has been described (5).

References

1. King H, Corry P, Wauchob T, Barclay P. Probable dystonic reaction after a single dose of cyclizine in a patient with a history of encephalitis. Anaesthesia 2003;58(3):257–60.

Cyclobenzaprine

General Information

Cyclobenzaprine is a centrally acting skeletal-muscle relaxant, claimed to be effective in providing relief of muscle spasm, pain and tenderness, and in reducing the limitations imposed thereby on normal daily activities. The recommended total oral daily dose is 10–30 mg (1). It is structurally similar to the tricyclic antidepressants and adverse effects similar to those seen with the tricyclic antidepressants are therefore to be expected.

The most common adverse effects of cyclobenzaprine are somnolence, dry mucous membranes, dizziness, and confusion. Less commonly, tachycardia, dysarthria, disorientation, and hallucinations have been reported (2).

Organs and Systems

Cardiovascular

Cyclobenzaprine can occasionally cause marked arteriolar spasm due to increased adrenergic tone, precipitating Raynaud's syndrome (SEDA-6, 132).

Psychological, psychiatric

Rarely, manic psychosis can be activated in patients with bipolar affective disorders (3).

First-onset paranoid psychosis has also been reported (4).

© 2006 Elsevier B.V. All rights reserved.

- A 36-year-old woman with no past psychiatric problems took 23 tablets of cyclobenzaprine (10 mg each) over 6 weeks to ease back pain resulting from a back injury. She developed insomnia, reduced appetite, poor concentration, irritability, disorganized thoughts, persecutory delusions, and auditory hallucinations. Cyclobenzaprine was withdrawn and a course of loxapine was started, leading to rapid and complete resolution of her agitation and psychotic symptoms within 72 hours. Loxapine was subsequently quickly withdrawn with no ill effects and she recovered fully.

The authors thought that this psychotic episode was related to cyclobenzaprine, in view of the temporal relation of the symptoms to the administration of cyclobenzaprine and their rapid resolution after withdrawal.

Drug Administration

Drug overdose

Common effects of cyclobenzaprine overdose were lethargy, agitation, sinus tachycardia, and both hypertension and hypotension (5).

Cyclofenil

General Information

Cyclofenil is a weak non-steroidal estrogen related to diethylstilbestrol. For a number of years it was used for inducing ovulation, but has lost favor; more recently there have been studies of its possible effects in Raynaud's phenomenon secondary to scleroderma (1).

Up to 2% of patients taking cyclofenil complain of nausea, vomiting, hot flushes, or headache. Mild abdominal pain has been reported in up to 18%, ovarian enlargement without cysts in 3%, and galactorrhea in 4%. There have been a few case reports of hemolytic anemia (SED-12, 1034) (2).

Organs and Systems

Liver

Cyclofenil can cause reversible mild cholestatic jaundice. The authors of a review of 30 patients with hepatic reactions to cyclofenil concluded that liver derangement due to cyclofenil is probably related to metabolic hypersusceptibility rather than to a direct toxic effect (3). There is a surprising lack of such reports from countries where cyclofenil was widely used: in France, at least, the number of cases of hepatitis occurring is known to have been much greater than that reported in print, and the drug was abandoned in that country in 1988.

Cyclopentolate hydrochloride

General Information

Cyclopentolate is an anticholinergic drug used as a mydriatic.

Organs and Systems

Skin

Contact urticaria has been reported with cyclopentolate (1).

- A 72-year-old man, with a history of adverse reactions to sulfonamides, had erythema, edema, itching, burning of the eye, and an urticarial rash on his right cheek after the administration of several drugs to his right eye. Patch testing was performed and the cyclopentolate hydrochloride patch showed erythema after 15 minutes and an itching wheal after 30 minutes. No immediate or delayed reaction was observed with any of the other eye-drops. Patch tests with cyclopentolate hydrochloride in eight healthy volunteers were negative.

Cyclophosphamide

General Information

Cyclophosphamide is an alkylating nitrogen mustard derivative mainly used in oncology patients (1) or in conditioning regimens for bone marrow transplantation. Its immunosuppressant properties have been used in organ transplantation and more often in chronic inflammatory disorders or autoimmune diseases.

Observational studies

Cyclophosphamide has been investigated in a wide range of diseases, but results in aplastic anemia and idiopathic pulmonary fibrosis have been disappointing. In a low dose (2 mg/kg/day), it produced minimal efficacy in 19 patients with idiopathic pulmonary fibrosis who had failed to respond to a glucocorticoid or who had had adverse effects (2). Moreover, 13 patients had cyclophosphamide-induced adverse effects, which required drug withdrawal in 9. The most frequent were severe gastrointestinal effects, leukopenia, and skin rashes. In another study, high-dose cyclophosphamide plus ciclosporin (50 mg/kg/day for 4 days) was compared with antithymocyte globulin plus ciclosporin in patients with severe aplastic anemia, but the trial was prematurely stopped after only 31 patients had been enrolled because of three early deaths in patients taking cyclophosphamide (3). Subsequent analysis showed excess morbidity and mortality in patients taking cyclophosphamide, with six proven or suspected cases of systemic fungal infection (including the three deaths) compared with no cases in the other group, but no significant difference in the hematological response rates between the groups. In addition, the durations of hospital stay, neutropenia, and antibacterial treatment were longer with cyclophosphamide. Based on these results, the authors concluded that cyclophosphamide should not be used in aplastic anemia.

General adverse effects

Common adverse effects observed at low doses of cyclophosphamide are similar to, but less frequent than, those observed in oncology patients. They include gastrointestinal disturbances (mostly nausea), hematological toxicity (mostly leukopenia), alopecia, and infectious complications (4,5).

Organs and Systems

Cardiovascular

Cardiac toxicity can be observed at high doses of cyclophosphamide (usually over 1.5 g/m^2/day), and acute myocardial necrosis or severe cardiac failure have been anecdotally reported after smaller dosages (SEDA-21, 386).

High-dose cyclophosphamide (120–200 mg/kg) can cause lethal cardiotoxicity, and severe congestive heart failure can develop 1–10 days after the first dose. Severe congestive heart failure is accompanied by electrocardiographic findings of diffuse voltage loss, cardiomegaly, pulmonary vascular congestion, and pleural and pericardial effusions. Pathological findings include hemorrhagic myocardial necrosis, thickening of the left ventricular wall, and fibrinous pericarditis.

Of 80 patients who received cyclophosphamide 50 mg/kg/day for 4 days in preparation for bone marrow grafting 17% had symptoms consistent with cyclophosphamide cardiotoxicity (6). Six died from congestive heart failure. Older patients were at greatest risk of developing cardiotoxicity.

In six patients who developed heart failure after high-dose conditioning therapy before stem cell transplantation, cyclophosphamide was suspected, despite the possible involvement of four drugs (7). The authors suggested monitoring high-risk patients.

Corrected QT dispersion was a predictor of acute heart failure after high-dose cyclophosphamide chemotherapy (5.6 g/m^2 over 4 days) in 19 patients (8).

Respiratory

Cyclophosphamide-induced pneumonitis has been described in 29 cases (9). Considering the widespread use of this drug over many years, this is a rare adverse effect. It does not clearly correlate with dosage (SED-8, 1112) (SED-13, 1122). From a review of 12 case reports and a retrospective analysis of six other patients (including four with Wegener's granulomatosis), in whom cyclophosphamide was thought to be the only causative factor, two distinct clinical patterns of pneumonitis with different prognoses were identified (10). Early-onset pneumonitis ($n = 8$) occurred acutely within 1–8 months of treatment, and complete recovery was noted after cyclophosphamide withdrawal and prednisone treatment. In contrast, late-onset pneumonitis ($n = 10$) developed insidiously over several months (eventually after cyclophosphamide withdrawal) in patients maintained taking low daily doses for months to years. These patients had progressive pulmonary fibrosis unresponsive to glucocorticoid therapy, and six died of respiratory failure. Radiological pleural thickening may be an early sign of late-onset lung toxicity.

Nervous system

Progressive multifocal leukoencephalopathy is sometimes associated with Wegener's granulomatosis, but one case occurred in a patient who was taking low-dose cyclophosphamide, with subsequent significant improvement on withdrawal of the drug (SEDA-19, 347).

Sensory systems

Blurred vision is sometimes reported after high intravenous doses of cyclophosphamide, and there has been one report of transient myopia that recurred after each monthly intravenous pulse (11).

Endocrine

Even low-dose intravenous cyclophosphamide can cause a syndrome that resembles inappropriate secretion of antidiuretic hormone, with severe hyponatremia and symptoms of water intoxication (SEDA-19, 347) (SEDA-21, 386). A direct effect on the renal tubules is likely, but no other nephrotoxic effects have been documented.

Hematologic

Leukopenia, and less commonly thrombocytopenia or anemia, due to cyclophosphamide are typically dose-related in the therapeutic range. Cyclophosphamide-induced anemia has led to retinopathy presenting as striated hemorrhage of the retina (12).

Relative eosinophilia and increased interleukin-4 secretion were found in one study, suggesting that an immune deviation toward a type-2 T helper cell (Th2) response can occur (13). The clinical relevance of these findings as regards hypersensitivity reactions is unknown.

The idea that the degree of leukocyte suppression can be used to predict the success of adjuvant chemotherapy has been applied to combined treatment with cyclophosphamide, methotrexate, and 5-fluorouracil for breast cancer; the lower the nadir leukocyte count, the greater the incidence of metastatic disease-free survival (14).

Mouth and teeth

Unilateral necrosis of the tongue has been attributed to cyclophosphamide (15).

- A 62-year-old woman with invasive ductal carcinoma of the breast was treated with epirubicin and cyclophosphamide. She rapidly developed swelling and necrosis of the tongue and consequent airway obstruction necessitating tracheostomy. After excision of the necrosis, the swelling of the tongue and the airway obstruction resolved.

Because of the temporal connection between the necrosis and the chemotherapy, the authors suspected an adverse effect, although they could not exclude a paraneoplastic pathogenesis.

Gastrointestinal

Nausea and vomiting are infrequent with daily low-dose cyclophosphamide (4).

Two-thirds of patients treated with cyclophosphamide orally for 4 months plus intravenous 5-fluorouracil and methotrexate for breast cancer developed Barrett's epithelium (16), perhaps as a result of esophagitis, rather than through mucosal re-epithelialization by undifferentiated stem cells (17).

Toxic megacolon occurred after five cycles of epirubicin 70 mg/m^2, 5-fluorouracil 500 mg/m^2, and oral cyclophosphamide 75 mg/m^2 for 14 days (18). The clinical presentation included a raised erythrocyte sedimentation rate and a colonic diameter of greater than 9 cm; the outcome can be fatal.

Liver

Cyclophosphamide-induced, dose-related liver damage is probably caused as a result of impaired clearance of its metabolite acrolein (19). This causes raised serum transaminases (20) and can be aggravated by prior exposure to azathioprine.

Acute reversible cytolytic or cholestatic jaundice can also occur after low-dose cyclophosphamide in adults and children (SED-13, 1122) (SEDA-19, 347) (SEDA-20, 342) (SEDA-21, 386). Acute liver failure required liver transplantation in one patient (21). Although glucocorticoids were given concomitantly in most of these patients, no data are available to indicate a possibly increased hepatotoxic potential of this drug combination.

Hepatic veno-occlusive disease was attributed to low-dose cyclophosphamide in a 2-year-old child, and in repeated episodes of serum transaminase fluctuations in a patient with hepatitis C virus infection (SEDA-19, 347).

Late hepatotoxicity has also been reported with low-dose cyclophosphamide (22).

- A 67-year-old man with Sjögren's syndrome took cyclophosphamide for 2 years, a cumulative dose of 40.5 g. He then developed severe progressive jaundice due to acute hepatocellular injury. Gallstones and acute viral hepatitis were excluded, and only anti-smooth muscle antibodies were weakly positive. Liver histology showed marked ballooning of the hepatocytes and cell loss, cytoplasmic and canalicular cholestasis, and infiltration of the portal tract with inflammatory cells. Complete resolution occurred 6 weeks after cyclophosphamide withdrawal.

The authors emphasized this was the first case suggesting a cumulative hepatotoxic effect of low-dose cyclophosphamide. Previous rare cases of low-dose cyclophosphamide-induced acute hepatitis have usually occurred within the first 2 months.

Urinary tract

Hemorrhagic cystitis and bladder cancer are well-known complications of cyclophosphamide. The damage to the urinary bladder epithelium is caused by acrolein, a metabolite of cyclophosphamide that is excreted in the urine. In bone marrow transplant recipients, prior administration of busulfan, which itself causes hemorrhagic cystitis, can increase this risk (23). Mesna (2-mercaptoethane sodium sulfonate) is used to prevent this adverse effect. It is excreted by the kidney, and it binds and detoxifies acrolein in the urine; mesna also prevents the breakdown of acrolein precursors. Intravesical prostaglandin E_2 has been suggested as an alternative treatment (23).

The incidence of cystitis and/or dysuria was only 8% in 531 women with breast cancer who were given oral cyclophosphamide 60 mg/m^2/day for 1 year; the majority of cases were only grade 1 (24).

Upper renal tract disorders with ureteric reflux and bilateral hydronephrosis has been briefly reported in a patient with a history of cyclophosphamide-induced cystitis (SEDA-22, 410–411).

In 155 patients with Wegener's granulomatosis, of whom 142 took daily oral cyclophosphamide, the most frequent long-term cyclophosphamide-related adverse effects were cystitis despite mesna therapy (12%) and myelodysplasia (8%) (25). Patients who took a cumulative dose of over 100 g had a two-fold greater risk of cystitis and/or myelodysplasia than patients who took under 100 g. The authors emphasized that cyclophosphamide therapy should be as short as possible, with mesna and close surveillance in order to reduce treatment-associated morbidity.

Cyclophosphamide was thought to have favored the development of emphysematous cystitis in a 73-year-old man (26).

© 2006 Elsevier B.V. All rights reserved.

Skin

High doses of cyclophosphamide can cause the erythrodysesthesia syndrome, that is erythema of the hands and feet (27).

Stevens–Johnson syndrome developed in two patients, including one with positive rechallenge (SEDA-20, 342).

Five of thirty-two patients treated with the alternating drug regimen CAMBO-VIP (cyclophosphamide, doxorubicin, methotrexate, bleomycin, vincristine, etoposide, ifosfamide, and prednisolone) for non-Hodgkin's lymphoma developed blisters under the thickened skin of the palms and/or soles, followed by desquamation (28).

Discrete cutaneous hyperpigmentation occurred in two patients after high-dose chemotherapy with cyclophosphamide, etoposide, and carboplatin (29).

Hair

Alopecia occurs in patients taking cyclophosphamide, but it is less common and less severe in patients taking low doses. Mild to moderate alopecia was observed in 17% of patients with Wegener's granulomatosis (4).

Nails

Beau's lines (transverse ridging of the nails) developed after multiple drug therapy for Hodgkin's disease, including cyclophosphamide (30).

Reproductive system

In autoimmune diseases cyclophosphamide can cause menstrual disorders (oligomenorrhea or sustained amenorrhea) and ultimately sterility or premature menopause. This has been particularly exemplified in lupus erythematosus, and several studies have shown a high prevalence of menstrual disorders or premature ovarian failure in cyclophosphamide-treated patients, or a significantly higher incidence of both complications compared with other immunosuppressive regimens or healthy controls (31–33).

Of 17 adult men who had been treated before puberty for sarcoma with high-dose pulse cyclophosphamide (median dose 20.5 m/m^2) as part of regimens containing vincristine, dactinomycin, and cyclophosphamide, with or without doxorubicin, 10 had azoospermia, five had oligospermia, and only two had normal sperm counts (34). The authors concluded that a previous suggestion that puberty acts as a protection to infertility was not borne out and that the risk of infertility was proportional to the cumulative dose of cyclophosphamide.

Susceptibility factors have been investigated in a large retrospective study of 274 patients aged under 45 years, of whom 70 had received cyclophosphamide, 84 azathioprine but not cyclophosphamide, and 88 either no drug or hydroxychloroquine alone (35). The overall incidence of ovarian failure, defined as sustained amenorrhea for at least 12 months and documented by reduced estradiol concentrations, was 26, 1, and 0% respectively. The mean delay to onset of the first missed menses was 4.4 months. A higher age at the start of treatment and cumulative dose were independent risk factors for cyclophosphamide-induced ovarian failure. The incidences were 14, 28, and 50% in patients aged under 30 years, 30–39 years, and over 40 years respectively, and 4, 26, 31, 70% for cumulative doses of under 10, 10–20, 20–30, and over 40 g, respectively.

Immunologic

Type I hypersensitivity

Anaphylactic reactions have very rarely occurred after intravenous cyclophosphamide (SED-8, 1126) (SEDA-17, 522) (36), and positive skin tests to the parent drug and/or 4-hydroxycyclophosphamide were found in several well-documented case reports (SEDA-19, 347). Although other mechanisms could be considered, a possible IgE antibody-mediated reaction was substantiated by the positivity of immediate skin tests to cyclophosphamide metabolites in five patients, and the recurrence of symptoms following intravenous or oral rechallenge in several of them (37).

Cyclophosphamide reportedly caused a type I hypersensitivity reaction in a patient with systemic lupus erythematosus (38).

- A 17-year-old Chinese girl with systemic lupus erythematosus developed acute angioedema over the neck, chest, and larynx, and required mechanical ventilation. She had received two previous courses of cyclophosphamide without incident. She developed urticaria 30 minutes after an infusion of cyclophosphamide, without angioedema, stridor, wheezing, or hypotension. Skin prick testing with cyclophosphamide was negative. Four weeks later, 15 minutes after the start of an infusion of cyclophosphamide, she developed generalized urticaria. Further infusions were given with diphenhydramine premedication.

In the absence of drug-induced angioedema or anaphylaxis, monthly therapy with cyclophosphamide can be continued with antihistamine premedication in patients who have allergic reactions.

Infection risk

Owing to its effects on cellular and humoral immune responses, and independently of leukopenia, cyclophosphamide can induce more frequent and more severe infectious complications (SED-13, 1123) (SEDA-20, 343). Older age and total cumulative dose are possible susceptibility factors for severe infectious episodes. More specifically, an increased risk of severe, life-threatening *Pneumocystis jiroveci* pneumonia has been identified, particularly in patients with lymphopenia (39,40). There was also a 10- to 20-fold increase in *Herpes zoster* infections (41,42). Fatal aspergillosis and disseminated cryptococcosis have been sometimes reported (SEDA-20, 343) (43). Infections were mostly reported in patients who were also taking glucocorticoids, and a synergistic effect with glucocorticoids is likely to be relevant in causation (41,44); all the same, there is direct evidence that cyclophosphamide itself is involved. Its role was investigated in a retrospective study of 100 patients with systemic lupus erythematosus: 45% developed serious bacterial infections (58%), opportunistic infections (24%), or *H. zoster* infections (18%), compared with 12% in 43 patients taking high-dose glucocorticoids alone (45). Infections were more frequent with sequential intravenous and oral cyclophosphamide (68%) than with intravenous

© 2006 Elsevier B.V. All rights reserved.

cyclophosphamide (39%) or oral cyclophosphamide (40%), and leukopenia was an additional risk factor. Other investigators have similarly adduced evidence of more frequent infections, particularly *P. jiroveci* pneumonia, in patients receiving cyclophosphamide plus glucocorticoids daily rather than alternate-day glucocorticoids (41).

- A 72-year-old man with autoimmune thrombocytopenia had taken prednisone (30 mg/day) for 1 year, when he was found to have systemic lupus erythematosus (46). Prednisone was continued and he started to take chloroquine (250 mg/day) and monthly cyclophosphamide (0.75 g/m^2). Three weeks after the first bolus of cyclophosphamide, he complained of fever and dyspnea, and chest X-rays showed bilateral pulmonary infiltrates. Despite prompt medical management, he died 5 days after admission with cytomegalovirus-induced interstitial pneumonia.

In addition to cyclophosphamide, this patient had several susceptibility factors for fatal infection, namely age (older than 50 years) and a low leukocyte nadir (2900×10^6/l) after treatment with cyclophosphamide and prednisone.

Long-Term Effects

Tumorigenicity

Although tumor induction has mostly been documented in patients treated for cancer, long-term cyclophosphamide treatment for non-neoplastic conditions can also increase the incidence of certain neoplasms. Whether this oncogenic effect is a consequence of drug-induced chromosomal aberrations rather than immunosuppression is unclear. An increased incidence of bladder cancers, skin cancers, and myeloproliferative disorders was found in a 20-year follow-up study of 119 patients with rheumatoid arthritis, and a high dose of cyclophosphamide (mean total dose of 80 g) was the main susceptibility factor (47).

In another study in patients with Wegener's granulomatosis there was an 11-fold increase in the incidence of lymphomas compared with the general population (41). In contrast, previous exposure to cyclophosphamide did not appear to be associated with a significantly higher risk of cancer in patients with systemic lupus erythematosus, but the number of cases was very low (48).

Myelodysplastic syndromes

Cyclophosphamide can cause myelodysplastic syndromes, particularly after prolonged treatment. The type of myelodysplastic syndromes and cytogenetic abnormalities that developed after treatment with alkylating agents for rheumatic diseases have been described in eight patients (mean age 57 years), of whom seven had taken oral cyclophosphamide and one chlorambucil (49). The mean cumulative dose of cyclophosphamide was 118 g for a mean cumulative duration of 4.4 years, and the myelodysplastic syndrome was diagnosed 0–4 years (mean 2.4 years) after the end of treatment. Concomitant immunosuppressive drugs were given in four of seven cyclophosphamide-treated patients. Cytogenetic abnormalities of chromosome 5 and/or 7, which are characteristic of treatment-related myelodysplastic syndromes, were found in all patients. Only two patients were still alive at the time of the report, and the outcome was remarkably poor in patients with chromosome 5 deletion. This study suggested that a high cumulative dose of cyclophosphamide is a risk factor for hematological malignancies, and that patients require long-term surveillance.

Urinary tract tumors

Squamous cell carcinoma of the bladder has been reported 4 years after pulsed cyclophosphamide therapy (50). However, the authors noted that other susceptibility factors, such as bladder diverticula and human papilloma virus infection, occurred in the intervening period and they speculated on the cumulative risk.

- A 72-year old woman who received 1400 mg cyclophosphamide over 2 weeks for Wegener's granulomatosis had gross hematuria and dysuria (51). Cystoscopy was normal, but there was marked irregularity of the mucosa of the upper ureteric mucosa, the renal pelvis, and the renal calyces on retrograde ureteropyelography. Nephroscopy showed a gray necrotic uroepithelium with dystrophic calcification.

The risk of bladder cancer persists for as long as 20 years after cyclophosphamide withdrawal. In a retrospective analysis, half of the 145 patients on long-term treatment for Wegener's granulomatosis had microscopic or gross hematuria, among whom 70% had cystoscopic features compatible with cyclophosphamide-induced bladder injury (52). Seven patients (5%) developed bladder cancer, a 31-fold higher incidence than in the general population. As previous episodes of hematuria were found in all seven patients and the drug was the only significant risk factor for bladder cancer, prompt cystoscopy should be done in any patient who develops gross hematuria, even after treatment withdrawal. Another study showed an excess in the incidence of bladder cancer in patients with multiple sclerosis who received cyclophosphamide and who also had an indwelling catheter (53).

Renal adenocarcinoma has been reported in a 50-year-old man after 3 years of cyclophosphamide treatment for hepatic sarcoidosis (54).

Other tumors

It has been suggested that cyclophosphamide can contribute to the risk of cervical dysplasia. In a retrospective study of 110 patients with systemic lupus erythematosus, cervical dysplasia was significantly more frequent in patients who had received intravenous cyclophosphamide (10 of 61) than in a control group who did not receive cyclophosphamide (two of 49) (55). In addition, cervical pathology worsened during cyclophosphamide therapy in all four patients with pre-existing cervical dysplasia, and one patient developed in situ cervical carcinoma.

- A 54-year-old man with polyarteritis nodosa developed hepatic angiosarcoma after taking cyclophosphamide for 13 years (56). Although this may have been coincidental, the authors found two other published reports of this very rare tumor in patients taking long-term cyclophosphamide.
