ELSEVIER

MEYLER'S Side Effects of Drugs

The International Encyclopedia of Adverse Drug Reactions and Interactions

Fifteenth Edition

J.K. ARONSON

Editor

JK Aronson, MA, DPhil, MBChB, FRCP, FBPharmacol S

Oxford, United Kingdom

Honorary Editor
MNG Dukes, MA, DPhil, MB, FRCP
Oslo, Norway

Contributors

In this list the main contributors to the Encyclopedia are identified according to the original chapter material to which they made the most contribution. Most have contributed the relevant chapters in one or more editions of the *Side Effects of Drugs Annuals* 23-27 and/or the 14th edition of *Meyler's Side Effects of Drugs*. A few have contributed individual monographs to this edition.

M. Allwood
Derby, United Kingdom
Intravenous infusions—solutions and emulsions

M. Andersen
Odense, Denmark
Antihistamines

M. Andrejak
Amiens, France
Drugs affecting blood coagulation, fibrinolysis, and hemostasis

J.K. Aronson
Oxford, United Kingdom
Antiepileptic drugs
Antiviral drugs
Positive inotropic drugs and drugs used in dysrhythmias

S. Arroyo
Milwaukee, Wisconsin, USA
Antiepileptic drugs

I. Aursnes
Oslo, Norway
Drugs that affect lipid metabolism

H. Bagheri
Toulouse, France
Radiological contrast agents

A.M. Baldacchino
London, United Kingdom
Opioid analgesics and narcotic antagonists

D. Battino
Milan, Italy
Antiepileptic drugs

Z. Baudoin
Zagreb, Croatia
General anesthetics and therapeutic gases

A.G.C. Bauer
Rotterdam, The Netherlands
Antihelminthic drugs
Dermatological drugs, topical agents, and cosmetics

M. Behrend
Deggendorf, Germany
Drugs acting on the immune system

T. Bicanic
London, United Kingdom
Antiprotozoal drugs

L. Biscarini
Perugia, Italy
Anti-inflammatory and antipyretic analgesics and drugs used in gout

J. Blaser
Zurich, Switzerland
Various antibacterial drugs

C. Bokemeyer
Tübingen, Germany
Cytostatic drugs

S. Borg
Stockholm, Sweden
Antidepressant drugs

J. Bousquet
Montpellier, France
Antihistamines

P.J. Bown
Redhill, Surrey, United Kingdom
Opioid analgesics and narcotic antagonists

C.N. Bradfield
Auckland, New Zealand
General anesthetics and therapeutic gases

C.C.E. Brodie-Meijer
Amstelveen, The Netherlands
Metal antagonists

P.W.G. Brown
Sheffield, United Kingdom
Radiological contrast agents

A. Buitenhuis
Amsterdam, The Netherlands
Sex hormones and related compounds, including hormonal contraceptives

H. Cardwell
Auckland, New Zealand
Local anesthetics

A. Carvajal
Valladolid, Spain
Antipsychotic drugs

R. Cathomas
Zurich, Switzerland
Drugs acting on the respiratory tract

A. Cerny
Zurich, Switzerland
Various antibacterial drugs

G. Chevrel
Lyon, France
Drugs acting on the immune system

C.C. Chiou
Bethesda, Maryland, USA
Antifungal drugs

N.H. Choulis
Attika, Greece
Metals
Miscellaneous drugs and materials, medical devices, and techniques not dealt with in other chapters

L.G. Cleland
Adelaide, Australia
Corticotrophins, corticosteroids, and prostaglandins

P. Coates
Adelaide, Australia
Miscellaneous hormones

J. Costa
Badalona, Spain
Corticotrophins, corticosteroids, and prostaglandins

P. Cottagnoud
Bern, Switzerland
Various antibacterial drugs

P.C. Cowen
Oxford, United Kingdom
Antidepressant drugs

S. Curran
Huddersfield, United Kingdom
Hypnosedatives and anxiolytics

H.C.S. Daly
Perth, Western Australia
Local anesthetics

A.C. De Groot
Hertogenbosch, The Netherlands
Dermatological drugs, topical agents, and cosmetics

M.D. De Jong
Amsterdam, The Netherlands
Antiviral drugs

A. Del Favero
Perugia, Italy
Anti-inflammatory and antipyretic analgesics and drugs used in gout

P. Demoly
Montpellier, France
Antihistamines

J. Descotes
Lyon, France
Drugs acting on the immune system

A.J. De Silva
Ragama, Sri Lanka
Snakebite antivenom

H.J. De Silva
Ragama, Sri Lanka
Gastrointestinal drugs

F.A. De Wolff
Leiden, The Netherlands
Metals

S. Dittmann
Berlin, Germany
Vaccines

M.N.G. Dukes
Oslo, Norway
Antiepileptic drugs
Antiviral drugs
Metals
Sex hormones and related compounds, including hormonal contraceptives

H.W. Eijkhout
Amsterdam, The Netherlands
Blood, blood components, plasma, and plasma products

E.H. Ellinwood
Durham, North Carolina, USA
Central nervous system stimulants and drugs that suppress appetite

C.J. Ellis
Birmingham, United Kingdom
Drugs used in tuberculosis and leprosy

P. Elsner
Jena, Germany
Dermatological drugs, topical agents, and cosmetics

T. Erikkson
Lund, Sweden
Thalidomide

E. Ernst
Exeter, United Kingdom
Treatments used in complementary and alternative medicine

M. Farré
Barcelona, Spain
Corticotrophins, corticosteroids, and prostaglandins

P.I. Folb
Cape Town, South Africa
Cytostatic drugs
Intravenous infusions—solutions and emulsions

J.A. Franklyn
Birmingham, United Kingdom
Thyroid hormones and antithyroid drugs

M.G. Franzosi
Milan, Italy
Beta-adrenoceptor antagonists and antianginal drugs

J. Fraser
Glasgow, Scotland
Cytostatic drugs

H.M.P. Freie
Maastricht, The Netherlands
Antipyretic analgesics

C. Fux
Bern, Switzerland
Various antibacterial drugs

P.J. Geerlings
Amsterdam, The Netherlands
Drugs of abuse

A.H. Ghodse
London, United Kingdom
Opioid analgesics and narcotic antagonists

P.L.F. Giangrande
Oxford, United Kingdom
Drugs affecting blood coagulation, fibrinolysis, and hemostasis

G. Gillespie
Perth, Australia
Local anaesthetics

G. Girish
Sheffield, United Kingdom
Radiological contrast agents

V. Gras-Champel
Amiens, France
Drugs affecting blood coagulation, fibrinolysis, and hemostasis

A.I. Green
Boston, Massachusetts, USA
Drugs of abuse

A.H. Groll
Münster, Germany
Antifungal drugs

H. Haak
Leiden, The Netherlands
Miscellaneous drugs and materials, medical devices, and techniques not dealt with in other chapters

F. Hackenberger
Bonn, Germany
Antiseptic drugs and disinfectants

J.T. Hartmann
Tübingen, Germany
Cytostatic drugs

K. Hartmann
Bern, Switzerland
Drugs acting on the respiratory tract

A. Havryk
Sydney, Australia
Drugs acting on the respiratory tract

E. Hedayati
Auckland, New Zealand
General anesthetics and therapeutic gases

E. Helsing
Oslo, Norway
Vitamins

R. Hoigné
Wabern, Switzerland
Various antibacterial drugs

A. Imhof
Seattle, Washington, USA
Various antibacterial drugs

L.L. Iversen
Oxford, United Kingdom
Cannbinoids

J. W. Jefferson
Madison, Wisconsin, USA
Lithium

D.J. Jeffries
London, United Kingdom
Antiviral drugs

M. Joerger
St Gallen, Switzerland
Drugs acting on the respiratory tract

G.D. Johnston
Belfast, Northern Ireland
Positive inotropic drugs and drugs used in dysrhythmias

P. Joubert
Pretoria, South Africa
Antihypertensive drugs

A.A.M. Kaddu
Entebbe, Uganda
Antihelminthic drugs

C. Koch
Copenhagen, Denmark
Blood, blood components, plasma, and plasma products

H. Kolve
Münster, Germany
Antifungal drugs

H.M.J. Krans
Hoogmade, The Netherlands
Insulin, glucagon, and oral hypoglycemic drugs

M. Krause
Scherzingen, Switzerland
Various antibacterial drugs

S. Krishna
London, United Kingdom
Antiprotozoal drugs

M. Kuhn
Chur, Switzerland
Drugs acting on the respiratory tract

R. Latini
Milan, Italy
Beta-adrenoceptor antagonists and antianginal drugs

T.H. Lee

Foreword

My doctor is
A good doctor
He made me no
Iller than I was

Willem Hussem (The Netherlands) 1900–1974
Translation: Peter Raven

"*Primum non nocere*"—in the first place, do no harm—is often cited as one of the foundation stones of sound medical care, yet its origin is uncertain. Hippocrates? There are some who will tell you so;[1] but the phrase is not a part of the Hippocratic Oath, and the Father of Medicine wrote in any case in his native Greek.[2] It could be that the Latin phrase is from the Roman physician Galenius, while others attribute it to Scribonius Largus, physician to one of the later Caesars,[3] and there is a lot of reason to believe that it actually originated in 19th century England.[4] Hippocrates himself, in the first volume of his *Epidemics*, put it at all events better in context: "When dealing with diseases have two precepts in mind: to procure benefit and not to harm."[5] One must not become overly obsessed by the safety issue, but it is a necessary element in good medical care.

The ability to do good with the help of medicines has developed immensely within the last century, but with it has come the need to keep a watchful eye on the possibility of inflicting harm on the way. The challenge is to recognize at the earliest possible stage the adverse effects that a valuable drug may induce, and to find ways of containing them, so that risk never becomes disproportionate to benefit. The process of drug development will sometimes result in methods of treatment that are more specific to their purpose than were their predecessors and hence less likely to produce unwanted complications; yet the more novel a therapeutic advance the greater the possibility of its eliciting adverse effects of a type so unfamiliar that they are not specifically looked for and long remained unrecognized when they do occur. The entire process of keeping medicines safe today involves all those concerned with them, whether as researchers, manufacturers, regulators, prescribers, dispensers, or users, and it demands an effective and honest flow of information and thought between them.

For several decennia, concerned by its own errors in the past, the science of therapeutics put unbounded faith in the ability of well-planned clinical trials to arrive at the truth about the properties of medicines. Insofar as efficacy was concerned that was and remains a sound move, closing the door to charlatanism as well as to well-meant amateurism. Therapeutic trials with a new medicine were also able to delineate those adverse effects that occurred in a fair proportion of users. If serious, they would bar the drug from entry to the market altogether, while if transient and reasonably tolerable they would form the basis for warnings and precautions as well as the occasional contraindication. The problem lay with those adverse drug reactions that occurred rather less commonly or not at all in populations recruited for therapeutic trials, yet which could soon arise in the much broader spectrum of patients exposed to the drug once it was marketed across the world. The influence of race or climate might explain some of them; others might reflect interactions with foods, alcohol, or other drugs; yet others could only be explained, if at all, in terms of the particular susceptibility of certain individuals. Scattered across the globe, these effects might readily be overlooked, regarded as coincidental, or at worst dismissed contemptuously as "merely anecdotal".

The seriousness of the adverse effects issue became very apparent even as the reputation of controlled trials deservedly grew, and it touched on both newer and older drugs. The thalidomide calamity, involving several thousand cases of drug-induced phocomelia, was fortunately recognized by Widukind Lenz and others in the light of individual case reports within two years of the introduction of the product. On the other hand, generations elapsed between the patenting of aspirin in 1899 and the realization in 1965 that it might induce Reye's syndrome when used to treat fever in children. Such events, and many less spectacular, showed that, however vital well-controlled studies had become, there was good reason to remain alert for signals emerging from individual cases. Unanticipated events occurring during drug treatment might indeed reflect mere coincidence, but again they might not; and for many of the patients who suffered in consequence there was nothing in the least anecdotal about them.

Fortunately, the 1950s and 1960s of the 20th century saw the first positive reactions to the adverse reaction issue. Effective drug regulation emerged in one country after another. In 1952, Prof. Leo Meyler of The Netherlands produced his first "Side Effect of Drugs" to pull together data from the world literature. A number of national adverse reaction monitoring bureaux were established to gather data from the field and examine carefully reports of suspected side effects of medicines, creating the basis for the World Health Organization to establish its global reporting system. The pharmaceutical industry has increasingly realized its duty to collect and pass on the information that comes into its possession through its wide contacts with the health professions. Later years have seen the emergence, notably in Sweden and in Britain, of systems through which patients themselves can report possible adverse effects to the medicines they have taken. All these processes fit together in what the French language so appropriately terms "pharmacovigilance", with vigilance as the watchword for all concerned.

In this continuing development, the medical literature provides a resource with vast potential. The world is believed to have some 20 000 medical journals, of which a nuclear group of a thousand or so can be relied upon to publish reports and analyses of adverse effects—not only in the framework of formal investigations but also in letters, editorials, and reports of meetings large and small. Much of that information comprises not so much firm facts as emergent knowledge, based directly on experience in the field and calling urgently for attention. The book that Leo Meyler created has, in the course of fifteen editions and with the support of an ever-larger team of professionals, provided the means by which that attention can be mobilized. It has become the world's principal tool in bringing together, encyclopedically but critically, the evidence on the basis of which adverse drug effects and interactions can be recognized, discussed, and accommodated into medical practice. Together with its massive database and its complementary *Side Effects of Drugs Annuals*, it has evolved into a vital instrument in ensuring that drugs are used wisely and well and with due caution, in the light of all that is known about them. There is nothing else like it, nor need there be; across the world, *Meyler* has become a pillar of responsible medical care.

M.N. Graham Dukes
Honorary Editor, *Meyler's Side Effects of Drugs*
Oslo, Norway

Notes

1. Lichtenhaeler C. Histoire de la Médicine, Fayard, Paris, 1978:117.
2. Smith CM. Origin and uses of *Primum non nocere*. J Clin Pharmacol 2005;45:371–7.
3. Albrecht H. Primum nil nocere. Die Zeit, 6 April, 2005.
4. Notably in a book by Inman T. *Foundation for a New Theory and Practice of Medicine*. London, 1860.
5. I am indebted to Jeffrey Aronson for his own translation of the Greek original from Hippocrates *Epidemics*, Book I, Section XI, which seems to convey the meaning of the original [ἀσκεῖν περὶ τὰ νοσημάτα δῦο, ὠφελειν ἢ μὴ βλάπτειν] rather better than the published translations of his work.

Preface

This is a completely new edition of what has become the standard reference text in the field of adverse drug reactions and interactions since Leopold Meyler published his first review of the subject 55 years ago. Although we have retained the old title, *Meyler's Side Effects of Drugs*, the subtitle of this edition, *The Encyclopedia of Adverse Drug Reactions and Interactions*, reflects both modern terminology and the scope of the review. The structure of the book may have changed, but the *Encyclopedia* remains the most comprehensive reference source on adverse drug reactions and interactions and a major source of informed discussion about them.

Scope

The scope of the *Encyclopedia* remains wide. It covers not only the vast majority of prescription drugs, old and new, but also non-prescribed substances (such as anesthetics, antiseptics, lifestyle compounds, and drugs of abuse), herbal medicines, devices (such as blood glucose meters), and methods in alternative and complementary medicine. For this edition, entries on some substances that were regarded as obsolete, such as thalidomide and smallpox vaccine, have been rewritten and restored. Other compounds, such as diethylstilbestrol, although no longer in use, continue to cast their shadow and are included. Yet others, currently regarded as obsolete, have been retained, both for historical reasons and because one can never be sure when an old compound may once more become relevant or provide useful information in relation to another compound. Some drugs have been withdrawn from the market in some countries since the last edition of *Meyler* was published; rofecoxib, cisapride, phenylpropanolamine, and kava (see Piperaceae) are examples. Nevertheless, detailed monographs have been included on these substances because of the lessons that they can teach us and in some cases because of their relevance to other compounds in their classes that are still available; it is also not possible to predict whether these compounds will eventually reappear in some other form or for some new indication.

In the last 15 years there has been increasing emphasis on the use of high-quality evidence in therapeutic practice, principally as obtained from large, randomized clinical trials and from systematic reviews of the results of many such trials. However, while it has been possible to obtain useful information about the beneficial effects of interventions in this way, evidence about harms, including adverse drug reactions, has been more difficult to obtain. Even trials that yield good estimates of benefits are poor at providing evidence about harms for several reasons:

- benefits are usually single, whereas harms are usually multiple;
- the chance of any single form of harm is usually smaller than the chance of benefit and therefore more difficult to detect; however, multiple harms can accumulate and affect the benefit-to-harm balance;
- benefits are identifiable in advance, whereas harms are not or not always;
- the likely time-course of benefits can generally be predicted, while the time-course of harms often cannot and may be much delayed by comparison with the duration of a trial.

For all these reasons, larger and sometimes longer studies are needed to detect harms. In recent years attempts have been made to conduct systematic reviews of adverse reactions, but these have also been limited by several problems:

- harms are in general poorly collected in randomized trials and trials may not last long enough to detect them all;
- even when they are well collected, as is increasingly happening, they are often poorly reported;
- even when they are well reported in the body of a report, they may not be mentioned in titles and abstracts;
- even when they are well reported in the body of a report, they may be poorly indexed in large databases.

All this means that it is difficult to collect information on adverse drug reactions from randomized, controlled trials for systematic review. This can be seen from the evidence provided in Table 1, which shows the proportion of different types of information that have been used in the preparation of two volumes of the *Side Effects of Drugs Annual*, proportions that are likely be the same in this *Encyclopedia*.

Wherever possible, emphasis in this *Encyclopedia* has been placed on information that has come from systematic reviews and clinical trials of all kinds; this is reflected in new headings under which trial results are reported (observational studies, randomized studies, placebo-controlled studies). However, because many reports of adverse drug reactions (about 30%) are anecdotal, with evidence from one or just a few cases, many individual case studies (see below) have also been included. We need better methods to make use of the information that this large body of anecdotes provides.

Structure

The first major change that readers will notice is that the chapter structure of previous editions has given way to a monographic structure. That is because some of the information about individual drugs has previously been scattered over different chapters in the book; for example ciclosporin was previously covered in Chapter 37 and in scattered sections throughout Chapter 45; it is now dealt with in a single monograph. The monographs are arranged in alphabetical order, with cross-referencing as required. For example, if you turn to the monograph on cetirizine, you will be referred to the complementary general monograph on antihistamines, where much information that is relevant to cetirizine is given; the monograph on cetirizine itself contains information that is relevant only to cetirizine and not to other antihistamines. Within each monograph the material is arranged in the same way as in the *Side Effects of Drugs Annuals* (see "How to use this book").

Case Reports

A new feature, recognizable from the Annuals, but not incorporated into previous editions, is the inclusion of case reports of adverse effects. This feature reflects the fact that about 30% of all the literature that is reported and discussed in the Annuals derives from such reports (see Table 1). In some cases the only information about an adverse effect is contained in an anecdotal report; in other cases the report illustrates a variant form of the reaction. A case report also gives more immediacy to an adverse reaction, allowing the reader to appreciate more precisely the exact nature of the reported event.

Classification of Adverse Drug Reactions

Another new feature of this edition is the introduction of the DoTS method of classifying adverse drug reactions, based on the **Dose** at which they occur relative to the beneficial dose, the **Time-course** of the reaction, and individual **Susceptibility factors** (see "How to use this book"). This has been done for selected adverse effects, and I hope that as volumes of SEDA continue to be published and the *Encyclopedia's* electronic database is expanded, it will be possible to classify increasing numbers of adverse reactions in this way.

References

Because all the primary and secondary literature is thoroughly surveyed in the Annuals, the *Encyclopedia* has become increasingly compact relative to the amount of information available (even though it has increased in absolute size), with many unreferenced statements and cross-references to the Annuals, on the assumption that all the information would be readily available to the reader, although that may not always be the case. To restore all the reference material on which the *Encyclopedia* has been based as it has evolved over so many years would be a gargantuan task, but in this edition a major start has been made. Many references to original material have been restored, and there is now hardly a statement that is not backed up by at least one reference to primary literature. In addition, almost all of the material that was published in Annuals 23 to 27 (SEDA-23 to SEDA-27) has been included, complete with citations. This has resulted in the inclusion of more than 40 000 references in this edition. Readers will still have to refer to earlier editions of the Annual (SEDA-1 to SEDA-22) and occasionally to earlier editions of *Meyler's Side Effects of Drugs* for more detailed descriptions, but now that the *Encyclopedia* is available electronically this will be repaired in future editions.

Methods and Contributors

I initially prepared the text of the *Encyclopedia* by combining text from the 14th edition of *Meyler's Side Effects of Drugs* and the five most recent annuals (SEDA-23 to SEDA-27). [Later literature is covered in SEDA-28 and the forthcoming SEDA-29.] I next restored missing references to the material and extended it where important information had not been included. The resulting monographs were then sent to experts for review, and their comments were incorporated into the finished monographs. I am grateful to all those, both authors of chapters in previous editions and Annuals and those who have reviewed the monographs for this edition, for their hard work and for making their expertise available.

Acknowledgements

This 15th edition of *Meyler's Side Effects of Drugs* was initiated and carefully planned with Joke Jaarsma at Elsevier, who has provided unstinting support during the production of several previous editions of *Meyler's Side Effects of Drugs* and the *Side Effects of Drugs Annuals*. Early discussions with Dieke van Wijnen at Elsevier about the structure of the text were invaluable. Professor Leufkens from the Faculty of Pharmacy at the University of Utrecht was instrumental in helping us to assemble the preliminary content for this edition; pharmacy students in his department entered the text

Table 1 Types of articles on adverse drug reactions published in 6576 papers in the world literature during 1999 and 2003 (as reviewed in SEDA-24 and SEDA-28)

Type of article	Number of descriptions* (%)
An anecdote or set of anecdotes (that is reported case histories)	2084 (29.9)
A major, randomized, controlled trial or observational study	1956 (28.1)
A minor, randomized, controlled trial or observational study or a non-randomized study (including case series)	1099 (15.8)
A major review, including non-systematic statistical analyses of published studies	951 (13.7)
A brief commentary (for example an editorial or a letter)	362 (5.19)
An experimental study (animal or in vitro)	263 (3.77)
A meta-analysis or other form of systematic review	172 (2.47)
Official statements (for example by Governmental organizations, the WHO, or manufacturers)	75 (1.07)
Total no. of descriptions*	6962
Total no. of articles	6576

* Some articles are described in more than one way

electronically into templates under the guidance of Joke Zwetsloot from Elsevier. Christine Ayorinde provided excellent assistance while I expanded and edited the material. The International Non-proprietary Names were checked by Renée Aronson. At Elsevier the references were then checked and collated by Liz Perill, who also copyedited the material, with Ed Stolting, and shepherded it through conversion to different electronic formats. Bill Todd created the indexes. Stephanie Diment oversaw the project and coordinated everyone's efforts.

The History of Meyler

The history of *Meyler's Side Effects of Drugs* goes back 55 years; a full account can be found at http://www.elsevier.-com/locate/Meyler and the various volumes are listed before the title page of this set. When Leopold Meyler, a physician, experienced unwanted effects of drugs that were used to treat his tuberculosis, he discovered that there was no single text to which medical practitioners could turn for information about the adverse effects of drug therapy; Louis Lewin's text *Die Nebenwirkungen der Arzneimittel* ("The Untoward Effects of Drugs") of 1881 had long been out of print (SEDA-27, xxv–xxix). Meyler therefore surveyed the current literature, initially in Dutch as *Schadelijke Nevenwerkingen van Geneesmiddelen* (Van Gorcum, 1951), and then in English as *Side Effects of Drugs* (Elsevier, 1952). He followed up with what he called surveys of unwanted effects of drugs. Each survey covered a period of two to four years and culminated in Volume VIII (1976), edited by Graham Dukes (SEDA-23, xxiii-xxvi), Meyler having died in 1973. By then the published literature was too extensive to be comfortably encompassed in a four-yearly cycle, and an annual cycle was started instead; the first *Side Effects of Drugs Annual* (SEDA-1) was published in 1977. The four-yearly review was replaced by a complementary critical encyclopaedic survey of the entire field; the first encyclopaedic edition of *Meyler's Side Effects of Drugs*, which appeared in 1980, was labeled the ninth edition.

Since then, *Meyler's Side Effects of Drugs* has been published every four years, providing an encyclopaedic survey of the entire field. Had the cycle been adhered to, the 15th edition would have been published in 2004, but over successive editions the quantity and nature of the information available in the text has changed. In the new millennium it was clear that for this edition a revolutionary approach was needed, and that has taken a little longer to achieve, with a great deal of effort from many different individuals.

We have come a long way since Meyler published his first account in a book of 192 pages. I think that he would have approved of this new *Encyclopedia*.

Jeffrey K. Aronson
Oxford, October 2005

Using the Encyclopedia

In a departure from its previous structure, this edition of *Meyler's Side Effects of Drugs* is presented as individual drug monographs in alphabetical order. In many cases a general monograph (for example Antihistamines) is complemented by monographs about specific drugs (for example acrivastine, antazoline, etc.); in that case a cross-reference is given from the latter to the former.

Monograph Structure

Within each monograph the information is presented in sections as follows:

GENERAL INFORMATION
Includes, when necessary, notes on nomenclature, information about the results of observational studies, comparative studies, and placebo-controlled studies in relation to reports of adverse drug reactions, and a general summary of the major adverse effects.

ORGANS AND SYSTEMS
- Cardiovascular (includes heart and blood vessels)
- Respiratory
- Ear, nose, throat
- Nervous system (includes central and peripheral nervous systems)
- Neuromuscular function
- Sensory systems (includes eyes, ears, taste)
- Psychological, psychiatric
- Endocrine (includes hypothalamus, pituitary, thyroid, parathyroid, adrenal, pancreas, sex hormones)
- Metabolism
- Nutrition (includes effects on amino acids, essential fatty acids, vitamins, micronutrients)
- Electrolyte balance (includes sodium, potassium)
- Mineral balance (includes calcium, phosphate)
- Metal metabolism (includes copper, iron, magnesium, zinc)
- Acid–base balance
- Fluid balance
- Hematologic (includes blood, spleen, and lymphatics)
- Mouth and teeth
- Salivary glands
- Gastrointestinal (includes esophagus, stomach, small bowel, large bowel)
- Liver
- Biliary tract
- Pancreas
- Urinary tract (includes kidneys, ureters, bladder, urethra)
- Skin
- Hair
- Nails
- Sweat glands
- Serosae (includes pleura, pericardium, peritoneum)
- Musculoskeletal (includes muscles, bones, joints)
- Sexual function
- Reproductive system (includes uterus, ovaries, breasts)
- Immunologic (includes effects on the immune system and hypersensitivity reactions)
- Autacoids
- Infection risk
- Body temperature
- Multiorgan failure
- Trauma
- Death

LONG-TERM EFFECTS
- Drug abuse
- Drug misuse
- Drug tolerance
- Drug resistance
- Drug dependence
- Drug withdrawal
- Genotoxicity
- Mutagenicity
- Tumorigenicity

SECOND-GENERATION EFFECTS
- Fertility
- Pregnancy
- Teratogenicity
- Fetotoxicity
- Lactation

SUSCEPTIBILITY FACTORS (relates to features of the patient)
- Genetic factors
- Age
- Sex
- Physiological factors
- Cardiac disease
- Renal disease
- Hepatic disease
- Thyroid disease
- Other features of the patient

DRUG ADMINISTRATION
- Drug formulations
- Drug additives
- Drug contamination (includes infective agents)
- Drug adulteration
- Drug dosage regimens (includes frequency and duration of administration)
- Drug administration route
- Drug overdose

DRUG–DRUG INTERACTIONS
FOOD–DRUG INTERACTIONS
SMOKING
OTHER ENVIRONMENTAL INTERACTIONS
INTERFERENCE WITH DIAGNOSTIC TESTS
DIAGNOSIS OF ADVERSE DRUG REACTIONS
MANAGEMENT OF ADVERSE DRUG REACTIONS
MONITORING THERAPY

Classification of Adverse Drug Reactions

Selected major reactions are classified according to the DoTS system (BMJ 2003;327:1222–5). In this system adverse reactions are classified according to the **Dose** at which they usually occur relative to the beneficial dose, the **Time-course** over which they occur, and the **Susceptibility factors** that make them more likely, as follows:

1 Relation to dose
- *Toxic reactions* (reactions that occur at supratherapeutic doses)
- *Collateral reactions* (reactions that occur at standard therapeutic doses)
- *Hypersusceptibility reactions* (reactions that occur at subtherapeutic doses in susceptible patients)

2 Time-course
- *Time-independent reactions* (reactions that occur at any time during a course of therapy)
- *Time-dependent reactions*
  - Immediate reactions (reactions that occur only when a drug is administered too rapidly)
  - First-dose reactions (reactions that occur after the first dose of a course of treatment and not necessarily thereafter)
  - Early reactions (reactions that occur early in treatment then abate with continuing treatment)
  - Intermediate reactions (reactions that occur after some delay but with less risk during longer- term therapy, owing to the "healthy survivor" effect)
  - Late reactions (reactions the risk of which increases with continued or repeated exposure), including withdrawal reactions (reactions that occur when, after prolonged treatment, a drug is withdrawn or its effective dose is reduced)
  - Delayed reactions (reactions that occur some time after exposure, even if the drug is withdrawn before the reaction appears)

3 Susceptibility factors
- *Genetic*
- *Age*
- *Sex*
- *Physiological variation*
- *Exogenous factors* (for example drug–drug or food–drug interactions, smoking)
- *Diseases*

Drug Names And Spelling

Drugs are usually designated by their recommended or proposed International Non-proprietary Names (rINN or pINN); when these are not available, chemical names have been used. If a fixed combination has a generic combination name (for example co-trimoxazole for trimethoprim + sulfamethoxazole) that name has been used; in some cases brand names have been used.

Spelling

Where necessary, for indexing purposes, American spelling has been used, for example anemia rather than anaemia, estrogen rather than oestrogen.

Cross-references

The various editions of *Meyler's Side Effects of Drugs* are cited in the text as SED-l3, SED-14, etc.; the *Side Effects of Drugs Annuals* 1-22 are cited as SEDA-1, SEDA-2, etc. This edition includes most of the contents of SEDA-23 to SEDA-27. SEDA-28 and SEDA-29 are separate publications, which were prepared in parallel with the preparation of this edition.

Searching the online edition

The print edition of this Reference Work contains two indexes, the "Index of Drug Names" and the "Index of Adverse Reactions". Both indexes are print oriented and point at pages in the main text in which a reaction is discussed or a drug name used.

In the online environment these are redundant as free-standing indexes since on ScienceDirect simple searches can achieve the same results more efficiently and quickly. In addition, whilst the print "Index of Adverse Reactions" was necessarily selective no such constraint affects the online edition.

On ScienceDirect (and assuming you are subscribed to this Reference Work) you may use either the Basic Search Form or Advanced Search. For the purposes of simplicity in these notes only the Basic Search is described. (Quick Search is also supported but offers less granular options than the other search types.)

Familiarity with the structure of the monographs in the print encyclopedia can be used to advantage in targeting precise locations in the text. As with all other searches on ScienceDirect, the results are returned as article titles (including citation information) and (for Reference Works) in book order by default.

For example, to locate the article on "Venlafaxine" you can either navigate to it via clicking on the "Article Titles" browse tab and then on the letter "V" and scroll down to this entry.

Alternatively, on the Basic Search form you can enter the term "Venlafaxine" in the search box and run the search against the "Article Titles" index. By default a search is run across "All Fields" and each field that is separately searchable is listed in the "within" drop-down list.

To extend the search to find this term wherever it occurs in the encyclopedia then you should run this search against "Full Text". Such a search will generate a list of all monographs in which the term appears. To rank the results by relevance rather than alphabetically by monograph title, select the option "by relevance" in the drop down on the Search Results List.

As noted above consistency of structure in the encyclopedia is a huge benefit in the online environment. For example, to recover all articles in which "Fluid balance" is affected in some way by any drug then you should run a search on the term "Fluid balance" in the field "Subheadings". This will recover all drugs for which some impact on fluid balance has been recorded.

Abacavir

See also Nucleoside analogue reverse transcriptase inhibitors (NRTIs)

General Information

Abacavir is a guanidine analogue that inhibits HIV reverse transcriptase. In vitro, its potency is similar to that of zidovudine, protease inhibitors, and dual nucleoside combinations. There is evidence that abacavir is effective in reducing viral load and increasing the CD4 count in HIV-infected patients. Viral resistance is not rapidly selected for, but cross-resistance has been shown to other analogues of cytosine and guanidine (didanosine, lamivudine, and zalcitabine).

Abacavir has good oral systemic availability and penetrates the nervous system. It does not interfere with drugs that are metabolized by liver microsomal cytochrome P450 (1). It has no other significant drug interactions and can be administered without food restrictions.

Observational studies

The effects of abacavir have been evaluated in a study in over 13 000 adults who no longer responded to commercially available treatment regimens (2). By month 2 of treatment with abacavir, plasma HIV-1 RNA concentrations fell by at least half a log unit in 31% of patients, and in 5.6% of the patients HIV-1 RNA concentrations fell to under 400 copies/ml. Serious drug-related adverse events were reported by 7.7% of patients. The most common were nausea, skin rash, diarrhea, malaise or fatigue, and fever. About 4.6% of patients had a hypersensitivity reaction that was possibly drug-related.

General adverse effects

The adverse effects of abacavir that have been most often observed in clinical trials are fatigue, nausea and vomiting, abdominal pain, diarrhea, headache, rash, and dyspepsia (3,4). Allergic reactions lead to withdrawal of therapy in about 3% of patients (5). These can be severe, and anaphylaxis has been reported after rechallenge in a patient with an apparent allergic reaction to abacavir (6). It is wise to avoid rechallenge when allergy is suspected (7). In one study nausea and vomiting occurred in 38–57% of patients, headache in 27–41%, malaise and fatigue in 28%, diarrhea in 18–23%, and weakness in 29% (8). There was also one case of agranulocytosis accompanied by a skin rash.

Organs and Systems

Nervous system

Vertigo has been attributed to abacavir (9).

- A 44-year-old African-American developed vertigo, tinnitus in both ears, headache behind the eyes, and left ear pain and hearing loss soon after starting to take abacavir, lamivudine, and stavudine. There was left-sided nystagmus and vestibular tests showed evidence of vestibular impairment. An MRI scan was normal. All the antiretroviral drugs were withdrawn and he improved. When lamivudine and stavudine were restarted, with nevirapine, the vertigo did not recur.

Metabolism

While abacavir has been associated with hyperglycemia in individual cases (10), there were no significant effects on blood glucose concentration in clinical trials.

- A 47-year-old man, with normoglycemia and no family history of diabetes mellitus, who was taking highly active antiretroviral therapy, was given abacavir for treatment intensification. He became lethargic and hyperglycemic. Despite metformin and glibenclamide, the hyperglycemia continued. Abacavir was withdrawn, and within 2 weeks his blood glucose concentration returned to baseline and the hypoglycemic drugs were withdrawn.

This patient was also taking hydrochlorothiazide, but the time-course of onset and resolution were consistent with abacavir-induced hyperglycemia.

Immunologic

The risk of allergic reactions to abacavir may be as high as 10% (11). However, the incidence is more usually reported to be 3–5% (12,13). Allergic reactions usually occur within the first 28 days of therapy and rarely thereafter. They are characterized by non-specific complaints suggestive of an upper respiratory tract infection, fever, rash, nausea, and vomiting. Resolution of the symptoms occurs within days of withdrawal. Severe and even fatal reactions to readministration have been observed, and it has been suggested that rechallenge is contraindicated in any patients who have had an allergic reaction (7). However, it is safe to rechallenge patients who have stopped treatment because of other types of adverse reaction. Of 1201 patients treated in clinical trials, 219 interrupted abacavir therapy for reasons other than allergy; on reintroduction there were no cases of allergy or anaphylaxis (14).

The susceptibility factors associated with allergic reactions have been sought in an analysis of all protocols conducted by GlaxoSmithKline that involved abacavir exposure for at least 24 weeks with a quality-assured or validated clinical database by 30 June 2000 ($n = 5332$) (15). There were 197 allergic reactions (3.7%). The risks of allergic reactions were lower in black people (OR = 0.59; 95% CI = 0.38, 0.91) than in other ethnic groups, and in patients who had received previous therapy for HIV-1 infection with other antiretroviral agents (OR = 0.58; 95% CI = 0.44, 0.78) compared with those receiving therapy for the first time.

Genetic factors affecting the immune response to abacavir have been sought in patients who had taken abacavir for more than 6 weeks, 18 with hypersensitivity reactions and 167 without (16). HLA-B*5701 was present in 14 of the 18 patients with abacavir hypersensitivity, and in four of the 167 others (OR = 117; 95% CI = 29, 481). The combination of HLA-DR7 and

© 2006 Elsevier B.V. All rights reserved.

HLA-DQ3 was found in 13 of the 18 and five of the 167 (OR = 73; CI = 20, 268). HLA-B*5701, HLA-DR7, and HLA-DQ3 were present in combination in 13 of the 18 and none of the 167 (OR = 822; CI = 43, 15 675). Other MHC markers also present on the 57.1 ancestral haplotype to which these three markers belong confirmed the presence of haplotype-specific linkage disequilibrium, and mapped potential susceptibility loci to a region bounded by C4A6 and HLA-C. HLA-B*5701, HLA-DR7, and HLA-DQ3 had a positive predictive value for hypersensitivity of 100%, and a negative predictive value of 97%. The authors concluded that susceptibility to abacavir hypersensitivity is carried on the 57.1 ancestral haplotype and that withholding abacavir from those with HLA-B*5701, HLA-DR7, and HLA-DQ3 should reduce the prevalence of hypersensitivity from 9% to 2.5% without inappropriately denying abacavir to any patient.

In a retrospective case-control study of patients with allergic reactions, HLA-B57 was present in 39 of 84 patients compared with 4 of 113 controls (17). However, there were few women and other ethnic groups in the study, and so these findings relate largely to white men.

In a multicenter trial, 128 children were randomly assigned to zidovudine + lamivudine ($n = 36$), to zidovudine + abacavir ($n = 45$), or to lamivudine + abacavir ($n = 47$) (18). One child had an allergic reaction to abacavir and stopped taking it, as did three with possible reactions.

Abciximab

See also Monoclonal antibodies

General Information

Abciximab is a Fab fragment of the chimeric human-murine monoclonal antibody 7E3, which binds to the platelet glycoprotein IIb/IIIa receptor and inhibits platelet aggregation (1).

Abciximab is used for prevention of cardiac ischemic events in patients undergoing percutaneous coronary intervention and to prevent myocardial infarction in patients with unstable angina who do not respond to conventional treatment. It has also been used for thrombolysis in patients with peripheral arterial occlusive disease and arterial thrombosis (2).

Besides bleeding, other adverse reactions that have been associated with abciximab include back pain,

Abciximab

See also Monoclonal antibodies

General Information

Abciximab is a Fab fragment of the chimeric human-murine monoclonal antibody 7E3, which binds to the platelet glycoprotein IIb/IIIa receptor and inhibits platelet aggregation (1).

Abciximab is used for prevention of cardiac ischemic events in patients undergoing percutaneous coronary intervention and to prevent myocardial infarction in patients with unstable angina who do not respond to conventional treatment. It has also been used for thrombolysis in patients with peripheral arterial occlusive disease and arterial thrombosis (2).

Besides bleeding, other adverse reactions that have been associated with abciximab include back pain,

© 2006 Elsevier B.V. All rights reserved.

hypotension, nausea, and chest pain (but with an incidence not significantly different from that observed with placebo).

Organs and Systems

Respiratory

Lung hemorrhage is a rare but potentially lethal complication of antithrombotic and antiplatelet therapy. The incidence of spontaneous pulmonary hemorrhage after the use of platelet glycoprotein IIb/IIIa inhibitors has been analysed from the medical records of 1020 consecutive patients who underwent coronary interventions (3). Diffuse pulmonary hemorrhage developed in seven patients, two of whom died and five of whom had activated clotting times greater than 250 seconds during the procedure. Activated partial thromboplastin time measured at the time of lung hemorrhage was raised in all cases (mean 85, range 69–95 seconds). All had a history of congestive heart failure, and had raised pulmonary capillary wedge pressures and/or left ventricular end-diastolic pressures at the time of the procedure. Six patients also had evidence of baseline radiographic abnormalities.

Nervous system

Seven patients undergoing neurointerventional procedures who received abciximab developed fatal intracerebral hemorrhages (4). The procedures included angioplasty and stent placement in the cervical internal carotid artery ($n = 4$), angioplasty of the intracranial carotid artery ($n = 1$), and angioplasty of the middle cerebral artery ($n = 2$). Aggressive antithrombotic treatment is used as adjuvant to angioplasty and/or stent placement to reduce the rate of ischemic and thrombotic complications associated with these procedures. Intravenous abciximab has a short life (10 minutes), but its inhibitory effect on platelets lasts for 48 hours. The exact cause of abciximab-associated intracerebral hemorrhage is unclear.

Hematologic

Bleeding

The primary risk associated with abciximab is bleeding. In the EPIC trial in high-risk angioplasty, 14% of patients who received a bolus of abciximab followed by an infusion had a major bleeding complication rate, versus 7% in the placebo group (5). The most marked excess of major bleeding episodes occurred at the site of vascular puncture, but there were also a substantial number of gastrointestinal haemorrhages. However, the therapeutic regimen used was not adjusted for body weight, and the risk of major bleeding was also related to the heparin dose per kg and not only to the use of abciximab (6).

In 7800 patients with chest pain and either ST segment depression or a positive troponin test, the addition of abciximab to unfractionated heparin or low molecular weight heparin in the treatment of acute coronary syndrome was not associated with any significant reduction in cardiac events, but a doubled risk of bleeding (7).

An analysis of data from the EPIC trial identified a series of factors that predicted vascular access site bleeding or the need for vascular access site surgery in abciximab-treated patients (8). They comprised larger vascular access sheath size, the presence of acute myocardial infarction at enrolment, female sex, higher baseline hematocrits, lower body weight, and a longer time spent in the catheterization laboratory.

It must be emphasized that patients in the EPIC trial received high-dose heparin and that vascular access site sheaths were left in place for 12–16 hours. In subsequent studies, the risk of vascular site bleeding was probably reduced by using lower doses of heparin and removing sheaths sooner. This was the case in the EPILOG trial in which heparin was withdrawn immediately after the coronary procedure and vascular sheaths were removed as soon as possible (9). The incidence of major bleeding in this study was not significantly higher with abciximab than with placebo. Nevertheless, the incidence of minor bleeding complications was significantly higher in the abciximab plus standard dose heparin group (but not in the abciximab plus low dose heparin group) compared with placebo. In the EPISTENT trial, all patients received low dose, body weight-adjusted heparin: Here the incidence of both major and minor bleeding complications was low and not significantly different between treatment groups (10).

It would therefore seem possible to reduce the incidence of bleeding complications when using abciximab during prophylactic coronary revascularization procedures. This is unfortunately not the case so far in the setting of primary angioplasty for myocardial infarction after intense anticoagulation (17% of major hemorrhagic complications versus 9.5 in placebo recipients) (11). The risk of serious bleeding complications is also increased in rescue situations when high doses of heparin have been used (12), but here it can be reduced by giving protamine to reverse heparin anticoagulation before abciximab therapy (13). There is also a high incidence of major bleeding in patients who receive abciximab during percutaneous coronary revascularization after unsuccessful thrombolytic therapy. It has been suggested that abciximab should not be administered within 18 hours after thrombolytic therapy (14).

It must be emphasized that very few episodes of abciximab-related bleeding are life-threatening and that in none of the trials with abciximab as well as with other glycoprotein IIb/IIIa antagonists has there been an excess of intracranial hemorrhage (15).

However, the bleeding risk in patients enrolled in trials may not be representative of the population actually being given abciximab. To clarify this, a review of adverse events in patients receiving glycoprotein IIb/IIIa inhibitors reported to the FDA has been undertaken (16,17). The FDA received 450 reports of deaths related to treatment with glycoprotein IIb/IIIa inhibitors between November 1, 1997 and December 31, 2000; these were reviewed and a standard rating system for assessing causation was applied to each event. Of the 450 deaths, 44% were considered to be definitely or probably attributable to glycoprotein IIb/IIIa inhibitors.

© 2006 Elsevier B.V. All rights reserved.

The mean age of patients who died was 69 years and 47% of the deaths were in women. All of the deaths that were deemed to be definitely or probably associated with glycoprotein IIb/IIIa inhibitors were associated with excessive bleeding, most often in the nervous system.

Thrombocytopenia

The other significant risk associated with abciximab is thrombocytopenia. Data pooled from three major trials showed that thrombocytopenia (under 100×10^9/l) was significantly more frequent in those who received a bolus dose of abciximab followed by an infusion than in placebo recipients (3.7 versus 2%). Severe thrombocytopenia (under 50×10^9/l) was also more frequent with abciximab (1.1 versus 0.5%) (18). Very acute and profound thrombocytopenia (under 20×10^9/l) within 24 hours after administration has been observed in 0.3–0.7% of patients treated with abciximab for the first time (15,18–20).

During postmarketing surveillance of the first 4000 patients treated with abciximab in France, 25 cases of thrombocytopenia (0.6%) were reported, with five severe cases (0.15%) and three acute profound forms (0.08%). In all cases reported, the role of heparin must be taken into account. The thrombocytopenia associated with abciximab differs with that associated with heparin by its rapid onset (within 24 hours), its reversal after platelet transfusion, and its possible association with hemorrhage but not with thrombosis.

Positive human anti-chimeric antibodies have been detected in 6% of patients (generally in low titers) but were not associated with hypersensitivity or allergic reactions. Preliminary data indicate that abciximab can be safety readministered, although a greater incidence of thrombocytopenia after administration has been reported with a lesser efficacy of platelet transfusion (12).

Thrombocytopenia due to abciximab usually occurs within 12–96 hours, but there has been a report of acute profound thrombocytopenia after 7 days (21).

- A 65-year-old woman with type 2 diabetes mellitus and coronary artery disease received a 0.25 mg/kg bolus of abciximab at the time of intervention followed by an infusion of 10 micrograms/minute for 12 hours. Her baseline platelet counts were 286×10^9/l before use, 385×10^9/l at 2 hours, and 296×10^9/l at 18 hours. On day 7 she developed petechiae over her legs and her platelet count was 1×10^9/l. Coagulation tests were normal and there was no evidence of heparin-induced thrombocytopenia. She received 10 units of single-donor platelets and recovered slowly over the next 4 days. The platelet count was 114×10^9/l on day 12.

In another case of profound thrombocytopenia after abciximab there was a delayed onset (6 days after therapy) (22). The authors speculated that preceding treatment with methylprednisolone may have delayed the onset of thrombocytopenia.The mechanism of severe thrombocytopenia associated with abciximab is unclear. Further administration should be avoided, but other glycoprotein IIb/IIIa inhibitors (eptifibatide and tirofiban) have been successfully used in patients with history of abciximab-induced thrombocytopenia.

Thrombocytopenia after a second exposure to abciximab in nine patients showed that each had a strong immunoglobulin IgG antibody that recognized platelets sensitized with abciximab (23). Five patients also had IgM antibodies. Thrombocytopenia occurred four times as often as after the first exposure. The mechanism is not understood, but these findings suggest that it may be antibody-mediated. These antibodies were also found in 77 of 104 healthy patients, but in the patients the antibodies were specific for murine sequences in abciximab, causing the life-threatening thrombocytopenia.

Nine patients who developed profound thrombocytopenia after a second exposure to abciximab had an IgG antibody that recognized platelets sensitized with abciximab. In contrast, in 104 healthy subjects, in whom IgG antibodies reactive with abciximab-coated platelets were found in 77, the antibodies were specific for murine sequences in abciximab and were capable of causing life-threatening thrombocytopenia (23).

Ethylenediaminetetra-acetate can cause pseudothrombocytopenia by activating platelet agglutination, resulting in a spuriously low platelet count (SEDA-21, 250). Of 66 patients who received abciximab after coronary revascularization, 17 developed thrombocytopenia and 9 developed severe thrombocytopenia (24). However, of these 26 patients, 18 had pseudothrombocytopenia. True thrombocytopenia occurred at 4 hours after infusion whereas pseudothrombocytopenia occurred within the first 24 hours. The mechanism of pseudothrombocytopenia may be the effect of EDTA on the calcium-dependant glycoprotein IIb/IIIa complex, which frees the antigenic binding site on glycoprotein IIb available to IgM antibody. This increased antibody binding may cause platelet clumping and lead to false thrombocytopenia. True thrombocytopenia did not lead to hemorrhagic complications, but the patients required platelet transfusion.

Immunologic

Human antichimeric antibodies, specific to the murine epitope of Fab antibody fragments, have been observed in patients treated with abciximab. These antibodies are IgG antibodies and have so far not correlated with any adverse effects (12).

Because of its antigenic potential, there are theoretical concerns about the readministration of abciximab, and this has been studied in 1342 patients, who underwent percutaneous coronary interventions and received abciximab at least twice (25). There were no cases of anaphylaxis, and there were only five minor allergic reactions, none of which required termination of the infusion. There was clinically significant bleeding in 31 patients, including one with intracranial hemorrhage. There was thrombocytopenia (platelet count below 100×10^9/l) in 5% and profound thrombocytopenia (platelet count below 20×10^9/l) in 2%. In patients who received abciximab within 1 month of a previous treatment ($n = 115$), the risks of thrombocytopenia and profound thrombocytopenia were 17 and 12% respectively. Human chimeric antibody titers before

© 2006 Elsevier B.V. All rights reserved.

readministration did not correlate with adverse outcomes or bleeding, but were associated with thrombocytopenia and profound thrombocytopenia.

An anaphylactic reaction to abciximab has been reported (26).

- An obese 46-year-old woman with prolonged angina pectoris underwent coronary angiography. She had no known drug allergies, but on administration of an iodinated contrast media she developed anaphylactic shock. After successful resuscitation angiography was completed and she was given aspirin, ticlopidine for a month, and metoprolol. Five months later she developed chest pain again, and angiography was repeated after pretreatment with prednisone and diphenhydramine and she was given abciximab. Within 5 minutes she had an anaphylactic reaction, requiring resuscitation.

This case shows that anaphylactic reactions to abciximab can occur even after pretreatment with prednisone and diphenhydramine for a known allergy to iodine.

Susceptibility Factors

Renal disease

The available data do not suggest an increased risk of bleeding with abciximab among patients with mild to moderate renal insufficiency (19), even though there is reduced platelet aggregation in renal insufficiency.

Abecarnil

General Information

Abecarnil is a partial agonist at the benzodiazepine-GABA receptor complex, and is used in generalized anxiety disorder. Its pharmacology suggests that it may be less likely to produce sedation and tolerance, but data thus far have not shown clear differences in its adverse effects from those of classical benzodiazepines, such as alprazolam, diazepam, and lorazepam. As expected, both acute adverse effects and tolerance are dose-related.

In a multicenter, double-blind trial, abecarnil (mean daily dose 12 mg), diazepam (mean daily dose 22 mg), or placebo were given in divided doses for 6 weeks to 310 patients with generalized anxiety disorder (1). Those who had improved at 6 weeks could volunteer to continue double-blind treatment for a total of 24 weeks. Slightly more patients who took diazepam (77%) and placebo (75%) completed the 6-week study than those who took abecarnil (66%). The major adverse events during abecarnil therapy were similar to those of diazepam, namely drowsiness, dizziness, fatigue, and difficulty in coordination. Abecarnil and diazepam both produced statistically significantly more symptom relief than placebo at 1 week, but at 6 weeks only diazepam was superior to placebo. In contrast to diazepam, abecarnil did not cause withdrawal symptoms. The absence of a placebo control makes it difficult to interpret the results of another study of the use of abecarnil and diazepam in alcohol withdrawal, which appeared to show comparable efficacy and adverse effects of the two drugs (2).

Abetimus

General Information

Abetimus is a selective immunomodulator for the treatment of systemic lupus erythematosus. It induces tolerance in B lymphocytes directed against double-stranded DNA by cross-linking surface antibodies. It also reduces serum double-stranded DNA antibodies and splenic double-stranded DNA antibody-producing cells in BXSB mice, giving improved renal function and histopathology, as well as prolonged survival (1).

In a phase-2, partly randomized, double-blind, placebo-controlled study of three different doses of abetimus in 58 patients, seven did not receive all doses because of adverse events (2). Five withdrew because of adverse events related to their lupus erythematosus: non-renal exacerbations ($n = 2$), hematuria and hypertension ($n = 1$), worsening rash ($n = 1$), and nephritis ($n = 1$). One patient withdrew because of cellulitis and another because of a localized *Herpes zoster* infection. None of the reported adverse events was considered to be definitely related to the drug.

Subsequently, La Jolla Pharmaceuticals terminated two previously established licensing agreements for abetimus (3). One of the agreements was with Leo Pharmaceutical Products of Denmark, which was licensed to market abetimus in Europe and the Middle East, and the other was with Abbott Laboratories. Abbott returned all rights to abetimus to La Jolla Pharmaceuticals in September 1999, based on the results of an analysis of a phase-2/phase-3 trial of abetimus in patients with systemic lupus erythematosus and a history of renal disease, which had been stopped in May 1999 because the primary end-point (the time to worsening of renal function) was much shorter than expected. A further analysis then showed that the number of exacerbations in responders treated with abetimus was less than half the number in the patients treated with placebo. Responders also had a significant reduction in the use of high-dose glucocorticoids and cyclophosphamide.

Another phase-3 placebo-controlled trial called PEARL (Program Enabling Antibody Reduction in Lupus) was conducted in the USA in 317 patients with lupus nephritis, who were treated with abetimus 100 mg/week. The trial was completed in December 2002 and preliminary results were reported in February 2003. However, in April 2003, La Jolla Pharmaceuticals ended the trial, in order to conserve resources for the continued development of the drug.

In September 2000, the US FDA granted orphan drug status to abetimus for the treatment of lupus nephritis; the EU did likewise in November 2001.

Acamprosate

General Information

Acamprosate (calcium acetylhomotaurinate) has been postulated to act by restoring the alcohol-induced neurotransmission imbalance of inhibition-excitation inputs believed to underlie alcohol dependence (1,2). The molecular structure of acamprosate explains its specificity toward the basic molecular mechanisms involved in the pathophysiology of alcohol dependence. A competitive interaction has been described between spermidine and acamprosate, suggesting a specific binding site for acamprosate on *N*-methyl-D-aspartate receptors (3).

To test the role of acamprosate as an aid in preventing relapse after detoxification, 296 alcohol-dependent patients entered a prospective, multicenter, randomized, double-blind, placebo-controlled study of acamprosate 666 mg tablets tds for 180 days (4). Unlike previous studies, acamprosate was prescribed from the start of alcohol withdrawal, rather than after the detoxification process. During the treatment period, 110 patients dropped out. The two treatment groups were balanced with regard to baseline values and reasons for discontinuation. There was no difference between the groups in the severity of withdrawal symptoms, as measured by the CIWA-Ar (Clinical Institute Withdrawal Assessment for Alcohol scale). Acamprosate given during withdrawal did not cause unwanted effects. The overall incidence of adverse events was similar in the two groups. The number of patients who presented at least one new adverse event (not present at baseline) during the course of the study was 99 with acamprosate and 94 with placebo. Nevertheless, there was a trend for gastrointestinal adverse events to be reported more often in the acamprosate-treated patients ($n = 61$) compared with placebo ($n = 46$). The individual adverse events that were reported more often with acamprosate were diarrhea, dyspepsia, constipation, and flatulence. Pruritus was reported by seven of those who took acamprosate and five of those who took placebo.

Organs and Systems

Gastrointestinal

Acamprosate can cause diarrhea and mild abdominal pain (5).

Acebutolol

See also Beta-adrenoceptor antagonists

General Information

Acebutolol is a beta-adrenoceptor antagonist with membrane-stabilizing activity that is sometimes cited as being cardioselective but has considerable effects on bronchioles and peripheral blood vessels.

Organs and Systems

Respiratory

Bronchiolitis obliterans has been attributed to acebutolol (1).

Liver

Six cases of reversible hepatitis have been attributed to acebutolol (2).

Immunologic

Patients taking acebutolol relatively commonly develop antinuclear antibodies (3,4).

Drug Administration

Drug overdose

The membrane-stabilizing activity of beta-blockers can play a major role in toxicity. Of 208 deaths in subjects who had taken beta-blockers, 206 occurred with drugs that have membrane-stabilizing activity. This quinidine-like effect can be reversed by sodium bicarbonate, which is also used to counteract the cardiotoxic effects of cyclic antidepressants, which also have membrane-stabilizing activity.

- An overdose of acebutolol (6.4 mg) in a 48-year-old man caused cardiac arrest with ventricular tachycardia (5). An intravenous bolus of sodium bicarbonate 50 mmol produced sinus rhythm.

Acecainide

See also Antidysrhythmic drugs

General Information

Acecainide (*N*-acetylprocainamide) is the main metabolite of procainamide, and it has antidysrhythmic activity (1). However, in contrast to procainamide, which has Class Ib activity, the main action of acecainide is that of Class III.

Apart from the lupus-like syndrome, the adverse effects of acecainide are as common as those of procainamide. The commonest affect the gastrointestinal tract and the central nervous system. Anorexia, nausea, vomiting, diarrhea, and abdominal pain are common, as are insomnia, dizziness, light-headedness, tingling sensations, and blurred vision. Other reported unwanted effects include skin rashes, constipation, and reduced sexual function (2–5).

Organs and Systems

Cardiovascular

Acecainide prolongs the QT interval and can therefore cause ventricular dysrhythmias (6). The risk is increased in renal insufficiency, since acecainide is mainly eliminated unchanged via the kidneys.

Immunologic

The main advantage of acecainide over procainamide is the lower incidence of the lupus-like syndrome. Many fewer patients develop antinuclear antibodies during long-term treatment with acecainide than during long-term treatment with procainamide (7).

There are also reports of remission of lupus-like syndrome without recurrence in patients in whom acecainide has been used as a replacement for procainamide (8–10). Furthermore, patients in whom procainamide has previously caused a lupus-like syndrome have been reported not to suffer from the syndrome on subsequent long-term treatment with acecainide (8). However, one patient suffered mild arthralgia while taking acecainide, having had a more severe arthropathy while taking procainamide (8).

Susceptibility Factors

Renal disease

Because acecainide is eliminated mostly unchanged by renal excretion, with a half-life of about 7 hours, its clearance is reduced in patients with renal impairment, who are at increased risk of adverse effects. This means that elderly people, who generally have a degree of renal impairment, are also at increased risk.

Monitoring Drug Therapy

The target plasma concentration range of acecainide is 15–25 μg/ml. The adverse effects of acecainide increase in frequency at concentrations above 30 μg/ml (11).

Aceclofenac

See also Non-steroidal anti-inflammatory drugs

General Information

Despite claims that aceclofenac is a COX-2 selective inhibitor, experience shows that its adverse effects profile is similar to that of the non-selective NSAIDs.

Organs and Systems

Gastrointestinal

Symptoms of gastrointestinal intolerance in patients taking aceclofenac commonly require withdrawal, at a rate of 3–15% (SEDA-20, 91).

Liver

Acute hepatitis has been reported with aceclofenac (SEDA-21, 103).

Skin

Aceclofenac cream can cause erythema, itching, and a burning sensation in under 3% of patients (SEDA-20, 91).

Aceclofenac can cause photosensitivity.

- After starting twice-daily topical application of a cream containing aceclofenac, a woman developed acute eczema affecting the sun-exposed areas of her legs (1).

Immunologic

A hypersensitivity reaction characterized by multiple purpuric lesions and reduced renal function has been described in an elderly patient (SEDA-18, 103), and there have been reports of hypersensitivity vasculitis (SEDA-20, 91) (SEDA-21, 103).

Acemetacin

See also Non-steroidal anti-inflammatory drugs

General Information

Acemetacin is an indometacin derivative with the same adverse effects profile (SEDA-6, 94). In an open multicenter study, 187 of 280 patients had adverse effects (57% gastrointestinal); treatment had to be stopped in 7% (1). The use of acemetacin is limited and there is no justification for claims that it has advantages over existing NSAIDs.

Acetylcholinesterase inhibitors

General Information

Cholinesterase inhibitors increase parasympathetic nervous system (cholinergic) activity indirectly by inhibiting acetylcholinesterase, thereby preventing the breakdown of acetylcholine. They are only effective in the presence of acetylcholine. They are listed in Table 1.

The cholinesterase inhibitors are used in the treatment of Alzheimer's disease (tacrine, 7-methoxytacrine, donepezil, metrifonate, and rivastigmine), the treatment and diagnosis of myasthenia gravis (distigmine, edrophonium, neostigmine, physostigmine, prostigmine, and pyridostigmine), and the treatment of atony of the intestine or bladder. In the eye, they increase the flow rate of aqueous humor across the trabeculum, reduce resistance to its flow, and consequently lower the intraocular pressure.

Use of acetylcholinesterase inhibitors in Alzheimer's disease

Of the acetylcholinesterase inhibitors, tacrine, methoxytacrine, metrifonate, donepezil hydrochloride, and rivastigmine are used in the treatment of Alzheimer's disease. In 12–30% of patients with Alzheimer's disease, tacrine causes an increase in hepatic transaminase activity. Abdominal adverse effects are very frequent, for example nausea, anorexia, diarrhea. The peripheral cholinomimetic effects of tacrine occur in a very high proportion of patients, probably the majority. The hepatic effects seem to be such that the use of these new (and in some cases still experimental) drugs would not be justified in

other-than-serious disease states, but they are reversible if the drug is withdrawn.

General adverse effects

The acetylcholinesterase inhibitors have the effects that one would expect to result from their promoting nicotinic and muscarinic cholinergic activity, including unwanted effects such as bradycardia, miosis, colic, and hypersalivation. Adverse reactions have been stated to be relatively more common with neostigmine than with some other drugs such as pyridostigmine or ambenonium, but it is doubtful whether the benefit to harm balance indeed differs, since neostigmine also tends to be more effective in certain patients. Ambenonium is relatively likely to cause headache. When neostigmine and pyridostigmine are used as bromide salts, bromide rashes can occur.

Local adverse effects

Acetylcholinesterase inhibitors as eye drops have more intense effects in myopic and young patients, causing aggravation of myopia, blurred vision, and periorbital pain, due to congestion of the iris and ciliary body. Anterior and posterior synechiae can develop. Allergic reactions have been reported as has epithelial toxicity. The acetylcholinesterase inhibitors can cause pseudopemphigoid reactions in the eyelids and occlusion of the lacrimal puncta (SED-12, 1198) (1). The danger that a miotic agent will produce retinal detachment is directly proportional to the capacity of the drug to produce spasm of the ciliary body. Retinal detachment has been reported after the use of cholinergic agents, but they can also be coincidental.

Systemic effects

The commonest effects of the acetylcholinesterase inhibitors are headache and periorbital pain. Signs of vagal stimulation can occur, with nausea, vomiting, sweating, hypersalivation, lacrimation, hypotension, bradycardia, bronchial constriction, respiratory failure, and nightmares. These reactions essentially occur during intensive treatment for acute closed-angle glaucoma, requiring frequent instillations of pilocarpine. Elderly people and young children are at particular risk.

Organs and Systems

Cardiovascular

With any acetylcholinesterase inhibitor, bradycardia can, with excessive dosage, proceed to dysrhythmias (SEDA-13, 114) and even asystole.

- A 67-year-old man underwent left upper lobectomy for a presumed malignancy 11 years after cardiac transplantation (2). He had had no cardiac symptoms since his transplant. Suxamethonium was used as a muscle relaxant and was reversed with glycopyrrolate 0.8 mg and neostigmine 4 mg. Within a few minutes, he developed asystole, which lasted for about 45 seconds. He subsequently made a full recovery.

The authors speculated that some degree of cardiac reinnervation may have occurred; they recommended that this type of response should be anticipated in future anesthesia in such patients and that therapeutic measures, such as a beta-adrenoceptor agonist, should be available.

Another case of asystole has been reported with the very short-acting cholinesterase inhibitor edrophonium (3).

- A 49-year-old woman was given intravenous edrophonium chloride 2 mg as part of the investigation of an acute myopathy following gastrointestinal surgery. She had also received 60 mg of intravenous labetalol in the 14 hours before the edrophonium was given: presumably this was for a raised blood pressure, but that was not specified. Labetalol caused transient but severe bradycardia (heart rate about 20/minute). Immediately after the injection of edrophonium, she developed asystole, which was treated immediately with atropine and recovered in 10 seconds.

Such reactions are extremely rare, but in this case the risk was undoubtedly enhanced by previous beta-blockade.

With physostigmine, hypertension has been both demonstrated in animal experiments and observed in a series of patients after intravenous use in relatively high doses; it has also occurred during use of low doses of oral physostigmine in an elderly patient with Alzheimer's disease (SEDA-12, 125).

Nervous system

During a trial of oral physostigmine, myoclonus occurred in two patients with probable Alzheimer's disease (SEDA-12, 125).

Gastrointestinal

To reduce the incidence of residual paralysis after the administration of non-depolarizing neuromuscular blocking agents, some advocate the routine use of anticholinesterase drugs at the end of surgery. However, it has been suggested that this practice might increase the risk of postoperative nausea and vomiting. Clinical trials have produced contradictory results. A meta-analysis of the available data suggested that omitting routine neostigmine may reduce the incidence of emesis only when a large dose (2.5 mg) is used (4). With a smaller dose (1.5 mg), there was no difference. The incidence of clinically relevant residual paralysis was 1 in 30 in the control groups. There were no cases of residual curarization in the treatment groups when either edrophonium 500 μg/kg or neostigmine 1.5 mg was given in combination with atropine. Therefore, the question of whether or not routine anticholinesterase administration is beneficial for the patient is still open to debate. Other adverse effects of anticholinesterase drugs, such as bronchial hypersecretion or intestinal hypermotility, could increase morbidity, and we do not know whether all of these adverse effects are completely blocked by the concomitant use of a parasympatholytic agent (5). It should be taken into account that the incidence of residual curarization may be reduced as effectively by the use of neuromuscular transmission monitoring (6,7). Some believe that anticholinesterase drugs should be used to reverse residual neuromuscular block that produces clinical symptoms or is detected by neuromuscular transmission monitoring.

© 2006 Elsevier B.V. All rights reserved.

Musculoskeletal

Any acetylcholinesterase inhibitor can produce muscular fasciculation followed by voluntary muscle paralysis, and these muscular effects can serve as a valuable sign of approaching overdosage. Two patients, one with dystrophia myotonica and the other with progressive muscular dystrophy, presented with respiratory difficulties, necessitating prolonged mechanical ventilation. As these difficulties are as good as impossible to predict, short-acting neuromuscular blockers should preferably be used, thus avoiding the need for pharmacological reversal (8).

Immunologic

Severe urticaria and anaphylaxis associated with pyridostigmine (an unspecified dose) occurred in a 54-year-old woman with myasthenia gravis (9). Urticaria started almost immediately after introduction of the drug but was partially controlled by the antihistamine cetirizine. However, pyridostigmine was stopped after 2 months and the urticaria resolved completely. Rechallenge with oral pyridostigmine led to an anaphylactic reaction that was treated with subcutaneous adrenaline. There were no sequelae.

Second-Generation Effects

Teratogenicity

Microcephaly occurred in the child of a woman taking a high dose of pyridostigmine (10).

- A 24-year-old woman had suffered from myasthenia gravis from the unusually early age of 10 years. During her first pregnancy, pyridostigmine was her sole medication. Because of deterioration in her symptoms during the pregnancy, the dosage was increased until she was taking 1500–3000 mg/day, or 4–8 times the maximum recommended dose. This still did not produce much clinical improvement but was nevertheless continued throughout the pregnancy. She needed an emergency cesarean section at 36 weeks because of fetal bradycardia. The baby was microcephalic.

The authors failed to find any other cause for this abnormality and concluded that the excessive dose of pyridostigmine had been responsible for the fetal damage.

Fetotoxicity

Acetylcholinesterase inhibitors can probably be safely used in pregnancy when needed, provided the dosage is carefully regulated. Reversible muscle weakness in a newborn infant was attributed to relative overdosage of the mother with pyridostigmine bromide (11).

Susceptibility Factors

Age

Elderly people need to be treated with caution because of their greater susceptibility to the cardiovascular effects of the acetylcholinesterase inhibitors; this is particularly relevant to their use in Alzheimer's disease.

Other features of the patient

Special caution is recommended when acetylcholinesterase inhibitors are given to patients with inflammatory, infiltrative, or degenerative disease of the cardiac conducting system, patients taking digitalis, calcium channel blockers, or beta-blockers, and patients with myocardial ischemia. Appropriate resuscitative equipment should be readily available.

Neostigmine or other anticholinesterase inhibitors are regularly used in anesthesia to reverse neuromuscular block; however, in patients with neuromuscular disorders, this reversal can present unforeseen difficulties. All anticholinesterase inhibitors must be cautiously dosed if severe adverse reactions are to be avoided. When these drugs are given orally, administration should be suspended during periods of severe constipation, in light of one reported case in which neostigmine accumulated in the gastrointestinal tract of a child during a constipative phase and was thereafter rapidly absorbed, with fatal results (SED-12, 326). Anticholinesterase drugs are contraindicated in bronchial asthma.

Drug–Drug Interactions

Anticholinergic drugs

The effect of acetylcholinesterase inhibitors can be reduced by drugs with anticholinergic effects, such as antihistamines or neuroleptic drugs (12).

Suxamethonium

Acetylcholinesterase inhibitor eye drops or exposure to organophosphate insecticides can reduce the activity of plasma cholinesterase and pseudocholinesterase, creating a potentially fatal hazard for surgical patients receiving suxamethonium. During induction of general anesthesia, the presence of anticholinesterase activity in the serum can potentiate the effect of curare-like drugs, such as suxamethonium, used as muscle relaxants, with prolonged apnea after intubation and death. Such eye drops should be stopped 6 weeks before the operation. The importance of inquiring about the use of drugs cannot be overemphasized. Patients often do not regard eye drops as medications and omit this information from their medical history. Complaints of excessive sweating, intermittent diarrhea, muscle weakness, and fatigue over a long period may be due to the usage of ecothiopate eye drops (phospholine iodide 0.25%) for glaucoma and can disappear when the eye drops are withdrawn (13).

Acetylcysteine

General Information

Acetylcysteine (*N*-acetylcysteine) is used as a mucolytic and to treat paracetamol overdose.

Acetylcysteine splits disulfide bonds in mucoproteins and thus lowers mucus viscosity, resulting in a larger volume of sputum. It is normally administered by inhalation as a nebulized solution or aerosol, although it can also be taken orally. Acetylcysteine is also an antioxidant and may protect the lung from free radicals generated by inflammatory cells activated by influenza virus infection. Treatment for 6 months with acetylcysteine 600 mg bd significantly reduced the frequency and severity of influenza-like episodes. Adverse effects were reported by 9% of patients who complained of dysuria, epigastric pain, nausea and vomiting, constipation or diarrhea, and flushing (SEDA-22, 195).

The place of mucolytic drugs in respiratory disease has recently been reviewed (1). The authors suggested that they have been inappropriately used in the past. As mucolytic agents do not improve lung function tests in COPD, the European Respiratory Society and the American Thoracic Society guidelines discourage their use in the treatment of COPD. Future trials should evaluate clinical symptoms and quality of life as well as lung function tests. Mucolytic agents should be evaluated earlier in the natural history of COPD, when mucus hypersecretion is the major feature and before lung function has deteriorated.

Acetylcysteine is used intravenously as an antidote for severe paracetamol poisoning, in which it acts as a thiol donor.

Oral acetylcysteine has been investigated for the treatment of cancer. Acetylcysteine 600 mg/day was compared with retinol 300 000 U/day, the combination, and a placebo in a total of 2191 patients treated for 2 years. Adverse effects were reported by 14% of those who took acetylcysteine, compared with 23% of those who took retinol and 25% of those who took the combination. The most common adverse effect attributed to acetylcysteine was dyspepsia. In healthy volunteers, higher doses of acetylcysteine, 600 mg taken two or three times daily for 4 weeks, caused more adverse effects: 25 and 61% of the volunteers, respectively, reported gastrointestinal adverse effects (SEDA-20, 184).

There has been a systematic review of published randomized studies of the use of *N*-acetylcysteine in chronic bronchitis (2). A total of 39 trials were considered, of which only nine were included in the meta-analysis. In all cases, oral *N*-acetylcysteine had been used in a dosage of 200–300 mg bd for 4–32 weeks. There were gastrointestinal adverse effects (dyspepsia, diarrhea, and heartburn) in 10% of 2011 patients, and 6.5% withdrew because of their symptoms. However, the rate of gastrointestinal adverse effects was higher in the placebo group (11% with a withdrawal rate of 7.1%). There was no exacerbation of chronic bronchitis in 49% of patients treated with acetylcysteine compared with 31% of placebo-treated patients, a relative benefit of 1.56 (95% CI = 1.37, 1.77). There was also symptom improvement with treatment: 61% reported improvement in symptoms with acetylcysteine compared with 35% with placebo.

Organs and Systems

Respiratory

Aerosol therapy with acetylcysteine can cause bronchoconstriction. In 31 ambulant asthmatics using 10% acetylcysteine solution, there was a mean reduction of 55% in the FEV_1 in 19 subjects. The addition of 0.05% isoprenaline reduced the number of patients who developed bronchoconstriction from 19 to 5 (SEDA-5, 170). In two placebo-controlled studies, involving over 700 patients, there was no difference in adverse effects between oral acetylcysteine and a placebo. There was, however, no improvement in FEV_1 in these studies (3).

Immunologic

Hypersensitivity reactions have been reported when acetylcysteine is given intravenously in paracetamol overdose. A generalized erythematous rash can develop, and itching, nausea, vomiting, dizziness, and severe breathlessness with bronchospasm and tachycardia have been reported (SEDA-5, 170). Angioedema with hypotension and bronchospasm have also been described (4). Wheal responses to high concentrations of acetylcysteine (20 mg/ml) were significantly greater in those who reacted to the drug. In two patients with a positive reaction the response could be inhibited by prior therapy with an antihistamine. As hypersensitivity reactions have been reported in up to

© 2006 Elsevier B.V. All rights reserved.

3% of patients receiving intravenous acetylcysteine for paracetamol overdose, physicians need to be prepared for these reactions (5). A pseudo-allergic reaction on the basis of histamine liberation, rather than an immunological etiology, is suggested as the mechanism (6,7).

Management guidelines for the treatment of anaphylactoid reactions to intravenous acetylcysteine have been developed. Patients who develop only flushing of the skin require no treatment. Urticaria should be treated with diphenhydramine and acetylcysteine infusion can be continued. If angioedema or respiratory distress occur, diphenhydramine should be given and the acetylcysteine infusion stopped; it can be restarted 1 hour after the administration of diphenhydramine if no symptoms are present (SEDA-22, 195).

Drug–Drug Interactions

Antibiotics

The 5% solution, for inhalation, almost completely inactivates penicillin and cephalosporins in vitro and reduces the activity of tetracycline.

Acetylsalicylic acid

General Information

A century after its introduction, acetylsalicylic acid (aspirin) is by far the most commonly used analgesic, sharing its leading position with the relative newcomer paracetamol (acetaminophen), and notwithstanding the fact that other widely used compounds of their class, like ibuprofen and naproxen, have in recent years been introduced in over-the-counter versions. Both are also still being prescribed by physicians and are generally used for mild to moderate pain, fever associated with common everyday illnesses, and disorders ranging from head colds and influenza to toothache and headache. Their greatest use is by consumers who obtain them directly at the pharmacy, and in many countries outside pharmacies as well. Perhaps this wide availability and advertising via mass media lead to a lack of appreciation by the lay public that these are medicines with associated adverse effects. Both have at any rate been subject to misuse and excessive use, leading to such problems as chronic salicylate intoxication with aspirin, and severe hepatic damage after overdose with paracetamol. Both aspirin and paracetamol have featured in accidental overdosage (particularly in children) as well as intentional overdosage.

In an investigation of Canadian donors who had not admitted to drug intake, 6–7% of the blood samples taken were found to have detectable concentrations of acetylsalicylic acid and paracetamol (1). Such drugs would be potentially capable of causing untoward reactions in the recipients.

To offer some protection against misuse of analgesics, many countries have insisted on the use of packs containing total quantities less than the minimum toxic dose (albeit usually the one obtained for healthy young volunteers and thus disregarding the majority of the population), and supplied in child-resistant packaging. Most important, however, is the need to provide education for the lay public to respect such medicines in general for the good they can do, but more especially for the harm that can arise but which can be avoided. There is a definite role for the prescribing physician, as informing the patient seems to prevent adverse events (2).

The sale of paracetamol or aspirin in dosage forms in which they are combined with other active ingredients offers considerable risk to the consumer, since the product as sold may not be clearly identified as containing either of these two analgesics. Brand names sometimes obscure the actual composition of older formulations that contain one or both of these analgesics in combination with, for example, a pyrazolone derivative and/or a potentially addictive substance. For instance, in Germany, with the EC harmonization of the Drug Law of 1990, the manufacturers of drugs already marketed before 1978 had the opportunity of exchanging even the active principles without being obliged to undergo a new approval procedure or to abandon their brand name. Combination formulations are still being promoted and sold, and not exclusively in developing countries. Consequently, the patient who is so anxious to allay all his symptoms that he takes several medications concurrently may without knowing it take several doses of aspirin or paracetamol at the same time, perhaps sufficient to cause toxicity. It is essential that product labels clearly state their active ingredients by approved name together with the quantity per dosage form (3).

The antipyretic analgesics, with the non-steroidal anti-inflammatory drugs (NSAIDs), share a common mechanism of action, namely the inhibition of prostaglandin synthesis from arachidonic acid and their release. More precisely their mode of action is thought to result from inhibition of both the constitutive and the

© 2006 Elsevier B.V. All rights reserved.

inducible isoenzymes (COX-1 and COX-2) of the cyclooxygenase pathway (4). However, aspirin and paracetamol are distinguishable from most of the NSAIDs by their ability to inhibit prostaglandin synthesis in the nervous system, and thus the hypothalamic center for body temperature regulation, rather than acting mainly in the periphery.

Endogenous pyrogens (and exogenous pyrogens that have their effects through the endogenous group) induce the hypothalamic vascular endothelium to produce prostaglandins, which activate the thermoregulatory neurons by increasing AMP concentrations. The capacity of the antipyretic analgesics to inhibit hypothalamic prostaglandin synthesis appears to be the basis of their antipyretic action. Neither aspirin nor paracetamol affects the synthesis or release of endogenous pyrogens and neither will lower body temperature if it is normal.

While aspirin significantly inhibits peripheral prostaglandin and thromboxane synthesis, paracetamol is less potent as a synthetase inhibitor than the NSAIDs, except in the brain, and paracetamol has only a weak anti-inflammatory action. It is simple to ascribe the analgesic activity of aspirin to its capacity to inhibit prostaglandin synthesis, with a consequent reduction in inflammatory edema and vasodilatation, since aspirin is most effective in the pain associated with inflammation or injury. However, such a peripheral effect cannot account for the analgesic activity of paracetamol, which is less well understood.

As a prostaglandin synthesis inhibitor, aspirin, like other NSAIDs, is associated with irritation of and damage to the gastrointestinal mucosa. In low doses it can also increase bleeding by inhibiting platelet aggregation; in high doses, prolongation of the prothrombin time will contribute to the bleeding tendency. Intensive treatment can also produce unwanted nervous system effects (salicylism).

Depending on the criteria used, the incidence of aspirin hypersensitivity is variously estimated as being as low as 1% or as high as 50%, the highest frequency being found in asthmatics. The condition is characterized by bronchospasm (asthma), urticaria, angioedema, and vasomotor rhinitis, each occurring alone or in combination, often leading to severe and even life-threatening reactions. There is no clear evidence of an association with tumors, apart from the possible peripheral contribution of aspirin to the development of urinary tract neoplasms in patients with analgesic nephropathy. Indeed, some authors have suggested a role for salicylates in reducing the incidence of colorectal tumors and breast tumors.

The following are absolute contraindications to the use of aspirin:

- children under 16;
- people with hypersensitivity to salicylates, NSAIDs, or tartrazine;
- people with peptic ulceration;
- people with known coagulopathies, including those induced as part of medical therapy.

The following are relative contraindications to the use of long-term analgesic doses of aspirin:

- gout, since normal analgesic doses impede the excretion of uric acid (high doses have a uricosuric effect); an additional problem in gout is that salicylates reduce the uricosuric effects of sulfinpyrazone and probenecid;
- variant angina; a daily dose of 4 g has been found to provoke attacks both at night-time and during the day (5,6), perhaps owing to direct triggering of coronary arterial spasm; blockade of the synthesis of PGI_z, which normally protects against vasoconstriction, could be involved;
- diabetes mellitus, in which aspirin can in theory interfere with the actions of insulin and glucagon sufficiently to derange control;
- some days before elective surgery (even in coronary artery bypass grafting) or delivery, especially if extradural anesthesia is used (7), although recent data seem reassuring (8); aspirin increases bleeding at dental extraction or perioperatively;
- in elderly people, who may develop gastrointestinal bleeding;
- anorectal inflammation (suppositories);
- pre-existing gastrointestinal disease, liver disease, hypoalbuminemia, hypovolemia, in the third trimester of pregnancy, perioperatively, or in patients with threatening abortion.

Assessing the benefit-to-harm balance of low-dose aspirin in preventing strokes and heart attacks

Although there is clear evidence of benefit of acetylsalicylic acid (aspirin) in secondary prevention of strokes and heart attacks, the question of whether aspirin should also be prescribed for primary prevention in asymptomatic people is still debatable. Trials in primary prevention have given contrasting results (9,10), and aspirin can cause major harms (for example severe gastrointestinal bleeding and hemorrhagic stroke).

Furthermore, despite evidence of the efficacy of aspirin in secondary prevention, its use in patients at high risk of strokes and heart attacks remains suboptimal (11). A possible explanation for this underuse may be concern about the relative benefit in relation to the potential risk for serious hemorrhagic events. Accurate evaluation of the benefits and harms of aspirin is therefore warranted.

Two meta-analyses have provided some information. The first examined the benefit and harms of aspirin in subjects without known cardiovascular or cerebrovascular disease (primary prevention) (12). The authors selected articles published between 1966 and 2000—five large controlled studies of primary prevention that lasted at least 1 year and nine studies of the effects of aspirin on gastrointestinal bleeding and hemorrhagic stroke. The five randomized, placebo-controlled trials included more than 50 000 patients and the meta-analysis showed that aspirin significantly reduced the risk of the combined outcome (confirmed non-fatal myocardial infarction or death from coronary heart disease) (OR = 0.72; 95% CI = 0.60, 0.87). However, aspirin increased the risk of major gastrointestinal bleeding (OR = 1.7; CI = 1.4, 2.1) significantly, while the small

© 2006 Elsevier B.V. All rights reserved.

increase found for hemorrhagic stroke (OR = 1.4; CI = 0.9, 2.0) was not statistically significant. All-cause mortality was not significantly affected (OR = 0.93; CI = 0.84; 1.02). Most important was the finding that the net effect of aspirin improved with increasing risk of coronary heart disease. The meta-analysis showed that for 1000 patients with a 5% risk of coronary heart disease events over 5 years, aspirin would prevent 6–20 myocardial infarctions but would cause also 0–2 hemorrhagic strokes and 2–4 major gastrointestinal bleeds. For patients at lower risk (1% over 5 years), aspirin would prevent 1–4 myocardial infarctions but would still cause 0–2 hemorrhagic strokes and 2-4 major gastrointestinal bleeds.

Therefore when deciding to use aspirin in primary prophylaxis, one should take account of the relative utility of the different outcomes that are prevented or caused by aspirin.

The other meta-analysis (13) compared the benefits of aspirin in secondary prevention with the risk of gastrointestinal bleeding. An earlier analysis of this problem included patients at various levels of risk and doses of aspirin that would currently be regarded as too high (14), and may therefore have either underrepresented the benefit or exaggerated the risk. In another analysis there was no difference in the risk of gastrointestinal bleeding across the whole range of doses used (15).

The meta-analysis reviewed all randomized, placebo-controlled, secondary prevention trials of at least 3-months duration published from 1970 to 2000. The dosage of aspirin was 50–325 mg/day. Six studies contributed 6300 patients to the analysis (3127 on aspirin and 3173 on placebo). Aspirin reduced all-cause mortality by 18%, the number of strokes by 20%, myocardial infarctions by 30%, and other vascular events by 30%. On the other hand, patients who took aspirin were 2.5 times more likely than those who took placebo to have gastrointestinal tract bleeds. The number of patients needed to be treated (NNT) to prevent one death from any cause was 67 and the NNT to cause one gastrointestinal bleeding event was 100. In other words 1.5 lives can be saved for every gastrointestinal bleed attributed to aspirin. Although the risk of gastrointestinal bleeding was increased by aspirin, the hemorrhagic events were manageable and led to no deaths. On the basis of these data we can conclude that the benefits–harm balance for low-dose aspirin in the secondary prevention of cardiovascular and cerebrovascular events is highly favorable. The same conclusions have been drawn from the systematic overview published by the Antithrombotic Trialists Collaboration Group, which analysed data from 287 studies involving 135 000 patients (16).

As far as primary prevention of cardiovascular events is concerned, it appears that aspirin can reduce heart attacks and strokes but increases gastrointestinal and intracranial bleeding. The decision to use aspirin in primary prevention should therefore take into account the fact that the net effect of aspirin improves with increasing risk of coronary heart disease as well as the values that patients attach to the main favorable and unfavorable outcomes.

Organs and Systems

Cardiovascular

Apart from rare reports of variant angina pectoris and vasculitis theoretically related to thromboxane, aspirin is not associated with adverse effects on the cardiovascular system (17,18), except an increase in circulating plasma volume after large doses.

Respiratory

The effect of aspirin on bronchial musculature is discussed in the section on Immunologic in this monograph.

Salicylates can cause pulmonary edema, particularly in the elderly, especially if they are or have been heavy smokers (19).

Chronic salicylate toxicity can cause pulmonary injury, leading to respiratory distress. Lung biopsy may show diffuse alveolar damage and fibrosis (20).

Nervous system

Salicylism is a reaction to very high circulating concentrations of salicylate, characterized by tinnitus, dizziness, confusion, and headache.

Encephalopathy secondary to hyperammonemia has been reported in those rare cases of liver failure that are associated with high doses of aspirin, and this also forms a major feature of Reye's syndrome (see the section on Liver in this monograph).

One case-control study showed no increased risk of intracerebral hemorrhage in patients using aspirin or other NSAIDs in low dosages as prophylaxis against thrombosis (21). However, intracerebral hemorrhage has been reported with aspirin, even in low doses, and in the SALT study (22) and the Physicians Health Study of 1989 (23) hemorrhagic stroke and associated deaths occurred with aspirin.

Sensory systems

Eyes

Well-documented acute myopia and increased ocular pressure attributed to aspirin has been described (24).

Ears

With the high concentrations achieved in attempted suicide, tinnitus and hearing loss, leading to deafness, develop within about 5 hours, usually with regression within 48 hours, but permanent damage can occur. Disturbed balance, often with vertigo, can develop, as well as nausea, usually with maintenance of consciousness, even without treatment. It has been postulated that in this state depolarization of the cochlear hair cells occurs, similar to the changes induced by pressure. Tinnitus is also a symptom of salicylism.

Metabolism

Aspirin lowers plasma glucose concentrations in C-peptide-positive diabetic subjects and in normoglycemic persons (25). This is of no clinical significance.

Fluid balance

NSAIDs can cause fluid retention, but this has rarely been reported with aspirin.

- Severe fluid retention, possibly due to impaired renal tubular secretion, has been reported in a 29-year-old woman taking aspirin (1.5 g/day for several days) for persistent headache (26). During rechallenge with aspirin (0.5 g tds for 3 days) a dynamic renal scintigram showed a substantial fall in tubular filtration. Withdrawal was followed by complete uneventful recovery.

Pulmonary edema is a feature of salicylate intoxication, but this patient was taking a therapeutic dosage.

Hematologic

Thrombocytopenia, agranulocytosis, neutropenia, aplastic anemia, and even pancytopenia have been reported in association with aspirin. The prospect for recovery from the latter is poor, mortality approaching 50%.

Hemolytic anemia can occur in patients with glucose-6-phosphate dehydrogenase deficiency or erythrocyte glutathione peroxidase deficiency (SED-9, 128) (27–29). Whether these reports have anything more than anecdotal value (SEDA-17, 97) is not known.

Simple iron deficiency caused by occult blood loss occurs with a frequency of 1%, and upper gastrointestinal bleeding resulting from regular aspirin ingestion is the reason for hospitalization in about 15 patients per 100 000 aspirin users per year. Aspirin causes bleeding of sufficient severity to lead to iron deficiency anemia in 10–15% of patients taking it continuously for chronic arthritis. Some individuals are particularly at risk because of pregnancy, age, inadequate diet, menorrhagia, gastrectomy, or malabsorption syndromes.

Macrocytic anemia associated with folate deficiency has been described in patients with rheumatoid arthritis (30) and also in patients who abuse analgesic mixtures containing aspirin (30).

Effects on coagulation

Aspirin in high doses for several days can reduce prothrombin concentrations and prolong the prothrombin time. This will contribute to bleeding problems initiated by other factors, including aspirin's local irritant effects on epithelial cells. It is therefore very risky to use aspirin in patients with bleeding disorders. The effect will contribute to increased blood loss at parturition, spontaneous abortion, or menorrhagia, and may be linked to persistent ocular hemorrhage, particularly in older people, with or without associated surgical intervention (31,32).

By virtue of its effects on both cyclo-oxygenase isoenzymes, aspirin inhibits platelet thromboxane A_2 formation. This effect in the platelet is irreversible and will persist for the lifetime of the platelet (that is up to 10 days), since the platelet cannot synthesize new cyclo-oxygenase. It is of clinical significance that the dose of aspirin necessary to inhibit platelet thromboxane A_2 (around 40 mg/day) is much lower than that needed to inactivate the subendothelial prostacyclin (PGI_2). Hence, platelet aggregation is inhibited, with some associated dilatation of coronary and cerebral arterioles, at doses that do not interfere with prostacyclin inhibition. It is important, in considering the dosage of aspirin for prophylaxis (see below), to appreciate that prostacyclin is a general inhibitor of platelet aggregation, while aspirin, as a cyclo-oxygenase inhibitor, affects aggregation from a limited number of stimuli, for example ADP, adrenaline, thromboxane A_2. It is also worth recalling that the vascular endothelium can synthesize new cyclo-oxygenase, so that any effect on prostacyclin synthesis is of limited duration only (SEDA-12, 74) (33).

Several long-term studies have been carried out since the 1980s to determine the prophylactic usefulness of these effects on clotting. It is now clear that aspirin in dosages of around 300 mg/day can be used successfully for secondary prophylaxis in patients with coronary artery disease, in order to reduce the incidence of severe myocardial infarction, and in patients with cerebrovascular disease to reduce the incidence of transient ischemic attacks and strokes. There is some suggestion that higher doses of aspirin may be required in women. A major drawback has been the high incidence of gastrointestinal adverse effects and particularly bleeding in aspirin-treated groups (5,6,10,34). In view of the age group involved, bleeding can have serious implications. In an attempt to avoid this high proportion of ill-effects and yet retain the benefits of prophylactic antithrombotic treatment, a few trials have been conducted using aspirin in a dose of 162 mg (ISIS-2) (35) and 75 mg (RISC) (36) in symptomatic coronary heart disease, with good evidence of efficacy. Two studies have been reported in patients with cerebrovascular events, namely the Dutch TIA trial with aspirin 30 versus 283 mg (21) and the SALT study with aspirin 75 mg (22). The former did not show any difference in efficacy between the 30 and 283 mg dose groups, but there was no placebo control. The latter study showed a significant reduction in thrombotic stroke. However, intracerebral hemorrhage has been reported with aspirin, even in low doses, and in this as well as in the Physicians Health Study of 1989 (23), hemorrhagic stroke and associated deaths occurred with aspirin. On the other hand, the incidence of serious gastrointestinal events was much lower than previously described.

As nearly all of the risks seem to be dose-related (SEDA-21, 96), there is a good prospect that an even lower daily dose of aspirin may offer advantages in antithrombotic prophylaxis without an increased risk of bleeding, but the results of further such studies are still awaited (9).

Relatively few patients developed a prolonged bleeding time while taking aspirin or other NSAIDs and only few had significant intraoperative blood loss. There is variation in the response of patients for unknown reasons and so the recommendation that NSAIDs should be withdrawn before elective surgery awaits confirmation (SEDA-19, 96).

Gastrointestinal

Gastric ulceration and hemorrhage

DoTS classification

Dose-relation: collateral effect
Time-course: intermediate
Susceptibility factors: age (over 65); sex (women); disease (peptic ulceration)

© 2006 Elsevier B.V. All rights reserved.

The gastrointestinal adverse effects of aspirin and the other NSAIDs are the most common. While some argue against a causative relation between aspirin ingestion and chronic gastric ulceration, the current consensus favors such a relation, while admitting that other factors, such as *Helicobacter pylori*, are likely to play a part. Patients aged over 65 years and women are more at risk, as are those who take aspirin over prolonged periods in a daily dose of about 2 g or more.

However, there is no ambiguity about the association of aspirin with gastritis, gastric erosions, or extensions of existing peptic ulcers, all of which are demonstrable by endoscopy. Even after one or two doses, superficial erosions have been described in over 50% of healthy subjects. This association is now almost universally accepted as the standard basis for comparative testing of NSAIDs and other drugs (21,37–39). Whether it is of benefit to use other drugs concomitantly to prevent the effect of gastric acid on the mucosa, and thus reduce the risk of gastric ulceration, is discussed further in this monograph.

Dyspepsia, nausea, and vomiting occur in 2–6% of patients after aspirin ingestion. Patients with rheumatoid arthritis seem to be more sensitive, and the frequency of aspirin-induced dyspepsia in this group is 10–30% (SEDA-9, 129). However, these symptoms are generally poor predictors of the incidence of mucosal damage (SEDA-18, 90).

The bleeding that occurs is usually triggered by erosions and aggravated by the antithrombotic action of aspirin. While it is reported to occur in up to 100% of regular aspirin takers, bleeding tends to be asymptomatic in young adults, unless it is associated with peptic ulceration, but it is readily detectable by endoscopy and the presence of occult blood in the feces. Hematemesis and melena are less often seen, the odds ratio being 1.5–2.0 in an overview of 21 low-dose aspirin prevention studies (40). A degree of resultant iron deficiency anemia is common. Such events are more commonly seen in older people in whom there is a significant proportion of serious bleeding and even deaths. Major gastrointestinal bleeding has an incidence of 15 per 100 000 so-called heavy aspirin users. However, the interpretation of "heavy" and of quantities of aspirin actually taken is to a large extent subjective and very dependent on the questionable accuracy of patient reporting. The risk appears to be greater in women, smokers, and patients concurrently taking other NSAIDs, and is possibly affected by other factors not yet established (41). Gastrointestinal perforation can occur without prodromes. Aspirin increases the risk of major upper gastrointestinal bleeding and perforation two- to three-fold in a dose-related manner, but deaths are rare.

Incidence

Of the estimated annual 65 000 upper gastrointestinal emergency admissions in the UK, nearly 20% (including deaths in 3.4%) are attributable to the use of prostaglandin synthesis inhibitors (42). As might be expected with an inhibitor of prostaglandin synthesis, the cytoprotective effects of prostaglandin E and prostacyclin (PGI_2) are reduced by aspirin, as is the inhibitory action on gastric acid secretion. This effect may be both direct, as is the case with aspirin released in the stomach (or the lower rectum in the case of aspirin suppositories), and indirect following absorption and distribution via the systemic circulation; attempts to reduce the problems by coating and buffering can therefore have only limited success. The indirect type of effect is shown by the fact that these adverse gastric effects can also be exerted by parenteral lysine acetylsalicylate (SEDA-10, 72). The local effects depend in part on the tablet particle size, solubility, and rate of gastric absorption, while the most important variable appears to be gastric pH. On the other hand, within-day changes in the pharmacokinetics of the analgesic compounds may be involved in the prevalence of gastrointestinal adverse effects.

The estimates of gastrointestinal complication rates from aspirin are generally derived from clinical trials (SEDA-21, 100). However, the applicability of the results of such trials to the general population may be debatable, as protocols for these studies often are designed precisely to avoid enrollment of patients who are at risk of complications. Indeed differences in benefit-to-harm balance have been found in trials using the same dose of aspirin (43,44). For this reason, a population-based historical cohort study on frequency of major complications of aspirin used for secondary stroke prevention may be of interest (45). The study identified 588 patients who had a first ischemic stroke, transient ischemic attack, or amaurosis fugax during the study period. Of these, 339 patients had taken aspirin for an average of 1.7 years. The mean age of patients who had taken aspirin was 74 years. Complications occurred within 30 days of initiation of treatment in one patient, between 30 days and 6 months in 10 patients, between 6 months and 1 year in seven patients, and between 1 year and 2 years in two patients. Estimated standardized morbidity ratio of gastrointestinal hemorrhage (determined on the basis of 10 observed events and 0.661 expected events, during 576 person-years of observation) was 15 (95% CI = 7, 28). The estimated standardized morbidity ratio of intracerebral hemorrhage (determined on the basis of only one event and 0.59 expected events) was 1.7 (CI = 0.04, 9.4). One patient had a fatal gastrointestinal hemorrhage. Unfortunately these complication rates must be considered estimates, because aspirin therapy was not consistently recorded. However, the rates of complications were similar to those observed in some randomized clinical trials. On the basis of these data and of those of a meta-analysis of 16 trials involving more than 95 000 patients (45), the overall benefits of aspirin, measured in terms of preventing myocardial infarction and ischemic stroke, clearly outweigh the risks.

Dose-relatedness

The question of whether the risk of gastrointestinal hemorrhage with long-term aspirin is related to dose within the usual therapeutic dosage range (SEDA-12, 100) (15,46) merits attention. In a meta-analysis of the incidence of gastrointestinal hemorrhage associated with

© 2006 Elsevier B.V. All rights reserved.

long-term aspirin and the effect of dose in 24 randomized, controlled clinical trials including almost 66 000 patients exposed for an average duration of 28 months to a wide range of different doses of aspirin (50–1500 mg/day), gastrointestinal hemorrhage occurred in 2.47% of patients taking aspirin compared with 1.42% taking placebo (OR = 1.68; 95% CI = 1.51, 1.88). In patients taking low doses of aspirin (50–162.5 mg/day; $n = 49\ 927$), gastrointestinal hemorrhage occurred in 2.3% compared with 1.45% taking placebo (OR = 1.56; 95% CI = 1.40, 1.81). The pooled OR for gastrointestinal hemorrhage with low-dose aspirin was 1.59 (95% CI = 1.4, 1.81). A meta-regression to test for a linear relation between the daily dose of aspirin and the risk of gastrointestinal hemorrhage gave a pooled OR of 1.015 (95% CI = 0.998, 1.047) per 100 mg dose reduction. The reduction in the incidence of gastrointestinal hemorrhage was estimated to be 1.5% per 100 mg dose reduction, but this was not significant.

These data are in apparent contrast with others previously reported (SEDA-21, 100) (14), which showed that gastrointestinal hemorrhage was related to dose in the usual dosage range. Many reasons may explain these contrasting results, the most important being differences in the definition of the hemorrhagic events, in study design, in the population studied, and in the presence of accessory risk factors (47–49).

The recent trends toward the use of lower doses of aspirin have been driven by the belief that these offer a better safety profile while retaining equivalent therapeutic efficacy. Despite the large number of patients enrolled in randomized clinical trials and included in meta-analyses, there is no firm evidence that dose reduction significantly lowers the risk of gastrointestinal bleeding. Patients and doctors therefore need to consider the trade-off between the benefits and harms of long-term treatment with aspirin. Meanwhile, it seems wise to use the lowest dose of proven efficacy.

A systematic review of 17 epidemiological studies conducted between 1990 and 2001 has provided further data on this topic (50). The effect of aspirin dosage was investigated in five studies. There was a greater risk of gastrointestinal complications with aspirin in dosages over 300 mg/day than in dosages of 300 mg/day or less. However, users of low-dose aspirin still had a two-fold increased risk of such complications compared with non-users, with no clear evidence of a dose-response relation at dosages under 300 mg/day, confirming previous findings (15). The study also addressed the question of whether the aspirin formulation affects gastrotoxicity. The pooled relative risks of gastrointestinal complications in four studies were 2.4 (95%; CI = 1.9, 2.9) for enteric-coated aspirin, 5.3 (3.0, 9.2) for buffered formulations, and 2.6 (2.3, 2.9) for plain aspirin, compared with non-use. These data confirm those from previous studies (SEDA-21, 100) (15), which negate any protective effect of the most frequently used aspirin formulations. Furthermore, there were higher relative risks, compared with non-use, for gastrointestinal complications in patients who used aspirin regularly (RR = 3.2; CI = 2.6, 5.9) than in patients who used it occasionally (2.1; 1.7, 2.6), and during the first month of use (4.4; 3.2, 6.1) compared with subsequent months (2.6; 2.1, 3.1).

Comparative studies

A comparative study of gastrointestinal blood loss after aspirin 972 mg qds for 4 days versus different doses of piroxicam (20 mg od, 5 mg qds, and 10 mg qds) showed that piroxicam did not increase fecal blood loss, whereas aspirin did. Gastroscopic evidence of irritation was also greater with aspirin (51).

In a randomized trial comparing ticlopidine (500 mg/day) with aspirin (1300 mg/day) for the prevention of stroke in high-risk patients, the incidence of bleeding was similar in both groups, although more patients treated with aspirin developed peptic ulceration or gastrointestinal hemorrhage (52).

Risk factors

A study of the risk factors for gastrointestinal perforation, a much less frequent event than bleeding, has confirmed that aspirin and other NSAIDs increase the risk of both upper and lower gastrointestinal perforation (OR 6.7, CI 3.1–14.5 for NSAIDs) (53). Gastrointestinal perforation has been associated with other factors, such as coffee consumption, a history of peptic ulcer, and smoking. The combination of NSAIDs, smoking, and alcohol increased the risk of gastrointestinal perforation (OR 10.7, CI 3.8–30) (SEDA-21, 97).

Associated effects

Aspirin can also play a role in esophageal bleeding, ulceration, or benign stricture, and it should be considered as a possible cause in patients, particularly the elderly, who present with any of these features. There have also been reports of rectal stricture in the elderly, associated with the use of aspirin suppositories. Effects on both these strictures emphasize the significance of a direct local action of aspirin as well as a systemic action and underlines the relevance of the involvement of oxygen-derived free radicals in the pathogenesis of mucosal lesions in the gastrointestinal tract (54–56).

A gastrocolic fistula developed in a 47-year-old woman taking aspirin and prednisone for rheumatoid arthritis (57). Other similar case reports have been published (58,59).

Long-term effects

The effects on the stomach of continued exposure to aspirin remain controversial. While in short-term use, gastric mucosal erosions may often be recurrent but transient and comparatively trivial lesions, with longer administration there seems to be an increased risk of progression to ulceration.

Prophylaxis

Intravenous administration, or the use of enteric-coated formulations or modified-release products all appear to reduce the risk both of bleeding and more particularly of erosions/ulceration. However, because of the indirect effect noted above, such formulations do not eliminate the risk, although they may reduce the incidence of

© 2006 Elsevier B.V. All rights reserved.

gastric or duodenal ulcer, as may buffered aspirin (60,61).

Considerable attention in recent years has been directed toward the efficacy of using synthetic forms of PGE_2, histamine H_2 receptor antagonists, proton pump inhibitors, or antacids, either to heal peptic ulcers associated with use of prostaglandin inhibitors or more significantly to act prophylactically to protect against ulceration or bleeding associated with aspirin or the NSAIDs. With the exception of PGE_2, there is no convincing evidence to justify their prophylactic use, as they do not reduce the risk of significant gastrointestinal events. In contrast, their soothing effect on gastrointestinal symptoms may ultimately result in more severe complications (62). Since all these agents carry their own potential risks, it is more than questionable whether administration to a patient with normal gastrointestinal mucosa is justified. Generally, use of prostaglandin inhibitors should be limited to the shortest possible duration, thereby minimizing, but not eliminating, the risk of gastrointestinal damage. Only high-risk patients should be eligible for prophylactic drug therapy. Well-known risk factors for the development of mucosal lesions of the gastrointestinal tract are age (over 75 years), a history of peptic ulcer, or gastrointestinal bleeding, and concomitant cardiac disease.

Liver

Aspirin can cause dose-related focal hepatic necrosis that is usually asymptomatic or anicteric. Much of the evidence for hepatotoxicity of aspirin and the salicylates has been shown in children (63,64), usually in patients with connective tissue disorders, taking relatively high long-term dosages for Still's disease, rheumatoid arthritis, or occasionally systemic lupus erythematosus. Rises in serum transaminases seem to be the most common feature (in up to 50% of patients) and are usually reversible on withdrawal, but they occasionally lead to fatal hepatic necrosis. Severe and even fatal metabolic encephalopathy can also occur, as in Reye's syndrome (see the section on Reye's syndrome in this monograph). One can easily overload the young patient's individual metabolic capacity. The co-existence of hypoalbuminemia may be a particular risk factor; in patients with hypoalbuminemia of 35 g/l or less, close monitoring of the aspartate transaminase is advisable, especially if the concentration of total serum salicylate is 1.1 mmol/l or higher (65). Plasma salicylate concentrations in serious cases have usually been in excess of 1.4 mmol/l and liver function tests return rapidly to normal when the drug is withdrawn. Finally, a very small number of cases of chronic active hepatitis have been attributed to aspirin (66).

Reye's syndrome

First defined as a distinct syndrome in 1963, Reye's syndrome came to be regarded some years later as an adverse effect of aspirin. In fact, the position is more complex, and the syndrome still cannot be assigned a specific cause. There is general agreement that the disorder presents a few days after the prodrome of a viral illness. Well over a dozen different viruses have so far been implicated, including influenza A and B, adenovirus, *Varicella*, and reovirus. Various other factors have also been incriminated, including aflatoxins, certain pesticides, and such antioxidants as butylated hydroxytoluene. Only in the case of aspirin have some epidemiological studies been conducted, and these appeared to show a close correlation with cases of Reye's syndrome. It was these studies that led to regulatory action against the promotion of salicylate use in children. However, doubt has been thrown on the clarity of the link, and it now seems increasingly likely that while there is some association with aspirin, the etiology is in fact multifactorial, including some genetic predisposition. Studies in Japan did not support the US findings, while studies in Thailand and Canada invoked other factors.

Two characteristic phenomena are present in Reye's syndrome.

1. Damage to mitochondrial structures, with pleomorphism, disorganization of matrix, proliferation of smooth endoplasmic reticulum, and an increase in peroxisomes; mitochondrial enzyme activity is severely reduced, but cytoplasmic enzymes are unaffected. The changes first appear in single cells, but may spread to all hepatocytes. Recovery may be complete by 5–7 days. While these changes are most evident in liver cells, similar effects have been seen in cerebral neurons and skeletal muscle. There appears to be a block in beta-oxidation of fatty acids (inhibition of oxidation of NAB-linked substrates). In vitro aspirin selectively inhibits mitochondrial oxidation of medium- and long-chain fatty acids.
2. An acute catabolic state with hypoglycemia, hyperammonemia, raised activities of serum aspartate transaminase and creatine phosphokinase, and increased urinary nitrogen and serum long chain dicarboxylic acid.

Despite our lack of understanding of the syndrome, the decision taken in many countries to advise against the use of salicylates in children under 12 made an impact, in terms of a falling incidence of Reye's syndrome (SEDA-16, 96; SEDA-17, 97).

Over the last 25 years, in the USA, the incidence of Reye's syndrome has fallen significantly—from the time that the advice was introduced up to 1999 there were 25 reported cases, but 15 were in adolescents aged 12–17 years, and 8% of cases occurred in patients aged 15 years or over (67). In the UK, in view of these findings, the Commission on Safety of Medicines (CSM) amended its original statement and advised that aspirin should be avoided in febrile illnesses or viral infections in patients aged under 16 years. However, the appropriateness of this decision has been challenged (68). This is because the incidence of Reye's syndrome is already low and is falling; furthermore, restricting the use of aspirin leaves paracetamol and ibuprofen as the only available therapeutic alternatives, and their safety is not absolutely guaranteed and might be even worse than that of aspirin.

Urinary tract

Aspirin is associated with a small but significant risk of hospitalization for acute renal insufficiency (SEDA-19, 95).

© 2006 Elsevier B.V. All rights reserved.

When aspirin is used by patients on sodium restriction or with congestive heart failure, there tends to be a reduction in the glomerular filtration rate, with preservation of normal renal plasma flow. Some renal tubular epithelial shedding can also occur.

Severe systemic disease involving the heart, liver, or kidneys seems to predispose the patient to the effects of aspirin and other NSAIDs on renal function (69).

Chronic renal disease

Renal papillary necrosis has been reported after long-term intake or abuse of aspirin and other NSAIDs (SEDA-11, 85) (SEDA-12, 79). The relation between long-term heavy exposure to analgesics and the risk of chronic renal disease has been the object of intensive toxicological and epidemiological research for many years (SEDA-24, 120) (70). Most of the earlier reports suggested that phenacetin-containing analgesics probably cause renal papillary necrosis and interstitial nephritis. In contrast, there was no convincing epidemiological evidence that non-phenacetin-containing analgesics (including paracetamol, aspirin, mixtures of the two, and NSAIDs) cause chronic renal disease. Moreover, findings from epidemiological studies should be interpreted with caution, because of a number of inherent limitations and potential biases in study design (71). Two methodologically sound studies have provided information on this topic.

The first was the largest cohort study conducted thus far to assess the risk of renal dysfunction associated with analgesic use (72). Details of analgesic use were obtained from 11 032 men without previous renal dysfunction participating in the Physicians' Health Study (PHS), which lasted 14 years. The main outcome measure was a raised creatinine concentration defined as 1.5 mg/dl (133 μmol/l) or higher and a reduced creatinine clearance of 55 ml/minute or less. In all, 460 men (4.2%) had a raised creatinine concentration and 1258 (11%) had a reduced creatinine clearance. Mean creatinine concentrations and creatinine clearances were similar among men who did not use analgesics and those who did. This was true for all categories of analgesics (paracetamol and paracetamol-containing mixtures, aspirin and aspirin-containing mixtures, and other NSAIDs) and for higher-risk groups, such as those aged 60 years or over or those with hypertension or diabetes.

These data are convincing, as the large size of the PHS cohort should make it possible to examine and detect even modest associations between analgesic use and a risk of renal disease. Furthermore, this study included more individuals who reported extensive use of analgesics than any prior case-control study. However, the study had some limitations, the most important being the fact that the cohort was composed of relatively healthy men, most of whom were white. These results cannot therefore be generalized to the entire population. However, the study clearly showed that there is not a strong association between chronic analgesic use and chronic renal dysfunction among a large cohort of men without a history of renal impairment.

The second study was a Swedish nationwide, population-based, case-control study of early-stage chronic renal insufficiency in men whose serum creatinine concentration exceeded 3.4 mg/dl (300 μmol/l) or women whose serum creatinine exceeded 2.8 mg/dl (250 μmol/l) (73). In all, 918 patients with newly diagnosed renal insufficiency and 980 controls were interviewed and completed questionnaires about their lifetime consumption of analgesics. Compared with controls, more patients with chronic renal insufficiency were regular users of aspirin (37 versus 19%) or paracetamol (25 versus 12%). Among subjects who did not use aspirin regularly, the regular use of paracetamol was associated with a risk of chronic renal insufficiency that was 2.5 times as high as that for non-users of paracetamol. The risk increased with increasing cumulative lifetime dose. Patients who took 500 g or more over a year (1.4 g/day) during periods of regular use had an increased odds ratio for chronic renal insufficiency (OR = 5.3; 95% CI = 1.8, 15). Among subjects who did not use paracetamol regularly, the regular use of aspirin was associated with a risk of chronic renal insufficiency that was 2.5 times as high as that for non-users of aspirin. The risk increased significantly with an increasing cumulative lifetime dose of aspirin. Among the patients with an average intake of 500 g or more of aspirin per year during periods of regular use, the risk of chronic renal insufficiency was increased about three-fold (OR = 3.3; CI = 1.4, 8.0). Among patients who used paracetamol in addition to aspirin, the risk of chronic renal insufficiency was increased about two-fold when regular aspirin users served as the reference group (OR = 2.2; CI = 1.4, 3.5) and non-significantly when regular paracetamol users were used as controls (OR = 1.6; CI = 0.9, 2.7). There was no relation between the use of other analgesics (propoxyphene, NSAIDs, codeine, and pyrazolones) and the risk of chronic renal insufficiency. Thus, the regular use of paracetamol, or aspirin, or both was associated dose-dependently with an increased risk of chronic renal insufficiency. The OR among regular users exceeded 1.0 for all types of chronic renal insufficiency, albeit not always significantly. These results are consistent with exacerbating effects of paracetamol and aspirin on chronic renal insufficiency, regardless of accompanying disease.

How can we explain the contrasting results of these two studies? A possible explanation lies in the different populations studied. In the PHS study, relatively healthy individuals were enrolled while in the Swedish study all the patients had pre-existing severe renal or systemic disease, suggesting that such disease has an important role in causing analgesic-associated chronic renal insufficiency. People without pre-existing disease who use analgesics may have only a small risk of end-stage renal disease.

Skin

Hypersensitivity reactions, such as urticaria and angioedema, are relatively common in subjects with aspirin hypersensitivity. Purpura, hemorrhagic vasculitis, erythema multiforme, Stevens–Johnson syndrome, and Lyell's syndrome have also been reported, but much less often. Fixed drug eruptions, probably hypersensitive in origin, are periodically described. In some patients they do not recur on rechallenge, that is the sensitivity disappears (74).

© 2006 Elsevier B.V. All rights reserved.

Musculoskeletal

There is evidence that salicylates together with at least some NSAIDs suppress proteoglycan biosynthesis independently of effects on prostaglandin synthesis (75). Thus, prolonged use of these agents can accentuate deterioration of articular cartilage in weight-bearing arthritic joints. If this is proved, the problem will be of greatest relevance to elderly people with osteoarthritis, a condition in which this use of prostaglandin inhibitors is questionable.

Immunologic

Aspirin hypersensitivity

Of adult asthmatics 2–20% have aspirin hypersensitivity (9). The mechanism is related to a deficiency in bronchodilator prostaglandins; prostaglandin inhibition may make arachidonic acid produce more leukotrienes with bronchoconstrictor activity. Oral challenge in asthmatic patients is an effective but potentially dangerous method for establishing the presence of aspirin hypersensitivity (63).

The term "aspirin allergy" is better avoided, in the absence of identification of a definite antigen–antibody reaction. This topic has been reviewed (SEDA-17, 94) (SEDA-18, 90).

Epidemiology

Aspirin hypersensitivity is relatively common in adults (about 20%). Estimates of the prevalence of aspirin-induced asthma vary from 3.3 to 44% in different reports (SEDA-5, 169), although it is often only demonstrable by challenge tests with spirometry, and only 4% have problems in practice. Patients with existing asthma and nasal polyps or chronic urticaria have a greater frequency of hypersensitivity (76), and women appear to be more susceptible than men, perhaps particularly during the childbearing period of life (77). Acute intolerance to aspirin can develop even in patients who have taken the drug for some years without problems.

There is considerable cross-reactivity with other NSAIDs and the now widely banned food colorant tartrazine (78). Cross-sensitization between aspirin and tartrazine is common; for example, in one series 24% of aspirin-sensitive patients also reacted to tartrazine (SEDA-9, 76).

Mechanism

The current theory of the mechanism relates to the inhibition of cyclo-oxygenases (79) and a greater degree of interference with PGE_2 synthesis, allowing the bronchoconstrictor PGF_2 to predominate in susceptible individuals.

PGE_2 inhibition in macrophages may also unleash bronchial cytotoxic lymphocytes, generated by chronic viral infection, leading to destruction of virus-infected cells in the respiratory tract (80). When urticaria occurs, it may result from increased release of leukotrienes LTC_4, D_4, and E_4, which also induces bronchoconstriction, with a shunt of arachidonic acid toward lipoxygenation in aspirin-sensitive asthmatics (SEDA-18, 93). Aspirin-induced asthma patients show hyper-reactivity to inhaled metacholine and sulpyrine.

Features

The features of aspirin hypersensitivity include bronchospasm, acute and usually generalized urticaria, angioedema, severe rhinitis, and shock. These reactions can occur alone or in various combinations, developing within minutes or a few hours of aspirin ingestion, and lasting until elimination is complete. They can be life-threatening. The bronchospastic type of reaction predominates in adults, only the urticarial type being found in children. The frequency of recurrent urticaria is significantly greater in adults (3.8 versus 0.3%).

People with asthma may be particularly sensitive to acetylsalicylic acid, which may be given alone or as a constituent of a combination medicine. The association between aspirin sensitivity, nasal polyps, and rhinitis in asthma is well known.

Henoch–Schönlein purpura has been reported (81).

Life-threatening respiratory distress, facial edema, and lethargy occurred in a woman with a history of severe asthma and aspirin hypersensitivity (SEDA-22, 118).

Aspirin-sensitive subjects may have attacks induced by other NSAIDs (82).

Fish oil can also cause exacerbation of asthma in aspirin-sensitive patients (83).

Prophylaxis and treatment

Asthma induced by aspirin is often severe and resistant to treatment. Avoidance of aspirin and substances to which there is cross-sensitivity is the only satisfactory solution. Desensitization is not usually successful and repeated treatments are needed to maintain any effect (84,85).

Long-Term Effects

Tumorigenicity

Studies on the tumor-inducing effects of heavy use of analgesics, especially those that contain phenacetin, have given contrasting results (SEDA-21, 100) (86,87). There has been a case-control study of the role of habitual intake of aspirin on the occurrence of urothelial cancer and renal cell carcinoma (88). In previous studies there was a consistent association between phenacetin and renal cell carcinoma, but inconclusive results with respect to non-phenacetin analgesics. In 1024 patients with renal cell carcinoma and an equal number of matched controls, regular use of analgesics was a significant risk factor for renal cell carcinoma (OR = 1.6; CI = 1.4, 1.9). The risk was significantly increased by aspirin, NSAIDs, paracetamol, and phenacetin, and within each class of analgesic the risk increased with increasing exposure. Individuals in the highest exposure categories had about a 2.5-fold increase in risk relative to non-users or irregular users of analgesics. However, exclusive users of aspirin who took aspirin 325 mg/day or less for cardiovascular problems were not at an increased risk of renal cell carcinoma (OR = 0.9; CI = 0.6, 1.4).

Second-Generation Effects

Teratogenicity

It is perhaps surprising that aspirin, which is teratogenic in rodents, and which by virtue of its capacity to inhibit prostaglandin synthesis would be expected to affect the development of the renal and cardiovascular systems, has shown no evidence of teratogenesis in humans, despite very widespread use in pregnant women. Perhaps increased production of prostaglandins during pregnancy overrides the effects of aspirin in the usual dosages, and the intervention of placental metabolism protects the human fetus from exposure to aspirin. Whatever the explanation, there are very few reports in which aspirin can be implicated as a human teratogen and a few studies (89,90) have provided positive reassurance.

Fetotoxicity

Because aspirin is an antithrombotic agent and can promote bleeding, it should be avoided in the third trimester of pregnancy and at parturition (91). At parturition there is a second reason for avoiding aspirin, since its prostaglandin-inhibiting capacity could mean that it will delay parturition and induce early closure of the ductus arteriosus in the near-term fetus, as other NSAIDs do (92). However, its use in low doses in pregnancy may prevent retardation of fetal growth (93).

Susceptibility Factors

Age

In view of the association with Reye's syndrome, aspirin should be avoided in children aged under 16.

Drug Administration

Drug formulations

Although the use of enteric-coated aspirin can reduce its direct adverse effect on the stomach (SEDA-10, 72), it could in principle transfer these to some extent to the intestine; modified-release NSAIDs have sometimes caused intestinal perforation.

Enteric coating reduces the rate of absorption of aspirin. In cases of severe overdosage this can cause difficulties in diagnosis and treatment, since early plasma salicylate measurements are unreliable, maximum blood concentrations sometimes not being reached until 60 or 70 hours after overdose (94,95). Another complication of the use of enteric-coated aspirin is the risk of gastric outlet obstruction and the resulting accumulation of tablets because of subclinical pyloric stenosis.

Drug overdose

Acute poisoning

Acute salicylate poisoning is a major clinical hazard (96), although it is associated with low major morbidity and mortality, in contrast to chronic intoxication (SEDA-17, 98). It can cause alkalemia or acidemia, alkaluria or aciduria, hyperglycemia or hypoglycemia, and water and electrolyte imbalances. However, the usual picture is one of hypokalemia with metabolic acidosis and respiratory alkalosis. Effects on hearing have been referred to in the section on Sensory systems in this monograph. Nausea, vomiting, tinnitus, hyperpnea, hyperpyrexia, confusion, disorientation, dizziness, coma, and/or convulsions are common. They are expressions of the nervous system effects of the salicylates. Gastrointestinal hemorrhage is frequent.

Serum salicylate concentrations above 3.6 mmol/l are likely to be toxic, and concentrations of 5.4 mmol/l can easily prove fatal.

After ingestion, drug absorption can be prevented by induction of emesis, gastric lavage, and the administration of active charcoal; drug excretion is enhanced by administering intravenous alkalinizing solutions, hemoperfusion, and hemodialysis (97). Forced diuresis is dangerous and unnecessary.

Fluid and electrolyte management is the mainstay of therapy. The immediate aim must be to correct acidosis, hyperpyrexia, hypokalemia, and dehydration. In severe cases vitamin K_1 should be given to counteract hypoprothrombinemia.

Chronic poisoning

Chronic salicylate intoxication is commonly associated with chronic daily headaches, lethargy, confusion, or coma. Since headache is a feature, it can easily be misdiagnosed if the physician is not aware that aspirin has been over-used. Depression of mental status is usually present at the time of diagnosis, when the serum salicylate concentration is at a peak. The explanation of depression, manifested by irritability, lethargy, and unresponsiveness, occurring 1–3 days after the start of therapy for aspirin intoxication, lies in a persistently high concentration of salicylate in the central nervous system, while the serum salicylate concentration falls to non-toxic values. The delayed unresponsiveness associated with salicylate intoxication appears to be closely associated with the development of cerebral edema of uncertain cause. The encephalopathy that ensues appears to be directly related to increased intracranial pressure, a known effect of prostaglandin synthesis inhibitors; it responds to mannitol (98).

Drug–Drug Interactions

Alcohol

Although ethanol itself has no effect on bleeding time, it enhances the effect of aspirin when given simultaneously or up to at least 36 hours after aspirin ingestion (99). Ethanol also promotes gastric bleeding.

The FDA has announced its intention to require alcohol warnings on all over-the-counter pain medications that contain acetylsalicylic acid, salicylates, paracetamol, ibuprofen, ketoprofen, or naproxen. The proposed warnings are aimed at alerting consumers to the specific risks incurred from heavy alcohol consumption and its interaction with analgesics. For products

© 2006 Elsevier B.V. All rights reserved.

that contain paracetamol, the warning indicates the risks of liver damage in those who drink more than three alcoholic beverages a day. For formulations that contain salicylates or the mentioned NSAIDs, three or more alcoholic beverages will increase the risk of stomach bleeding (100).

Anticoagulants

The effects on coagulation are additive if aspirin is used concurrently with anticoagulants. There are also other interaction mechanisms: the effect of the coumarins is temporarily increased by protein binding displacement, and if aspirin causes gastric hemorrhages, the latter may well be more severe when anticoagulants are being given.

Aspirin should therefore generally be avoided in patients adequately treated with anticoagulants. The most relevant information on hemorrhagic complications occurring during prophylaxis with antiplatelet drugs, whether used singly or in combination, has been provided by well-controlled prospective trials with aspirin (17), aspirin combined with dipyridamole (101), or aspirin compared with oral anticoagulants (102).

Antihypertensive drugs

An increase in mean supine blood pressure has been reported with aspirin (SEDA-19, 92). Aspirin may therefore interfere with antihypertensive pharmacotherapy, warranting caution, especially in the elderly.

Captopril

Aspirin is thought to reduce the antihypertensive effect of captopril (103).

Carbonic anhydrase inhibitors

In two children, aspirin potentiated the slight metabolic acidosis induced by carbonic anhydrase inhibitors (SEDA-9, 79) (104).

Glucocorticoids

The effects of aspirin on gastrointestinal mucosa will lead to additive effects if it is used concurrently with other drugs that have an irritant effect on the stomach, notably other NSAIDs or glucocorticoids (105,106).

Heparin

Risk factors for heparin-induced bleeding include concomitant use of aspirin (107).

Intrauterine contraceptive devices

The supposed mechanisms of action of intrauterine contraceptive devices (IUCDs) include a local inflammatory response and increased local production of prostaglandins that prevent sperm from fertilizing ova (108,109). As aspirin has both anti-inflammatory and antiprostaglandin properties, the contraceptive effectiveness of an IUCD can be reduced by the drug, although the effect on periodic bleeding may prevail.

Methotrexate

Aspirin displaces methotrexate from its binding sites and also inhibits its renal tubular elimination, so that the dosage of concurrently used methotrexate should be reduced (except once-a-week low-dose treatment in rheumatoid arthritis) (110).

Nitrates

Aspirin in low dosages (under 300 mg/day) is widely used in cardiovascular prophylaxis, but its use is accompanied by an increased risk of gastrointestinal bleeding (SEDA-21, 100). Of particular interest therefore are data from a retrospective case-control study showing that nitrate therapy may reduce the risk of aspirin-induced gastrointestinal bleeding (111). As nitrates are often used in the same population of patients, such data merit further confirmation from larger prospective studies.

NSAIDs

The effects of aspirin on gastrointestinal mucosa will lead to additive effects if it is used concurrently with other drugs that have an irritant effect on the stomach, notably other NSAIDs or glucocorticoids (105,106). Salicylates can be displaced from binding sites by some NSAIDs such as naproxen, or in turn displace others such as piroxicam.

Sodium valproate

Aspirin displaces sodium valproate from protein binding sites (112) and reduces its hepatic metabolism (113).

Streptokinase

Major hemorrhagic complications, including cerebral hemorrhage, can occur with aspirin (SEDA-23, 116) and the same is also true for thrombolytic therapy of acute ischemic stroke (114). A post hoc analysis of the Multicenter Acute Stroke Trial in Italy showed a negative interaction of aspirin and streptokinase in acute ischemic stroke (115). In 156 patients who received streptokinase plus aspirin and 157 patients treated with streptokinase alone, the combined regimen significantly increased early case fatality at days 3–10 (53 versus 30; OR = 2.5; CI = 1.2, 3.6). The excess in deaths was solely due to treatment and was not explained by the main prognostic predictors. Deaths in the combination group were mainly cerebral (42 versus 24; OR = 2.0; CI = 1.3, 3.7) and associated with hemorrhagic transformation (22 versus 11; OR = 2.2; CI = 1.0, 5.0). The data suggest that aspirin should be avoided when thrombolytic agents are used for acute ischemic stroke.

Uricosuric drugs

In low dosages (up to 2 g/day), aspirin reduces urate excretion and blocks the effects of probenecid and other uricosuric agents (116). However, in 11 patients with gout, aspirin 325 mg/day had no effect on the uricosuric action of probenecid (117). In higher dosages (over 5 g/day), salicylates increase urate excretion and inhibit the effects

© 2006 Elsevier B.V. All rights reserved.

of spironolactone, but it is not clear that these phenomena are of importance.

Food-Drug Interactions

Food allergens

Aspirin seems to potentiate the effects of food allergens, but this is uncertain (SEDA-10, 72).

Interference with Diagnostic Tests

Thyroid function tests

Through competitive binding to thyroid-binding globulin, salicylates in high concentrations can displace thyroxine and triiodothyronine, thus interfering with the results of diagnostic thyroid function tests (118).

Aciclovir

General Information

Aciclovir is an acyclic purine nucleoside. Its antiviral activity depends upon intracellular phosphorylation to its triphosphate derivative. Because of its higher affinity for viral thymidine kinase, aciclovir is phosphorylated at a much higher rate by the viral enzyme. Thus, it is almost exclusively active in infected cells, fulfilling one of the selectivity principles of antiviral drugs. In addition, aciclovir triphosphate serves as a better substrate for viral than for host cell DNA polymerase and thereby causes preferential termination of viral DNA synthesis (1).

Aciclovir is active against *Herpes simplex* virus type 1 (HSV-1), HSV-2, *Varicella zoster* virus (VZV), *Herpesvirus simiae*, and to a lesser degree Epstein–Barr virus (EBV). Resistant strains of HSV can arise owing to the emergence of thymidine kinase-deficient mutants. Other forms of resistance patterns are less common (2,3).

Aciclovir is used topically or systemically, orally or intravenously. Its therapeutic potential is most impressive in active parenchymal or systemic HSV infections. The latency stage of the viral infection is not affected. Since the blood–brain barrier is well penetrated, aciclovir is the treatment of choice for HSV encephalitis.

Very few adverse effects, generally of minor importance, have been reported (4). In immunosuppressed patients abnormal liver function, encephalopathy, and myelosuppression have been observed; however, it is unclear at present whether these adverse effects are related to the drug itself or to the underlying disorder (5–7).

Comparative studies

The effects of aciclovir and valaciclovir for anogenital herpes have been studied in HIV-infected individuals in two controlled trials (8). In the first study, 1062 patients with CD4+ counts over 100×10^6/l received valaciclovir or aciclovir for 1 year and were assessed monthly. In the second study, 467 patients were treated episodically for at least 5 days with valaciclovir or aciclovir and were assessed daily. Valaciclovir was as effective as aciclovir for suppression and episodic treatment of herpesvirus infections. Hazard ratios for the time to recurrence with valaciclovir 500 mg bd and 1000 mg od compared with aciclovir were 0.73 (95% CI = 0.50, 1.06) and 1.31 (0.94, 1.82). Valaciclovir 1000 mg bd and aciclovir had similar effects on the duration of infective episodes (HR = 0.92; CI = 0.75, 1.14). The most common adverse events, which occurred at similar rates with all regimens, were diarrhea, headache, infections, rashes, nausea, rhinitis, pharyngitis, abdominal pain, fever, depression, and cough.

Organs and Systems

Nervous system

Neurotoxicity secondary to aciclovir is rare and is associated with high plasma concentrations (SEDA-18, 299), such as result from impaired renal function (9). Although the risk is greatest with intravenous administration, neurotoxicity has previously been noted with oral use.

Symptoms of neurotoxicity, which usually appear within the first 24–72 hours of administration, include tremor, myoclonus, confusion, lethargy, agitation, hallucinations, dysarthria, asterixis, ataxia, hemiparesthesia, and seizures. While aciclovir-induced neurotoxicity is most prevalent with intravenous administration, it has also been reported after oral use in patients with terminal renal insufficiency on hemodialysis.

Neurotoxicity possibly secondary to the topical use of aciclovir has also been described (10).

- A 59-year-old woman on hemodialysis was treated with oral aciclovir 200 mg/day for ophthalmic Herpes zoster. After a few days, an ophthalmic aciclovir cream was started (one application every 6 hours) because of ipsilateral *Herpes* keratitis. After 1 week of combined oral and topical treatment, she became confused, with dysarthria and audiovisual hallucinations. Aciclovir was withdrawn and hemodialysis was initiated. Complete resolution of symptoms was achieved after three hemodialysis sessions in 3 days. Aciclovir plasma concentrations before hemodialysis were high (45 μmol/l) and fell rapidly during hemodialysis.

There is no conclusive evidence for the contribution of the topically administered aciclovir to the high plasma concentrations and subsequent neurotoxicity in this case. However, the authors argued that the existence of high aciclovir plasma concentrations, in spite of careful adjustment of the oral dosage, pointed to significant topical absorption of the drug, especially since the absorption of aciclovir through the skin and mucous membranes may be unpredictable.

Coma has been attributed to oral aciclovir (11).

- A 73-year-old man with acute respiratory failure, presumed to be secondary to amiodarone toxicity, developed sepsis and acute renal insufficiency, and required intermittent hemodialysis. Following a *Herpes simplex* labialis infection he was treated with oral aciclovir (400 mg tds). The next day he became sleepy, disoriented, and agitated. Over the next 48 hours his neurological condition deteriorated and he responded to pain

© 2006 Elsevier B.V. All rights reserved.

only, had uncoordinated eye movements, tremors, facial and jaw myoclonus, increased reflexes, and hypertonia. After 7 days of aciclovir he became unresponsive and comatose. Aciclovir was withdrawn and hemodialysis carried out more frequently. His neurological status improved over a period of 4 days. Trough plasma concentrations of aciclovir were well above the upper limit of the usual target range.

This appears to be the first case of coma attributable to oral aciclovir. The fact that the patient was receiving oral rather than intravenous aciclovir and was on regular hemodialysis made neurotoxicity unlikely, and this emphasizes the need to be wary of this potentially serious complication in seriously ill elderly patients.

Sensory systems

Local application of 3% ophthalmic ointment can cause mild transient stinging. Diffuse, superficial, punctate, non-progressive keratopathy can develop. This quickly resolves after withdrawal (12,13).

Psychological, psychiatric

One report described reversible psychiatric adverse effects in three dialysis patients receiving intravenous aciclovir (8–10 mg/kg/day) (14).

Hematologic

Neutropenia and thrombocytopenia occurred in an 8-year-old boy who was treated with aciclovir 200 mg bd for 5 months for "chronic cold sores" (15). After withdrawal of aciclovir, the absolute neutrophil and platelet counts normalized within days. There was no recurrence of oral herpes lesions during the ensuing month.

Urinary tract

Renal impairment has been associated with the use of intravenous aciclovir. Transient increases in serum creatinine and urea have been observed in 14% of patients treated with bolus injections (16). These are related to crystal formation in the lower renal tubules when the solubility of aciclovir in urine is exceeded. Slow (1-hour) intravenous infusion and adequate hydration are therefore mandatory. Bolus doses are to be avoided. Dosage modifications for patients with renal insufficiency are based on creatinine clearance (4).

- Crystalluria due to aciclovir occurred within 24 hours of the start of therapy with 500 mg 8-hourly in a 4-year-old African-American boy (17). Slow intravenous infusion over 1–2 hours and volume repletion avoids the problem.

Renal toxicity has not been described in infants treated with intravenous aciclovir, 5–10 mg/kg every 8 hours for 5–10 days (18) or in children receiving aciclovir 500 mg/m^2 intravenously (19) or orally (4).

Skin

Skin reactions to aciclovir are mostly mild and transitory, including pruritus, pain, rashes, contact dermatitis, and photoallergic contact dermatitis. However, serious reactions occasionally occur (20). Antiviral drugs that have been implicated include topical aciclovir, cidofovir, idoxuridine, imiquimod, lamivudine, penciclovir, podophyllin, podophyllotoxin, trifluridine, tromantadine, vidarabine, intralesional and ophthalmic solutions of interferon, intravitreal injections of fomivirsen and foscarnet, and intraocular implants of ganciclovir. Patch-testing in these cases only rarely caused positive reactions to the antiviral drug.

A case of possible aciclovir-induced Stevens–Johnson syndrome has been reported in an HIV-positive patient with mycobacterial disease (21). However, Stevens–Johnson syndrome is associated with *Herpes simplex* infection and can be prevented by aciclovir (22).

Immunologic

Although allergy to aciclovir is unusual, it can occur; in one case it resulted in a skin rash (23).

- A 38-year-old woman of African descent, with a history of atopy and mild asthma, developed a periumbilical, erythematous, maculopapular rash and generalized pruritus after starting aciclovir. The reaction resolved within a few days after withdrawal, recurred when famciclovir was used, and again resolved when famciclovir was withdrawn. She was successfully stabilized on suppressive therapy after a graded challenge with aciclovir four times a day for 5 days.

Cross-reactivity between aciclovir and famciclovir is unusual. Aciclovir desensitization may be a novel method of treating patients with aciclovir allergy.

Contact sensitization to aciclovir is rare, but frequent application to inflamed skin in relapsing *Herpes simplex* may increase the risk of allergy. Severe contact dermatitis in a teenager has been reported.

- A 16-year-old girl with an 11-year history of frequent cold sores developed an erythematous rash and severe contact dermatitis during oral and topical aciclovir therapy (24). Patch tests showed contact sensitization to aciclovir and to the related compound ganciclovir.
- In a 44-year-old woman who used topical aciclovir for genital herpes, aciclovir contact allergy was associated with a systemic contact allergic reaction with an erythematous vesiculobullous eruption in the labial and perioral skin and a rash on the upper trunk and extremities (25). Patch tests were positive to aciclovir, valaciclovir, and ganciclovir, but not to famciclovir.

Pre-existing vesicular edematous cheilitis (probably due to contact allergy to the protecting lip salve) was aggravated after application of Zovirax cream (26). Patch tests to the lip salve were positive, but in addition there were positive photopatch tests to Zovirax cream, but not to its separate constituents.

Second-Generation Effects

Pregnancy

Animal data suggest that aciclovir is probably safe in pregnancy. There are no reports of teratogenicity in

© 2006 Elsevier B.V. All rights reserved.

humans, and a report of 312 pregnant women exposed to aciclovir showed no increase in the number of birth defects compared with the numbers expected in the general population (27). However, data from larger numbers of human pregnancies are not available to draw reliable conclusions about the safety of aciclovir in pregnancy.

Drug Administration

Drug administration route

Local necrosis and inflammation can occur due to extravasation of the drug at the site of injection (28).

Various local adverse effects of aciclovir eye-drops have been reported, including pruritus, burning sensations, and irritative or allergic conjunctivitis. Persistent superficial punctate keratitis, delayed epithelial healing, and epithelial dysplasia can develop (29).

Acipimox

General Information

Acipimox (*S*-methylpyrazine-2-carboxylic acid 4-oxide) is structurally related to nicotinic acid. There were flushing and gastrointestinal disturbances in 7137 patients, of whom 15% stopped taking the drug because of adverse effects; there were no adverse effects on blood glucose or uric acid (1). Of 32 patients with hypertriglyceridemia, excessive hypertriglyceridemia, and combined hyperlipidemia, acipimox had to be withdrawn in 10 cases, because of adverse effects or absence of clinical response (2). The other 22 completed 6 months of treatment with no adverse effects. The authors claimed that acipimox is much better tolerated than nicotinic acid; it has fewer adverse effects and can therefore be used as a second-line drug.

Organs and Systems

Metabolism

In an open study, blood glucose was on average slightly lowered in 3009 type II diabetics given acipimox for at least 2 months (3).

Acivicin

See also Cytostatic and immunosuppressant drugs

General Information

Acivicin is a cytostatic antibiotic, a glutamine analogue, which is a potent inhibitor of l-asparagine synthetase and other l-glutamine amidotransferases and has its cytotoxic action by blocking nucleotide biosynthesis.

Besides myelotoxicity, acivicin is neurotoxic, and can cause lethargy and auditory and visual hallucinations. Some patients have nystagmus, incontinence, and severe depression (1,2).

Acoraceae

See also Herbal medicines

General Information

Acorus calamus was originally classified as a member of the arum family (Araceae), but is now designated as belonging to its own family, the Acoraceae, of which it is the only member.

Acorus calamus

Acorus calamus (calamus root, sweet flag, rat root, sweet sedge, flag root, sweet calomel, sweet myrtle, sweet cane, sweet rush, beewort, muskrat root, pine root) contains several active constituents called "asarones." The basic structure is 2,4,5-trimethoxy-1-propenylbenzene, which is related to the hallucinogen 3,4-methylenedioxyphenylisopropylamine (MDA). The amounts of the asarones in calamus rhizomes vary considerably with the botanical variety. For example, there are high concentrations in triploid calamus from Eastern Europe but none detectable in the diploid North American variety.

Acorus calamus has been used as a hallucinogen since ancient times and it has several uses in folk medicine. It may have been one of the constituents of the Holy Oil that God commanded Moses to make (Exodus 30) and is mentioned by ancient writers on medicine, such as Hippocrates, Theophrastus, Dioscorides, and Celsus (http://www.a1b2c3.com/drugs/var002.htm). Walt Whitman's 39 "Calamus poems" are to be found in his well-known collection "Leaves of Grass."

Acorus calamus has in vitro antiproliferative and immunosuppressive actions (1).

Acorus calamus contains beta-asarone [(Z)-1,2,4-trimethoxy-5-prop-1-enyl-benzene], which is carcinogenic (2). Commercial calamus preparations have mutagenic effects in bacteria (3), while calamus oil (Jammu variety) is carcinogenic in rats.

Acrisorcin

See also Disinfectants and antiseptics

General Information

Acrisorcin (aminoacridine 4-hexylresorcinolate) has been used for induction of abortion in mid-trimester pregnancies. Abortion was produced when a 0.1% solution of acrisorcin was introduced into the extra-amniotic space in 23 women. All patients aborted after a mean induction-delivery interval of 59 hours (SEDA-11, 474) (1).

Acrivastine

See also Antihistamines

General Information

Acrivastine is a second-generation antihistamine that has not been the subject of recent studies; earlier work was insufficient to substantiate statements that it was non-sedating.

Organs and Systems

Nervous system

Five of thirty-five patients taking acrivastine reported drowsiness compared with none in the placebo group (SEDA-14, 135). In another study acrivastine 8 mg did not impair nervous system function (SEDA-21, 172). The usual dose is 8 mg tds, which is effective in treating seasonal allergic rhinitis and has been stated to be without sedative effects (1). However, acrivastine does have a small but significant additive effect with alcohol at a dose of 8 mg (2).

Acrylic bone cement

General Information

Local biocompatibility

Although polymerized polymethylmethacrylate is a biocompatible material, it is not biocompatible during the brief time it takes to set, during which it releases 130 calories/gram and can cause a rise in temperature up to 120°C. This temperature rise can be reduced by various techniques, although the thermal tolerance of the tissues affected is low (56°C and 72°C for coagulation of body proteins and bone collagen respectively). This is the main factor that is responsible for bone necrosis associated with acrylic bone cement. To avoid this, sucrose crystals have been added to acrylic cement. The mixture has a lower polymerization temperature and greater porosity, allowing for better ingrowth of bone into the cement pores (1); however, the resultant lower mechanical resistance limits its use (2,3). The same can be achieved by adding tricalcium phosphate, which lowers the reaction temperature. The non-polymerized monomer is cytotoxic (4), which can cause histopathological changes in soft tissues and bones.

Regional damage

Regional damage from methylmethacrylate is generally the result of poor surgical technique, whereby the cement inadvertently reaches other tissues and structures. For example, leaking methylmethacrylate cement during fixation of the acetabular cup in a total hip replacement can cause sciatic nerve compression and result in severe lasting leg pain (5).

Organs and Systems

Cardiovascular

Cardiovascular reactions to acrylic bone cement are a common complication in bone surgery. It is believed that cementation activates an adrenocortical response, increasing the blood pressure during general anesthesia (6,7); during spinal anesthesia this response is suppressed and the blood pressure falls. The mechanism is thought to be by a direct effect on the blood pressure through the kallikrein–kinin system, since aprotinin (Trasylol), an inhibitor of kallikrein, prevents the fall in arterial pressure if it is given during the application of acrylic bone cement (8).

Some investigators suggested that implantation of acrylic bone cement into the femur increases plasma histamine, which, especially in elderly patients with pre-existing cardiac diseases and/or hypovolemia, can cause serious, sometimes fatal, cardiovascular complications (9).

Respiratory

Since adverse effects in humans develop within 2–5 minutes of fixation, with features of pulmonary insufficiency, direct pulmonary damage has been

postulated, with the cardiovascular effects being a consequence of hypoxemia (10–12). This has been demonstrated by lactase dehydrogenase isomer determinations, fractions 3 and 4 being significantly raised. These isozymes are released as a result of pulmonary mitochondrial injury caused by hypoxia. Methylmethacrylate monomer vapour can irritate the respiratory tract, eyes, and skin.

Immunologic

Methylmethacrylate is essentially an immunologically inert implant material, but it induces an inflammatory mononuclear cell migration (13,14). Both cemented and cementless prostheses cause a foreign-body-type host response. A new connective tissue capsule is formed around the artificial joint, which is coarser than normal. The reaction is partly granulomatous, with a tendency to necrosis and loosening of the prosthesis. After an initial necrotic phase of 2–3 weeks repair follows, leading to stabilization within 2 years.

Sensitization can occur in patients, surgeons, and dentists and is occasionally reported (15). As most surgical gloves do not provide a reliable barrier, additional gloves are recommended. Contact dermatitis, dizziness, and nausea and vomiting occur. Ethylene oxide present in acrylic bone cement can cause acute allergic reactions in sensitized patients (16).

Infection risk

Addition of materials (for example antimicrobial drugs or radio-opaque contrast materials) to acrylic bone cement can cause mechanical weakness due to loss of homogeneity and greater water resorption. Antimicrobial drugs have been added to combat the problem of microbial adherence. However, this can lead to a considerable dead biofilm mass on the polymethylmethacrylate surface, promoting late infections by providing a surface attractive to other strains of bacteria (17).

Activated charcoal

General Information

Activated charcoal is a standard therapy for gut decontamination after self-poisoning. It has two uses. If given within an hour or two after acute self-poisoning it can adsorb the drug and prevent it from being absorbed; in this case a single dose of activated charcoal 50 g is sufficient. However, some drugs are secreted into the gut after absorption and can be adsorbed by charcoal, preventing re-absorption; in this case repeated doses of activated charcoal 50 g 6-hourly can be used.

In a randomized study in 401 patients who had taken an overdose of oleander seeds, which contain cardiac glycosides, activated charcoal 50 g every 6 hours for 3 days was compared with sterile water. There were fewer deaths in the treatment group, 2.5% versus 8% (1). There were no important adverse effects.

© 2006 Elsevier B.V. All rights reserved.

Organs and Systems

Respiratory

Pulmonary aspiration is an ever-present risk of using charcoal, especially in semi-conscious patients (2). Povidone, which is used as a suspending agent of charcoal, can cause pneumonitis, which can lead to respiratory failure and death.

Electrolyte balance

Hyponatremic dehydration has been described when charcoal was combined with sorbitol to treat theophylline overdose in a child (SED-12, 951) (3).

Gastrointestinal

- Esophageal laceration with charcoal mediastinum has been reported in a 19-year-old woman who underwent multiple attempts at orogastric lavage with isotonic saline followed by 50 g of activated charcoal and sorbitol via the orogastric tube for a drug overdose (4). She recovered after surgical intervention.

Two formulations of activated charcoal 50 g (Carbomix, made into a slurry with 400 ml of tap water, and Actidose-Aqua, which came as a 240 ml suspension) have been compared in a prospective, randomized, single-blind study in 97 patients (5). The mean total dose of Carbomix (26.5 g) was significantly higher than the mean total dose of Actidose-Aqua (19.5 g); the reasons for this difference were not stated. The rates of vomiting did not differ between patients who received Carbomix (6%) or Actidose-Aqua (8%), and were low compared with previous reports (13%).

Though usually innocuous, activated charcoal can in large or multiple doses, such as may be needed in severe poisoning, cause intestinal obstruction (3,6). Pseudo-obstruction can also occur if drugs that inhibit intestinal motility are given at the same time, and sometimes it is not clear which process has occurred (SED-12, 951) (SEDA-17, 426) (6).

Adefovir

General Information

Adefovir is an adenine analogue reverse transcriptase inhibitor. While it has activity against both HIV and hepatitis B, its use in HIV infection is limited by nephrotoxicity due to the high doses needed (1). The dose used for treatment of hepatitis B is about one-tenth that needed to treat HIV infection, so patients with hepatitis B must have co-infection with HIV ruled out before treatment is started.

Organs and Systems

Liver

In 35 patients co-infected with hepatitis B virus and HIV given adefovir 10 mg/day plus lamivudine 150 mg bd as part of treatment for hepatitis B and followed for 48 weeks, common adverse effects included raised transaminases, particularly alanine transaminase, increased serum creatinine, and increased blood glucose (2). Concerns about the study include the small number of patients and the lack of a comparison group.

Urinary tract

Adefovir is nephrotoxic, particularly at high doses, and the possible mechanism has been investigated in a 39-year-old man, who had severe acute tubular degenerative changes mainly affecting the proximal tubule; the mitochondria were significantly enlarged, possibly as a result of depletion of mitochondrial DNA (3).

Ademetionine

General Information

Ademetionine (*S*-adenosylmethionine) has anti-inflammatory and analgesic effects in animals. Convincing evidence of these effects in man is still lacking. In trials in osteoarthritis, as presented at a symposium organized by the manufacturers (and thus open to selection bias), ademetionine was well tolerated

© 2006 Elsevier B.V. All rights reserved.

(1). In a large, uncontrolled, short-term Phase IV trial, adverse effects (moderate or severe) were reported by 21% of the patients, with withdrawal in 5.2%. Adverse effects were mainly gastrointestinal (nausea, stomachache, heartburn, diarrhea), CNS symptoms (headache, dizziness, sleep disturbances, fatigue), and skin rashes.

Adenosine and adenosine triphosphate (ATP)

See also Antidysrhythmic drugs

General Information

Adenosine and adenosine triphosphate (ATP), its phosphorylated derivative, have been used to treat acute paroxysmal supraventricular tachycardias and adenosine has also been used in the diagnosis of narrow-and broad-complex tachycardias (SEDA-16, 176).

Several reviews of the clinical pharmacology, actions, therapeutic uses, and adverse reactions and interactions of adenosine and ATP have appeared (1–4). After intravenous administration adenosine enters cells, disappearing from the blood with a half-life of less than 10 seconds; intracellularly it is phosphorylated to cyclic AMP. Its mechanism of action as an antidysrhythmic drug is not known, but it may act by an effect at adenosine receptors on the cell membrane. Its electrophysiological effects are to prolong AV nodal conduction time by prolonging the AH interval, without an effect on the HV interval. The pharmacological and adverse effects of adenosine triphosphate are similar to those of adenosine.

Although adenosine and ATP very commonly cause adverse effects, they are generally mild and usually transient, because adenosine is rapidly eliminated from the blood (with a half-life of less than 10 seconds). Adverse effects have been reported in 81% of patients given adenosine and 94% of patients given ATP (5). Exercise reduces the non-cardiac adverse effects and the incidence of major dysrhythmias (6). Reducing the duration of adenosine infusion from 6 to 4 minutes reduced the incidence of chest discomfort and ischemic ST segment changes, but had no impact on non-cardiac effects (7).

Several studies have reported the efficacy and safety of adenosine and ATP in the treatment of tachycardias in children (8–11).

In 18 children with aortic valve disease or Kawasaki disease, adenosine stress myocardial perfusion imaging was associated with the usual adverse effects, most commonly flushing and dyspnea (12).

Exercise reduces both non-cardiac adverse effects and dysrhythmias in patients who are given adenosine for diagnostic purposes in myocardial perfusion imaging (SEDA-21, 197). This has been confirmed in two studies. In the first of these, 793 patients were given an intravenous infusion of adenosine 140 micrograms/kg/minute while exercising for 6 minutes or for a similar time without exercise (13). The rate of hypotension and dysrhythmias was significantly less in those who exercised (14 of 507) than in those who did not exercise (16 of 286). Overall reactions were more common in women than in men (5.7 versus 1.8%). All the adverse effects were transient and no specific therapy was required. The authors attributed the difference to the increase in sympathetic tone during exercise, which would have partly counteracted the hypotension and the negative chronotropic and negative dromotropic effects of adenosine. However, there was a major difference between the two groups, in that those who did not take exercise were considered unfit for exercise, which may have been associated with an increased risk of adverse effects. Nevertheless, the authors discarded that possibility, because the frequency of adverse reactions in those who did not take exercise was similar to frequencies that have previously been reported.

In the second study 19 patients received an intravenous infusion of adenosine 140 micrograms/kg/minute for 4 minutes during exercise or for 6 minutes without exercise; the patients undertook both protocols (14). Again, there were fewer adverse effects in those who took exercise, but only hypotension, chest pain, and headache were significantly different; there was a reduction in the frequency of flushing, which was almost significant. In addition, adverse effects were experienced for longer and the severity was greater in those who did not take exercise.

Organs and Systems

Cardiovascular

The most common cardiac effects are atrioventricular block, sinus bradycardia, and ventricular extra beats. Occasionally serious dysrhythmias occur (SEDA-17, 219), including ventricular fibrillation (15). ATP can cause transient atrial fibrillation (16). Chest pain occurs in 30–50% of patients and dyspnea and chest discomfort in 35–55%. Chest pain can occur in patients with and without coronary artery disease, and the symptoms are not always typical of cardiac pain.

Myocardial ischemia

Adenosine can cause cardiac ischemia by activating adenosine A1 receptors in the heart. However, in a double-blind, placebo-controlled, crossover study in eight healthy volunteers, adenosine 100 μg/kg/minute did not alter ischemic pain in an exercising arm (17). Otherwise, the usual adverse effects were noted, including facial flushing and mild chest tightness.

Hypotension

When adenosine (70 micrograms/kg/minute) was given by intravenous infusion to 45 patients with acute myocardial infarction preceding balloon angioplasty, one patient developed persisting hypotension in conjunction with a large inferolateral myocardial infarction (18). Transient hypotension in three other patients resolved with a reduction in dosage. There were no cases of atrioventricular block.

© 2006 Elsevier B.V. All rights reserved.

Symptomatic hypotension has occasionally been reported in patients with myocardial infarction who have been given adenosine (SEDA-20, 174).

An infusion of adenosine, 25 micrograms/kg, in 15 women undergoing anesthesia for major gynecological procedures was effective in maintaining hemodynamic stability during operation in addition to conventional anesthesia (19). It caused a significantly greater fall in systolic blood pressure and increase in heart rate than remifentanil in a comparable group. In four cases ephedrine was required for hypotension that was refractory to intravenous fluids or a temporary reduction in the infusion rate of adenosine. Two patients also required atropine for prolonged bradycardia.

Cardiac dysrhythmias

In patients with ischemic heart disease adenosine can prolong the QT_c interval and can increase the frequency of ventricular extra beats when there is myocardial scarring. It also causes increased release of catecholamines, and this may be the mechanism whereby it causes dysrhythmias in susceptible patients. If a dysrhythmia occurs, theophylline or one of its derivatives may be beneficial (20).

Of 100 patients who received intravenous adenosine in hospital (mean dose 7.8 mg) two had a dysrhythmia other than that for which they were being treated (21).

- A 53-year-old man with a dilated cardiomyopathy was given adenosine 6 mg for a regular broad-complex tachycardia; the dysrhythmia resolved but was followed by prolonged asystole and cyanosis for about 15 seconds.
- A 64-year-old woman with atrial fibrillation was given adenosine 12 mg; she developed a non-sustained polymorphous ventricular tachycardia followed by sustained ventricular fibrillation requiring DC shock.

In the whole series, about 40% of the patients received adenosine unnecessarily, having atrial fibrillation or atrial flutter, and the authors suggested that misuse of this sort resulted in unnecessary expense and increased risks of adverse effects. Most of this misuse was attributed to misdiagnosis by house officers who thought that rapid atrial fibrillation was a paroxysmal supraventricular tachycardia. Very few thought that adenosine would be likely to terminate atrial fibrillation.

Adenosine is contraindicated in patients with aberrant conduction pathways, because it can cause cardiac dysrhythmias. Supraventricular dysrhythmias occurred in three children with Wolff–Parkinson–White syndrome who were given intravenous adenosine (22).

There have been reports of cardiac dysrhythmias in patients given either an intravenous infusion of adenosine or a single bolus dose.

- A 38-year-old man was given intravenous adenosine 6 mg for a narrow-complex tachycardia (20). Within about 1 minute his heart rate fell from 230/minute to bradycardia and then asystole. Cardiopulmonary resuscitation was ineffective. At autopsy there was a 75% occlusion of one of the coronary arteries (unspecified).

The cause of the dysrhythmia in response to adenosine was not clear. He was not known to be taking other drugs (for example dipyridamole) that might have potentiated the action of adenosine.

- A 56-year-old man was given adenosine 12 mg for a narrow-complex tachycardia on four occasions, and on each occasion developed transient atrial fibrillation for a few minutes thereafter. He had a concealed left-sided accessory pathway, which was successfully ablated (23).
- An 86-year-old woman was given adenosine 12 mg intravenously for sustained supraventricular tachycardia, which terminated but was followed by atrial fibrillation and paroxysmal ventricular tachycardia (24). Cardioversion was unsuccessful, but normal sinus rhythm was obtained with procainamide. This followed an anteroseptal myocardial infarction.
- A 75-year-old man who had had coronary bypass surgery was given an intravenous infusion of adenosine for stress testing (25). After 1 minute he developed a three-beat run of wide-complex tachycardia, followed by a 20-second run of a regular wide-complex tachycardia at a rate of 115/minute. There was left bundle branch block, and the tachycardia ended spontaneously. Adenosine infusion was continued and some ventricular extra beats with the same configuration occurred. In this case there was impaired perfusion of the left ventricle.
- In a 60-year-old woman with atrial flutter with 2:1 block and a ventricular rate of 130/minute, the ventricular rate increased paradoxically to 260/minute with 1:1 conduction after intravenous administration of adenosine 6 mg; it responded to intravenous amiodarone 300 mg (26).
- A 52-year-old woman with a wide-complex tachycardia was given adenosine 6, 12, and another 12 mg as intravenous bolus doses; immediately after the third dose she developed ventricular fibrillation (27). She recovered with cardioversion.

In the last case the authors did not discuss the possibility that the presence of digoxin (serum concentration 1.8 ng/ml) may have contributed; the risk of cardiac dysrhythmias after electrical cardioversion is increased in the presence of digoxin (SEDA-8, 174), and the same might be true of chemical cardioversion.

In a prospective study of 187 episodes of tachycardia in 127 unselected patients adenosine was given in an average dose of 9.7 mg (28). In 108 cases, adenosine induced transient ventricular extra beats or non-sustained ventricular tachycardia after successful termination of supraventricular tachycardia; more than half had a right bundle branch block morphology that suggested that the dysrhythmias had originated from the inferior left ventricular septum.

Heart block

The frequency of atrioventricular block has been studied in 600 patients who underwent stress testing with intravenous adenosine 140 micrograms/kg/minute for 6 minutes (29). The patients were young (under 49 years old; $n = 75$), middle-aged (50–65 years; $n = 214$), old (66–75 years; $n = 195$), or very old (over 75 years; $n = 116$). The respective frequencies of first-degree atrioventricular block were 15, 9.3, 14, and 17% (overall

© 2006 Elsevier B.V. All rights reserved.

Table 1 The incidence of atrioventricular block with adenosine

Type of block	Baseline PR interval over 200 ms ($n = 43$)	Baseline PR interval under 200 ms ($n = 557$)
Further prolongation of PR interval	49%	10%
Second-degree block	37%	8%
Third-degree block	14%	1%

average 13%), of second-degree block 15, 7.0, 8.7, and 16% (overall average 10%), and of third-degree block 2.7, 2.3, 1.0, and 2.6% (overall average 2.0%). The differences with age were not statistically significant. All types of atrioventricular block were of short duration, were well tolerated, and did not require withdrawal of adenosine or specific treatment.

In four out of nine patients with heart transplants second-degree or third-degree atrioventricular block occurred during the administration of adenosine 140 micrograms/kg/minute over 6 minutes (30). In two patients the infusion had to be interrupted because of severe discomfort and chest pain.

The incidence of atrioventricular block has been reported in 600 consecutive patients who underwent stress myocardial perfusion imaging with adenosine (140 micrograms/kg/minute for 6 minutes), and of whom 43 had first-degree heart block before adenosine and 557 had a baseline PR interval less than 200 ms (Table 1) (31). The heart block in all cases was of short duration, was not associated with any specific symptoms, and in no case required specific treatment. The risk of atrioventricular block during adenosine infusion was not increased by the presence of other drugs that might have caused atrioventricular block (digitalis, beta-blockers, diltiazem, verapamil).

Respiratory

Adenosine can cause bronchoconstriction with asthma (32), and a history of bronchoconstriction is a contraindication to intravenous adenosine.

In 94 patients with chronic obstructive pulmonary disease who were given adenosine in an initial dosage of 50 micrograms/kg/minute, increasing to 140 micrograms/kg/minute if adverse effects did not occur, there was only a slight and insignificant fall in FEV_1 at the highest dose of adenosine (33). However, four patients had a fall in FEV_1 of 20% or more, although without shortness of breath or evidence of bronchospasm; in these the dosage of adenosine was reduced to 100 micrograms/kg/minute. Two other patients had shortness of breath with no fall in FEV_1 or bronchospasm, and the dosage was reduced to 100 micrograms/kg/minute. There was no difference in the fall in FEV_1 between patients who had a history of asthma and those who did not. Other adverse effects included light-headedness ($n = 26$), dyspnea ($n = 17$), headache ($n = 14$), flushing ($n = 8$), hypotension ($n = 7$), chest pain ($n = 6$), and nausea ($n = 2$). In a subsequent study in 117 patients, two had symptomatic bronchospasm during adenosine infusion. In two other patients in whom bronchospasm was present before treatment, bronchospasm did not develop when adenosine was infused at the highest dosage.

In another study, 63 of 122 patients had breathlessness during cardiac stress testing with adenosine but none had associated bronchospasm (34). Pre-test lung function did not predict the risk of breathlessness and neither chronic obstructive airways disease nor smoking increased the risk. The authors concluded that breathlessness during adenosine stress testing is not due to bronchospasm.

Nervous system

Adenosine has been used intrathecally to treat pain, but can itself cause backache (SEDA-23, 197) (35). In a placebo-controlled study in 40 healthy volunteers, who were given intrathecal adenosine 2 mg in 2 ml of saline, 13 had a mild headache, nine had mild to moderate backache, and one had mild aching in the thigh, compared with none of those who were given saline alone (36). No headaches or leg aches occurred later than 6 hours after the injection, but the backaches occurred at 6–24 hours; there were no later symptoms.

In a randomized, double-blind study of two doses of intrathecal adenosine in 35 volunteers with experimental hypersensitivity induced by capsaicin, intrathecal adenosine 0.5 or 2 mg in 2 ml of saline, but not saline alone, equally reduced areas of allodynia and hyperalgesia from capsaicin (37). There were adverse effects in 1, 2, and 6 of the volunteers who received saline, 0.5 mg, and 2.0 mg of adenosine respectively. The adverse effects were headache, backache, and leg or groin ache. Intravenous aminophylline 5 mg/kg, given 2 hours after the adenosine, did not reverse the effects of adenosine.

Of 12 healthy volunteers given an intrathecal injection of adenosine (500–2000 micrograms) one volunteer had transient lumbar pain lasting 30 minutes after an injection of 2000 micrograms (38). There were no adverse effects at lower doses.

Adenosine can cause increased intracranial pressure (39).

Gastrointestinal

Adenosine can cause transient epigastric pain mimicking that of peptic ulceration (40).

Immunologic

- An anaphylactic reaction has been reported in a 75-year-old woman who was given adenosine 12 mg for a supraventricular tachycardia. She developed bronchospasm and profound inspiratory stridor, her arterial blood pressure fell to 50/30 mmHg from an arterial systolic pressure of 70 mmHg, and she recovered with appropriate treatment (41).

Death

Two cases of sudden death have been reported soon after the administration of adenosine for presumed supraventricular tachycardia, which turned out to be atrial fibrillation (42). The authors thought that both patients may have been unable to cope with the sudden momentary loss of cardiac function that would have occurred

immediately after the administration of adenosine; in one case, a patient with chronic lung disease, bronchospasm may have contributed.

Drug Administration

Drug administration route

The standard regimen for stress testing with intravenous adenosine is 140 micrograms/kg/minute for 6 minutes. However, in 599 patients a 3-minute infusion was associated with a lower frequency of some adverse effects (specifically flushing, headache, neck pain, and atrioventricular block) and had similar sensitivity in the diagnosis of coronary artery disease (43).

Intracoronary adenosine has been compared with intravenous adenosine for the measure of fractional flow reserve in 52 patients with coronary artery lesions (44). The intravenous dose was 140 micrograms/kg/minute and the intracoronary bolus dose was 15–20 micrograms to the right coronary artery and 18–24 micrograms to the left coronary artery. The two routes of administration were equally effective in measuring hyperemic flow, and adverse effects were limited to two patients who received intravenous adenosine; one patient had severe nausea and one patient with asthma had an episode of bronchospasm.

The use of intrathecal adenosine in patients with chronic neuropathic pain (35,45) has been briefly reviewed (46).

Drug–Drug Interactions

General

Adenosine does not interact with digoxin, disopyramide, flecainide, or quinidine.

Ciclosporin

Endogenous plasma adenosine concentrations were measured in 14 kidney transplant recipients taking ciclosporin and compared with five transplant recipients not taking ciclosporin, two taking sirolimus (FK506), six patients with chronic renal insufficiency, and ten controls (47). Plasma adenosine concentrations were significantly higher in those taking ciclosporin and sirolimus and in the patients taking ciclosporin the plasma adenosine concentrations correlated with serum ciclosporin concentrations. An in vitro study showed that ciclosporin inhibited the uptake of adenosine by erythrocytes. The authors concluded that since adenosine is immunosuppressant, the raised concentrations of adenosine in patients taking ciclosporin might contribute to the immunosuppressive action of ciclosporin. A further mechanism of the increase in adenosine concentration was possibly increased tissue release secondary to ciclosporin-induced vasoconstriction. The relevance of these results to the use of therapeutic intravenous adenosine in patients already taking ciclosporin is not clear.

Dipyridamole

Dipyridamole inhibits the uptake of adenosine by cells and so increases its effects; this causes a large reduction in the effective dose of adenosine (48).

Sirolimus

In two kidney transplant recipients taking sirolimus (FK506), plasma adenosine concentrations were significantly increased (47). The relevance of these results to the use of therapeutic intravenous adenosine in patients already taking sirolimus is not clear.

Xanthines

Antagonists at adenosine receptors should inhibit the action of adenosine, and indeed theophylline increases the dose of adenosine needed for conversion of supraventricular tachycardia (49).

Diagnosis of Adverse Drug Reactions

In 34 patients given midazolam or placebo in a double-blind study, midazolam significantly reduced patients' experiences of palpitation and chest pain but had no effects on other adverse events (50). These effects were probably due to amnesia rather than a true reduction in the incidence of adverse events, and it is uncertain that the benefit to harm ratio is worth while. However, the authors suggested that midazolam might be useful in patients who have previously had unpleasant adverse reactions to adenosine.

Adiphenine

General Information

Adiphenine, in the doses generally used (up to 60 mg/day), is of disputed value. It may have a non-specific relaxant action on the gastrointestinal muscle and some local anesthetic effect on the buccal mucosa. The evidence on its effects is meager and it seems like an anticholinergic drug that has been promoted in doses that are often too low to result in either a useful therapeutic effect or in adverse effects.

Adrenaline

See also Anticholinergic drugs

General Information

Note on nomenclature

Although epinephrine is the recommended International Non-proprietary Name (rINN), there are good reasons why the name adrenaline should be preferred, based on usage, history, etymology, and, most importantly, risk of clinical errors (1).

Adrenaline is a catecholamine with agonist effects at both α- and β-adrenoceptors.

The use of adrenaline is largely limited to subcutaneous administration for the immediate relief of anaphylactic shock. Intramuscular doses of 0.1 ml of a 1:1000 solution are often given repeatedly, up to a maximum of some 2 ml in 5 minutes. Although the sensitivity of individuals to adrenaline varies considerably, the adverse reactions to such doses are generally limited to mild cardiovascular effects.

Intravenous administration of adrenaline for treatment of systemic anaphylactic shock should be undertaken with extreme caution, even in patients without a history of cardiovascular disease. At all times the patient must be monitored and emergency treatment should be available. Even the infiltration of low doses of adrenaline for local hemostasis can be attended by these risks; one patient developed ventricular tachycardia and severe hypertension after receiving 3.75 mg locally for this purpose (SEDA-17, 160), and the value of this treatment is in any case today regarded as dubious (SEDA-17, 161).

Subcutaneous adrenaline has been used to prevent the immediate adverse effects of snake antivenom, although evidence of its efficacy is scanty (2). A large clinical trial is under way in Sri Lanka.

Adrenaline was at one time a component of asthma sprays, and dilated cardiomyopathy was described after many years of use (3).

Adrenaline has been largely abandoned as an adjuvant to local anesthetics, although in a 1:80 000 concentration it is still sometimes used in dental and in epidural anesthesia.

Dipivefrin

Dipivefrin (dipivalyl epinephrine) is a prodrug of adrenaline, used topically in the treatment of glaucoma. Its potential advantages include a longer duration of action, increased local availability, greater potency, greater stability, and fewer adverse effects. The effect on pupil size is insignificant, no objective sight-threatening effects are observed, and central visual acuity and visual fields are not affected after application of a 0.1% solution of dipivefrine. However, minor sporadic and transient burning or stinging sensations can occur.

Organs and Systems

Cardiovascular

When the limits of tolerance are approached, there may be palpitation, extra beats, and a rise in blood pressure. In sensitive individuals or at high doses, ventricular fibrillation, subarachnoid hemorrhage, and even hemiplegia have been known to occur. Adrenaline can occasionally cause pulmonary edema (4,5). It is possible that in at least some of these cases the drug has been inadvertently injected intravenously.

Ventricular dysrhythmias have been reported in a case of adrenaline overdose (6).

- A 5-year-old boy was given subcutaneous adrenaline 1:1000 after a severe allergic reaction to a bee sting. Inadvertently, 10 times the correct dose was given. He developed extra beats and two brief runs of ventricular tachycardia, but recovered fully after about 20 minutes. Creatine kinase activity, both total and the MB fraction, was slightly raised in this patient (total 603 IU/l, MB fraction 161 IU/l; upper limits of the local reference range 243 and 15 IU/l), suggesting cardiac damage.

Life-threatening torsade de pointes has been observed when an epidural anesthetic was given using 20 ml of bupivacaine containing only 1:200 000 adrenaline (7).

When adrenaline 0.4 ml of a 1 mg/ml solution was inadvertently injected into the penile skin of a 12-hour-old neonate the skin blanched and the error was immediately understood (8). After repeated doses of phentolamine (total 0.65 mg) the skin regained its normal color. There were no sequelae.

Adrenaline is occasionally used as a hemostatic agent, with rare complications. However, they do occur, as noted in a report from Lyon (9).

© 2006 Elsevier B.V. All rights reserved.

- A 64-year-old man with diabetes and hypertension bled from a site in the lower rectum. A local injection of adrenaline 0.2 mg successfully stopped the hemorrhage, but very soon after he became hypotensive, with rapid atrial fibrillation (ventricular rate not given), the first time he had experienced this. He reverted spontaneously to sinus rhythm within 24 hours.

The authors suggested that if this type of procedure is contemplated in elderly patients with cardiovascular disease an anesthetist should be present to monitor cardiovascular status; it may in any case be wiser to avoid adrenaline altogether in favor of other means of hemostasis.

A more unusual site of adrenaline injection has been described in a Canadian report (10).

- A 79-year-old woman developed pituitary apoplexy in an adenomatous gland and was being prepared for *trans*-sphenoidal hypophysectomy. Topical adrenaline (1:1000) was applied to both nostrils and then 1.5 ml of 1% lidocaine containing 1:100 000 adrenaline was injected into the nasal mucosa. The blood pressure immediately rose from 100/50 to 230/148 mmHg and the pulse rate from 48 to 140/minute. Although she was treated immediately with esmolol and intravenous glyceryl trinitrate, resulting in normalization of her blood pressure, subsequent investigations showed that she had had a painless myocardial infarction. She made a full recovery after pituitary surgery.

The authors suggested that if adrenaline is to be used in such cases, even lower concentrations might be advisable. This is reasonable, although one also wonders in this case whether her blood pressure may have been lowered too rapidly.

Sensory systems

Melanic conjunctivocorneal pigmentation has been reported with an incidence of 30% with adrenaline (11,12).

Cystoid macular edema has been reported to occur in 2.8% of the patients receiving adrenaline especially in aphakic or pseudophakic eyes (13). Cystoid macular edema has also been seen after the use of dipivefrine, but in the classic case described in 1982 pretreatment with timolol maleate may have predisposed the eye to this complication (14).

Central retinal vein thrombosis occurred in a 75-year-old man 20 minutes after the ipsilateral insertion of a 1% adrenaline-soaked cotton wool stick (15). Unfortunately, his visual acuity did not improve.

Metabolism

Lactic acidosis has been observed, persisting for some hours after deliberate intravenous misuse of 20 mg adrenaline by an addict (SED-12, 308). Six of 19 patients who were given adrenaline for hypotension after undergoing cardiopulmonary bypass developed lactic acidosis, though the ultimate outcome was favorable (SEDA-22, 154).

Mouth and teeth

Facial swelling due to drug-induced sialadenosis was repeatedly observed in one patient who controlled her asthma symptoms with an adrenaline inhaler (SEDA-14, 119).

Susceptibility Factors

Cardiovascular

In susceptible individuals, an attack of angina pectoris can be precipitated by adrenaline, and in any form of cardiac disease caution is indicated; at one time an attempt was made to use high doses of adrenaline for the early treatment of ventricular fibrillation, but its pharmacological effects swing the balance against its use, the immediate survival rate actually being reduced.

Hyperthyroidism

Patients with hyperthyroidism are unduly sensitive to the effects of adrenaline (SEDA-14, 179).

Drug Administration

Drug administration route

While the absorption of adrenaline from a subcutaneous injection in healthy subjects is variable (and sometimes very slow) absorption from an inhaled dose is rapid and reliable (16). The main adverse effect from the inhaled route, for example in a dose of 3–4.5 mg, is gastrointestinal discomfort, with nausea and sometimes vomiting; this seems to be a local effect since it does not occur with injections. However, both forms produce mild tremor and palpitation in some individuals.

Since adrenaline is so short acting, the metabolic and other adrenergic effects which it can produce are unlikely to be elicited unless a depot formulation is used; in the latter event, hyperglycemia may occur.

Drug–Drug Interactions

Beta-adrenoceptor antagonists

Small quantities of adrenaline, such as are present as an additive in local anesthetic formulations, can be dangerously potentiated by beta-adrenoceptor blockers; propranolol should be discontinued at least 3 days in advance of administering such products for local anesthesia. A combined infusion of adrenaline and propranolol has been used for diagnosing insulin resistance, but it can evoke cardiac dysrhythmias, even in patients without signs of coronary disease (17).

Halothane

Halothane and some other anesthetics sensitize patients to the risk of adrenaline-induced ventricular dysrhythmias and acute pulmonary edema, especially if hypoxia is present (18,19).

© 2006 Elsevier B.V. All rights reserved.

Hyaluronidase

Adrenaline is physically incompatible with hyaluronidase (20).

Monoamine oxidase inhibitors

Monoamine oxidase inhibitors have been said to potentiate the hypertensive effects of adrenaline, but there is no good clinical evidence of such an interaction (21). Nevertheless, care should be taken when contemplating the use of adrenaline in patients taking a monoamine oxidase inhibitor.

Sodium novobiocin

Adrenaline is physically incompatible with sodium novobiocin (20).

Sodium warfarin

Adrenaline is physically incompatible with sodium warfarin (20).

Tricyclic antidepressants

Tricyclic antidepressants inhibit the uptake of catecholamines, such as adrenaline, into sympathetic neurons and can enhance the cardiovascular effects, so that even the small amounts of adrenaline present as additives in some local anesthetics can have a marked effect on the cardiovascular system.

Adrenoceptor agonists

See also Individual agents

General Information

Adrenoceptor agonists evoke physiological responses similar to those produced by stimulation of adrenergic nerves or the physiological release of adrenaline (see Table 1). For many of these responses it is currently possible to conclude that only an alpha-adrenoceptor or a beta-adrenoceptor is involved, and in some cases one can distinguish a $beta_1$ from a $beta_2$ response. In some cases, however, the distinction is not clear: most adrenoceptor agonists, however specific to a particular receptor type they are claimed to be, will for example on occasion stimulate central nervous functions, resulting in nervousness, insomnia, tremors, dizziness, or headache. In some organ systems both alpha-adrenoceptors and beta-adrenoceptors are present; thus, the nature of the response produced will depend either on the concentrations achieved or on other factors; whether, for example, the uterus contracts or relaxes in response to an adrenergic drug depends in part on the hormonal balance in the system at that moment.

Alpha-adrenoceptor agonists, such as clonidine, are little used nowadays in the treatment of hypertension or migraine. Clonidine is used epidurally, in combination with opioids, neostigmine, and anesthetic and analgesic agents, to produce segmental analgesia, particularly for postoperative relief of pain after obstetrical and surgical

Table 1 Adrenoceptors and the effects of agonists

Organs and systems	Receptor	Response to an agonist
Cardiovascular		
Heart		
Sinoatrial node	β_1	Increased heart rate
Atria	β_1	Increased contractility and conduction velocity
Atrioventricular node and conduction system	β_1	Increased conduction velocity and automaticity
Ventricles	β_1	Increased contractility, conduction velocity, automaticity, rate of idiopathic pacemakers
Blood vessels		
Coronary	α, β_2	Constriction
Skin, mucosa	α	Constriction
Skeletal muscle	α or β_2	Constriction or dilatation
Cerebral	α	Slight constriction
Pulmonary	α or β_2	Constriction or dilatation
Abdominal viscera	α or β_2	Constriction or dilatation
Salivary glands	α	Constriction
Respiratory		
Bronchial muscle	β_2	Relaxation
Bronchial glands	α_1, β_2	Decreased or increased secretion
Nervous system		
Cerebral function	Various	Stimulation
Eyes		
Radial muscle, iris	α	Contraction (mydriasis)
Ciliary muscle	β	Relaxation for far vision (slight)
Hematologic		
Spleen capsule	α	Contraction
Salivary glands	α_1	Potassium and water secretion
	β	Amylase secretion
Gastrointestinal		
Motility and tone	α_1, β_1, β_2	Decrease (usually)
Sphincters	α	Contraction (usually)
Secretion of various substances	Various	Inhibition
Liver		
Glycogenolysis and gluconeogenesis	α_1, β_2	Stimulation
Gallbladder		
Bile ducts	β_2	Relaxation
Urinary tract		
Ureter; tone, motility	β_2	Relaxation (usually)
Bladder; detrusor	β	Relaxation (usually)
Trigone, sphincter	α	Contraction
Renal vessels	α_1, β_1, β_2	Primary contraction
Skin		
Pilomotor muscles	α	Contraction
Sweat glands	α	Slight local secretion
Musculoskeletal		
Muscle glycogenolysis	β	Stimulation
Sexual function		
Uterus	α, β_2	Variable effect[a]
Male sex function	α_1	Ejaculation

[a] Response depends inter alia on hormonal status.

procedures. Apraclonidine is available for the short-term reduction of intraocular pressure.

The drugs that were developed some 40 years ago as general beta-adrenoceptor agonists have largely fallen into disuse with the development of more selective beta$_1$-adrenoceptor agonists (for use in cardiac failure) and beta$_2$-adrenoceptor agonists (for use in airways disease and threatened premature labor).

Beta$_3$-adrenoceptor agonists

Stimulation of beta-adrenoceptors on the cell surface of adipocytes promotes lipolysis and energy expenditure. These receptors are neither beta$_1$-adrenoceptors nor beta$_2$-adrenoceptors, and they have been termed atypical or beta$_3$-adrenoceptors. Some atypical agonists (BRL 26830 A, BRL 35135, CL 316243, and D 7114) have been developed and assessed for their ability to stimulate

© 2006 Elsevier B.V. All rights reserved.

these receptors and hence to induce weight loss. The BRL compounds appear to exaggerate physiological tremor, presumably through an effect on $beta_2$-adrenoceptors; the two other compounds are said to be more selective.

Ajmaline and its derivatives

See also Antidysrhythmic drugs

General Information

Ajmaline and its derivatives, prajmalium bitartrate (rINN; *N*-propylajmaline), lorajmine (rINN; chloroacetylajmaline), detajmium bitartrate (rINN), and diethylaminohydroxypropylajmaline, are *Rauwolfia* alkaloids. Their use is restricted by serious adverse effects, such as neutropenia and cardiac dysrhythmias, which have been reviewed (1). Other adverse effects include dizziness, headache, and a sensation of warmth after intravenous injection.

Organs and Systems

Cardiovascular

Ajmaline occasionally causes cardiac dysrhythmias (SEDA-17, 219). Of 1995 patients who were given ajmaline 1 mg/kg intravenously during an electrophysiological study, 63 developed a supraventricular tachydysrhythmia (atrial flutter, fibrillation, or tachycardia), and seven an atrioventricular re-entrant tachycardia (2). Those most at risk were older patients, those with underlying cardiac disease, and those with a history of dysrhythmias or sinus node dysfunction.

Two cases of torsade de pointes have been reported in association with prolongation of the QT interval (3). Polymorphous ventricular tachycardia has been reported in three cases (4–6).

- A 13-year-old boy with Brugada syndrome (right bundle branch block with persistent ST segment elevation) was given an injection of ajmaline 1 mg/kg and developed greater ST segment elevation and more marked right bundle branch block morphology (7). This was followed by short runs of non-sustained polymorphic ventricular tachycardia, gradually increasing until monomorphic ventricular tachycardia occurred. The dysrhythmia eventually resolved without further treatment.

It is unwise to give antidysrhythmic drugs to patients with Brugada syndrome.

Nervous system

Neurological effects have occasionally been reported in patients taking ajmaline derivatives; they include confusion and cranial nerve palsies (8,9).

Hematologic

Neutropenia is a relatively common and important adverse effect of ajmaline (10). Of the three main mechanisms that cause neutropenia (immune, toxic, and autoimmune) two have been associated with ajmaline: immune and autoimmune neutropenia.

Liver

Ajmaline can cause hepatitis or cholestasis. Cholestasis has been reported in association with neutropenia (11) and with fever and eosinophilia (12). Although acute liver damage due to ajmaline is usually reversible, there has been a report of persistent jaundice due to long-lasting cholestasis (13).

Immunologic

Hypersensitivity to ajmaline is rare, but there has been a report of an immune interstitial nephritis in association with fever (14).

Drug Administration

Drug overdose

In overdosage ajmaline can cause heart block and dysrhythmias, hypotension, malaise, vertigo, respiratory depression, and coma (15). In one series of 38 cases there were nine deaths (24%) (16). Treatment of overdosage includes the intravenous administration of molar sodium lactate for dysrhythmias, conduction disturbances, and circulatory failure; a pacemaker may be required.

- After an overdose of detajmium bitartrate in a dose of 18 mg/kg, a 36-year-old woman developed ventricular flutter, which responded to treatment with lidocaine, defibrillation, glucagon, noradrenaline, and sodium chloride (17). Hypokalemia responded to intravenous potassium chloride.
- A 57-year-old man took ajmaline 1000 mg with suicidal intent (18). He was unconscious and hypotensive and had serious disturbances in cardiac conduction. His serum and urine ajmaline concentrations were high. Although only 4% of the ingested dose was excreted following forced diuresis, all evidence of toxicity disappeared within 21 hours.

Various types of cardiac dysrhythmia have previously been reported after overdosage of ajmaline (SEDA-2, 162).

Alatrofloxacin and trovafloxacin

See also Fluoroquinolones

General Information

Alatrofloxacin is a fluoronaphthyridone that is hydrolysed to the active moiety, trovafloxacin, after intravenous administration. This fourth-generation broad-spectrum fluoroquinolone has activity against Gram-positive, Gram-negative, anerobic, and atypical respiratory pathogens. Because it has significant hepatotoxicity, the list of appropriate indications for trovafloxacin has been restricted.

In a multicenter, double-blind, randomized comparison of trovafloxacin 200 mg and clarithromycin 500 mg bd in 176 subjects with acute exacerbations of chronic bronchitis, the most common adverse effects of trovafloxacin were nausea (5%), dizziness (5%), vomiting (3%), and constipation (3%) (1). Because trovafloxacin is hepatotoxic, the list of appropriate indications has been limited to patients who have at least one of several specified infections, such as nosocomial pneumonia or complicated intra-abdominal infections that are serious and life- or limb-threatening in the physician's judgement.

Trovafloxacin may down-regulate cytokine mRNA transcription in human peripheral blood mononuclear cells stimulated with lipopolysaccharide or lipoteichoic acid (2). Likewise, trovafloxacin inhibited *Salmonella typhimurium*-induced production of TNFα, HIV-1 replication, and reactivation of latent HIV-1 in promonocytic U1 cells at concentrations comparable to the plasma and tissue concentrations achieved by therapeutic dosages (3).

Organs and Systems

Cardiovascular

Phlebitis can occur during parenteral administration of trovafloxacin. High concentrations of trovafloxacin (2 mg/ml) significantly reduced intracellular ATP content in cultured endothelial cells and reduced concentrations of ADP, GTP, and GDP (4). These in vitro data suggest that high doses of trovafloxacin are not compatible with maintenance of endothelial cell function and may explain the occurrence of phlebitis. Commercial formulations should be diluted and given into large veins.

Nervous system

Alatrofloxacin can cause seizures (5).

- A 37-year-old Asian man received several antibiotics (including intravenous ceftazidime, gentamicin, meropenem, metronidazole, and vancomycin) postoperatively. After 3 weeks he was given alatrofloxacin 75 mg in 25 ml of dextrose 5% (1.875 mg/ml) and developed generalized clonus. On rechallenge, infusing at half the initial rate, the seizure recurred. A CT scan of the brain was normal.

Seizures are rare but have occurred during treatment with other fluoroquinolones. This is the first report of a case of seizures associated with slow infusion of alatrofloxacin. However, as of 21 June 2000, the manufacturers had received 53 reports of seizures through worldwide postmarketing surveillance. In rat hippocampus slices, trovafloxacin had significant convulsive potential; the underlying mechanism is hitherto incompletely understood.

Trovafloxacin has been associated with diffuse weakness due to a demyelinating polyneuropathy in a patient without an underlying neurological disorder (6).

Hematologic

Alatrofloxacin has been associated with severe leukopenia (7).

- A 79-year-old white man was treated with intravenous alatrofloxacin mesylate 200 mg bd for 5 days. His

© 2006 Elsevier B.V. All rights reserved.

leukocyte count fell from 10.9 × 10^9/l to 2.2 × 10^9/l; the hemoglobin did not change. Alatrofloxacin was withdrawn, and 3 days later the leukocyte count had increased to 11.5 × 10^9/l.

The mechanism of trovafloxacin-induced leukopenia is unknown. Nevertheless, since quinolones exert their antibacterial effect by inhibiting bacterial DNA gyrase and since similar topoisomerases are involved in the organization and function of mammalian DNA, it is possible that trovafloxacin acts by modulating bone marrow stem-cell DNA production.

Alatrofloxacin has been associated with severe thrombocytopenia (8).

- A 54-year-old woman was given alatrofloxacin 300 mg intravenously qds and on day 4 developed epistaxis. Her platelet count was 7 × 10^9/l, with normal hemoglobin and white blood cell counts. Direct antiglobulin testing showed coating of erythrocytes with polyspecific immunoproteins, and platelet-associated antibody testing was positive for IgM and IgG antibodies. Alatrofloxacin was withdrawn and azithromycin was given instead. She was given methylprednisolone 125 mg intravenously bd and the platelet count fell to 2 × 10^9/l and then rose, reaching 60 × 10^9/l on day 8.

During clinical trials, thrombocytopenia occurred in under 1% of more than 7000 patients who received alatrofloxacin or trovafloxacin.

Liver

More than 100 cases of hepatotoxicity associated with trovafloxacin have been reported to the FDA.

- A 19-year-old woman developed severe acute hepatitis and peripheral eosinophilia during oral trovafloxacin therapy for recurrent sinusitis (9). Liver biopsy showed extensive centrilobular hepatocyte necrosis, probably causing veno-occlusive disease. Clinical and laboratory abnormalities resolved completely after prolonged treatment with steroids.
- A 66-year-old man had taken trovafloxacin 100 mg/day for 4 weeks for refractory chronic sinusitis (10). For several years he had also taken allopurinol, doxepin, hydrochlorothiazide, losartan, metoprolol, and nabumetone. He developed nausea, vomiting, malaise, and abdominal distension. His white cell count was 8000 × 10^9/l with 16% eosinophils; his serum aspartate transaminase was 537 IU/l, alanine transaminase 841 IU/l, direct bilirubin 17 μmol/l; total bilirubin 27 μmol/l, alkaline phosphatase 111 IU/l; blood urea nitrogen 5 μmol/l; and creatinine 190 μmol/l. Tests for hepatitis A, B, and C were negative. A biopsy of the liver showed centrilobular and focal periportal necrosis and eosinophilic infiltration; the sinusoids were dilated and contained lymphocytes and eosinophils; many hepatocytes were undergoing mitosis. After withdrawal of trovafloxacin and treatment with prednisone, his hepatic and renal function returned to normal, and the eosinophilia gradually resolved.

Skin

The photosensitizing potential of trovafloxacin 200 mg od has been compared with that of ciprofloxacin 500 mg bd, lomefloxacin 400 mg od, and placebo in 48 healthy men (aged 19–45 years) (11). Trovafloxacin had significantly less photosensitizing potential than either ciprofloxacin or lomefloxacin. Photosensitivity seemed to be induced only by wavelengths in the UVA region, was maximal at 24 hours, and had a short-term effect.

Musculoskeletal

Trovafloxacin inhibited growth and extracellular matrix mineralization in MC3T3-E1 osteoblast-like cell cultures (12). The IC_{50} was 0.5 μg/ml, which is below clinically achievable serum concentrations. The authors suggested that the clinical relevance of this observation to bone healing in orthopedic patients should be evaluated.

Second-Generation Effects

Teratogenicity

In an ex vivo study, trovafloxacin crossed the human placenta by simple diffusion and neither accumulated in the media nor bound to tissues or accumulated in the placenta (13). This implies that it should have no effects on the fetus if given during pregnancy.

Susceptibility Factors

Age

The pharmacokinetics of a single intravenous dose of alatrofloxacin have been determined in six infants aged 3–12 months and in 14 children aged 2–12 years (14). The peak trovafloxacin concentration at the end of the infusion was 4.3 μg/ml; the volume of distribution at steady state was 1.6 l/kg, clearance 2.5 ml/min/kg, and the half-life 9.8 hours, with no age-related differences. Less than 5% of the administered dose was excreted in the urine over 24 hours.

Other features of the patient

The pharmacokinetics of trovafloxacin after the administration of alatrofloxacin were not substantially altered in seven critically ill patients (three men, four women) with APACHE II scores of 27 (range 15–32) and normal or mildly impaired hepatic function (15).

Monitoring Therapy

In 17 patients aged over 18 years with severe acute community-acquired pneumonia trovafloxacin concentrations were persistently high in the sputum, bronchial secretions, bronchoalveolar lavage fluid, and epithelial lining fluid, with no significant difference between these compartments (16). The authors proposed that measurement of sputum concentrations could be used to monitor the outcome of treatment.

Albendazole

See also Benzimidazoles

General Information

Albendazole, a benzimidazole derivative closely related to mebendazole (qv), is used in the treatment of helminth infections, such as gastrointestinal roundworms, hydatid disease, neurocysticercosis, larva migrans cutanea, and strongyloidiasis (1). Provided that an adequate concentration is attained within the cyst, it is scolicidal. In high doses given for prolonged periods or cyclically, it is effective in echinococcosis, in which it is given in a dosage of 10 mg/kg/day for 4 weeks, repeated in six cycles with 2-week rest periods between each cycle, although even with this high dose only about one-third of patients enjoy a complete cure, some 70% having a partial response. Albendazole is also active against *Pneumocystis jiroveci*, and is effective in prophylaxis and treatment in immunosuppressed mice (2). In hydatid disease a combination of albendazole and praziquantel is effective when either agent has failed when used alone (SED-12, 707) (3).

Observational studies

Ankylostomiasis

Albendazole has been used in the treatment of human hookworm and trichuriasis. In a mass-treatment report from Western Australia 295 individuals in a remote rural area were treated with albendazole 400 mg/day for 5 days because of possible *Giardia lamblia* and hookworm infections (4). The 37% prevalence of *Giardia* fell to 12% between days 6 and 9, but rose again to 28% between days 18 and 30. The effect on hookworms (*Ankylostoma duodenale*) was more pronounced and more sustained with a reduction of the pretreatment prevalence of hookworm infections from 76% before treatment to 0% after 3–4 weeks. The tolerability of the drug was judged to be excellent by 89%, good by 1%, and moderately good by 1%, while 9% gave no response. Adverse effects were reported by five individuals and consisted of mild abdominal pain ($n = 2$), mild or moderate diarrhea ($n = 2$), moderate fever ($n = 1$), and weakness ($n = 1$).

Ascariasis

The efficacy of 2 years of mass chemotherapy against ascariasis has been evaluated in Iran (5). A single dose of albendazole 400 mg was given at 3-month intervals for 2 years to every person, except children under 2 years of age and pregnant women. After 2 years of treatment the prevalences, based on 2667 post-treatment samples, had fallen (Table 1). There were no adverse effects of mass treatment with albendazole.

Echinococcosis

Hydatid disease is a common zoonosis caused by the larval cysts of *Echinococcus granulosus*. Hydatid cysts most commonly form in the liver, but can occur in any organ. The management and operative complications in 70 patients with hydatid disease aged 10–78 years have been studied retrospectively to assess the impact of albendazole and praziquantel compared with surgery (6). In all,

Table 1 Changes in prevalences of helminthic infections in patients treated with albendazole

Helminth	Number (%) of positive tests before treatment ($n = 3098$)	Number (%) of positive tests after treatment ($n = 2667$)
Ascaris lumbricoides	1198 (39%)	196 (7.4%)
Trichuris trichiura	22 (0.7%)	5 (0.2%)
Hymenolepis nana	63 (2%)	49 (1.8%)

© 2006 Elsevier B.V. All rights reserved.

39 patients received albendazole and praziquantel in combination and 19 received albendazole alone; none was treated with praziquantel alone. The combined use of albendazole and praziquantel preoperatively significantly reduced the number of cysts that contained viable protoscolices. During the 12-year follow-up period an initial 3 months of drug treatment (albendazole throughout and praziquantel for 2 weeks), re-assessment, followed by either surgery or continuation with chemotherapy was found to be a rational treatment algorithm. In 11 patients albendazole, given for a median of 3 months at a dose of 400 mg bd, had adverse effects: five patients developed nausea and six had abnormal liver function tests. Therapy was withdrawn in two patients owing to altered liver function.

The efficacy of albendazole emulsion has been studied in 212 patients with hydatid disease of the liver, aged 4–82 years (7). Two regimens of albendazole were given for a variable period (3 months to more than 1 year); 67 adults received albendazole 10 mg/kg/day and 145 adults received 12.5 mg/kg/day. The overall cure rate was 75%. In the follow-up study the recurrence rate was 10%. The highest cure rate was observed in those who received albendazole 12.5 mg/kg/day for 9 months. At the start of therapy about 15% of the patients had mild pruritus, rash, and transient gastric pain, which resolved without specific therapy. Two patients had alopecia. There were frequent rises in serum transaminase activities in both groups but not to above 30–50 IU/l, except in six patients, who had values above 200 IU/l. In two patients albendazole was withdrawn because of vomiting. In one patient who took 12.5 mg/kg/day severe adverse effects, such as anorexia, jaundice, anemia, edema, and hypoproteinemia, developed, necessitating withdrawal. Reintroduction of albendazole 10 mg/kg/day was uneventful.

The use of albendazole and mebendazole in patients with hydatidosis has been evaluated in 448 patients with *E. granulosis* hydatid cysts who received continuous treatment with albendazole 10–12 mg/kg/day for 3–6 months daily orally in a total dose of (323 patients) twice or mebendazole 50 mg/kg/day (8). At the end of treatment, 82% of the cysts treated with albendazole and 56% of the cysts treated with mebendazole showed degenerative changes. During long-term follow-up 25% of these cysts showed relapse, which took place within 2 years in 78% of cases. Further treatment with albendazole induced degenerative changes in over 90% of the relapsed cysts, without induction of more frequent or more severe adverse effects, as observed during the first treatment period. Adverse effects during the first treatment period consisted of raised transaminases with albendazole (67 of 323 patients) and mebendazole (16 of 125 patients), and abdominal pain in 12 and 11% respectively. With both drugs, occasional patients experienced headache, abdominal distension, vertigo, urticaria, jaundice, thrombocytopenia, fever, or dyspepsia, but most of these are known manifestations of *Echinococcus* infection. Six of 323 patients taking albendazole withdrew because of adverse effects compared with eight of 125 patients taking mebendazole. It appears that albendazole is more effective than mebendazole in the treatment of hydatid cysts caused by *E. granulosis* and that both the intensity and frequency of the usually mild adverse effects are comparable.

Filariasis

Treatment of patients with high *Loa loa* microfilaraemia is sometimes complicated by an encephalopathy, suggested to be related to a rapid killing of large number of *L. loa* microfilariae. If the *L. loa* microfilarial count could be reduced more slowly, before ivermectin is distributed, ivermectin-related encephalopathy might be prevented. In 125 patients with *L. loa* microfilariasis the effect of albendazole (800 mg/day for three consecutive days) or multivitamin tablets on *L. loa* microfilarial load and the occurrence of encephalopathy were studied (9). *L. loa* microfilarial loads were followed for 9 months. There was no significant change in the overall microfilarial loads among those treated with albendazole, although the loads in patients with more than 8000 microfilariae/ml tended to fall more progressively during the first 3 months of follow-up. There were no cases of encephalopathy. The main adverse effects reported were itching (in eight patients taking albendazole and seven taking multivitamins), abdominal pain (two taking albendazole), and diarrhea (one taking albendazole, two taking multivitamins); overall analysis showed no significant difference in these events between the groups. Albendazole was associated with modest but significantly raised plasma transaminase activities.

Neurocysticercosis

In a report on the use of albendazole 15 mg/kg/day in two divided doses for 14 days in the treatment of persistent neurocysticercosis (10), adverse reactions were monitored in 43 patients with seizures and a solitary cysticercal cyst, who had not been treated before. In all patients CT scans confirmed the presence of a solitary cyst less than 2 cm in diameter. Antiepileptic treatment was continued. In seven patients dexamethasone 8 mg/day in four divided doses was given for the first 5–7 days after the start of treatment. Follow-up CT scans at 4–10 weeks after the start of treatment showed responses in 20 patients, with complete disappearance in seven patients and a reduction to 50% of the pretreatment size in the other 13. There were adverse effects in 15 patients, with a maximum on the fifth day after the start of treatment. Six patients had severe headaches, 11 had partial seizures, and 2 had epileptic seizures and severe postictal hemiparesis that persisted for a week or more. Because of these serious adverse effects treatment was discontinued in seven patients and dexamethasone was added in those patients who were not already taking it, although its use proved questionable. Adverse effects were seen in three of seven patients who took prophylactic steroid therapy and in 12 of 36 patients who did not.

Albendazole was effective in neurocysticercosis in an optimal dosage of 15 mg/kg/day divided in two doses every 12 hours for 8 days (11). It was generally well tolerated, although several patients had adverse reactions during the first few days after the start of treatment, consisting of headache, vomiting, and exacerbation of neurological symptoms caused by an inflammatory reaction to antigens from degenerating cysts, necessitating the concomitant use of glucocorticoids. In very large cysticerci, or cysticerci located in risky areas like the brainstem, these reactions may rarely be life-threatening.

Protozoal infections

The efficacy of albendazole 800 mg bd for 14 days for persistent diarrhea due to cryptosporidiosis ($n = 10$), isosporiasis ($n = 54$), or microsporidiosis ($n = 23$) has been studied in 153 HIV-positive patients (12). Albendazole reduced the burden of protozoal infection and promoted mucosal recovery in 87 patients who had a complete clinical response. Two patients reported nausea and vomiting. One patient developed leukopenia (1.9×10^9/l) after treatment and four patients developed thrombocytopenia ($51–98 \times 10^9$/l).

Toxocariasis

The efficacy of albendazole plus prednisolone has been studied in five patients aged 11–72 years with ocular toxocariasis (13). All had uveitis and retinochoroidal granulomas. Their symptoms had persisted for a mean of 14 months (range 3 days to 24 months). The adults were treated with albendazole 800 mg bd for 2 weeks plus prednisolone starting at 1.5 mg/kg/day tapering over 3 months. The children were treated with 400 mg bd for 2 weeks plus prednisolone 1.0 mg/kg/day. All tolerated the therapy well without adverse effects. In particular, there were no significant hypersensitivity reactions to dying *Toxocara* larvae. The uveitis resolved in all cases and there were no relapses. After treatment, all the granulomas had disappeared, leaving heavily pigmented chorioretinal scars without loss of vision.

Comparative studies

The use of albendazole and mebendazole in patients with hydatidosis has been evaluated in 448 patients with *E. granulosis* hydatid cysts who received continuous treatment with albendazole 10–12 mg/kg/day for 3–6 months daily orally in a total dose of (323 patients) twice or mebendazole 50 mg/kg/day (8). At the end of treatment, 82% of the cysts treated with albendazole and 56% of the cysts treated with mebendazole showed degenerative changes. During long-term follow-up 25% of these cysts showed relapse, which took place within 2 years in 78% of cases. Further treatment with albendazole induced degenerative changes in over 90% of the relapsed cysts, without induction of more frequent or more severe adverse effects, as observed during the first treatment period. Adverse effects during the first treatment period consisted of raised transaminases with albendazole (67 of 323 patients) and mebendazole (16 of 125 patients), and abdominal pain in 12 and 11% respectively. Headache occurred in eight patients taking albendazole and three taking mebendazole, abdominal distension in seven and five patients, vertigo in five and one, urticaria in five and three, jaundice in one and one, thrombocytopenia in two and none, fever in three and none, dyspepsia in two and four, and tachycardia in two and none. Six of 323 patients taking albendazole withdrew because of adverse effects compared with eight of 125 patients taking mebendazole. It appears that albendazole is more effective than mebendazole in the treatment of hydatid cysts caused by *E. granulosis* and that both the intensity and frequency of the usually mild adverse effects are comparable.

In a randomized trial in Mexico (14) 622 children with *Trichuris* were randomized to either albendazole 400 mg/day for 3 days, one dose of albendazole 400 mg, or one dose of pyrantel 11 mg/kg. The aim was to study efficacy and the effects on growth. After three courses at 1 year the level of infection with *Trichuris* was reduced by 99% in the 3-day albendazole treatment group, by 87% in the single-dose albendazole treatment group, and by 67% in the pyrantel group. There were no significant differences in the increases in height, weight, or arm circumference, but contrary to expectations there was a lower increase in the thickness of the triceps skin fold in those given 3-day courses of albendazole. This was only found in the patients with lower pretreatment *Trichuris* stool egg counts. These findings suggest that although elimination of *Trichuris* may promote growth in children, albendazole in a dose of 1200 mg/kg every 4 months may have an independent negative effect on growth. In an accompanying commentary (15) it was concluded that the suggestion that relatively high doses of albendazole may affect growth deserves study, but that this possible effect must be weighed against the negative effect of prolonged helminthic infestation on children's health, growth, and cognitive function. However, it is unlikely that high-dose treatment will be standard in mass-treatment campaigns, and these results should not deter the use of single-dose albendazole in mass-treatment programs in high-risk populations.

In 110 children with ascariasis or trichuriasis the efficacy of a single dose of albendazole 400 mg has been compared with that of nitazoxanide 100 mg bd for 3 days in children aged 1–3 years and 200 mg bd for 3 days in children aged 4–11 years (16). Nitazoxanide cured 89 and 89% of the cases of ascariasis and trichuriasis respectively. Albendazole cured 91 and 58% of the cases of ascariasis and trichuriasis respectively. Abdominal pain ($n = 9$), nausea ($n = 1$), diarrhea ($n = 2$), and headache ($n = 1$) were reported as mild adverse effects in 105 patients who took nitazoxanide, and abdominal pain ($n = 1$), nausea ($n = 1$), and vomiting ($n = 1$) were reported as adverse effects in 54 patients who took albendazole. All the adverse events were mild and transient and drug withdrawal was not necessary.

Placebo-controlled studies

Albendazole has been used in the treatment and prophylaxis of microsporidiosis in patients with AIDS. In a small, double-blind, placebo-controlled trial from France (17) the efficacy and safety of treatment with albendazole was studied in four patients treated with albendazole 400 mg bd for 3 weeks and in four patients treated with placebo. Microsporidia were cleared in all patients given albendazole but in none of those given placebo. Afterwards all eight patients were again randomized to receive either maintenance treatment with albendazole 400 mg bd or no treatment for the next 12 months; none of the three patients taking maintenance treatment had a recurrence, while three of the five who took no maintenance therapy developed a recurrence. During the double-blind part of the trial there were no serious adverse effects in the patients who took albendazole, although two complained of headache, one of abdominal pain, one had raised transaminase activities, and one had

© 2006 Elsevier B.V. All rights reserved.

thrombocytopenia. However, half the patients were also taking anti-HIV triple therapy, which makes it difficult to assess these abnormalities. The authors concluded that the adverse effects were not serious and did not hinder maintenance therapy. The tentative conclusion derived from these findings is that albendazole may be useful in the treatment of microsporidiosis, which in patients with AIDS often leads to debilitating chronic diarrhea and is difficult to treat.

Use in non-infective conditions

The efficacy of albendazole has been evaluated in a few patients with either hepatocellular carcinoma ($n = 1$) or colorectal cancer and hepatic metastases refractory to other forms of treatment ($n = 8$) (18). Apart from hematological and biochemical indices, the tumor markers carcinoembryonic antigen (CEA) and alpha-fetoprotein (AFP) were measured to monitor treatment efficacy. One other patient with a neuroendocrine cancer and a mesothelioma was treated on a compassionate basis and only monitored for adverse effects. Albendazole was given orally in a dose of 10 mg/kg/day in two divided doses for 28 days. Albendazole reduced CEA in two patients and in the other five patients with measurable tumor markers, serum CEA or AFP was stabilized in three. In the seven patients who completed this pilot study, albendazole was well tolerated and there were no significant changes in any hematological, kidney, or liver function tests. However, three patients were withdrawn because of severe neutropenia, which resulted in the death of one. Neutropenia was more frequent than is usually experienced in the treatment of hydatid disease. The authors speculated that this may relate to reduced metabolism in patients with liver cancer or liver metastases, leading to the passage of unmetabolized drug into the circulation.

General adverse effects

As with other antihelminthic drugs, the general adverse effects of albendazole can reflect the destruction of the parasite rather than a direct action of the drug; pyrexia is likely to be seen, even in the absence of other problems. Albendazole was well tolerated in 30-day courses of 10–14 mg/kg/day separated by 2-week intervals.

Its adverse effects are similar to those of mebendazole and are possibly more common because of better and more reliable absorption.

The direct adverse effects of albendazole are few and usually minor, and consist of gastrointestinal upsets, dizziness, rash, and alopecia, which usually do not require drug withdrawal. Early pyrexia and neutropenia can also occur. Cyst rupture can also occur, as with mebendazole. About 15% of patients treated with albendazole at higher doses develop raised serum transaminases, necessitating careful monitoring and sometimes withdrawal of treatment after prolonged use. Careful monitoring of leukocyte and platelet counts is also indicated. The possibility of teratogenicity and embryotoxicity from animal studies suggests that the drug should be avoided in pregnancy.

Organs and Systems

Nervous system

Used in the treatment of neurocysticercosis, albendazole (like praziquantel) can cause a CSF syndrome characterized by fever, headaches, meningism, and exacerbation of some or many of the neurological signs of the disease; it is thought to be due to a local reaction to dying and dead larvae and can be attenuated by prednisone (SED-12, 707) (19,20).

Since neurocysticercosis is a neurological infection, it is not surprising that when treating it with any drug some of the neurological reactions to that drug (or to the death of the parasite) are particularly pronounced. For example, with a dose of 1.5 mg/kg continued for some time in cases of neurocysticercosis, a majority of patients initially develop intolerance in the form of headache, vomiting, fever, and occasionally diplopia and meningeal irritation (21). Even shorter and less intensive treatment has produced similar effects. However, all of these symptoms are probably due to the death of the parasite, and if therapy is continued they usually disappear within a few days. Nevertheless, they can be alarming and demand treatment. Data from large studies mention somnolence and even transient hemiparesis as incidental adverse effects.

Very rarely, in cases of neurocysticercosis, the reaction of the nervous system to the death of the parasite is extremely violent. In one case cerebral edema resulted in permanent neurological damage (22), while other patients have suffered hydrocephalus or acute intracranial hypertension requiring treatment, for example with glucocorticoids or mannitol (23).

Albendazole has sometimes aggravated extrapyramidal disorders or precipitated seizures in patients with prior epileptic symptoms. The risk of intracranial hypertension has led some to suggest that glucocorticoids should be given preventively when using albendazole in neurocysticercosis (24); however, dexamethasone can interact with albendazole, increasing its plasma concentrations (25), and it is not clear whether this might produce new problems.

Encephalopathy is an adverse event related to the treatment of *L. loa* with diethylcarbamazine or ivermectin, and it has also been related to albendazole (11).

- A 55-year-old woman from Cameroon took oral albendazole 200 mg bd for a symptomatic *L. loa* infection with microfilaremia of 152 microfilariae/ml and a *Mansonella perstans* infection of 133 microfilariae/ml. Three days after the start of therapy she developed an encephalopathy. Albendazole was withdrawn and she recovered without any specific treatment within the next 16 hours. On day 4, the *L. loa* microfilarial count was 29 microfilariae/ml.

The clinical presentation, the interval after starting treatment, the evolution of the episode, and the results of cerebral spinal fluid analysis and electroencephalography in this case were similar to those seen in cases of encephalopathy following treatment of *L. loa* with ivermectin or diethylcarbamazine. However, pretreatment filaremia was relatively low and *L. loa* microfilariae were not detectable in the cerebral spinal fluid. Thus, pre-existing conditions might increase the susceptibility to encephalopathy.

Sensory systems

An allergic conjunctivitis was seen in cases of industrial occupational skin reactions to albendazole (26).

Hematologic

There have been various reports of bone marrow depression. In one study (27) two of 20 patients had a reversible drop in leukocyte count. Pancytopenia, reversible on withdrawal, has been documented in an elderly woman (28). Even with high doses neutropenia occurs in under 1% of cases. In the older literature an occasional hematological death was reported.

A megakaryocytic thrombocytopenia attributed to albendazole has been reported (29).

- A 25-year-old woman who had been taking albendazole 13 mg/kg/day for 5 months for hepatic and pulmonary echinococcosis developed fatigue, bleeding gums, and prolonged menstrual bleeding. She had ecchymoses and petechiae over her legs, marked thrombocytopenia (10×10^9/l), a mild iron deficiency anemia, and a normal leukocyte count. There was no antiplatelet immunoglobulin. A bone marrow aspiration showed absent megakaryocytes with normal granulocytes and mild erythroid hyperplasia. A cytogenetic study of the bone marrow showed normal karyotype and immunophenotype. The albendazole was withdrawn and oral iron given. At follow-up 2 months later all laboratory abnormalities had resolved.

Gastrointestinal

With a single oral dose of albendazole 400 mg, there is usually little more in the way of adverse effects than mild gastrointestinal disturbances (notably epigastric pain or dry mouth), occurring only in about 6% of patients in some large series; a few patients have abdominal pain. With higher doses, irritation of the central nervous system can lead to nausea and vomiting.

Diarrhea occurs in a few patients taking albendazole and is usually mild. However, a typical case of pseudomembranous colitis has been documented, although the patient also had AIDS and intestinal microsporidiosis and had taken a number of other drugs; the complication responded to vancomycin (30).

Liver

Even in single low doses a transient increase in transaminase activities has been repeatedly reported, generally affecting up to 13–20% of patients taking albendazole (SEDA-18, 315) (31). At the higher doses some evidence of moderate hepatitis has been claimed to be present in almost all patients, but in one series with high doses of albendazole or mebendazole for echinococcosis only 17% had a (generally slight) increase in serum transaminases, and a fair number of these had pre-existent liver disorders (32). Like various other adverse effects, the increase in transaminases may be attributable to the breakdown of liver cysts; it is almost always reversible and is usually not a reason for withdrawal; it does not become more marked during long-term treatment. A very occasional individual develops jaundice (33) or some other manifestation of hepatitis (34).

Skin

A generalized rash has sometimes been seen in patients taking albendazole (SEDA-15, 334), and skin complications (including urticaria and contact dermatitis) are a potential problem in employees in the pharmaceutical industry if they undergo heavy exposure to the drug (26).

- A 38-year-old woman with cough, eosinophilia, and pulmonary infiltrates due to visceral larva migrans from *Toxocara canis* infection took albendazole 600 mg for 8 weeks and developed slight transient skin eruptions (35).

Stevens–Johnson syndrome was reported in a man who took albendazole 400 mg/day for toxocariasis (36).

Hair

There are various well-documented reports of reversible alopecia in patients taking albendazole (SEDA-17, 358) (SEDA-22, 324), which in one study occurred in 2% of cases (SEDA-18, 315) and in another study in one case of 20 (SED-13, 913) (27).

- Severe alopecia has been described in an almost 3-year-old child who took albendazole 400 mg/d for 3 days; 2 months later alopecia developed and resolved within 1 month (37).
- When one woman took 400 mg bd for 10 months for hydatid disease, she lost much of her hair; no other likely cause could be identified, and her hair growth recovered when the drug was stopped (38).

Oddly, however, a fair proportion of patients when specifically questioned seem to remark that their hair growth has actually improved during treatment (SED-13, 913) (27).

Musculoskeletal

Myalgia and arthralgia can occur in patients taking albendazole (39). However, these symptoms are often features of the disease being treated.

Second-Generation Effects

Teratogenicity

It has been emphasized that albendazole is teratogenic in animals and should not be used in pregnancy (40).

Drug–Drug Interactions

Antiepileptic drugs

The pharmacological interactions of the antiepileptic drugs phenytoin, carbamazepine, and phenobarbital with albendazole have been studied in 32 adults with active intraparenchymatous neurocysticercosis (41):

- nine patients took phenytoin 3–4 mg/kg/day;
- nine patients took carbamazepine 10–20 mg/kg/day;
- five patients took phenobarbital 1.5–4.5 mg/kg/day;
- nine patients took no antiepileptic drugs.

© 2006 Elsevier B.V. All rights reserved.

All were treated with albendazole 7.5 mg/kg every 12 hours on 8 consecutive days. Phenytoin, carbamazepine, and phenobarbital all induced the oxidative metabolism of albendazole to a similar extent in a non-enantioselective manner. In consequence, there was a significant reduction in the plasma concentration of the active metabolite of albendazole, albendazole sulfoxide.

Cimetidine

The poor intestinal absorption of albendazole, which may be enhanced by a fatty meal, contributes to difficulties in predicting its therapeutic response in echinococcosis. The effect of cimetidine co-administration on the systemic availability of albendazole has been studied in six healthy men (42). After an overnight fast, a single oral dose of albendazole (10 mg/kg) was administered on an empty stomach with water, a fatty meal, grapefruit juice, or grapefruit juice plus cimetidine. The systemic availability of albendazole was reduced by cimetidine. There were no adverse events. These results are consistent with presystemic metabolism of albendazole by CYP3A4.

Albumin

General Information

Adverse reactions to human serum albumin are uncommon and usually mild, such as itching and urticaria. Serious reactions are rare. A patient who has reacted violently to albumin on one occasion may tolerate it well on another after being given an antihistamine such as diphenhydramine (1). Aggregates present in protein preparations may be the cause of some reactions. Another postulated cause may be the presence of antibodies against genetic variants of human albumin (2). Hypotensive reactions due to the presence of a prekallikrein activator in some batches of formulations can occur.

Albumin has been used to prevent the ovarian hyperstimulation syndrome (OHSS) associated with ovulation stimulation. In 98 women albumin had no positive effect on OHSS (3). Because of adverse effects, such as exacerbation of ascites in OHSS, nausea, vomiting, febrile reactions, allergic reactions, anaphylaxis, and the risk of pathogen transmission, albumin should not be used to prevent OHSS.

Adverse events during plasma exchanges in 28 adults with Guillain–Barré syndrome have been described in a study of 28 French and Swiss intensive care units (4). The study was based on 220 patients allocated either to plasma exchange or not. A total of 105 patients underwent 390 plasma exchanges (55 received albumin in 208 sessions as replacement fluid and 50 received fresh plasma in 182 sessions). Altogether, 253 adverse incidents were recorded, and in 15 patients plasma exchange had to be discontinued because of severe intolerance, which included bradycardia ($n = 3$), intercurrent complications (mainly infections), and technical difficulties. Fresh frozen plasma was associated with significantly more adverse incidents than albumin. The occurrence of adverse events was related to the preplasma exchange hemoglobin. Age, sex, previous history, neurological severity, and the need for mechanical ventilation did not modify the risk of adverse effects. The possibility that some of the events described in this series were attributable to the underlying disease rather than to the plasma exchange was not ruled out.

Organs and Systems

Cardiovascular

Albumin infusions can increase capillary permeability (5) and albumin infusion during resuscitation can result in hypervolemia, due to overfilling of the circulation (6).

It has been postulated that cardiac pump function can be reduced by binding of free calcium to albumin (6).

Metabolism

Acute normovolemic hemodilution to a hematocrit of 22% was performed in a prospective randomized study in 20 patients undergoing gynecological surgery (7). In one group 35% of the blood volume was replaced by 5% albumin while the other group received 6% hydroxyethyl starch solutions containing chloride concentrations of 150 and 15 mmol/l. Neither solution contained bicarbonate or citrate. After acute normovolemic hemodilution the blood volume remained constant in both groups. The plasma albumin concentration fell after hemodilution with hydroxyethyl starch and increased after hemodilution with albumin. There was a slight metabolic acidosis with hyperchloremia and a concomitant fall in anion gap in both groups. The acidosis, which was attributed to hyperchloremia and dilution of bicarbonate in the extracellular volume, was considered to be of no clinical relevance. The authors proposed that acidosis during acute normovolemic hemodilution can be avoided when the composition of electrolytes in colloid solutions is more physiological, as in lactate-buffered solutions.

Hematologic

Albumin can inhibit platelet aggregation (6). In addition, coagulation defects can result from dilution after albumin administration (6).

© 2006 Elsevier B.V. All rights reserved.

Liver

Intravenous albumin formulations contain a significant amount of ammonium, with concentrations up to 800 μmol/l (8). The concentration of ammonium seems to be batch dependent and related to storage time, the highest concentration being in the oldest formulations. Ammonium is probably liberated from protein and/or amino acids during storage, enhanced in the presence of oxygen. Although this might potentially contribute to deterioration of hepatic encephalopathy in patients receiving this treatment, that was not shown in this small study.

Immunologic

Immunological reactions to human serum albumin tend to be non-IgE-mediated anaphylactic reactions (0.011% of cases treated), about a third of which are life-threatening (9). A case in which the mechanism seemed to be IgE-mediated anaphylaxis against native albumin has been reported (10).

A meta-analysis of 193 albumin-treated women versus 185 controls showed a significant reduction of severe OHSS after administration of human albumin; two cases of urticaria and one case of an anaphylactic reaction were reported (11).

Death

In July 1998, The Cochrane Injuries Group Albumin Reviewers published a meta-analysis comparing the use of albumin with the use of crystalloids or no treatment in critically ill patients (12). The review was based on 30 randomized, controlled studies, involving a total of 1419 patients with hypovolemia due to trauma, surgery, burns, or hypoalbuminemia. There was excess mortality in the albumin group of about 6%, and the authors concluded that albumin should not be used outside rigorously conducted randomized controlled trials. The review elicited numerous mostly critical comments. For example, it was commented that a meta-analysis is not exact and that in this specific studythe study had conflated three separate indications that were not comparable (5).

An Expert Working Party of the Committee on Safety of Medicines was set up to examine these findings and to advise on any necessary regulatory action. The Working Party concluded that there is insufficient evidence of harm to warrant withdrawal of albumin products from the market and that the effect of albumin on mortality can only be discovered by conducting large, purpose-designed, randomized, controlled trials (13). It was recommended that a number of changes be made to the product information for human albumin. Specifically, the Expert Working Party recommended that the indication for human albumin solutions should be focused on the use of albumin to replace lost fluids, rather than the underlying illness that resulted in hypovolemia, and that albumin deficiency in itself was not an appropriate indication. The product information should contain warnings about the risks of hypervolemia and cardiovascular overload and emphasize that hemodynamic monitoring in patients who receive albumin should be undertaken to avoid these complications. A warning that special care should be taken when administering albumin in pathological states that affect capillary integrity should also be included.

However, the validity of these findings has been questioned, because some papers chosen for meta-analysis by the Cochrane group were suggested to have been incorrectly included (14,15). The results obtained from the meta-analysis have also been challenged by another meta-analysis of albumin administration in critically ill patients, which showed no increased risk in mortality (16). This illustrates the need for high-quality, randomized, controlled trials to generate definitive evidence.

Second-Generation Effects

Pregnancy

Hypovolemic shock due to acute blood loss during delivery is one of the major causes of maternal mortality. It has been suggested that albumin may increase the risk of death, and crystalloids have been suggested to be the volume expanders of choice (17).

Drug Administration

Drug contamination

Aluminium

Contamination of albumin solutions with aluminium and consequent toxic effects have been described (18). Analysis of albumin from 20 suppliers showed aluminium contents varying from 1.03 to 1301 μmol/l depending on the batch and the manufacturer (19). Aluminium overloading is especially likely to occur in patients with impaired renal function who receive large volumes of albumin, leading to osteodystrophy and encephalopathy (20).

The source of contamination is the fractionation apparatus and can be located to containers, filters, and final product containers. The increase in aluminium content over the shelf-life period is due to the fact that the glass vial releases aluminium ions. This process is catalysed by the residual citrate content of albumin formulations and depends on the storage temperature as well as on the relation of the inner glass surface to the amount of liquid. For 10 ml bottles, stability of the aluminium content below 200 ng/ml cannot be guaranteed for the shelf life, irrespective of storage conditions.

In 50 ml and 100 ml bottles stored at temperatures below 8°C, the increase in aluminium content is sufficiently slowed down, so that it does not rise beyond 200 ng/ml within the 3-year shelf life. However, at storage temperatures exceeding 8°C, the aluminium content can increase beyond 200 ng/ml. According to stability studies, this threshold value is not passed before 12 months of storage at these higher temperatures.

An Austrian manufacturer of human albumin 20 and 25% voluntarily recalled the products because the pharmacopoeial specification for aluminium (200 ng/ml or less) for treatment of premature infants and dialysis patients cannot be guaranteed over the whole shelf life of 3 years when stored at temperatures above 8°C (21).

© 2006 Elsevier B.V. All rights reserved.

The Paul Ehrlich Institut of Germany recalled certain batches of human albumin products (Human Albumin 20%, Human Albumin 20% Immuno, Human Albumin Immuno 20%, Human Albumin 25% Immuno), including batches that had exceeded 12 months of shelf life (22). This action was taken after quality assurance tests had shown that the aluminium content of these batches had exceeded the maximum acceptable concentration of 200 ng/ml.

Infections

The transmission of viral infections via albumin can be eliminated through pasteurization, and albumin treated in this way has an unblemished safety record in this regard, although there is little information on the safety of albumin with respect to hepatitis A and parvovirus (5). The production process excludes transmission of viruses such as hepatitis B and C and HIV (6). There have been no cases of HIV transmission attributed to this type of product, although many batches are known in retrospect to have been derived from HIV-contaminated pools (23).

Drug–Drug Interactions

ACE inhibitors

In a child with chronic renal insufficiency perioperative hypotension occurred after plasma volume expansion using 4% albumin (24). The fall in blood pressure was attributed to the combination of a low concentration of prekallikrein-activating factor in albumin and the use of an angiotensin-converting enzyme (ACE) inhibitor. When ACE is inhibited, the half-life of bradykinin is significantly prolonged and the concomitant administration of prekallikrein activator is likely to cause significant prolonged hypotension. To prevent this, the authors suggested withdrawing ACE inhibitors 24 hours before surgery or alternatively avoiding albumin in patients taking ACE inhibitors.

Furosemide

In children with the nephrotic syndrome, albumin in combination with furosemide carries a risk of thrombotic complications. In 12 children although antithrombin and alpha-2 macroglobulin fell, which is in accordance with a thrombotic tendency, there were no thrombotic complications (25). Furthermore, there was a fall in fibrinogen concentration, which is not consistent with a thrombotic tendency.

Alclofenac

See also Non-steroidal anti-inflammatory drugs

General Information

While the pattern of alclofenac toxicity resembles that of other NSAIDs, the frequency of adverse effects differs widely. Allergic reactions have been reported more frequently and skin rashes have been particularly common. Hypersensitivity reactions, including anaphylactic shock, severe generalized vasculitis, hepatotoxicity, and nephrotoxicity, have been observed. Alclofenac has therefore been withdrawn in several countries (1). Blood dyscrasias and neurological symptoms are rare.

Alcuronium

See also Neuromuscular blocking drugs

General Information

Alcuronium is a synthetic derivative of toxiferine, an alkaloid of calabash curare, and is a non-depolarizing relaxant with properties and adverse effects similar to those of D-tubocurarine. It is about twice as potent as D-tubocurarine, 0.15–0.25 mg/kg usually being adequate for abdominal relaxation, and has a similar onset time and a slightly shorter duration of action. It is bound to albumin (40%), and requirements for alcuronium are less if the plasma albumin levels are low, as may occur in hepatic disease.

Like D-tubocurarine, alcuronium does not undergo biotransformation. Excretion occurs mainly in the urine (80–85%), but, as with D-tubocurarine, some is also excreted in the bile (15–20%) (1). Persistent relaxation has been reported in renal insufficiency (2) and the drug is relatively contraindicated in this condition.

Organs and Systems

Cardiovascular

Tachycardia, hypotension, and a fall in total peripheral resistance all occur to an extent similar to that seen with D-tubocurarine, according to most studies (3–6). Others have reported that these effects are short-lived (7). Doses of 0.2 mg/kg or more may be associated with the more extreme cardiovascular effects. Blockade of cardiac muscarinic receptors (8), histamine release, and, possibly, some ganglionic blockade (although it has a very low ganglion-blocking activity in animals) (8) may all play a role in the production of the cardiovascular effects of alcuronium.

Nervous system

Two patients in intensive care treated with infusions of large amounts of alcuronium developed fixed dilated pupils. Within 6–24 hours after stopping the infusion the pupils became normally reactive again (9).

This is a very important and dangerous adverse effect, since the presence of fixed dilated pupils may lead to the mistaken diagnosis of brain death in coma patients if other neurological diagnostic procedures are not carried out.

Immunologic

Histamine release and anaphylactoid reactions occur with alcuronium (10–12). The precise incidence is not clear. Erythema is said to occur much less frequently than after D-tubocurarine (3). A retrospective study in Australia (13) showed that 37% of serious anaphylactoid reactions reported there were associated with alcuronium; alcuronium, however, at that time accounted for almost 50% of the total muscle relaxant consumption in Australia, and if this is taken into account the likelihood of a serious reaction is less than with D-tubocurarine, as others have also concluded (14). Clinical features reported range from erythema to severe hypotension and tachycardia (15) and bronchospasm (16,17). In a large prospective surveillance study (SEDA-15, 125) (SED-12, 473) involving over 1400 patients given alcuronium (initial dose 0.25 + 0.09 mg/kg), there were adverse reactions in almost 18% of the patients, with moderate hypotension (20–50% fall) in 13%, severe hypotension in 0.8%, and bronchospasm in 0.1%.

Second-Generation Effects

Fetotoxicity

Placental transfer (SEDA-6, 130) (18), occurs and is increased if alcuronium is rapidly injected (19). No complications attributable to neuromuscular block were seen in the newborn.

Susceptibility Factors

Hepatic disease

In liver cancer in children, resistance to alcuronium has been reported (SEDA-13, 104) (20).

Other features of the patient

In patients with burns, dosage requirements are increased (21).

Drug–Drug Interactions

Penicillamine

Penicillamine-induced myasthenia gravis (SED-10, 415) was probably the cause of extremely prolonged apnea

© 2006 Elsevier B.V. All rights reserved.

occurring in two patients given alcuronium (SEDA-12, 111) (22,23). Patients receiving penicillamine should be treated as if they had no myasthenia; if a muscle relaxant is required, they should be given a test dose (of about one-tenth the usual dose), with monitoring of the response, before a full dose is administered.

Aldesleukin

General Information

Aldesleukin (interleukin-2, celmoleukin, proleukin, teceleukin) is produced by activated T lymphocytes and has pleiotropic immunological effects, including the proliferation of T lymphocytes. Non-glycosylated recombinant aldesleukin has been approved for the treatment of metastatic renal cell carcinoma (1) and is also being investigated in other malignant neoplasms. Low-dose aldesleukin is a relatively safe treatment of HIV infection (SEDA-20, 334).

The adverse effects of aldesleukin include fever, chills, malaise, skin rash, nausea, vomiting (often resistant to antiemetics), diarrhea, fluid retention, myalgia, insomnia, disorientation, life-threatening hypotension, and the capillary leak syndrome (which can be preceded by weight gain) (SEDA-15, 491) (2).

In early trials, aldesleukin was given with lymphokine-activated killer (LAK) cells or tumor-infiltrating lymphocytes. However, later data showed that the addition of LAK cells does not improve the therapeutic response in renal cell carcinoma and can produce more pulmonary toxicity and hypotension (1). Compared with aldesleukin or interferon alfa alone, the combination of aldesleukin plus interferon alfa produces a significantly longer event-free survival without effect on the overall survival, but induces substantial toxicity with severe and resistant hypotension (3). The optimal safe and effective dose and schedule of administration of aldesleukin is not yet well defined, and a variety of regimens have been tested, with doses of 600 000 units/kg by intermittent bolus intravenous infusion or 18 106 units/m^2 by continuous subcutaneous or intravenous infusion.

Considerable efforts have been made to limit the toxic effects of aldesleukin, which are dose- and schedule-dependent (4). Low-dose aldesleukin, continuous infusion, and/or subcutaneous administration are preferred by various investigators, because of their reluctance to use conventional high-dose or bolus dose administration. Such regimens were considered as effective and safe for outpatients (5,6).

A thorough analysis of 255 patients from seven phase II trials treated with the currently recommended high dose of aldesleukin for metastatic renal cell carcinoma has

© 2006 Elsevier B.V. All rights reserved.

been presented (7). Although severe toxicity, generally attributable to the capillary leak syndrome, was found in most patients, the problems receded promptly after withdrawal of treatment. Deaths related to aldesleukin-induced toxicity were reported in 4% of patients, and were caused by myocardial infarction, respiratory failure, gastrointestinal toxicity, or sepsis.

Use in patients with HIV infection

The use, benefits, and adverse effects of aldesleukin in HIV-infected patients have been extensively reviewed (8). Aldesleukin significantly increased the $CD4^+$ cell count without an increase in viral load. However, many questions remain unanswered. In particular, it is still not known whether immunological improvements translate into clinical benefit. Regardless of how aldesleukin is administered—intravenously, subcutaneously, or as polyethylene glycol-modified (pegylated) aldesleukin—adverse effects are generally not treatment-limiting. As the duration of adverse effects was shorter with the subcutaneous route, these patients may be treated as outpatients (9).

In two randomized, controlled studies (44 patients given subcutaneous aldesleukin, 58 given a modified-release polyethylene glycol-modified formulation, 27 given continuous intravenous aldesleukin, and 50 controls), aldesleukin was well tolerated and a minority of patients required drug withdrawal because of adverse events (10,11). The overall adverse effects profile of both routes of administration was very similar, but was substantially less severe than previously described with high-dose aldesleukin. It consisted mostly of fatigue, nasal/sinus congestion, fever above 38°C, headache, gastrointestinal disorders, stomatitis, somnolence, and mood change. Increased bilirubin and alanine transaminase activities were more frequent than in the control group. None of the patients developed the capillary leak syndrome or significant hypertension, but cardiomyopathy, attempted suicide, ulcerative colitis, and exacerbation of hepatitis B were identified in one patient each among 85 patients treated with aldesleukin (10). Erythema and injection site reactions were observed in 66–69% of patients who received subcutaneous aldesleukin, and skin biopsies showed a perivascular infiltrate with lymphocytes and some eosinophils.

Use in patients with metastatic melanoma

In an analysis of data from 270 patients with metastatic melanoma in eight clinical trials, high-dose aldesleukin (8.4–9.8 MU/kg during each cycle) produced an overall objective response rate of 16%, with 17 complete responses and 26 partial responses (12). Although the response rate was low, there was a durable response for at least 24 months in 10 of 17 complete responders. Adverse effects were primarily the same as those previously described in patients with metastatic renal cell carcinoma, and severe hypotension (64%) was the most frequent. Six patients died from bacterial sepsis, but none was taking prophylactic antibiotics.

In a randomized trial, 102 patients with metastatic melanoma had more frequent treatment-related adverse effects, particularly hematological suppression in patients treated with tamoxifen, cisplatin, and dacarbazine followed by interferon alfa and aldesleukin, than in patients treated with chemotherapy alone, but there was no increase in survival (13).

General adverse effects

The frequencies of severe adverse effects of aldesleukin (7) are listed in Table 1 and the most frequent reasons for withdrawal of high-dose intravenous aldesleukin in Table 2.

Table 1 The frequencies of severe adverse effects of aldesleukin

General symptoms	
Fever and chills	24%
Weakness	4%
Edema	2%
Sepsis	6%
Cardiovascular	
Hypotension	74%
Supraventricular dysrhythmias	3%
Myocardial damage (angina, infarction)	4%
Respiratory	
Dyspnea	17%
Adult respiratory distress syndrome	<1%
Respiratory failure	2%
Nervous system	
Coma, seizures	4%
Psychiatric	
Behavioral changes	28%
Hematologic	
Thrombocytopenia	21%
Anemia	18%
Gastrointestinal	
Nausea and vomiting	25%
Diarrhea	22%
Stomatitis	4%
Gastrointestinal bleeding	4%
Intestinal perforation	<1%

Hyperbilirubinemia	5%
Urinary tract	
Oliguria	9%
Raised creatinine concentration	13%

High-dose aldesleukin is associated with a wide range of adverse effects, and practical guidelines for their avoidance and management have been detailed (14). Constitutional symptoms (malaise, fever, chills and asthenia) are universal in patients treated with high-dose aldesleukin (4). Although they are usually suppressed by paracetamol (acetaminophen), indometacin, or pethidine, they are one of the major reasons for stopping treatment. Myalgia and arthralgia are sometimes associated with the flu-like symptoms.

A wide range of aldesleukin-induced adverse effects is associated with the capillary leak syndrome, which is characterized by an increase in vascular permeability with subsequent leakage of fluids and proteins into the extravascular space (4). This results in a third–space clinical syndrome, generalized or peripheral edema, weight gain, cardiovascular and pulmonary complications with hypotension, pericardial, and pleural effusions, ascites, oliguria, and prerenal azotemia. Symptoms usually resolve in a few days after aldesleukin withdrawal. Studies on the mechanism have raised a number of hypotheses, such as damage to the endothelial cells, release of secondary cytokines, and activation of the complement cascade (15).

Denileukin diftitox

Denileukin diftitox is a fusion protein formed by binding human aldesleukin to the cytotoxic A chain of diphtheria toxin. This product binds to the aldesleukin receptor and inhibits protein synthesis, resulting in cell death. It has been approved for treatment of persistent or recurrent cutaneous T cell lymphoma and is being evaluated in patients with severe psoriasis.

In 71 patients with cutaneous T cell lymphomas randomized to denileukin diftitox 9 or 18 μg/kg/day, flu-like and gastrointestinal symptoms were observed in 92% (16). About 60% had an acute hypersensitivity reaction, with dyspnea, back pain, hypotension, and chest pain or tightness within 24 hours of infusion. A vascular leak syndrome, as defined by the presence of at least two of edema, hypoalbuminemia, and hypotension, occurred in 25%.

A dose-escalation study in 35 patients with psoriasis confirmed that constitutional symptoms in response to denileukin diftitox were dose-related and less frequent at lower doses (below 5 micrograms/kg/day) (17). There was only one case of mild vascular leak syndrome. Skin reactions compatible with delayed hypersensitivity reactions were noted in three patients, including one case of exfoliative dermatitis.

The more severe adverse effects of denileukin diftitox consisted of acute hypersensitivity reactions during or within 24 hours of infusion in 69% of patients, and a vascular leak syndrome in 27% of patients, which was severe in 6%. In contrast to acute hypersensitivity reactions, the vascular leak syndrome was typically delayed and occurred within the first 2 weeks of infusion (18). Whether this was due to a direct action of denileukin diftitox or to tumor lysis syndrome is unknown.

Organs and Systems

Cardiovascular

Hemodynamic and cardiac complications are the major limitations of high-dose aldesleukin and have been described in both adults (19,20) and children (21). Significant hypotension requiring meticulous maintenance therapy with intravenous fluids or low-dose vasopressors was observed in most patients (22). The clinical findings were very similar to the hemodynamic pattern seen in early septic shock. Aldesleukin-induced increases in plasma nitrate and nitrite concentrations correlated with the severity of hypotension (23).

Among other cardiovascular complications, cardiac dysrhythmias were reported in 6–10% of patients, angina pectoris or documented myocardial infarction in 3–4%, and mortality due to myocardial infarction in 1–2% (4). Severe myocardial dysfunction, myocarditis, and cardiomyopathy have been seldom reported (SED-13, 1103) (SEDA-20, 334) (SEDA-22, 406).

The cardiopulmonary toxicity of high-dose intravenous bolus aldesleukin has been analysed in 199 metastatic melanoma or renal cell carcinoma patients without underlying cardiac disease (24). Cardiovascular events occurred within hours after starting infusion, persisted throughout aldesleukin therapy, and normalized within 1–3 days after treatment withdrawal. Hypotension was the most frequent adverse effect (53% of treatment courses) and resolved promptly with vasopressor treatment. Unexpectedly, the response to treatment was significantly better in patients with melanoma who had hypotension. There were cardiac dysrhythmias in 9% of patients; they mostly consisted of easily manageable atrial fibrillation or supraventricular tachycardia. Further courses of aldesleukin in 11 of these patients produced recurrent dysrhythmias in only two, and long-term treatment of dysrhythmias was never required. High-degree atrioventricular block and repetitive episodes of ventricular

© 2006 Elsevier B.V. All rights reserved.

tachycardia were each observed once. Although 11% of patients had raised creatine kinase activity before or during treatment, only 2.5% had a documented rise in the MB isoenzyme fraction.

At-risk patients include those with pre-existing cardiac disease, whereas age, performance status, and sex are not significantly associated with cardiopulmonary toxicity. In view of this risk, it is reasonable to monitor cardiac function and creatine kinase activity closely in all patients, or to exclude those with significant underlying coronary or cardiorespiratory disease. Pretreatment cardiac screening has greatly reduced the incidence of myocardial infarction, ischemia, and related dysrhythmias, and two-dimensional and Doppler echocardiography was suggested to be helpful to anticipate cardiovascular toxicity (25). A reduction in systemic vascular resistance, stroke work index, and left ventricular ejection fraction are usually involved in the pathophysiology of cardiac dysfunction. Clinical, electrocardiographic, and radionuclide ventriculography monitoring in 22 patients undergoing a 5-day continuous intravenous infusion of aldesleukin for various cancers showed that reversible left ventricular dysfunction accounted for most of the observed hemodynamic changes (26). Indeed, significant coronary disease was usually not observed in patients undergoing cardiac catheterization, which argues for direct myocardial damage (24). In isolated reports, clinical and histological findings of eosinophilic, lymphocytic, or mixed lymphocytic–eosinophilic myocarditis also suggested an immune-mediated drug reaction (SED-13, 1103) (SEDA-22, 406).

Aldesleukin-induced cardiac eosinophilic infiltration has been reported (27).

- After 25 days of treatment with continuous aldesleukin infusion (up to 150 000 units/kg/day) for stage IV Hodgkin's disease, a 26-year-old woman had increased fatigue, tachycardia, hypotension, and hypothermia. Echocardiography showed bilateral intraventricular masses. Her maximal absolute eosinophil count was 11.4×10^9/l and the platelet count was 17×10^9/l. Despite aldesleukin withdrawal, her condition deteriorated and she died. Postmortem examination showed biventricular thrombi and prominent eosinophilic infiltration of the endomyocardium.

Of 10 subsequent patients who received prolonged infusions of aldesleukin and were monitored by echocardiography, one developed asymptomatic changes in cardiac function, with features suggestive of early thrombus formation and a reduced ejection fraction during weeks 6–8. The maximal absolute eosinophil count was 5×10^9/l. These abnormalities resolved on aldesleukin withdrawal.

Conjugates of aldesleukin with polyethylene glycol produce less cardiovascular toxicity (SEDA-20, 333).

Respiratory

Dose-related cough has been reported as the most frequent adverse effect of inhaled aldesleukin (28).

Among 199 patients with metastatic melanoma or renal cell carcinoma treated with high-dose intravenous bolus aldesleukin, there was severe respiratory distress in 3.2% of treatment courses, but intubation was required in only one (24). This is far less common than earlier estimates that 10–30% of patients develop respiratory distress severe enough to warrant mechanical ventilation in 5–20% of cases (4). The improvement may be related to the current strict selection criteria for the evaluation of pulmonary function, limited fluid management strategy, prophylactic antibiotics, and prompt withdrawal of treatment in patients presenting with shortness of breath, rales, or persistent hypoxemia.

Pulmonary features of the adverse effects of aldesleukin include lung opacities, diffuse pulmonary interstitial edema, pleural effusions, alveolar edema, and hypoxemia, with full and rapid recovery after treatment withdrawal (29,30).

Aldesleukin-induced increase in lung capillary permeability or direct cardiac dysfunction is thought to be a likely mechanism of this adverse effect, and a localized vascular leak syndrome, attributed to activation of eosinophils in the lung and subsequent deposition of the eosinophil major basic protein, has also been suggested, as reported in a 49-year-old woman with breast cancer (31).

There is no significant association between pre-existing clinical dysfunction and radiological interstitial edema (30). Very severe adult respiratory distress syndrome requiring double lung transplantation has been reported in one patient (32).

Nervous system

Severe pain resulting from a previously asymptomatic thoracic spine metastasis has been attributed to aldesleukin in a 64-year-old man with metastatic renal cell carcinoma (33).

Fatal acute leukoencephalopathy with brain perivascular foci demyelination (34) and delayed progressive cognitive dysfunction (35) have been reported in isolated cases.

The neurotoxicity of aldesleukin is usually dose-related and can be treatment-limiting (36).

Sensory systems

Transient episodes of amaurosis or scotomata, both of which recurred after aldesleukin rechallenge, have been described (37). Three other patients had visual phenomena, including diplopia, scotomata, and palinopsia during treatment, which resolved on withdrawal of aldesleukin (38).

Psychological, psychiatric

Aldesleukin can cause moderate impairment of cognitive function, with disorientation, confusion, hallucinations, sleep disturbances, and sometimes severe behavioral changes requiring transient neuroleptic drug administration (39–41). Some of the cognitive deficits mimicked those observed in dementias, such as Alzheimer's disease. Several studies have also shown increased latency and reduced amplitude of event-related evoked potentials in patients with cognitive impairment (41,42). Other infrequent adverse effects included paranoid delusions, hallucinations, loss of interest, sleep disturbances or drowsiness, reduced energy, fatigue, anorexia, and malaise. Coma and seizures were exceptionally noted.

© 2006 Elsevier B.V. All rights reserved.

Symptoms occurred within 1 week of treatment and complete recovery was usually noted after aldesleukin withdrawal.

In 10 patients with advanced tumors, low-dose subcutaneous aldesleukin produced significant psychological changes; increased depression scores, psychasthenia, and conversion hysteria were the most common findings (43).

The short-term occurrence of depressive symptoms has been investigated by using the Montgomery and Asberg Depression Rating Scale (MADRS) before and after 3 and 5 days of treatment in 48 patients without a previous psychiatric history and treated for renal cell carcinoma or melanoma with aldesleukin alone ($n = 20$), aldesleukin plus interferon alfa-2b ($n = 6$), or interferon alfa-2b alone ($n = 22$) (44). On day 5, patients in the aldesleukin groups had significantly higher MADRS scores, whereas there were no significant changes in the patients who received interferon alfa-2b alone. Eight of 26 patients given aldesleukin and only three of 22 given interferon alfa-2b alone had severe depressive symptoms. Depressive symptoms occurred as early as the second day of aldesleukin treatment and were more severe in the patients who received both cytokines. Early detection of mood changes can be useful in pinpointing patients at risk of subsequent severe neuropsychiatric complications.

Neuropsychiatric symptoms are less frequent with subcutaneous aldesleukin (4). No predictive or predisposing factors have been clearly identified. Whether a direct effect of aldesleukin on neuronal tissues, an increased vascular brain permeability with a subsequent increased brain water content, or an aldesleukin-induced release of neuroendocrine hormones (beta-endorphin, ACTH, or cortisol), accounted for these effects, is unknown. A possible immune-mediated cerebral vasculitis has also been reported in one patient (SEDA-20, 334).

Endocrine

Various hormonal and metabolic effects of aldesleukin are temporally related to hypotension. Transient serum rises in ACTH, cortisol, beta-endorphin, adrenaline and noradrenaline have been found, whereas there were no significant changes in the plasma concentrations of several other hormones (4).

An acute episode of adrenal insufficiency secondary to adrenal hemorrhage occurred in one patient receiving aldesleukin (45).

Thyroid

Since the first reports of hypothyroidism, a number of studies have reported the occurrence of thyroid dysfunction in patients receiving aldesleukin alone or in combination with LAK cells, interferon alfa, interferon gamma, or tumor necrosis factor alfa (SED-13, 1104) (46). Symptoms were usually observed after 2–4 months of treatment (47–49), and mostly consisted of moderate hypothyroidism, which resolved after immunotherapy withdrawal or thyroxine treatment (49,50). Patients treated with aldesleukin plus interferon alfa more commonly developed biphasic thyroiditis with subsequent hypothyroidism or hyperthyroidism (50–53).

The possibility of a positive correlation between the development of thyroid dysfunction and the probability of a favorable tumor response has been debated (47,49,54). The incidence of thyroid dysfunction did not correlate with the dose or the underlying disease, but increased with treatment duration (46). In a large survey of 281 cancer patients receiving low-dose (72 000 IU/kg) or high-dose (720 000 IU/kg) aldesleukin, up to 41% of previously euthyroid cancer patients developed thyroid dysfunction (55). Combined immunotherapy was also associated with more frequent thyroid disorders. Aldesleukin plus interferon alfa produced thyroid dysfunction in 20–91% of patients (46), and the incidence of laboratory thyroid dysfunction reached 100% in patients given five or six cycles of both cytokines (51). Aldesleukin plus interferon alfa also tended to be a risk factor for the development of biphasic thyroiditis (49).

Female sex and the presence of antithyroid antibodies correlated significantly with the development of thyroid disease (49,56). This, together with the findings of strong expression of HLA-DR antigens on thyrocytes or the presence of mononuclear cell infiltrates on histological examination of the thyroid, makes an autoimmune phenomenon likely (49,52). However, a possible direct effect of immunotherapy on thyroid hormonal function has also been suggested in patients who had no detectable thyroid antibodies. There was a significant decrease in TSH concentration, while thyroid autoantibodies were not significantly raised (57).

Metabolism

Reversible insulin-dependent diabetes mellitus has been described in a predisposed patient (SEDA-20, 334).

Aldesleukin can cause lipid disorders. Recurrent and marked hypocholesterolemia with reduced high- and low-density lipoproteins, and slight increases in plasma triglycerides have been observed after high-dose aldesleukin (SEDA-21, 375) (4).

Nutrition

Severe, but reversible hypovitaminosis C was noted in patients receiving high-dose aldesleukin plus LAK cells (58).

Hematologic

Hematological adverse effects of aldesleukin typically included transient anemia, thrombocytopenia, eosinophilia, neutropenia, extreme lymphopenia, and rebound lymphocytosis (4,59). Transient suppression of hemopoiesis by secondary cytokines, peripheral platelet destruction, and increased endothelium margination of lymphocytes are possible mechanisms.

Hematological toxicity was analysed in 199 patients treated with a high-dose intravenous bolus aldesleukin regimen for metastatic melanoma or renal cell carcinoma (60). Anemia requiring transfusions was noted in 14% of all treatment courses and severe thrombocytopenia occurred in 2.2%, with three patients suffering from serious hemorrhages. Severe leukopenia was infrequent and not associated with infectious episodes. Early transient lymphopenia (93% reduction) was followed by rebound lymphocytosis up to 198% above baseline values. Except for severe thrombocytopenia, treatment withdrawal was

© 2006 Elsevier B.V. All rights reserved.

not required in this study. Other investigators found that reductions in platelet count correlated with a significant increase in ex vivo platelet functional activity, but there were no episodes of bleeding or thrombosis (61).

Aldesleukin can produce sustained eosinophilia, possibly mediated by interleukin-5 or GM-CSF, but this was not associated with allergic reactions (62).

In 42 patients with advanced cancer treated with aldesleukin and lymphokine-activated killer cells from autologous lymphocytes, there were reduced numbers of circulating erythroid and granulocyte/macrophage progenitors, with recovery after withdrawal (63). Patients developed severe anemia (partly due to phlebotomy, cytopheresis, and hemodilution), thrombocytopenia, lymphopenia, and eosinophilia, with mild neutropenia and rebound lymphocytosis after treatment was stopped.

The severity of hematological disorders was not affected by previous chemotherapy for metastatic melanoma or renal cell carcinoma and there was no correlation with response to treatment (60). However, others have found that moderate to severe dose-related thrombocytopenia occurred particularly in patients previously treated with cytotoxic agents (64). Subcutaneous low-dose aldesleukin therapy reduced the frequency and intensity of hematological toxicity, and the combination of aldesleukin plus interferon alfa produced either moderate additional toxicity or no significant enhancement (65).

Most patients develop significant, but promptly reversible coagulation disorders with prolongation of the partial thromboplastin time (the most frequent effect), hypoprothrombinemia, and reduced functional concentrations of several clotting factors II, IX, X, XI, and XII (60,66,67). No clear mechanism of aldesleukin-induced coagulopathy has been identified, and the efficacy of prophylactic vitamin K has been disputed (67). Other data suggest that aldesleukin may activate the coagulation and fibrinolytic system (64,68), but the clinical relevance of these findings is not clear.

A mean splenic index increase of 64% was found on computed tomography after a mean of 66 days of aldesleukin treatment for non-hematological malignancies (69). Splenomegaly persisted after an average of 215 days after the completion of aldesleukin treatment and was not associated with tumor progression.

Mouth and teeth

Oral effects of aldesleukin include xerostomia with reversible salivary gland hypofunction, a burning sensation in the mouth, taste disorders, mucosal atrophy, mucositis, glossitis, and ulcerative lesions (70,71).

Gastrointestinal

Minor gastrointestinal adverse effects, that is anorexia, nausea, vomiting, and diarrhea, were noted in about 80% of patients (4).

Incidental case reports included symptomatic exacerbation of Crohn's disease (72) and transient painful swelling of the appendix (SEDA-21, 376).

Severe and sometimes fatal intestinal complications have been described in 1.3–7% of patients receiving aldesleukin alone or in combination with LAK cells or interferon alfa, including intestinal ischemia, bowel ulceration or perforation, and colosplenic fistula (73–75). It has been suggested that severe diarrhea may be an indicator of subsequent colonic ischemia (75).

Liver

Mild liver dysfunction, hypophosphatemia, and hypomagnesmia are the most common laboratory abnormalities caused by aldesleukin (76,77). About 20% of patients develop mild to severe intrahepatic cholestasis with reversible and dose-dependent rises in bilirubin and alkaline phosphatase while serum transaminases were only slightly increased (4,78). Recurrence of cholestasis after aldesleukin rechallenge was not always observed (79). The mechanism of aldesleukin-induced intrahepatic cholestasis is unknown, but it might be mediated by activation of Kupfer cells and the subsequent release of cytokines (SEDA-20, 335). Focal fatty infiltrates of the liver mimicking metastases were also reported in a patient receiving both aldesleukin and a short course of interferon alfa (80).

Biliary tract

Gall-bladder changes have been reported in patients given aldesleukin and should be promptly recognized to avoid unnecessary intervention in symptomatic patients (SED-13, 1105) (81). Further systematic ultrasonographic examination in 25 HIV-infected patients treated with low-dose aldesleukin (6–18 MU/day) confirmed that most patients had gall-bladder wall thickening (80%), abnormal echo texture (64%), and intramural fluid (52%) or pericholecystic fluid (20%) (82). The frequency and severity of ultrasonographic abnormalities correlated with a higher dose of aldesleukin, as did complaints of right upper quadrant pain (24%). Although these findings mimicked those observed with acute cholecystitis, clinical symptoms and ultrasonographic abnormalities rapidly reversed after aldesleukin withdrawal or between two cycles.

Aldesleukin-induced cholecystopathy has been described in patients with cancer and was fully investigated in seven of 29 HIV-infected patients (81). Right upper quadrant abdominal pain and gallbladder wall thickening at sonography developed after 4–5 days of treatment and spontaneously resolved after withdrawal or dosage reduction. Similar symptoms recurred after renewed administration of aldesleukin. Although suggestive of acalculous cholecystitis, surgery is not required because this disorder is usually benign.

Pancreas

Acute pancreatitis has been described after high-dose bolus aldesleukin therapy (83).

Urinary tract

The renal toxicity associated with aldesleukin is dose-related. It manifests as uremia, oliguria, fluid retention, and pronounced renal tubular sodium reabsorption (77). No evidence of tubular dysfunction has been found. There is reduced renal plasma flow associated with reduced renal prostaglandin synthesis and increased plasma renin activity, which may explain the mechanism (84).

© 2006 Elsevier B.V. All rights reserved.

Oliguria or anuria, and increased serum creatinine concentrations occurred in over 90% of patients receiving high-dose aldesleukin (4).

Proteinuria, ranging in degree from traces to a frank, but reversible nephrotic syndrome (85,86), was sometimes observed, and a possible role of contaminants has been discussed (87).

In 199 patients with metastatic melanoma or renal cell carcinoma with high-dose intravenous bolus aldesleukin, severe oliguria, hypotension, and weight gain were frequent, and raised serum creatinine concentrations (mean peak 2.7 mg/dl) were the cause of treatment withdrawal in 13% of cycles (88). There were also various changes on urinalysis. The highest creatinine concentrations were found in patients with renal carcinoma and in elderly, male, or nephrectomized patients. There was no evidence of any long-term renal defect, and renal dysfunction was therefore not considered to be a treatment-limiting factor provided that patients were carefully managed for hypotension or oliguria.

It has been suggested that low-to-intermediate doses of aldesleukin alone or associated with interferon alfa may be safer under outpatient conditions (5). Patients over 60 years of age and individuals with previously raised serum creatinine concentrations have been thought to be likely to have longer-lasting and more severe renal impairment, but neither previous nephrectomy nor the interval between nephrectomy and initiation of aldesleukin therapy were associated with a higher risk of renal insufficiency (4).

A prerenal mechanism secondary to the vascular leak syndrome is commonly involved in the pathophysiology of acute renal insufficiency. In addition it has been suggested that a direct intrinsic intrarenal effect of aldesleukin with a higher than expected reduction in glomerular filtration rate or tubular dysfunction (85,89) is involved. Several isolated cases of acute interstitial or tubulointerstitial nephritis with predominant T lymphocyte infiltration of the kidneys (90–92) and the exacerbation of a subclinical IgA glomerulonephritis (93) suggested altered cell-mediated immunity.

Risk factors for renal dysfunction have been analysed in 72 patients with metastatic renal cell cancer treated with high-dose aldesleukin (18 MU/m^2/day), interferon alfa (5 MU/m^2/day), and lymphokine-activated killer lymphocytes (94). There was some type of renal dysfunction in 97%, of whom 69% developed renal toxicity of grade 2 (creatinine 260–525 μmol/l) or grade 3 (creatinine 525–1050 μmol/l). Although renal function commonly resolved between successive treatment courses, six patients had a persistently raised creatinine concentration (more than 20% above baseline). Among the various potential risk factors, a multivariate analysis showed that the significant risk factors for severe renal dysfunction were male sex, pre-treatment hypertension, and sepsis during treatment.

Skin

Cutaneous reactions to aldesleukin generally comprise pruritus, flushing, mild to moderate erythematous macular and desquamative eruptions, while generalized erythroderma or photosensitivity have occasionally been observed (95). The severity was not dose-dependent and did not correlate with other systemic reactions. Histological and immunopathological examination of the skin showed mild infiltrates of activated T helper lymphocytes and increased expression of HLA-DR and intercellular adhesion molecule-1 on keratinocytes and endothelial cells, and a possible role of interferon gamma has been suggested (96–98). Other adverse effects included erosions in surgical scars, multiple superficial cutaneous ulcers, and telogen effluvium (95).

Injection site reactions have been noted after subcutaneous aldesleukin (SEDA-21, 376). Localized lobular panniculitis after subcutaneous injections was further exacerbated by intravenous aldesleukin in one patient (99).

An unusually high incidence of skin erythema (70–85%) was noted in patients who received aldesleukin after autologous bone marrow transplantation. Histological examination showed features of cutaneous graft-versus-host disease or T cell epidermal infiltrates, but cutaneous toxicity was not reproduced in patients receiving low-dose aldesleukin (100,101).

The potential role of localized vertebral palliative radiotherapy before aldesleukin treatment was denied, since the area of cutaneous toxicity was broader than the irradiated field.

Aldesleukin given alone or aldesleukin plus interferon alfa produced a high incidence of vitiligo in patients with metastatic melanoma, irrespective of whether or not they had received chemotherapy (102–104). A possible correlation between aldesleukin-induced vitiligo and a favorable tumor response was found (102) but has also been disputed (103).

Some isolated reports have given rise to the suggestion that aldesleukin can exacerbate cutaneous reactions compatible with an immune-mediated phenomenon (105). Case reports included recurrence of quiescent pemphigus vulgaris, fatal dermatitis exfoliativa compatible with pemphigus vulgaris, exacerbation of localized or widespread psoriasis, acute reactivation of eczema, rapid progression of scleroderma with myositis, and leukocytoclastic vasculitis (SED-13, 1106) (SEDA-20, 335) (SEDA-21, 376).

Immunostimulation due to aldesleukin may have also played a role in the occurrence or unmasking of erythema nodosum, linear IgA bullous dermatosis, and life-threatening extensive bullous skin eruption or toxic epidermal necrolysis (SED-13, 1106) (SEDA-21, 376) (106).

Because aldesleukin stimulates T cells, it has been suggested to have favored the development of successive episodes of multifocal fixed drug eruption in response to chemically unrelated drugs (paracetamol, ondansetron, and tropisetron) in a 43-year-old patient (107).

Musculoskeletal

Joint or muscle pains have sometimes been reported in patients receiving aldesleukin, as has shoulder arthralgia with normal radiography and scintigraphic imaging consistent with bilateral synovitis (4,108).

Rare reports have suggested that aldesleukin can reactivate or cause rheumatoid arthritis (109) or cause necrotizing myositis with positive antinuclear antibodies (SEDA-20, 335).

Interstitial edema and local fluid retention resulting from increased vascular permeability has been suggested to

© 2006 Elsevier B.V. All rights reserved.

cause unilateral or bilateral carpal tunnel syndrome with sensorimotor median neuropathy (SEDA-20, 334) (110).

Sexual function

A reversible reduction in testosterone concentrations has been observed in men who have received aldesleukin (4).

Immunologic

Aldesleukin was thought to be the triggering factor in the occurrence of sarcoidosis in a 36-year-old patient with AIDS stabilized for a long time by highly active antiretroviral therapy (111).

There have been very few reports of angioedema in patients receiving aldesleukin (112).

Interleukin antibodies

Recombinant aldesleukin-binding antibodies were detected in the half of 205 patients with metastatic cancer but there were neutralizing antibodies in only 7% (113). No significant difference in incidence was found between subcutaneous and continuous intravenous administration. In another study, none of the patients receiving aldesleukin alone developed neutralizing antibodies, whereas 18% of patients treated with aldesleukin and interferon alfa-2b had antibodies (114). Whatsoever, the clinical relevance of recombinant aldesleukin-neutralizing antibodies has not been accurately evaluated and a loss of response was apparently documented in only one patient (115).

Autoimmune disorders

Aldesleukin sometimes causes acute exacerbation of latent autoimmune disease, as has been further exemplified by the following description, which also included the first report of aldesleukin-induced myasthenia gravis (116).

- A 64-year-old man with non-insulin-dependent diabetes was given 14 large doses of aldesleukin (600 000 IU/kg every 8 hours) for metastatic renal cell carcinoma. One week after the completion of the first cycle he had a reversible episode of hyperosmolar, non-ketotic hyperglycemia, and insulin was started. A second cycle 3 months later was associated with hypotension, mild weakness of the right shoulder, and increased activity of creatine kinase (CK)-MB fraction. After four doses of the third cycle he again had hypotension and a raised CK-MB fraction. Two weeks later, he developed typical features of myasthenia gravis and required mechanical ventilation. Acetylcholine receptor antibodies were found and there was an inflammatory primary myositis on muscle biopsy. He gradually recovered with prednisone, pyridostigmine, and daily insulin.

In this case, which was marked by three autoimmune complications (insulin-dependent diabetes mellitus, myositis, and myasthenia gravis) in a single patient, a retrospective analysis of the patient's serum before aldesleukin therapy showed the presence of antibodies against glutamic acid decarboxylase, insulin, islet cell antigen, and striated muscle, but was negative for acetylcholine receptor antibodies. Immune stimulation by aldesleukin was therefore thought to have caused broken tolerance to self-antigens and enhanced latent autoimmunity.

Infection risk

Clinically relevant infectious complications occurred with an incidence of 10–40% after intravenous aldesleukin (4). A retrospective study showed a 13% incidence of confirmed bacterial infections during 935 treatment courses of high-dose aldesleukin; opportunistic infections were not more frequent (117). The most commonly isolated pathogens were *Staphylococcus aureus*, *Staphylococcus epidermidis*, and *Escherichia coli*. Documented infections affected mostly the catheter site or the urinary tract. Infections were usually noted during the first (68%) or second (21%) course of aldesleukin therapy, that is 4–9 days and 13–18 days after the start of treatment. Bacterial sepsis was mostly related to the use of central venous catheters and fatal septic shock was rarely recorded. There was also an increased incidence of infectious complications in patients receiving subcutaneous aldesleukin plus interferon alfa (118), but these findings were not confirmed in patients who received subcutaneous aldesleukin alone (119,120). Previous colonization of the skin with *S. aureus* and skin desquamation increased the risk of nosocomial bacteremia (117). Age, underlying tumor, source, dose and duration of intravenous aldesleukin, or the concomitant use of LAK cells were not risks factors, and severe neutropenia was not associated with bacteremia. The prophylactic use of antibiotics and systematic screening led to a significant reduction in the frequency of infections, from 22 to 7% of patients over 3 years (117).

The mechanism of these complications is not fully understood. A reduction in neutrophil chemotaxis, superoxide production, and/or neutrophil Fc receptor expression have been suggested to be involved. Impaired cell-mediated or humoral immune responses have also been shown after high-dose aldesleukin, but the clinical consequences of these findings are unknown.

Long-Term Effects

Tumorigenicity

Isolated case reports have described relapses of acute myeloid leukemia or the proliferation of leukemic blasts cells with phenotypic changes in a patient with acute myelocytic leukemia; a high percentage of blasts expressed the CD25 antigen in both reports (121,122). A reversible increase in peripheral monoclonal B cell lymphocyte count in a patient with B cell lymphocytic lymphoma and Hodgkin's disease in a woman receiving aldesleukin for metastatic melanoma were also documented in single reports.

Drug–Drug Interactions

General

The potential of aldesleukin to participate in drug interactions has been investigated in 18 patients who underwent surgical resection of hepatic metastases (123). Compared with seven control patients who did not

© 2006 Elsevier B.V. All rights reserved.

receive aldesleukin before surgery, six patients who received 9 or 12 MU/m^2 from days 7–3 before hepatectomy had a significant fall in the activities of total cytochromes and several mono-oxygenases. No such effect was found in five patients treated with 3 or 6 MU/m^2 before hepatectomy. This suggests that high-dose aldesleukin might cause drug interactions by inhibiting hepatic drug metabolism.

Contrast media

More frequent allergic reactions to iodinated and non-ionic contrast media injection were observed when radiological examination was performed within a period ranging from 2 to 6 weeks up to 2 years after withdrawal of aldesleukin in patients who had previously tolerated contrast media well (124,125). These reactions usually appeared within 1–4 hours after contrast media injection, but delayed reactions up to 24 hours were sometimes noted. The most frequent symptoms were diarrhea, vomiting, influenza-like symptoms, skin rash, pruritus, and facial edema, and rarely included hypotension, dyspnea, and oliguria. The overall incidence was 5–15%, but as high as 28% of patients receiving aldesleukin via arterial infusion (126). This incidence is therefore about 3–4 times higher than in the general population undergoing contrast media examination. "Recall" reactions to aldesleukin have been suggested as an explanation, since these complications more closely resemble immediate adverse effects to aldesleukin than typical contrast media reactions. Putative enhancement of the immune response to iodine-containing contrast media after aldesleukin has also been suggested.

Cytotoxic drugs

An unexpected high incidence of type I allergic reactions to cisplatin and dacarbazine has been observed, several hours after administration to patients on a combination of aldesleukin and interferon alfa (127). The reactions occurred at least after the first cycle and increased in incidence thereafter, suggesting that immunotherapy can sensitize patients to several chemotherapeutic agents.

In a phase III trial in 190 patients with metastatic melanoma, sequential chemotherapy with dacarbazine, cisplatin, and vinblastine plus interferon alfa and aldesleukin modestly increased the response rates and produced considerably more frequent and severe adverse effects than chemotherapy alone (128). In particular, severe episodes of anemia and thrombocytopenia that required blood or platelet transfusions were 2–6 times more frequent in the chemotherapy group.

Morphine

Acute encephalopathy with typical signs of morphine intoxication occurred in a patient taking aldesleukin (129).

Non-steroid anti-inflammatory agents

Non-steroidal anti-inflammatory agents used to reduce fever and other aldesleukin adverse effects can theoretically potentiate aldesleukin nephrotoxicity by inhibiting prostaglandin synthesis. However this effect was deemed unlikely by several authors (85).

Aldose reductase inhibitors

General Information

Aldose reductase inhibitors (SEDA-19, 397) (SEDA-20, 399) (SEDA-21, 447) (SEDA-22, 477) have been developed for the treatment of secondary complications in diabetes (1,2). They include alrestatin, benurestat, epalrestat, fidarestat, imirestat, lidorestat, minalrestat, ponalrestat, ranirestat, risarestat, sorbinil, tolrestat, zenarestat, and zopolrestat (all rINNs).

The aldose reductase inhibitors inhibit or reduce secondary complications induced by diabetes, specifically in tissues in which glucose uptake is not insulin-dependent (probably neural tissue, the lens, and glomeruli). Many of them (including alrestatin, imirestat, ponalrestat, and sorbinil) have been used in clinical trials, but have been withdrawn because of adverse effects or lack of effect (2). Their main adverse effects include fever, nausea, diarrhea, increases in liver enzymes, skin rashes, including toxic epidermal necrolysis and Stevens–Johnson syndrome, marked thrombocytopenia, lymphadenopathy, splenomegaly, and adult respiratory distress syndrome.

Tolrestat was withdrawn because of deaths from fatal hepatic necrosis (3) and poor efficacy in clinical trials. Sorbinil was withdrawn because of hypersensitivity reactions in more than 10% of patients.

Organs and Systems

Gastrointestinal

Nausea, vomiting, abdominal fullness, and diarrhea are reported with aldose reductase inhibitors (1).

Alemtuzumab

See also Monoclonal antibodies

General Information

Alemtuzumab (campath-1H) is a humanized monoclonal antibody specific for the CDw52 antigen, present on cell membranes of lymphocytes and monocytes. It has been used for treatment of patients with rheumatoid arthritis and vasculitis, is being investigated for the treatment of chronic lymphocytic leukemia, and has been used to deplete circulating lymphocytes in patients with multiple sclerosis (1). In 2001, alemtuzumab was approved in Europe for the treatment of chronic B cell lymphocytic leukemia that had been treated previously with alkylating agents and was refractory to fludarabine (2). It has also been used for induction of immunosuppression/tolerance in liver transplant recipients (3,4) and kidney/pancreas transplant recipients (5).

The major adverse effects (fever, nausea, skin rash, and hypotension) may well be related to the release of cytokines as a consequence of lysis of the target lymphocytes (6). Of four patients treated with alemtuzumab, three developed antibodies against it, but without affecting the plasma concentrations and without obvious clinical consequences. Other adverse effects have included mild renal impairment and transient thrombocytopenia.

Organs and Systems

Respiratory

Of 22 patients, median age 61 years, who had received a median of three previous types of therapy for mycosis fungoides or Sézary syndrome and were given alemtuzumab in increasing doses (from 3 to 30 mg three times a week for 12 weeks), 11 had no infectious complications, one had fatal pulmonary aspergillosis 2.5 months after the end of treatment, and another contracted fatal *Mycobacterium* pneumonia 10 months after the end of treatment (7).

Endocrine

Nine of 27 patients with multiple sclerosis developed antibodies against the thyrotropin receptor and carbimazole-responsive autoimmune hyperthyroidism after a 5-day pulse of alemtuzumab, a finding that was not reported in patients treated for other disorders (1).

Hematologic

In 50 patients with advanced, low-grade, non-Hodgkin's lymphoma alemtuzumab produced marked lymphopenia and neutropenia, which were the probable cause of frequent severe infections (8). Seven patients developed opportunistic infections and nine had bacterial septicemia; three patients died from infectious complications. Severe resistant autoimmune thrombocytopenia has also been noted in one patient, but the evidence that alemtuzumab was involved was limited (9).

Immunologic

Reactivation of cytomegalovirus is a frequent complication during treatment with alemtuzumab in patients with chronic lymphocytic leukemia (10), and other organisms are occasionally described.

- A 52-year-old man with B cell chronic lymphocytic leukemia had weight loss and a steadily rising blood lymphocyte count (11). He received alemtuzumab as first-line treatment as part of a clinical trial. After 12 weeks the leukemia completely remitted. Three years later he received chlorambucil for progressive disease and had a partial remission. After another 2 years his chemotherapy regimen was change to fludarabine and cyclophosphamide. After a further year his disease became rapidly progressive, with anemia, splenomegaly, and lymphadenopathy. Alemtuzumab was reintroduced and standard prophylaxis treatment was started with co-trimoxazole, valaciclovir, and fluconazole. After 8 weeks he developed fever up to 39°C. There was no evidence of bacterial or viral infection. His general condition worsened rapidly and he showed signs of acute hepatitis, renal insufficiency, disseminated intravascular coagulation, and finally respiratory failure. He died 14 days after the start of the fever. Adenovirus 5 was recovered from the lung, spleen, liver, and blood.

Among 18 patients with chronic lymphocytic leukemia, one with a long-lasting lymphocytopenia died 3 months after treatment, owing to progressive multifocal leukoencephalopathy; papovavirus was isolated from the cerebrospinal fluid (12).

Alfadolone and alfaxolone

See also General anesthetics

General Information

Alfadolone and alfaxolone are two steroid anesthetics that were used in combination. However, the mixture has been withdrawn because of safety considerations regarding the solvent used, polyethoxylated castor oil (Cremophor EL), which can cause non-IgE-mediated anaphylactic (anaphylactoid) reactions (SED-10, 189) (1).

Alfentanil

General Information

Alfentanil is a potent short-acting opioid used in anesthesia. Beside its effects on opioid receptors, there is some evidence that it may affect acetylcholine, since intrathecal neostigmine produced a dose-dependent increase in the effect of alfentanil (SEDA-22, 3). Its rapid onset and short duration of action make alfentanil suitable for use in day care, although it is important to treat adverse effects before discharge.

Alfentanil is an ideal analgesic for focused and ambulatory interventions. In a prospective, uncontrolled study in three consecutive groups of outpatients undergoing shock-wave lithotripsy, group 1 (152 patients) had an induction dose of a combination of propofol 0.8 mg/kg and alfentanil 8 μg/kg; in group 2 (78 patients) and group 3 (250 patients), the induction dose was reduced by 20% (1). For all three groups the maintenance dose was a mixture of propofol 0.25 mg/kg and alfentanil 5 μg/kg given via a PCA device with a lock-out time of 5 minutes. In groups 1 and 2 the lithotripter was equipped with a standard electromagnetic shock-wave emitter (the EMSE 200), while in group 3 an upgraded EMSE F150 was used. Analgesic consumption was lower in the patients treated with the EMSE 150; groups 2 and 3, with a 20% reduction in induction dose, did not compensate by using more PCA. Groups 2 and 3 also had a significant reduction in the incidence of oxygen desaturation. The intravenous administration of a mixture of alfentanil and propofol, using the updated EMSE F150 device as in group 3, was therefore considered to be safe and reliable, with good patient tolerance and rapid recovery.

In a non-comparative study of 24 consecutive outpatients undergoing extracorporeal shock-wave lithotripsy, alfentanil (initial dose 15 μg/kg followed by 0.38 μg/kg/minute) and propofol (initial dose 1 mg/kg followed by 59 μg/kg/minute) were used for sedation (2). Both alfentanil and propofol were effective and safe, provided respiratory and cardiovascular parameters were routinely monitored.

Organs and Systems

Cardiovascular

When alfentanil 30 μg/kg was given to six healthy volunteers there were no clinical changes in respiratory or cardiovascular function (SEDA-16, 78).

Bradycardia often occurs with the combination of a potent short-acting opioid with suxamethonium during induction of anesthesia, and alfentanil has been reported to have caused sinus arrest in three patients (SEDA-17, 79) (3).

In one study alfentanil was particularly likely to cause hemodynamic instability and myocardial ischemia; however, drug interactions or the dosage regimen may have been responsible (4).

Respiratory

Significant respiratory depression occurs after alfentanil in doses in excess of 1000 μg and delayed-onset respiratory depression has been reported. Used as a general anesthetic for urgent cesarean section, alfentanil can cause marked neonatal respiratory depression, which is reversible with naloxone (SEDA-16, 78).

- A 35-year-old man developed recurrent respiratory depression after being given alfentanil 0.0125 mg/kg for vitreoretinal surgery (5). General anesthesia was induced with a combination of propofol, rocuronium, and alfentanil, subsequent inhalation of isoflurane, and three additional doses of alfentanil (total 0.04 mg/kg over 2 hours). The pulse oxygen saturation fluctuated and was as low as 89% 180 minutes after extubation.

© 2006 Elsevier B.V. All rights reserved.

The severity of respiratory depression with alfentanil has been assessed in 49 patients undergoing abdominal hysterectomy under general anesthetic, who were randomly allocated to three groups (6). Group 1 did not receive alfentanil during surgery, group 2 received alfentanil 30 μg/kg, and group 3 received a bolus dose of alfentanil 10–20 μg/kg and an alfentanil infusion increasing in increments of 0.25–0.5 mg/kg/minute. In this randomized double-blind study alfentanil had respiratory depressant effects (measured by plethysmography and pulse oximetry), in one patient in group 1 and three each in groups 2 and 3, but there were no cases of clear-cut recurrent respiratory depression.

Nervous system

Increased intracranial pressure in normal pressure hydrocephalus patients has been described (SEDA-17, 79). An acute dystonic reaction has been reported in an untreated patient with Parkinson's disease (SEDA-16, 78).

Simultaneous scalp and depth electrode recordings were performed on five patients with complex partial epilepsy who underwent alfentanil anesthesia induction before depth electrode removal (7). Five equal bolus doses of alfentanil 100 μg were given to each patient at 60-second intervals (total dose 500 μg). Epileptiform activity was increased in three of the five, but without clinical evidence of seizure activity.

Gastrointestinal

Alfentanil is associated with a high incidence of nausea and vomiting. Droperidol can reduce emetic symptoms but moclobemide does not (SEDA-17, 79).

- A 30-year-old woman with multiple body injuries required five general anesthetics in under 7 days for reconstructive surgery and dressing changes. In order to avoid further general anesthesia she was given a target-controlled infusion of alfentanil in 50 ml of 0.9% sodium chloride (a total dose of 5 mg over 35 minutes). There was one self-limiting episode of nausea with no vomiting. Oxygen saturation was 93–98% on air. There were no episodes of hypotension, cardiac dysrhythmias, or sedation (8).

Musculoskeletal

Muscular rigidity involving many muscle groups has been described with alfentanil (SEDA-12, 62).

Immunologic

A possible hypersensitivity reaction to alfentanil was reported in an atopic 13-year-old girl who developed life-threatening bronchospasm and confluent urticarial wheals (9).

Second-Generation Effects

Fetotoxicity

Alfentanil 10 μg/kg in normal parturients does not reduce Apgar scores, but a higher dose (15–30 μg/kg) is recommended for attenuation of the "stress" response in nonpregnant patients. In a randomized, placebo-controlled, double-blind study alfentanil was used in 40 patients in a dose of 10 μg/kg 1 minute before induction of anesthesia in 40 uncomplicated cesarean deliveries to determine whether it would reduce the maternal stress response after tracheal intubation without subsequent neonatal depression (10). There was a small but significant improvement in maternal hemodynamic stability in the alfentanil group at the expense of early but transient neonatal depression.

Susceptibility Factors

Age

Care is needed when alfentanil is used in the elderly, in whom the elimination of alfentanil is slower (11).

Other features of the patient

Recovery times were shorter in smokers than in nonsmokers (12).

Alfentanil is 90% protein bound, and variability in protein binding can affect its actions. In 10 patients who received standardized anesthesia and alfentanil to a target concentration of 150 ng/ml for postoperative analgesia interindividual variation in plasma protein binding explained at least 39% of the interindividual variability in alfentanil requirements (13). There was a high incidence of adverse effects: seven patients had emesis and five had urinary retention.

Drug–Drug Interactions

Benzodiazepines

Muscle rigidity after high-dose opioid can be reduced by the benzodiazepines midazolam and diazepam (SEDA-19, 82).

Diltiazem

Diltiazem reduces the elimination of alfentanil and prolongs the time to tracheal extubation (SEDA-21, 86); erythromycin may do the same (14).

Fluconazole

There has been a double-blind randomized control study of the effect of the antifungal drug fluconazole 400 mg on the pharmacokinetics and pharmacodynamics of intravenous alfentanil (15). Fluconazole given either orally or intravenously 1 hour before alfentanil 20 μg/kg intravenously caused a significant doubling of the half-life, by inhibition of CYP3A4, which metabolizes alfentanil. Intravenous and oral fluconazole both increased alfentanil-induced respiratory depression by reducing the respiratory rate by 10–15% compared with alfentanil alone. Alfentanil should therefore be given cautiously to patients taking fluconazole and the authors suggested that such patients require 60% less alfentanil for maintenance of analgesia, irrespective of the mode of administration of the antifungal drug.

Ketamine

Eight healthy men participated in a 2-day study in which alfentanil was given to a constant plasma concentration of

© 2006 Elsevier B.V. All rights reserved.

50 ng/ml followed by the addition of ketamine at escalating plasma concentrations of 50, 100, and 200 ng/ml (16). The resting hypoventilation induced by alfentanil was antagonized by ketamine 200 ng/ml, but not 50 ng/ml.

Reserpine

The combination of reserpine with alfentanil is reported to cause ventricular dysrhythmias (SEDA-17, 79).

Tranylcypromine

There is no interaction of alfentanil with the monoamine oxidase inhibitor tranylcypromine (SEDA-17, 79).

Alfuzosin

See also Alpha-adrenoceptor antagonists

General Information

Alfuzosin is a uroselective alpha$_1$-adrenoceptor antagonist used to relieve the symptoms of prostatic hyperplasia (1). Its safety has been investigated in a large prospective 3-year open trial in 3228 patients with benign prostatic hyperplasia. There were no unexpected adverse effects. Only 4.2% of the patients dropped out owing to adverse effects.

In a large database of 7093 patients with lower urinary tract symptoms related to benign prostatic hyperplasia treated for up to 3 years with alfuzosin in general practice, adverse events were reported in a very complex and uninformative way (2). In another paper, the same authors reported on a subcohort of 2829 patients, with special focus on effects on quality of life. Adverse events occurred in 15% of the patients, 1.7% died during the study, and 5.2% had serious effects, which the authors did not detail, but which they stated were not related to treatment. Most adverse effects occurred during the first 3 months of treatment (3). In another database of 3095 Spanish patients taking alfuzosin 5 mg bd for 60 days, adverse events were reported in 3.3% of the patients, and led to drug withdrawal in 1.6%; postural hypotension occurred in 1.8% (4).

Organs and Systems

Nervous system

Dizziness, headache, postural hypertension, and other symptoms familiar from the older alpha-blockers occur primarily during the first 2 weeks of treatment with alfuzosin (1).

Liver

Hepatitis potentially related to alfuzosin has been reported (5).

- A 63-year-old man, who had taken amiloride and alfuzosin for 9 months for hypertension and benign prostatic hyperplasia, became jaundiced. His aspartate transaminase was 3013 IU/l, alanine transaminase 2711 IU/l, alkaline phosphatase 500 IU/l, and total bilirubin 415 μmol/l. Viral causes, autoimmune hepatitis, and biliary obstruction were excluded. After withdrawal of alfuzosin, his liver function tests gradually returned to normal within 6 months.

Immunologic

Dermatomyositis has been attributed to alfuzosin.

- A 75-year-old man, who had taken alfuzosin for 1 year, developed muscle pain and weakness over 4 days,

© 2006 Elsevier B.V. All rights reserved.

accompanied by tenderness and swelling of the deltoid muscles (6). There was erythema, with rash, periungual purpura, and erythematous plaques over the finger joints. Serum CK, LDH, and transaminase activities were raised and ANA was positive. An MRI scan showed findings consistent with inflammation of muscle and a biopsy confirmed the diagnosis of dermatomyositis. Three days after drug withdrawal there was no improvement, so prednisone was started and he recovered within a few days. The temporal relation in this case was weak.

- Dermatomyositis, with typical clinical effects, biochemical tests, electromyography, and muscle biopsy, occurred in a 75-year-old man who had taken alfuzosin for 1 year (7). There was no malignancy and he recovered fully after alfuzosin withdrawal (timing not given).

Algae

General Information

Algae are members of the kingdom Protista. They include Bacillariophyta (unicellular diatoms), Charophyta (freshwater stoneworts), Chrysophyta (photosynthetic, unicellular organisms), Cyanobacteria (photosynthetic bacteria), Dinophyta (dinoflagellates), and the various types of seaweeds.

There are three major groups of seaweeds: the green algae (Chlorophyta), the brown algae (Phaeophyta), and the red algae (Rhodophyta).

Kelp is a general name for seaweed preparations obtained from different species of Phaeophyta (such as *Ascophyllum nodosum*, *Fucus vesiculosus*, *Fucus serratus*, *Laminaria* species, and *Macrocystis pyrifera*). As kelp contains iodine, it occasionally produces hyperthyroidism (1), hypothyroidism, or extrathyroidal reactions, such as skin eruptions. It can also contain contaminants such as arsenic, and bone marrow depression and autoimmune thrombocytopenia have been described in consequence (2).

Anaphylaxis to *Laminaria* has been described (3–5).

Laminaria has been used to induce abortion and can cause uterine rupture especially in primipara.

- A 32-year-old woman in her 25th week of gestation was hospitalized for endouterine fetal death (6). She had had two previous cesarean sections. Cervical dilatation was induced with a Hagar dilator and laminaria tents, and sudden spontaneous and strong contractions led to uterine rupture.

Alimemazine

See also Neuroleptic drugs

General Information

Alimemazine is a phenothiazine derivative with sedative antihistaminic and antimuscarinic effects.

Organs and Systems

Nervous system

Neuroleptic malignant syndrome has been reported with alimemazine (1).

- A 4-year-old girl with damage in the basal ganglia who was receiving increasing doses of alimemazine for sedative purposes developed neuroleptic malignant syndrome. The alimemazine was withdrawn and she received dantrolene and supportive measures, including

© 2006 Elsevier B.V. All rights reserved.

ventilation under sedation and paralysis with midazolam and vecuronium. As her symptoms were unchanged, she was given increasing doses of bromocriptine and improved. A few days after bromocriptine withdrawal, the neuroleptic malignant syndrome recurred and was complicated by cardiorespiratory arrest.

Aliphatic alcohols

See also Disinfectants and antiseptics

General Information

The lower aliphatic alcohols (ethanol, isopropanol, 2-propanol, *N*-propanol, and 1-propanol) are widely used for skin antisepsis. In appropriate concentrations, these alcohols are bactericidal to most of the common pathogenic bacteria, but some rare species survive and can grow, especially since these alcohols are inactive against dried spores.

Seven cases of gaseous edema were observed in the former German Democratic Republic (GDR) after intramuscular injections following rubbing of the skin with ethanol (SEDA-11, 474); this led to a national recommendation that alcohols should not be used to cleanse the skin before intramuscular injection, injection of vasoconstrictors, injections in patients with disturbed peripheral circulation, or before lumbar, paraneural, or intra-articular injection and puncture (SEDA-11, 474) (1).

Organs and Systems

Cardiovascular

Skin disinfection before insertion of peripheral infusion catheters is standard practice. Ethanol 70% has been compared with 2% iodine dissolved in 70% ethanol in a prospective, randomized trial in 109 patients who were given infusions of prednisone and theophylline (2). Phlebitis occurred six times in the ethanol group and 12 times in the iodine group. The relative risk reduction of 53% failed to reach significance, but the power of the study was only 0.55, so there was a 45% chance of missing a true difference. As vast numbers of catheters are inserted each year, a small difference in phlebitis rate could save many patients discomfort.

Skin

Skin reactions to ethanol are extremely rare, although allergic contact dermatitis due to lower aliphatic alcohols has been described (SEDA-11, 474) (3). However, in premature infants of very low birth weight, second-degree and third-degree chemical skin burns were reported after the use of isopropanol, either for conduction in electrocardiography, for the preparation of the umbilical stump for arterial catheterization, or for cleansing before herniotomy (SEDA-11, 474) (4,5). Possible causes are hypoperfusion of the skin by local pressure and general hypoperfusion derived from hypoxia, hypothermia, and acidosis. Immediate drying of the skin of small premature infants after antisepsis with alcoholic formulations and carefully avoiding that the alcohol is absorbed by the diapers is recommended.

Drug Administration

Drug administration route

When it is not possible to perform surgical treatment for omphalocele, application of ethanol is probably the safest method. However, dosage and frequency of application should be as limited, since absorption and intoxication can occur (SEDA-11, 474) (6).

Alizapride

General Information

Alizapride is a substituted benzamide related to some neuroleptic drugs. In one study alizapride, in doses that were less effective than normal doses of metoclopramide, was equally likely to cause extrapyramidal effects and more likely to cause hypotension (SED-12, 939) (SEDA-17, 413).

In another study, doses of 5 mg/kg (but not less) caused diarrhea and orthostatic hypotension (SEDA-9, 311); the incidence of diarrhea may well be higher than with metoclopramide (1). Other recorded effects include a sensation of bodily heat and trismus (SEDA-10, 323).

© 2006 Elsevier B.V. All rights reserved.

Drug–Drug Interactions

Diazepam

Alizapride increases the absorption rate of concurrently administered diazepam (2).

Alkylating cytostatic agents — nitrosoureas

See also Cytostatic and immunosuppressant drugs

General Information

Alkylating cytostatic drugs include (all rINNs):

- Nitrosoureas: carmustine, lomustine, nimustine, streptozocin
- *N*-lost derivatives: chlormethine, cyclophosphamide, estramustine
- Others: busulfan, chlorambucil, dacarbazine, ifosfamide, melphalan, mitobronitol, mitomycin, procarbazine, thiotepa, temozolomide, treosulfan.

The first two groups (apart from cyclophosphamide) are covered in this monograph.

Nitrosoureas

Carmustine (BCNU) is used to treat myeloma, lymphomas, breast cancer, and brain tumors, Topical carmustine has been used to treat mycosis fungoides (1).

Lomustine (CCNU) is used to treat lymphomas and some solid tumors, particularly brain tumors, often in combination with procarbazine and vincristine (2).

Nimustine (ACNU) is used to treat malignant glioma (3).

Streptozocin (streptozotocin) is produced by *Streptomyces achromogenes*. It is used to treat metastatic islet cell carcinoma of the pancreas, but because of its high nephrotoxic and emetogenic potential should be reserved for patients with symptomatic or progressive disease.

N-lost derivatives

Chlormethine (mechlorethamine, mustine, nitrogen mustard) is mainly used topically in the early stages of mycosis fungoides (4).

Cyclophosphamide (see separate monograph) is used in the treatment of various solid tumors, and as an immunosuppressant in conditions such as Wegener's granulomatosis and in conditioning regimens for bone marrow transplantation.

Estramustine is a conjugated derivative of estradiol and chlormethine, mainly used to treat prostate cancer (5,6).

Organs and Systems

Respiratory

Carmustine pulmonary toxicity is well documented. Eight patients developed interstitial pulmonary fibrosis 12–17 years after exposure to carmustine in a total dose of carmustine of 770–1410 mg/m^2 (7).

Lung fibrosis has been described in a long-term follow up 13–17 years after treatment of 31 children given carmustine for brain tumors; 6 died, and of 8 still available for study, 6 had upper zone fibrotic changes of their lungs on X-ray (8).

Sensory systems

A 2.7% ocular complication rate in 112 patients treated with a cumulative dose of carmustine 370 mg/m^2 for intracranial tumors has been recorded (9).

Eye pain and blindness due to retinal and optic nerve damage are recognized hazards of intracarotid carmustine therapy reference. They are thought to be due, at least in part, to the ethanol content of the diluent. Nimustine (ACNU) is water-soluble and ethanol-free. In a study of 30 patients with malignant gliomas, 123 infusions of nimustine and 53 of carmustine were administered (10). Eye pain was experienced during all carmustine infusions but not with nimustine, and one patient developed unilateral blindness after carmustine. In another study, carmustine was administered in solution with 5% dextrose in water (11). All the patients experienced ipsilateral orbital pain and scleral erythema, suggesting that carmustine itself contributes to the toxicity. Seven additional patients were treated wearing an ocular compression device to decrease blood flow and had not experienced any ocular complications.

Mineral balance

A patient with androgen-independent prostate cancer developed hypocalcemia during treatment with estramustine (12). The total serum calcium concentrations before and after the initiation of estramustine were 2.1 and 1.1 mmol/l respectively. This prompted a retrospective survey of hypocalcemia in 135 consecutive patients taking estramustine; 20% were affected. The authors speculated that estramustine may cause hypocalcemia by inhibiting mobilization of calcium and the action of parathyroid hormone on the skeleton.

Hematologic

Of 91 patients treated with topical carmustine, three developed reversible bone marrow depression (13).

Urinary tract

Nephrotoxicity can rarely occur with lomustine, and all cases have been associated with cumulative doses of greater than 1500 mg/m^2 (14).

© 2006 Elsevier B.V. All rights reserved.

Skin

Local adverse effects of topical carmustine include tender erythema, superficial denudation or bullae, contact allergy, pigment alterations, and patchy telangiectasia (1).

Reproductive system

Gynecomastia severe enough to necessitate withdrawal of therapy was the main adverse effect of estramustine 560 mg/day for more than 1 year in prostatic carcinoma (15).

Breast pain with vaginal bleeding and diarrhea were dose-limiting when estramustine 840 mg/day was given for breast cancer (16).

Immunologic

Topical carmustine can cause hypersensitivity reactions, and three previous cases have been supplemented by a fourth (17).

- A 67-year-old woman used topical carmustine for a stage-I cutaneous T cell lymphoma. A second course was started after 6 months and resulted in severe erosive inflammation at the site of treatment. Patch tests with carmustine 0.1, 0.5, and 1% in water all gave positive results; 22 controls were tested with 0.1% carmustine and lomustine and were all negative.

The most common adverse effect of chlormethine is an allergic contact dermatitis (18). Neither reducing the concentration of drug applied nor shortening the time of contact appreciably reduces the frequency of this adverse effect, which occurs in 30–80% of patients, although in one study of 203 patients with mycosis fungoides the use of chlormethine ointment was associated with contact hypersensitivity in under 10% of cases (4). In an open, prospective study in 39 patients with cutaneous T cell lymphomas or parapsoriasis, chlormethine was applied topically and then washed off after 1 hour (19). There was cutaneous intolerance in 19 patients, six of whom had an allergic contact dermatitis after a mean period of 9.3 weeks, while the other 13 developed irritant contact dermatitis after a longer period. Cutaneous intolerance did not differ significantly according to the number of applications per week or the extent of body area treated. Comparison with published studies showed no significant difference in the number of cases of cutaneous intolerance after short-term application, although their occurrence was delayed. Therapeutic response was decreased appreciably by short-term application as compared with results in the literature.

Long-Term Effects

Tumorigenicity

Chlormethine can act as a tumor promotor. In most cases squamous cell carcinomas and basal cell carcinomas have been reported. Two cases of small malignant melanoma, 3 mm in diameter, have been reported in patients with mycosis fungoides stage 1a, with latency intervals of 18 and 10 months after withdrawal of local application, which had been conducted for 18 months and almost 3 years respectively (20).

Second-Generation Effects

Fertility

In 21 boys treated with carmustine or lomustine alone or in combination with procarbazine and vincristine for brain tumors, there were 20 cases of persistent testicular damage (21). From assessment of testicular size it was thought that most those affected would remain infertile. This supports the idea that germinal epithelium is more susceptible than Leydig cells to cytostatic-induced damage.

Alkylating cytostatic agents — *N*-lost derivatives

See also Cytostatic and immunosuppressant drugs

General Information

The *N*-lost cytostatic drugs are alkylating agents that include chlormethine (mechlorethamine, mustine, nitrogen mustard), cyclophosphamide, and estramustine (all rINNs). Chlormethine is mainly used topically in the early stages of mycosis fungoides (1). Estramustine is a conjugated derivative of estradiol and chlormethine, mainly used to treat prostate cancer (2).

Organs and Systems

Mineral balance

A patient with androgen-independent prostate cancer developed hypocalcemia during treatment with estramustine (3). The total serum calcium concentrations before and after the initiation of estramustine were 2.1 and 1.1 mmol/l respectively. This prompted a retrospective survey of hypocalcemia in 135 consecutive patients taking estramustine; 20% were affected. The authors speculated that estramustine may cause hypocalcemia by inhibiting mobilization of calcium and the action of parathyroid hormone on the skeleton.

Reproductive system

Gynecomastia severe enough to necessitate withdrawal of therapy was the main adverse effect of estramustine 560 mg/day for more than 1 year in prostatic carcinoma (4).

Breast pain with vaginal bleeding and diarrhea were dose-limiting when estramustine 840 mg/day was given for breast cancer (5).

Immunologic

The most common adverse effect of chlormethine is an allergic contact dermatitis (6). Neither reducing the concentration of drug applied nor shortening the time of contact appreciably reduces the frequency of this adverse effect, which occurs in 30–80% of patients, although in one study of 203 patients with mycosis fungoides, the use of chlormethine ointment was associated with contact hypersensitivity in under 10% of cases (1). In an open, prospective study in 39 patients with cutaneous T cell lymphomas or parapsoriasis, chlormethine was applied topically and then washed off after 1 hour (7). There was cutaneous intolerance in 19 patients, six of whom had an allergic contact dermatitis after a mean period of 9.3 weeks, while the other 13 developed irritant contact dermatitis after a longer period. Cutaneous intolerance did not differ significantly according to the number of applications per week or the extent of body area treated. Comparison with published studies showed no significant difference in the number of cases of cutaneous intolerance after short-term application, although their occurrence was delayed. Therapeutic response was decreased appreciably by short-term application as compared with results in the literature.

Long-Term Effects

Tumorigenicity

Chlormethine can act as a tumor promotor. In most cases squamous cell carcinomas and basal cell carcinomas have been reported. Two cases of small malignant melanoma, 3 mm in diameter, have been reported in patients with mycosis fungoides stage 1a, with latency intervals of 18 and 10 months after withdrawal of local application, which had been conducted for 18 months and almost 3 years respectively (8).

Allopurinol

General Information

Allopurinol is an inhibitor of xanthine oxidase, used to lower serum uric acid concentrations in the long-term treatment of gout and in the prevention of acute gout in people who are susceptible to hyperuricemia. Allopurinol is itself metabolized to its active metabolite, oxipurinol, by xanthine oxidase.

Comparisons with antimonials in leishmaniasis

Allopurinol has an antileishmanial effect in vitro and in animals, its effect being strongly increased by the addition of antimonial compounds. Allopurinol alone as well as in combination with meglumine antimoniate has been used in clinical studies. In a small study in patients with leishmaniasis and HIV infection, clinical and parasitological cure was achieved in four of five cases treated for 4 weeks, but in only one of the six treated for 3 weeks (1).

Allopurinol and meglumine antimoniate (Glucantime) have been evaluated in a randomized controlled trial in 150 patients with cutaneous leishmaniasis (2). They received oral allopurinol (15 mg/kg/day) for 3 weeks or intramuscular meglumine antimoniate (30 mg/kg/day, corresponding to 8 mg/kg/day of pentavalent antimony, for 2 weeks), or combined therapy. There were a few adverse effects in those who used allopurinol: nausea, heartburn ($n = 3$), and mild increases in transaminases ($n = 2$). These symptoms subsided on drug withdrawal.

In an open study, 72 patients each received meglumine antimoniate (60 mg/kg/day) or allopurinol (20 mg/kg/day) plus low-dose meglumine antimoniate (30 mg/kg/day) for 20 days, and each was followed for 30 days after the end of treatment (3). Only six patients in the combined treatment group complained of mild abdominal pain and nausea; however, one patient who received meglumine antimoniate developed a skin eruption. Generalized muscle pain and weakness occurred in four patients.

Organs and Systems

Nervous system

Apart from headache and vertigo, adverse effects of allopurinol involving the nervous system are rare. Transient peripheral neuropathy has been reported (SEDA-18, 107).

Seizures, which were unresponsive to standard anticonvulsive therapy, disappeared when allopurinol was withdrawn in a patient with a primary neurological disorder (4).

In contrast, occasional reports that allopurinol may have an anticonvulsive effect prompted its use in therapy-resistant epileptic patients. Withdrawal in one of these patients precipitated a convulsive status epilepticus (SEDA-16, 114).

- A 60-year-old man developed aseptic meningitis after taking allopurinol on two separate occasions (5).

Sensory systems

Allopurinol can reportedly cause cataracts (6), but in one study there was no evidence to confirm this risk (SEDA-15, 104).

Hematologic

Eosinophilia and leukocytosis are part of a general hypersensitivity reaction to allopurinol. Leukopenia and neutropenia are sometimes associated with allopurinol. Patients taking cytostatic therapy are more susceptible to bone marrow depression if they take allopurinol as well (SED-9, 155); however, this has not been confirmed in other reports (7). Agranulocytosis is extremely rare.

Cases of aplastic anemia, some in patients with renal insufficiency, have been reported (SEDA-13, 84) (8–10), confirming the need to reduce the dose of allopurinol in patients with renal insufficiency and to monitor toxicity (SEDA-16, 114).

Liver

Hepatitis can be part of a generalized hypersensitivity reaction. Hepatotoxicity ranges from mild granulomatous hepatitis to severe hepatocellular necrosis (SED-5, 155) (SEDA-4, 70). Renal impairment seems to be a prerequisite for a severe hepatic reaction.

Urinary tract

Vasculitis due to a general hypersensitivity reaction can cause renal insufficiency and oliguria. Histological

© 2006 Elsevier B.V. All rights reserved.

findings are vasculitis and tubular necrosis with fibrinoid deposits. Acute renal insufficiency due to xanthine crystals in the kidney tubules during antineoplastic chemotherapy has been reported (11).

Since allopurinol blocks xanthine conversion to uric acid, urinary xanthine excretion is increased, creating a risk of xanthine crystal formation in the urinary system or even in muscles; this can result in nephrolithiasis (12). It is still an open question whether a predisposition to renal disease or renal disease itself is required to precipitate these adverse effects. It is also not known whether increased excretion of orotic acid, due to an interaction of allopurinol with pyrimidine formation, has any consequences for these adverse effects or for its role in reducing glucose tolerance.

Granulomatous interstitial nephritis (SEDA-12, 94) and two cases of interstitial cystitis have been described during long-term treatment with allopurinol (SEDA-21, 108).

Skin

Skin reactions have a general incidence of 10%, are more common in patients with renal disorders and in those taking thiazide diuretics, and are closely correlated with persistently high serum concentrations of oxipurinol (13). The positive association of severe skin reactions with HLA haplotypes AW33 and B17 suggests a genetic predisposition to these reactions (14).

Rash, urticaria, erythematous eruptions, papulovesicular reactions, and pruritus may be the only signs of hypersensitivity or may be part of a generalized reaction.

Dangerous reactions such as exfoliative dermatitis and Lyell's syndrome rarely develop (SEDA-5, 108).

Unusual skin lesions with a benign lymphocyte infiltration have been documented (SEDA-14, 96). Toxic pustuloderma can be added to the list (SEDA-18, 108).

An allopurinol-induced fixed drug eruption was successfully treated by desensitization (SEDA-21, 108).

Allopurinol can uncover latent lichen planus (15).

Musculoskeletal

Myositis and rhabdomyolysis have been attributed to allopurinol (16).

- A 73-year-old woman with chronic renal insufficiency developed generalized muscular weakness and pain 6 days after starting to take allopurinol 200 mg/day. Her serum creatine kinase activity was increased and the diagnosis was rhabdomyolysis, attributed to severe myositis. The serum concentration of oxipurinol was also high. The muscle weakness resolved in 7 weeks with intermittent hemodiafiltration.

Fever, myalgia, and arthralgia have been reported in a patient taking captopril and allopurinol (17).

Acute gout can be exacerbated at the beginning of allopurinol treatment unless the drug is combined with colchicine or an anti-inflammatory drug (18).

Immunologic

Hypersensitivity reactions to allopurinol occur in about 10–15% of patients. Desensitization with both oral and intravenous allopurinol has been successful (SEDA-17, 114). In the allopurinol hypersensitivity syndrome, the skin is most prominently involved (19). Symptoms develop after 2–5 weeks of treatment. Hepatic involvement is present in 40% and renal involvement in 45%; 25% of patients have combined renal and hepatic lesions. The hypersensitivity syndrome has been estimated to occur in 1 in 1000 hospitalized patients. A major complication is an extensive cutaneous staphylococcal infection with septicemia and endocarditis. Gastrointestinal hemorrhage, disseminated intravascular coagulation, adult respiratory distress syndrome, cerebral vasculitis, and peripheral axonal neuropathy have also been described (SEDA-21, 109). Death occurs in 20–30% of patients with severe hypersensitivity syndrome.

One report has presented evidence of a possible association between severe drug-induced erythema multiforme and reactivation of infection with human herpesvirus 6. The reactivation is thought to have contributed in some way to the development of allopurinol hypersensitivity reactions (20).

Allopurinol has been associated, albeit rarely, with pANCA (antineutrophil cytoplasmic antibodies with a peripheral pattern) positivity. A generalized cutaneous vasculitis has been associated with the presence in the serum of pANCA and antimyeloperoxidase antibodies (21). A skin biopsy of a lesion showed leukocytoclastic vasculitis with eosinophilic infiltration. Allopurinol was withdrawn and the symptoms resolved completely. The possible drug causes of ANCA-positive vasculitis with high titers of antimyeloperoxidase antibodies in 30 new patients have been reviewed (22). The findings illustrate that this type of vasculitis is a predominantly drug-induced disorder. Only 12 of the 30 cases were not related to a drug. Allopurinol was implicated in two of the other 18 cases.

Treatment of the allopurinol hypersensitivity syndrome includes drug withdrawal and the administration of systemic corticosteroids (prednisone 40–200 mg/day) for several months. Desensitization strategies allow some patients to resume allopurinol therapy later without any further problem (23–25). The standard desensitization protocol consists of an initial allopurinol dosage of 50 μg/day, increasing every 3 days to a target of 50–100 mg/day. The interval between dosage increases can be extended to 5 days or more in elderly patients with multiple co-morbidity. Using this protocol, desensitization was successful in 25 out of 32 patients (78%); 28 patients completed the desensitization protocol and 21 did so without requiring deviation from the standard dosage schedule and without adverse effects. During the follow-up for 902 patient-months, seven of the 28 patients had recurrent skin eruptions after completing the desensitization protocol and after rechallenge with allopurinol. Desensitization to allopurinol is not recommended for all patients, but it can be useful in selected patients who have had a pruritic maculopapular eruption during treatment with allopurinol and who cannot be treated with other drugs.

Susceptibility Factors

Renal disease

Renal impairment and diuretic therapy predispose to an increased frequency of adverse effects. The exact

© 2006 Elsevier B.V. All rights reserved.

mechanisms have still to be elucidated. The active metabolite, oxipurinol or alloxanthine, accumulates in renal insufficiency and also in patients taking a low protein diet (13).

Drug–Drug Interactions

Aluminium hydroxide

When aluminium hydroxide is given with allopurinol, the serum uric acid concentration can increase, probably because the antacid reduces the absorption of allopurinol (SEDA-13, 84).

Ampicillin

Concomitant administration of allopurinol with ampicillin may increase the incidence of adverse skin reactions. In one study, these occurred in 22% of patients taking the combination (26). However, this interaction was not confirmed in a later investigation (27).

Ciclosporin

Two well-documented reports have described a marked increase in ciclosporin serum concentrations when allopurinol was co-administered (SEDA-18, 108).

Cytostatic drugs

The risk of bone marrow depression by cytostatic drugs is potentiated by allopurinol, which also appears to potentiate the therapeutic effect of purine cytostatic drugs, since it competitively inhibits their metabolic breakdown. Studies in animals suggest that this reaction occurs only with oral mercaptopurine (28), although there is older evidence that the toxicity of cyclophosphamide and other cytostatic drugs can be increased by allopurinol (SED-9, 156). The danger of combining allopurinol with azathioprine has been confirmed by cases of bone marrow suppression, particularly in patients with impaired renal function (SEDA-16, 114).

Thiazides

Thiazides enhance the excretion of orotic acid, which is already increased during allopurinol treatment, but the implications for the frequency of adverse effects are not known.

Almitrine

General Information

Almitrine is a respiratory stimulant that improves hypoxemia in about 80% of patients with severe chronic obstructive pulmonary disease (SEDA-17, 212). Oral almitrine bimesilate (100 mg/day) increased PaO_2 in patients with severe chronic obstructive pulmonary disease without altering mean pulmonary artery pressure (1). Adverse effects were rarely observed and it was concluded that long-term treatment was safe. In other studies, respiratory, digestive, and neurological symptoms have been noted but were often pre-existent (2,3).

Organs and Systems

Gastrointestinal

Mild gastrointestinal symptoms have sometimes occurred (nausea, accelerated intestinal transit) but they regress spontaneously or after symptomatic treatment (2,3).

Aloeaceae

See also Herbal medicines

General Information

The family of Aloeaceae contains the single genus *Aloe*.

Aloe capensis and *Aloe vera*

Aloe capensis and *Aloe vera* (*Aloe barbadensis*) (Barbados aloe, burn plant, Curacao aloe, elephant's gall, first-aid plant, Hsiang dan, lily of the desert) contain several active constituents called aloins, including barbaloin, isobarbaloin, and aloe-emodin. Laxative anthranoid derivatives occur primarily in various laxative herbs (such as aloe, cascara sagrada, medicinal rhubarb, and senna) in the form of free anthraquinones, anthrones, dianthrones, and/or O- and C-glycosides derived from these substances. They produce harmless discoloration of the urine. Depending on intrinsic activity and dose, they can also produce abdominal discomfort and cramps, nausea, violent purgation, and dehydration. They can be distributed into breast milk, but not always in sufficient amounts to affect the suckling infant. Long-term use can result in electrolyte disturbances and in atony and dilatation of the colon. Several anthranoid derivatives (notably the aglycones aloe-emodin, chrysophanol, emodin, and physicon) are genotoxic in bacterial and/or mammalian test systems (SEDA-12, 409).

Aloe species contain laxative anthranoid derivatives, the main active ingredient being isobarbaloin. Large doses are claimed to cause nephritis and use during pregnancy is discouraged, since intestinal irritation might lead to pelvic congestion.

Aloes have been used on the skin to reduce the pain and swelling of burns, improve the symptoms of genital herpes and other skin conditions such as psoriasis, and to help heal wounds and frostbite. Aloe has been used orally to treat arthritis, asthma, diabetes, pruritus, peptic ulcers, and constipation. It may be effective in inflammatory bowel disease (1). It may reduce blood glucose in diabetes mellitus and blood lipid concentrations in hyperlipidemia (2).

Adverse effects

Aloe can reportedly cause muscle weakness, cardiac dysrhythmias, peripheral edema, bloody diarrhea, weight loss, stomach cramps, itching, redness, rash, pruritus, and a red coloration of the urine.

Liver

Hepatitis in a 57-year-old woman was linked to the ingestion of *A. vera*; the hepatitis resolved completely after withdrawal (3).

© 2006 Elsevier B.V. All rights reserved.

Gastrointestinal

- Melanosis coli occurred in a 39-year-old liver transplant patient who took an over-the-counter product containing aloe, rheum, and frangula (4). The typical brownish pigmentation of the colonic mucosa developed over 10 months. The medication was withdrawn and follow-up colonoscopy 1 year later showed normal looking mucosa. However, a sessile polypoid lesion was found in the transverse colon. Histology showed tubulovillous adenoma with extensive low-grade dysplasia.

Skin

Four patients had severe burning sensations after the application of *A. vera* to skin that had been subjected to chemical peel or dermabrasion (5).

Aloes can cause contact sensitivity (6,7).

Urinary tract

Acute renal insufficiency been attributed to *A. capensis*.

- A 47-year-old South African man developed acute oliguric renal insufficiency and liver dysfunction after taking an herbal medicine prescribed by a traditional healer to "clean his stomach" (8). After withdrawal of the remedy and dialysis he recovered slowly, but his creatinine concentration did not fully normalize. Analysis of the remedy showed that it consisted of *A. capensis* (*Aloe ferox* Miller), which contains the nephrotoxic compounds aloesin and aloesin A.

The authors also mentioned that 35% of all cases of acute renal insufficiency in Africa are due to traditional remedies.

Drug interactions

Massive intraoperative bleeding in a 35-year-old woman has been attributed to an interaction of preoperative *A. vera* tablets and sevoflurane, since both may inhibit platelet function (9).

Alpha$_1$-antitrypsin

General Information

Alpha$_1$-antitrypsin neutralizes the activity of neutrophil elastase and is used to treat patients with homozygous deficiency of Alpha$_1$-antitrypsin (1). Adverse effects occur only rarely (2).

Organs and Systems

Cardiovascular

Chest pain and cyanosis occurred in 14 patients but the symptoms seemed to be related to the presence of sucrose in the product (1).

Immunologic

An acute allergic reaction to alpha$_1$-protease inhibitor has been reported (3).

References

Alpha-adrenoceptor antagonists

See also Individual agents

General Information

The postsynaptic alpha-adrenoceptor antagonists, indoramin, prazosin, and related quinazoline derivatives, block alpha$_1$-adrenoceptor-mediated vasoconstriction of peripheral blood vessels (both arterial and venous) and are effectively peripheral vasodilators (1,2). Qualitatively and quantitatively common adverse effects are generally similar, although indoramin has additional effects on other neurotransmitter systems and therefore tends to be considered separately. Their use in benign prostatic hyperplasia has been reviewed (3,4).

Several recent articles have reviewed the pharmacology, pharmacokinetics, mode of action, use, efficacy, and adverse effects of the selective alpha$_1$-adrenoceptor

© 2006 Elsevier B.V. All rights reserved.

blockers doxazosin, prazosin, and terazosin in benign prostatic hyperplasia (5).

The frequencies and the profile of adverse effects of five major classes of antihypertensive agents have been assessed in an unselected group of 2586 chronically drug-treated hypertensive patients (6). This was accompanied by a questionnaire-based survey among patients attending a general practitioner. The percentage of patients who reported adverse effects spontaneously, on general inquiry, and on specific questioning were 16, 24, and 62% respectively. With alpha-blockers the figures were 15, 25, and 50%. The percentage of patients in whom discontinuation was due to adverse effects was 6.8% with alpha-blockers. Alpha-blockers were associated with less fatigue, cold extremities, sexual urge, and insomnia, and more bouts of palpitation than other antihypertensive drugs (RR = 2.5; CI = 1.2, 5.4). The authors did not find a significant effect of age on the pattern of adverse effects. Women reported more effects and effects that were less related to the pharmacological treatment.

The first-dose effect (profound postural hypotension and reflex tachycardia) is a well-recognized complication of the first dose of prazosin and related agents. This phenomenon is dose-related and can usually be avoided by using a low initial dosage taken at bedtime. During long-term treatment, orthostatic hypotension and dizziness is reported by about 10% of patients.

Alpha-glucosidase inhibitors

General Information

Alpha-glucosidase inhibitors are competitive inhibitors of 1α-glucosidases, enzymes that are located in the brush border of epithelial cells, mainly in the upper half of the small intestine. The enzymes degrade complex carbohydrates into monosaccharides, which are absorbed. The alpha-glucosidase inhibitors bind reversibly in a dose-dependent manner to the oligosaccharide binding site of these enzymes and delay the degradation of polysaccharides and starch to glucose. They slow down food digestion in the gut, reducing peak blood glucose concentrations after meals. They also prevent reactive hypoglycemia, as can be seen after gastric operations, in dumping syndrome, and in idiopathic forms. When carbohydrates appear in the colon, bacterial fermentation can occur, leading to gastrointestinal adverse effects, of which flatulence and loose stools are the most frequent. During long-term treatment the colonic bacterial mass can increase. In elderly patients acarbose increases insulin sensitivity but not insulin release (1). Acarbose may reduce the incidence of colon cancer, the risk of which is 30% higher in people with diabetes than in the non-diabetic population (2).

The alpha-glucosidase inhibitors (polyhexose mimickers) in use are acarbose (rINN) (2–4), miglitol (rINN) (5–7), and voglibose (rINN), which is 20 times more potent (8).

Acarbose is not well absorbed and is mostly excreted in the feces. Miglitol is well absorbed from the gut and is almost completely excreted unchanged in the urine (9).

Observational studies

In a 2-year study of the tolerability and safety of acarbose in 2035 patients the incidence of adverse effects was 7.5% and of withdrawals 2.5% (10). Of 1907 patients, 444 (23%) reported one or more adverse events. In 143 patients the physician considered that there was a probable or possible relation between the adverse event (all gastrointestinal) and acarbose. There were 77 deaths, but none was considered to be related to acarbose; 52 stopped taking acarbose because of an adverse event and 45 were considered to be related to acarbose. Laboratory analyses were all within the reference ranges. HbA_{1c} fell by 1.92%.

The addition of metformin to acarbose in 49 patients produced a synergistic effect (11).

Of 1027 patients, 283 used acarbose as the treatment of choice (12). In 250 cases the physician was not sure of the benefit; 124 of these patients took acarbose and 126 patients took placebo besides regular therapy. In those taking acarbose HbA_{1c} fell. The adverse effects were bloating, flatulence, abdominal cramps, and diarrhea; there were moderate increases in serum transaminases.

Comparative studies

Voglibose and acarbose have been compared in 32 patients insufficiently treated by diet in an open crossover study (13). The metabolic results were identical. There were fewer adverse reactions in those who took voglibose. There was increased flatulence with acarbose in 96% and with voglibose in 57%; abdominal distension was reported in 17 and 10% respectively.

In an open study in 57 patients acarbose and gliclazide had the same effects on HbA_{1c}, blood glucose, and lipids, but the ratio of HDL to LDL cholesterol increased with acarbose (14). Acarbose caused flatulence in 30% and diarrhea in 3% and gliclazide caused at least one mild attack of hypoglycemia in 10%.

Placebo-controlled studies

The effect of adding acarbose (maximum 100 mg tds) or placebo to insulin (15) or metformin (16) has been investigated in 1946 patients with type 2 diabetes. The results were comparable with the results of the UK Prospective

© 2006 Elsevier B.V. All rights reserved.

Diabetes Study (17). After 3 years, 39% were still using acarbose compared with 58% using placebo. The main reasons for stopping were flatulence (30 versus 12%) or diarrhea (16 versus 8%). After 3 years the HbA_{1c} concentration was 0.5% lower (median 8.1 versus 8.6%). Acarbose was equally effective when added to diet, sulfonylurea, metformin, or insulin.

When acarbose or placebo was given to patients with type 1 diabetes taking insulin, acarbose reduced postprandial blood glucose but there was no difference in HbA_{1c}; the only adverse effects were gastrointestinal (18).

In a double-blind, placebo-controlled study in 74 patients for 2 years, acarbose 100 mg tds, after a stepwise increase in dosage over 5 weeks, improved HbA_{1c} (–1.71%) more than placebo (19). Two patients taking acarbose withdrew with drug-related adverse effects.

In a randomized, double-blind, placebo-controlled, crossover study 12 healthy subjects took acarbose 100 mg or voglibose 0.3 mg tds (20). Postprandial glucose, the rise in plasma immunoreactive insulin, and urinary immunoreactive C-peptide were higher with acarbose than voglibose. The flatus score was higher with acarbose than voglibose, but the stool score was not different and was higher than with placebo. Voglibose before the evening meal may improve nocturnal hypoglycemia during intensive insulin therapy (21).

Acarbose reduced insulin resistance in 192 patients over 65 years of age (mean age 70) in a double-blind, placebo-controlled study (22). HbA_{1c} was significantly but modestly reduced. The most frequent adverse effect was flatulence, which caused 12 patients (9 taking acarbose and 3 taking placebo) to withdraw.

In a multicenter, double-blind, placebo-controlled study, 81 patients, in whom treatment with metformin was inadequate, received extra acarbose or placebo during 24 weeks after a 4-week run-in period to establish the optimal dose of acarbose (23). HbA_{1c} was reduced by 1.02% and fasting blood glucose by 1.13 mmol/l. Gastrointestinal adverse effects were more common in the acarbose group.

In a placebo-controlled study of 154 patients taking glibenclamide or metformin, miglitol (starting at 25 mg tds and increasing to 50 or 100 mg tds for 24 weeks) caused more meteorism, flatulence, and diarrhea (24). When miglitol was added to metformin, HbA_{1c} improved and there was weight loss. In another study in 318 patients, more of the patients taking miglitol only or miglitol plus metformin withdrew because of flatulence and diarrhea than in the other groups (25).

The effects of miglitol 25 or 50 mg tds have been compared with placebo and various doses of glibenclamide in 411 patients aged over 60 years (mean 68 years) with mild type 2 diabetes insufficiently controlled by diet for 56 weeks (26). HbA_{1c} fell after 1 year by 0.92% (glibenclamide), 0.49% (miglitol 25 mg), and 0.40% (miglitol 50 mg). Gastrointestinal events were most common in patients taking miglitol. Most (88%) of the hypoglycemic events were minor and occurred in the patients taking glibenclamide. Mean body weight increased continuously and significantly in those taking glibenclamide. In the other groups weight fell by more than 1 kg. The rate of withdrawal was the same in all groups; withdrawal was mostly occasioned by cardiovascular effects in those taking glibenclamide and by hyperglycemia, flatulence, or diarrhea in those taking miglitol.

When patients with inadequately controlled type 2 diabetes used glibenclamide plus metformin, miglitol, or placebo for 24 weeks in addition to their earlier therapy, fasting blood glucose concentrations improved with miglitol (24). Flatulence and diarrhea were significantly more common with miglitol. No patient stopped taking miglitol because of adverse effects.

General adverse effects

Acarbose and miglitol have been reviewed (13,27,28). Their major adverse effects are flatulence, abdominal discomfort, diarrhea, and bloating, particularly at the start of therapy, which sometimes prevent further use. They should not be given to patients with intestinal obstruction, malabsorption, inflammatory bowel disease, or hepatic impairment.

Organs and Systems

Sensory systems

Acarbose can cause altered taste sensation (29).

Metabolism

When acarbose is combined with insulin, the greatest effects are seen with regimens that involve only once- or twice-daily administration. The alpha-glucosidase inhibitors seem to be less effective when they are combined with intensive insulin therapy (30). In combination with insulin or oral hypoglycemic drugs the frequency of hypoglycemic episodes can increase; sucrose or higher carbohydrates are reported to be less effective, which can be understood from the mechanism of action.

Extreme weight loss has been attributed to acarbose (31).

- A 47-year-old woman weighing 59 kg took acarbose 50 mg tds. Her blood glucose improved but she lost about 1 kg/month. She had a sore tongue without oral ulcers and no evidence of malabsorption. Later she developed general weakness and iron deficiency anemia but no other evidence of malabsorption. After she had lost 7 kg in 5 months, acarbose was withdrawn. Her complaints disappeared, her weight normalized, and she had no signs of iron deficiency anemia, even without iron therapy.

Extreme weight loss due to acarbose is rare. In this case the mechanism was unclear.

In 36 Japanese patients who were relatively lean but had excess abdominal fat, glibenclamide and voglibose caused loss of weight and abdominal fat (32). The loss of abdominal fat was related to glycemic control. The ratio of subcutaneous to abdominal fat shifted toward subcutaneous fat only in those who took voglibose. Both voglibose and glibenclamide improved insulin sensitivity and the acute response to insulin.

Gastrointestinal

Abdominal pain and diarrhea with malabsorption have been described in patients taking acarbose, which can also cause carbohydrate malabsorption (33).

© 2006 Elsevier B.V. All rights reserved.

A review of miglitol included data on adverse effects in 3585 patients in well-designed clinical trials (34). Only the adverse effects in the gastrointestinal tract occurred with a significantly greater incidence with miglitol 50 or 100 mg tds. The adverse effects were the same as with other drugs in this class: flatulence, diarrhea, dyspepsia, and abdominal pain. There were no differences with monotherapy or combination therapy or in relation to age or ethnicity. There were more episodes of hypoglycemia when miglitol was combined with insulin but not with oral agents. The incidence of cardiovascular events was the same as with placebo.

Long-term acarbose had a good effect on late dumping syndrome in six patients with type 2 diabetes; one patient complained of increased flatulence (35).

Although acarbose often causes abdominal complaints, dietary manipulation has not been used to reduce the complaints (36).

In 120 patients with type 1 diabetes, acarbose lowered postprandial glucose but did not reduce HbA_{1c} (17). Four patients taking acarbose withdrew because of gastrointestinal effects, which improved after withdrawal. One of the placebo group withdrew because of gastrointestinal problems and one other patient taking acarbose withdrew with a Bell's palsy, which was not considered to be related to acarbose.

Ileus has also been reported with acarbose (37–40).

Paralytic ileus with intestinal pneumatosis cystoides has been reported (39).

- An 87-year-old woman, who took acarbose, glibenclamide, and mannitol (for constipation), developed abdominal distention and loss of appetite. An X-ray showed distention of the small intestine, with pockets of small gas bubbles in the submucosal space. When her drugs were withdrawn, her symptoms subsided and the radiological evidence of ileus disappeared by 5 days. Although she had an atonic bladder, there were no signs of neuropathy. She was also hypothyroid, which could have contributed.

Acarbose may also have caused pneumatosis cystoides intestinalis in a 55-year-old woman with pemphigus vulgaris (41).

Most cases of ileus with acarbose have been reported in Japan.

- A 73-year-old man with diabetic gangrene who had used insulin and acarbose 300 mg/day for 15 months developed ileus with abdominal pain and vomiting after he took PL granules (containing salicylamide, paracetamol, anhydrous caffeine, and promethazine methylene disalicylate) for a common cold (40). The ileus subsided after acarbose and the other drugs were withdrawn.

Although the ileus in this case was not clearly related to the use of acarbose, the combination of acarbose, which can cause ileus, with the other drugs that the patient was taking, may have caused it. The anticholinergic effect of promethazine methylene disalicylate may have contributed.

Lymphocytic colitis activated by acarbose has been reported (42).

- A 52-year-old man developed watery diarrhea 6–8 times a day 2 weeks after he had started to take acarbose 100 mg. In 3 weeks he lost 3 kg. Duodenal biopsies were normal; colon biopsies showed a large increase in intraepithelial lymphocytes. The mononuclear cells expressed CD-25, and HLA-DR antigen was increased in epithelial cells. Within 4 days of acarbose withdrawal the diarrhea had disappeared, and biopsies 4 months later showed that CD-25 expression in the cells of the lamina propria was improved and HLA-DR was no longer expressed by the epithelial cells. On rechallenge the diarrhea recurred within 3 days. Biopsies showed pronounced HLA-DR in the epithelial cells and CD-25 expression in some mononuclear cells in the lamina propria.

Non-digestable sugar substitutes and alpha-glucosidase inhibitors should probably not be used in combination.

Liver

Liver damage with raised liver enzymes has been described (16,43). Four case of liver damage by acarbose have been described in women aged 52–57, three established (44) and one probable (45). All had signs of liver impairment within 2–8 months after starting to take acarbose and the changes subsidized within a month after withdrawal. The first patient was given acarbose again; her liver enzymes increased after 3 days and normalized within 10 days after withdrawal. The second and third patients had liver biopsies, which confirmed hepatic changes.

- A 45-year-old man took acarbose 50 mg tds for a year and developed an aspartate transaminase of 62 U/l and an alanine transaminase of 127 /l, with negative serology; 3 months later the alanine transaminase was 153 U/l. After withdrawal of acarbose his liver enzymes normalized (46).
- A 54-year-old woman had fatigue and dark urine after taking acarbose 50 mg tds for 5 months (46). Her aspartate transaminase was 2436 U/l, alanine transaminase 2556 U/l, γ-glutamyl transpeptidase 601 U/l, and alkaline phosphatase 174 U/l; serology was negative and she had a normal liver and gall bladder on ultrasound. Her liver enzymes normalized 5 months after withdrawal.
- A 58-year-old man taking gliclazide 80 mg/day, atenolol 100 mg/day, and pravastatin 10 mg/day started to take acarbose 150 mg/day and benazepril 10 mg/day (47). After 2 weeks he developed weakness and myalgia and 1 week later his alanine transaminase was 22 times higher and aspartate transaminase 9 times higher than the upper limits of the reference ranges. Benazepril and pravastatin were withdrawn and his hypoglycemic therapy was changed to insulin. No viral or other antibodies related to liver disease were found. He improved and was given glibenclamide and acarbose instead of insulin. His enzymes increased 3 weeks later without subjective signs and he had an eosinophilia. A liver biopsy showed intralobular and periportal necrosis of liver cells and mononuclear infiltrates. Acarbose was withdrawn and he improved.
- A 57-year-old woman developed hepatitis 2 months after starting to take acarbose 100 mg tds (48). No other causes of hepatitis were found. Liver function tests normalized 3 months after withdrawal. Acarbose was reintroduced 3 years later and she again developed acute hepatitis. Liver function tests became normal 2 months after withdrawal.

© 2006 Elsevier B.V. All rights reserved.

- A 74-year-old woman who had used acarbose for 3 months developed progressive weakness and jaundice (49). Her bilirubin was 152 μmol/l (direct bilirubin 96 μmol/l). All of her liver enzymes were substantially raised. All other investigations were normal, except that she was positive for hepatitis C antigen. After withdrawal of acarbose everything became normal within 1 month.
- A 73-year-old woman who had taken acarbose 450 mg/day for 3 months became very tired and icteric (50). Her total bilirubin was 427 μmol/l (direct bilirubin 335 μmol/l) and her liver enzymes were very high. Liver biopsy showed cholestasis and cytolysis without eosinophils. Acarbose was continued for 3 days and her condition did not change. When the acarbose was withdrawn she improved rapidly.
- Another patient taking acarbose also had a serum alanine transaminase three times the upper limit of the reference range, but she had positive serology for hepatitis A (16).

Comparable reports have prompted a questionnaire investigation of 770 patients with type 2 diabetes at the start of acarbose therapy (51). Patients with one or more susceptibility factors for liver damage underwent ultrasonography and autoantibody assays. There was silent liver disease in 13% and 20 patients had a fatty liver without hepatic disease. In 15% of these patients there were slight reversible changes in transaminase activity after acarbose. This supports the supposition that severe hepatotoxic reactions to acarbose are idiosyncratic.

However, in a double-blind study in 100 patients with compensated non-alcoholic liver cirrhosis and type 2 diabetes, acarbose for 28 weeks did not alter liver function (52). The number of hypoglycemic episodes was reduced.

Skin

Erythema multiforme has been attributed to acarbose (53).

- A skin biopsy from a 58-year-old man showed necrosis of keratinocytes with lymphocytic and eosinophilic infiltration. Liver enzymes were normal. After withdrawal the rash disappeared. After 3 weeks, rechallenge with acarbose 50 mg caused the skin changes to reappear.

Second-Generation Effects

Pregnancy

In six women with gestational diabetes, acarbose 50 mg before meals normalized fasting and postprandial glucose concentrations (54). The pregnancies were uneventful and the neonates were healthy. Internal discomfort persisted during the whole pregnancy.

Drug–Drug Interactions

Colestyramine

Acarbose increases bowel motility, which reduces the effect of colestyramine.

Digoxin

Acarbose can reduce plasma concentrations of digoxin by impairing its absorption.

- An 82-year-old man with type 2 diabetes, taking digoxin and voglibose 0.9 mg/day, had digoxin serum concentrations in the target range (55). He was given acarbose 300 mg/day instead of voglibose and his digoxin concentrations fell from 0.8–2.0 ng/ml to 0.2–0.4 ng/ml. One month after restarting voglibose the digoxin concentrations were again in the target range.
- A 69-year-old woman with diabetes mellitus and heart failure repeatedly had unusual subtherapeutic plasma digoxin concentrations (56). When acarbose was withdrawn the plasma digoxin concentration rose.

In a randomized, crossover study in healthy men, acarbose 100–200 mg reduced the AUC and C_{max} of digoxin and prolonged its t_{max}, consistent with reduced absorption (57). However, in another study acarbose 50 mg tds for 12 days had no significant effect on the pharmacokinetics of a single oral dose of digoxin 0.75 mg (58).

In one study there was no interaction of voglibose with digoxin (59).

Glibenclamide

In a placebo-controlled study in six patients with type 2 diabetes, acarbose 300 mg/day for 7 days had no significant effect on the pharmacokinetics of a single dose of glibenclamide 5 mg (60).

Miglitol did not reduce the t_{max} or C_{max} of glibenclamide, but the 9-hour AUC was significantly reduced (61).

In a double-blind, crossover study in 12 healthy men, voglibose 5 mg tds for 8 days had no significant effect on the pharmacokinetics of a single dose of glibenclamide 1.75 mg (62).

Metformin

Acarbose reduces the absorption of metformin (63), as does miglitol (61).

Thioctic acid

In 24 healthy volunteers thioctic acid 600 mg orally had no significant effect on the actions of acarbose 50 mg and acarbose did not alter the pharmacokinetics of thioctic acid (64).

Warfarin

Acarbose may increase the availability of warfarin (65). However, neither miglitol (66) nor voglibose (67) has any effect.

Alphaprodine

General Information

Alphaprodine is a synthetic opioid that is rapidly absorbed after oral submucosal injection (1). It is used in pediatric dentistry, but it has been withdrawn from the market on a number of occasions because of concerns about its safety. Problems include hypoxia, reduced respiratory rate, and generalized venodilatation with local cyanosis.

Alpidem

General Information

Alpidem, like zolpidem, is an imidazopyridine, chemically distinct from the benzodiazepines. It binds selectively to a subset of benzodiazepine receptors (1), which may account for its apparently milder withdrawal effects and a relative dominance of anxiolytic over sedative and cognitive effects (2). Its effects are reversed by flumazenil (3). Alpidem was withdrawn in 1953 in France, the only country in which it was marketed, because of hepatotoxicity (4).

Alprazolam

See also Benzodiazepines

General Information

Alprazolam, a triazolobenzodiazepine, has been marketed as an anxiolytic with additional antidepressant properties; an analogue, adinazolam, also has partial antidepressant activity (1) and is useful in panic disorder. Like other benzodiazepines, alprazolam is effective in acute and generalized anxiety; its efficacy in panic disorder (2,3), premenstrual syndrome (4), and chronic pain (5) is complicated by high rates of adverse effects (6). On the other hand, low-dose alprazolam (1.4 mg/day) is useful and well tolerated in the treatment of anxiety associated with schizophrenia (SEDA-19, 34).

The value of the Saskatchewan data files in an acute adverse event signalling scheme has been evaluated using two benzodiazepines (7). The first 20 000 patients taking lorazepam and the first 8525 patients taking alprazolam were followed for 12 months after the initial prescription. The most frequent adverse drug reactions associated with these benzodiazepines were drowsiness, depression, impaired intellectual function and memory, lethargy, impaired coordination, dizziness, nausea and/or vomiting, skin rashes, and respiratory disturbance. Sleep disorders, depression, dizziness and/or vertigo, respiratory depression, gastrointestinal disorders, and inflammatory skin conditions occurred significantly more often during the first 30 days after the initial prescription than during the next 6 months.

Organs and Systems

Cardiovascular

Alprazolam has been associated with hypotension (8).

- A 76-year-old woman, who had a history of hypertension, valvular heart disease (mitral regurgitation) with chronic atrial fibrillation, chronic obstructive airways disease, diverticular disease of the sigmoid colon, and generalized anxiety disorder, developed severe hypotension with a tachycardia after taking alprazolam for 7 days. She also had severe weakness, depressed mood, and impaired gait and balance, without clinical features of neuromuscular disease.

Psychological, psychiatric

Rapid and sometimes serious mood swings to mania or depression, and other adverse effects, including enuresis, aggression, impaired memory, sedation, and ataxia, can occur in patients with panic disorder treated with alprazolam (SEDA-19, 34)(SEDA-20, 31).

Disinhibition has been reported as a major problem with alprazolam, particularly in patients with borderline personality disorder (9). Several case reports have suggested that alprazolam can cause behavioral disinhibition (10), in common with other benzodiazepines that are occasionally used for recreational or criminal purposes (11). In one study, covering the period January 1989 to June 1990, the medical records of 323 psychiatric inpatients treated with alprazolam, clonazepam, or no benzodiazepine were reviewed (12). The frequencies of behavioral disturbances were not significantly different in the different groups, suggesting that alprazolam does not have unique disinhibitory activity and that disinhibition with benzodiazepines may not be an important clinical problem in all psychiatric populations. The study design did not allow the establishment of a relation between the prescription of the benzodiazepine and worsening behaviors, and the findings need to be interpreted conservatively, because it was a retrospective review of a heterogeneous population.

Agoraphobia/panic disorder occurred in 31 patients, 15 of whom had originally been treated with alprazolam and 16 with placebo, had been previously followed during an 8-week treatment period, and had alprazolam-induced memory impairment (13). These patients were reviewed 3.5 years after treatment to determine whether the memory impairment persisted. Those who had used alprazolam performed as well as those who had taken placebo on the memory task and other objective tests. The performances in both groups were similar to pretreatment values. However, there were differences in subjective ratings: those who had used alprazolam rated themselves as less attentive and clear-headed and more incompetent and clumsy. Memory impairment found while patients were taking alprazolam did not persist 3.5 years later.

Abrupt withdrawal of alprazolam after prolonged treatment of panic disorder is associated with panic attacks.

© 2006 Elsevier B.V. All rights reserved.

- A 77-year-old married woman with panic attacks did not experience them while she took alprazolam 0.5 mg bd for 5 months; however, the attacks recurred after an increase in dose to 0.5 mg qds (14).

The authors suggested that the duration of action of alprazolam is too brief to prevent rebound anxiety with administration four times a day, but this explanation is highly speculative. This case illustrates the potential severity of alprazolam rebound and how its long-term use can exacerbate the symptoms for which it was originally administered.

Endocrine

Alprazolam can alter dehydroepiandrosterone and cortisol concentrations. Of 38 healthy volunteers who received a single intravenous dose of alprazolam 2 mg over 2 minutes (phase I), 15 of 25 young men (aged 22–35 years) and all 13 elderly men (aged 65–75 years) responded to alprazolam and agreed to participate in a crossover study of placebo and alprazolam infusion to plateau for 9 hours (15). Plasma samples at 0, 1, 4, and 7 hours were assayed for steroid concentrations. Alprazolam produced:

(a) significant increases in dehydroepiandrosterone concentrations at 7 hours in both the young and elderly men;
(b) significant reductions in cortisol concentrations;
(c) no change in dehydroepiandrosterone-S concentrations.

The results suggest that alprazolam modulates peripheral concentrations of dehydroepiandrosterone and that dehydroepiandrosterone and/or dehydroepiandrosterone-S may have an in vivo role in modulating GABA receptor-mediated responses.

Skin

Alprazolam, which is lipid-soluble, can cause photosensitivity after a long duration of administration.

- A 65-year-old man developed pruritic erythema on sun-exposed areas (photosensitivity) due to alprazolam (16). A photopatch test was negative, but an oral photochallenge test with UVA irradiation was positive after he had taken alprazolam for 17 days.

Long-Term Effects

Drug dependence

Dependence on alprazolam and withdrawal symptoms appear to present greater problems than with other benzodiazepines (SED-12, 98).

Drug withdrawal

Withdrawal symptoms have been described with alprazolam.

- A woman with paranoid schizophrenia developed catatonia 5 days after the abrupt withdrawal of olanzapine and alprazolam (17). The catatonic symptoms included mutism, prostration, waxy flexibility, oculogyric movements, and an inability to swallow. Her symptoms disappeared after administration of alprazolam and haloperidol, and there was no recurrence.
- A 39-year-old woman had withdrawal symptoms after her dose of alprazolam was reduced (18). Cognitive symptoms made it almost impossible for her to stop taking alprazolam or to continue psychotherapeutic treatment. The medication was stopped by means of a behavioral experiment, in which both patient and therapist were unaware of the way in which the medication was reduced, after which continuation of treatment became possible.

Pharmacological strategies for withdrawing alprazolam, by switching to a longer-acting agent, have been proposed (19).

Drug Administration

Drug overdose

The effects of alprazolam overdose have been reported (20,21).

- A 28-year-old African-American man took alprazolam 12 mg. He denied using alcohol, other prescription medications, over-the-counter medications, or illicit drugs. He denied any suicidal intent. He stated that he had taken this large dose because his usual dose of 1–2 mg had failed to relieve his anxiety. He was drowsy and his heart rate was 58/minute. He had marked first-degree atrioventricular block, with a PR interval of 500 ms.
- A 30-year-old woman, with a history of depression, was found dead after taking an unknown quantity of alprazolam, tramadol, and alcohol. At autopsy, only slight decomposition and diffuse visceral congestion were observed. Blood concentrations of alprazolam, alcohol, and tramadol were 0.21 mg/l, 1.29 g/kg, and 38 mg/l respectively.

Drug–Drug Interactions

Alcohol

In common with other benzodiazepines, alprazolam produces additional impairment of performance when it is taken together with alcohol (22). The combination can also produce behavioral disturbance and aggression (11,23).

Alosetron

In an open, randomized, crossover study in 12 healthy men and women, alosetron 1 mg bd did not affect the pharmacokinetics of a single oral dose of alprazolam 1 mg (24).

Dextropropoxyphene

Inhibition of alprazolam metabolism by dextropropoxyphene has been reported (25).

Grapefruit juice

There have been two studies of the effects of repeated ingestion of grapefruit juice on the pharmacokinetics and

© 2006 Elsevier B.V. All rights reserved.

pharmacodynamics of both single and multiple oral doses of alprazolam in a total of 19 subjects (26). Grapefruit juice altered neither the steady-state plasma concentration of alprazolam nor its clinical effects.

Ketoconazole

In a double-blind, crossover, pharmacokinetic and pharmacodynamic study of the interaction of ketoconazole with alprazolam and triazolam, two CYP3A4 substrate drugs with different kinetic profiles, impaired clearance by ketoconazole had more profound clinical consequences for triazolam than for alprazolam (27).

Miocamycin

Hydroxylation of miocamycin metabolites is mainly performed by CYP3A4. Some macrolide antibiotics cause drug interactions that result in altered metabolism of concomitantly administered drugs by the formation of a metabolic intermediate complex with CYP450 or competitive inhibition of CYP450 (28). The resulting interactions can cause rhabdomyolysis (associated with the coadministration of some statins, for example lovastatin or simvastatin), hypoprothrombinemia (associated with warfarin), excessive sedation (associated with certain benzodiazepines, for example alprazolam, diazepam, midazolam, or triazolam), ataxia (associated with carbamazepine), and ergotism (associated with ergotamine).

Moclobemide

- A 44-year-old man developed the serotonin syndrome after taking moclobemide and alprazolam for 1 year (29). The symptoms developed after 4 days of extreme heat, which was thought to have contributed.

Nefazodone

Nefazodone is a weak inhibitor of CYP2D6 but a potent inhibitor of CYP3A4 and it increases plasma concentrations of drugs that are substrates of CYP3A4, such as alprazolam, astemizole, carbamazepine, ciclosporin, cisapride, terfenadine, and triazolam.

Oral contraceptives

Oral contraceptives alter the metabolism of some benzodiazepines that undergo oxidation (alprazolam, chlordiazepoxide, and diazepam) or nitroreduction (nitrazepam) (30). Oral contraceptives inhibit enzyme activity and reduce the clearances of these drugs. There is nevertheless no evidence that this interaction is of clinical importance. It should be noted that for other benzodiazepines that undergo oxidative metabolism, such as bromazepam or clotiazepam, no change has ever been found in oral contraceptive users. Some other benzodiazepines are metabolized by glucuronic acid conjugation. The clearance of temazepam was increased when oral contraceptives were administered concomitantly, but the clearances of lorazepam and oxazepam were not (31). Again, it is unlikely that this is an interaction of clinical importance.

Ritonavir

The inhibitory effect of ritonavir (a viral protease inhibitor) on the metabolism of alprazolam, a CYP3A-mediated reaction, has been investigated in a double-blind study (32). Ten subjects took alprazolam 1.0 mg plus either low-dose ritonavir (four doses of 200 mg) or placebo. Ritonavir reduced alprazolam clearance by 60%, prolonged its half-life, and magnified its benzodiazepine agonist effects, such as sedation and impairment of performance.

Sertraline

Sertraline (50–150 mg/day) had no effects on alprazolam metabolism in a randomized, double-blind, placebo-controlled study in 10 healthy volunteers (33).

Troleandomycin

Troleandomycin inhibits the metabolism of ecabapide and alprazolam by inhibition of CYP3A4 (34,35).

Venlafaxine

The effects of venlafaxine on the pharmacokinetics of alprazolam have been investigated in 16 healthy volunteers. Steady-state venlafaxine 75 mg bd did not inhibit CYP3A4 metabolism of a single dose of alprazolam 2 mg (36).

Alprostadil

See also Prostaglandins

General Information

Alprostadil is PGE_1 available for exogenous administration. Alprostadil is widely used in neonates with cyanotic congenital heart disease to maintain the patency of the ductus arteriosus. Reported adverse effects include fever, apnea, flushing, bradycardia, and hyperostosis. Continuous chronic infusion of alprostadil via a portable pump and neuromuscular electrical stimulation help to improve the quality of life in patients with severe chronic heart failure waiting for a donor heart, as both treatments can be performed at home.

Of 15 neonates with hypoplastic left heart syndrome (nine boys and six girls; median weight 3123 g) included in a cardiac transplant program between January 1993 and August 1996, who received continuous perfusion of alprostadil from the time of diagnosis of the cardiomyopathy, 13 received transplants and 6 died in the operating room (1). All had short-term adverse effects from the continuous perfusion of alprostadil, including slight fever and irritability. However, none had apneic pauses. Cortical hyperostosis occurred in 13 and antral hyperplasia in 12, but in all transplanted cases regression of the antral hyperplasia was seen after 6 months and regression of the cortical hyperostosis was seen after 12 months.

Organs and Systems

Cardiovascular

Moderate or severe phlebitis can occur at the site of venepuncture in some patients who receive alprostadil by infusion. It is sometimes severe enough to necessitate withdrawal of therapy. The frequency and severity of

© 2006 Elsevier B.V. All rights reserved.

phlebitis has been investigated in 18 men, mean age 63 (range 47–78) years, with peripheral vascular disease who received a 2-hour infusion twice daily (2). Although it is usual to dissolve 60 micrograms of alprostadil in 500 ml of fluid to avoid phlebitis, in this study 200 ml was used to prevent volume overload. The solution was neutralized to pH 7.4 with 4 ml of 7% sodium bicarbonate. Two patients had grade 0, four grade 1, 11 grade 2, and one grade 3 phlebitis (by Dinley's criteria (3)). Age correlated negatively with the severity of phlebitis. Usually, alprostadil infusion therapy is stopped when phlebitis reaches grade 4 or more, but there were no such cases in this study.

Hematologic

Investigators from the Department of Pediatrics in Johns Hopkins Hospital, after seeing a neonate who had marked leukocytosis temporally related to alprostadil, conducted a retrospective study of neonatal leukocytosis induced by alprostadil in 45 neonates (4). They concluded that alprostadil infusion is a predictable cause of leukocytosis in neonates with congenital heart disease. Alprostadil-induced leukocytosis was especially prominent in three patients with splenic disorders associated with the heterotaxy syndrome. Many of the other adverse effects of alprostadil, including respiratory depression, hypotension, fever, and lethargy, were also associated with sepsis. The authors considered that it is reasonable to look for sepsis in infants receiving alprostadil, but that it is equally reasonable to withdraw empirical therapy once infection has been ruled out. Leukocytosis associated with alprostadil infusion has not been previously reported and is not listed in the alprostadil package insert.

Skin

Penile shaft lichen sclerosus has been reported in a 63-year-old man in association with alprostadil intracavernous injection for erectile dysfunction (5). The authors suggested that the lichen sclerosus had been caused by (1) an isomorphic response to the trauma of repeated needle injection; (2) a local cutaneous response to alprostadil-induced collagen synthesis or alprostadil-induced fibroblast production of IL-6, with secondary paracrine/autocrine-induced collagen synthesis by improper skin exposure by direct injection to the skin or by retrograde flow of alprostadil through the needle puncture tract; or (3) a random occurrence of separate events.

A neonate with transposition of the great vessels developed urticaria during treatment with alprostadil (6). While flushing and peripheral edema are well recognized, urticaria has not been described before.

Allergic contact dermatitis has been attributed to latanoprost (7).

- An 85-year-old man with glaucoma developed tearing, red eyes, and pruritic, edematous, eczematous eyelids. Treatment for presumed ocular rosacea and seborrhea with oral tetracyclines, topical glucocorticoids, and metronidazole gel was unhelpful. He was using topical carboxymethylcellulose sodium 1%, propylmethylcellulose 0.3%, polyvinyl alcohol 1.4%, latanoprost, and levobunolol. Patch-testing with a standard 64-antigen patch elicited a strong reaction only to balsam of Peru. However, repeated open application of levobunolol and latanoprost for 4 days elicited a strong positive reaction to latanoprost.

Musculoskeletal

Alprostadil infusion can produce bone cortical hyperostosis. Periosteal changes have been described in 15 neonates after the administration of alprostadil for more than 1 week (8). Serum alkaline phosphatase activity was significantly raised. The long bones and clavicles were most commonly involved and symmetrically affected. The scapula was involved in two cases and the ribs in seven. The involvement of clavicles has not been previously reported.

Hypertrophic osteoarthropathy has been reported in a woman with severe chronic heart failure who was referred for cardiac rehabilitation (9).

- A 56-year-old woman with muscle weakness and severe chronic heart failure (NYHA Class III) caused by aortic coarctation received an intravenous infusion of alprostadil 5 nanograms/kg/minute. Although her hemodynamics improved, her muscle weakness and exercise intolerance persisted. Neuromuscular electrical stimulation of both thigh muscles was begun. However, during simultaneous continuous intravenous infusion of alprostadil, she developed pain in her knees and elbows. The overlying skin was warm and dusky red and the subcutaneous tissues were swollen. The discomfort was aggravated by motion. There were signs of non-inflammatory synovial effusions and X-rays showed symmetric bilateral periosteal bone deposition in the distal humerus and synovial effusions in both knees. The bone scintigram showed increased bilateral symmetrical tracer uptake in both knees, ankles, wrists, and carpal bones, and increased radionuclide uptake in periarticular regions. Secondary hypertrophic osteoarthropathy caused by continuous intravenous infusion of alprostadil was diagnosed. The dosage of alprostadil was reduced to 2.5 nanograms/kg/minute, and the signs of osteoarthropathy disappeared within 5 days.

Sexual function

Intracavernosal alprostadil was effective and well tolerated in the treatment of erectile dysfunction, according to the results of a 6-month study (funded by Pharmacia & Upjohn) in 848 men (mean age 52 years) with at least a 4-month history of erectile dysfunction (10). This is provided that the individual dose is established by titration and patients receive training in injection techniques and periodic supervision during treatment. An initial dose was established for each patient and the patients then administered the alprostadil themselves at home. Of 727 evaluable patients, 682 (94%) had at least one erectile response after the injection of alprostadil, and 88% of injections lead to a satisfactory sexual response. The most commonly reported adverse event was penile pain, reported by 44% of patients, but only after 8% of injections. In just over half of the patients who had penile pain, the condition was reported as mild.

© 2006 Elsevier B.V. All rights reserved.

Prolonged erection, penile fibrosis, and priapism occurred in 8, 4, and 0.9% of patients respectively. Treatment was withdrawn because of medical events in 4% of patients, and drug-related events accounted for treatment withdrawal in 2% of patients.

There is a high dropout rate from self-injection therapy for erectile dysfunction. Of 86 patients aged 36–76 years who had been using home treatment for at least 3 months, 17 had discontinued treatment (11). The patients were evaluated by interview and clinical examination. Patients still in the program used one injection every 2 weeks, and those who had given up treatment had used one injection in 3 weeks. They were in the program for 39 and 16 months respectively, and had used a mean of 50 versus 12 injections respectively. There was no difference in the number of injections that produced unsatisfactory penile rigidity, prolonged erections, hematomas at the injection site, corporeal fibrosis, secondary penile deviation, or mean estimated duration of a drug-induced erection. Patient satisfaction, estimated partner satisfaction, increase in self-esteem, and negligible effort in performing injections were all significantly better for those still in the program. The authors commented that the reasons for dropout from self-injection therapy were not based on objective adverse effects and discomfort. Patients who leave the program are less motivated, less satisfied with the quality of drug-induced sexuality, consider the effort of giving the injections to be substantial, and have not achieved improved self-esteem.

There has been a report of a long-term follow-up program for treatment of erectile dysfunction in 32 patients who used alprostadil for a minimum of 5 years under standardized protocol conditions (12). All the patients had organic erectile dysfunction, and their mean age was 59 years. The period of observation was on average 75 months, and the mean dose of alprostadil was 14 μg. In all, 6799 injections were registered. The average number of injections was 213 per patient, 2.8 injections per month per patient. As regards adverse effects, hematomas occurred in 1.9% of the patients and there were five cases of prolonged erection (0.07%) caused by unauthorized redosing. Three patients developed reversible penile nodules. In 10 patients, the initial dosage had to be increased. Five patients dropped out after 5 years, none of them because of treatment complications.

The impact of treatment with transurethral alprostadil for erectile dysfunction on the quality of life of 249 men and their partners has been evaluated (13). The men had organic erectile dysfunction of more than 3 months' duration and self-administered transurethral alprostadil in an open, dose-escalating, outpatient study. Patients with a sufficient response ($n = 159$) were randomly assigned double-blind to either active medication or placebo for 3 months at home. Drug-related urogenital pain was reported by 12% of patients during outpatient dosing. However, this pain was usually mild, and only five patients (2%) discontinued treatment. One patient reported minor urethral bleeding/spotting. The transurethral administration of alprostadil was associated with minimal or no discomfort in 83–88% of patients. In the outpatient study, dizziness occurred in one patient and hypotension in one patient. During home treatment, drug-related urogenital pain was reported by 11 patients (14%), minor urethral bleeding/spotting by one (1.3%), and dizziness by 2 (2.6%). One patient reported prolonged erections on two occasions during home treatment, each lasting less than 5 hours.

The incidence of priapism after intracorporeal administration of alprostadil is 1%. Priapism after medicated urethral system for erection (MUSE) has been reported (14).

- A 57-year-old man with erectile impotence, who had previously been treated with intracorporeal injections of papaverine and alprostadil, resulting in recurrent episodes of priapism necessitating aspiration, decided to try intraurethral alprostadil (MUSE). The dose needed to achieve a full erection in the clinic was titrated to 1 μg, but after 5 months this was found to be inadequate unless supplemented by a hot bath before MUSE administration. The patient stated that with MUSE alone the erection lasted for 5–10 minutes but on the two previous occasions when he had had a hot bath for 20 minutes and then used MUSE, the erection had lasted 3–4 hours. However, on the third occasion, priapism lasted 20 hours and necessitated corporeal aspiration for detumescence.

Immunologic

When latanoprost was applied for 4 months to the eyes in 14 patients, there was an increase in HLA-DR expression (15). Since HLA-DR is a marker of ocular surface inflammation, these results suggested a subclinical inflammatory reaction to latanoprost. However, the clinical significance of HLA-DR expression is not clear.

Aluminium

General Information

Aluminium is a metallic element (symbol Al; atomic no. 13), a light, silver-colored, malleable metal.

Aluminium is the most abundant of all metals and is obtained from bauxite ores by the production of alumina, which is then smelted to produce aluminium. Its abundance is demonstrated by the vast number of minerals and precious stones that contain aluminium, which include: albite, analcime, anorthite, beryl, chabazite, cimolite, dumortierite, epidote, euclase, feldspar, fuller's earth, glauconite, halloysite, harmotome, iolite, jadeite, kaolinite, kyanite, lazurite, leucite, margarite, melilite, montmorillonite, muscovite, natrolite, nepheline, noselite, penninite, phillipsite, piedmontite, pinite, prehnite, saponite, sapphirine, scapolite, scolecite, sillimanite, sodalite, spessartite, spodumene, staurolite, topaz, and vesuvianite (all of which contain salts or pure crystals of aluminium silicate); alunite (hydrous aluminium sulfate); cryolite (sodium aluminium fluoride); diaspore, gibbsite, and laterite (aluminium hydroxide); lazulite, sphaerite, turquoise, variscite, and wavellite (aluminium phosphate); scorodite and synadelphite (aluminium arsenate); and gmelinite (aluminium zeolite).

Note on nomenclature

Aluminium was first named (although not isolated) by Sir Humphry Davy, who originally called it alumium (1808) because it was found in alum, a name that had been extant since at least the 14th century. He later called it aluminum (1812), but others soon changed it to aluminium, in order to harmonize it with the many other elements whose names end in "ium" and because "aluminum" was thought not to have a particularly classical sound. For many years, both "aluminium" and "aluminum" were used in the USA, until the American Chemical Society adopted the form "aluminum" in 1925. However, "aluminium" is the official name recognized by the International Union of Pure and Applied Chemistry (IUPAC) and is the form that is used here.

Sources of exposure

Aluminium is widely used in medicine, pharmacy, food technology, and cosmetics. It is also a popular metal for making everyday objects, including kitchen utensils and other devices associated with food preparation. There is also some exposure, although generally limited, from the environment. Toxic effects of aluminium have been seen in patients treated with total parenteral nutrition contaminated with aluminium (1); high concentrations of aluminium have been detected in some intravenously administered solutions, such as human serum albumin (2) and in artificial breast milk substitutes. Exceptionally, a metallic aluminium object can become lodged in the body and give rise to aluminium toxicity (SEDA-20, 207). Additive intake from multiple medical and/or non-medical sources can prove excessive, and it can be important to recognize the many circumstances in which exposure occurs. Aluminium absorbed into the system is excreted in the bile, generally without obvious consequences (SEDA-12, 316).

Hyperaluminemia has been described in premature infants receiving prolonged intravenous alimentation, and in recipients of plasmapheresis receiving large volumes of replacement albumin solutions, which contain high concentrations of aluminium (3–4).

Many aluminium salts, including aluminium hydroxide gel, aluminium carbonate, aluminium glycinate, and aluminosilicate, are used therapeutically, and the absorption rate depends on the chemical species. Aluminium citrate is well absorbed (5), but aluminium hydroxide gel antacid is poorly absorbed (0.003%) (6). Aluminium glycinate is well absorbed and excreted in the urine. Poorly absorbed aluminium-containing formulations should be preferred for those who have poor renal function particularly elderly people.

Sucralfate is a basic aluminium salt of sucrose octasulfate.

Medical uses

The external medical uses of aluminium are many; water-soluble compounds such as alum have long been used as mild external antiseptic, astringent, antihydrotic, or styptic agents, and more recently in deodorants and antiperspirants. Metallic aluminium is also used in some wound dressings.

Internal use in medicine can exploit the alkaline nature and adsorptive capacities of aluminium compounds (as in antacid mixtures, antidiarrheal drugs, and vaccines). Aluminium is found in medications for antacid therapy and phosphate depletion; alternatives are under investigation (7). Patients on dialysis take large amounts of oral aluminium hydroxide as a means of reducing serum phosphate. Sucralfate is used to treat peptic ulceration and gastritis.

Aluminium is used as a vaccine adjuvant (8).

© 2006 Elsevier B.V. All rights reserved.

General adverse effects

Topical aluminium can occasionally cause skin irritation in sensitive individuals.

The systemic availability of aluminium is normally very low, because the gastrointestinal tract, skin, and lungs are excellent barriers to its entry; furthermore, the small amounts that pass these barriers are efficiently eliminated by the kidneys. However, problems can arise if the natural protective barriers are bypassed or if there is impaired renal function. Significant systemic effects are rare unless there is a high degree of absorption.

- Acute aluminium toxicity in one reported case followed the introduction of aluminium sulfate (alum) into the urinary tract to treat hemorrhagic cystitis; there was apparently both increased absorption, due to the mucosal lesion of the bladder wall, and an increased susceptibility due to pre-existing renal insufficiency (SED-13, 585).

Aluminium is toxic in patients on chronic hemodialysis and peritoneal dialysis and in those taking oral aluminium-containing medications. Aspects of aluminium safety (9) and metabolism (10) have been reviewed. The association between aluminium in drinking water and Alzheimer's disease continues to be discussed and remains controversial (11).

Although aluminium adjuvants have proven to be safe over six decades, adverse effects, such as erythema, subcutaneous nodules, and contact hypersensitivity, sometimes occur (12). The aluminium body burden has been estimated in infants during the first year of life for a standard immunization schedule compared with breast milk and formula diets (13). The calculated body burden of aluminium from immunization exceeds that from dietary sources, but is still below the minimal risk level equivalent curve during the brief period after injection.

Organs and Systems

Respiratory

Specific chemical exposures and exposure assessment methods relating to studies in the alumina and primary aluminium industry have been reviewed (14). In aluminium smelting, exposure to fluorides, coal tar pitch volatiles, and sulfur dioxide has tended to abate in recent years, but there is insufficient information about other exposures. Published epidemiological studies and quantitative exposure data for bauxite mining and alumina refining are virtually non-existent. Determination of possible exposure–response relations for this part of the industry through improved exposure assessment methods should be the focus of future studies.

Dental technicians are potentially exposed to various occupational dusts and chemicals and pulmonary granulomatosis has been reported (15).

- A dental laboratory technician developed progressive exertional dyspnea and cough associated with pulmonary granulomatosis. Lung function studies showed a restrictive pattern with a low diffusion capacity. A high-resolution CT scan showed micronodules in both lungs, corresponding to non-caseating foreign body granulomas at histological examination. Mineralogical studies showed the presence of silica, silicates, and aluminium. The lymphocytic transformation test was positive for beryllium with the bronchoalveolar lavage.

Combined histological, mineralogical, and immunological studies led to a diagnosis of pneumoconiosis, most likely related to occupational exposure to beryllium and aluminium.

The role of aluminium in the development of occupational asthma has never been convincingly substantiated. Occupational asthma has been attributed to aluminium welding (16).

- A 32-year-old man working in a leather plant performed electric arc welding on mild steel, using manual metal arc and inert gas metal arc techniques. About once a month he welded aluminium pieces using a manual arc process with a flux-coated electrode. After 4 years of intermittent exposure to these various welding processes, he developed chest tightness and wheezing that occurred specifically on days when he was welding aluminium. His asthmatic symptoms started 1–4 hours after the end of exposure to aluminium and persisted for several hours. He never had myalgia, chills, or fever. He was treated with inhaled budesonide (400 micrograms/day) and salbutamol when necessary. Inhalation challenges combined with exposure assessment provided evidence that aluminium can cause asthmatic reactions.

A syndrome known as "pot-room asthma" occurs in around 2% of new aluminium smelters each year, with a wide range of incidences around the world (17).

- In 1529 men in two smelting factories, work-related respiratory symptoms were reported significantly more often among the ingot mill, anode, and pot-room groups in factory A after adjusting for age and smoking, while in factory B, ingot employees were more likely to report work-related wheeze and pot-room employees were more likely to report work-related rhinitis (18). Symptoms tended to increase with increasing time in the pot-rooms, but were more likely to occur in new employees in the ingot mill and anode process groups.

Nervous system

The toxicology of aluminium in the brain has been reviewed (19,20).

Since 1976, aluminium has been known to be a cause of encephalopathy, a potentially fatal condition occurring primarily in patients on chronic dialysis (21). Difficulties in speech, disturbances of consciousness, and ataxia can be followed by psychotic episodes, personality changes, myoclonic jerks, electroencephalographic abnormalities, convulsions, and dementia. Accumulation of aluminium can be demonstrated in the gray matter of the brain and in other tissues. If not too advanced, the condition can recede after reduction of aluminium intake and use of deferoxamine.

- Intravesical irrigation with 1% alum for hemorrhagic cystitis resulted in sufficient absorption to produce encephalopathic symptoms in a teenage girl (22).

© 2006 Elsevier B.V. All rights reserved.

An identical condition can occur in aluminium plant workers and miners, and can be reproduced in animal experiments. However, some clinically similar encephalopathies do occur spontaneously (or possibly as a result of uremia) in children where no link with aluminium exposure can be found.

There have been reports that the use of surgical aluminium-containing bone cement can cause epileptic seizures as well as encephalopathy, at least when the cement is in direct contact with the cerebrospinal fluid, as can happen in neurosurgery (23,24) (SEDA-21, 232). In this connection it should be noted that such bone cements can produce high circulating concentrations of aluminium. One French study in six patients (25) noted mean plasma aluminium concentrations of up to 9.2 ng/ml, while up to 176 ng/ml was present in the postauricular cerebrospinal fluid (SEDA-22, 242). This aspect of aluminium cement merits further study.

Aluminium-containing antacids have been suggested to be the cause of idiopathic Parkinson's disease in a study of 200 patients and 200 age- and sex-matched controls. There was a significantly higher incidence of ulcers (diagnosed by X-ray or surgery) in the patients with Parkinson's disease compared with controls (14 versus 4%) (26,27). The ulcers typically preceded the diagnosis of Parkinson's disease by 10–20 years. Parkinson's disease occurs worldwide, suggesting perhaps that some ubiquitous toxin plays a role in its pathogenesis. Aluminium absorption resulting in raised blood concentrations has been detected in babies given "Infant Gaviscon" (which is based on aluminium alginate and is not in fact recommended by the manufacturers in the very young) and in adults given aluminium sucrose sulfate, though without apparent ill-effect.

Acute neurotoxic adverse effects of aluminium have been attributed to aluminium-containing surgical cement.

- A 52-year-old woman had a resection of an acoustic neuroma (28). Bone reconstruction was performed with an aluminium-containing cement and 6 weeks later she had loss of consciousness, myoclonic jerks, and persistent tonic-clonic seizures, effects resembling those of dialysis encephalopathy. She died 6 months later with septic complications. Light microscopy and electron microscopy of the brain showed pathognomonic aluminium-containing intracytoplasmic argyrophilic inclusions in the choroid plexus epithelia, neurons, and cortical glia. These changes are characteristic of dialysis-associated encephalopathy. Atomic absorption spectrometry showed an increase in the mean aluminium concentration in the cortex and subcortex, up to 9.3 μg/g (reference range under 2 μg/g); a laser microprobe showed increased aluminium in subcellular structures.

This case shows again the extraordinary neurotoxic potency of aluminium, which was initiated by about 30 mg and apparently caused by direct access of aluminium to the brain parenchyma via cerebrospinal fluid leakage.

Aluminium and Alzheimer's disease

The association between aluminium in drinking water and Alzheimer's disease continues to be discussed and remains controversial (11,29,30). The theory has been advanced that aluminium may be linked to the etiology of Alzheimer's disease (31), one suggestion being that the mechanism is the inhibition of tetrahydrobiopterin synthesis in the temporal cortex. This hypothesis has led to much debate (32–34), and more knowledge is accumulating regarding possible mechanisms of neurotoxicity (35).

One study has suggested that researchers looking for a connection between aluminium and Alzheimer's disease may have ignored the most important source of aluminium for the average person—foodstuffs that contain aluminium additives (36). The results implied that aluminium, added to such foods as anticaking agents, emulsifiers, thickeners, leaveners, and stabilizers, may have long-term adverse effects on health. However, the small sample size hampers any definitive conclusions, the odds ratios were very unstable, and the study had limited statistical power to rule out random errors.

The relation between different chemical forms of aluminium in drinking water and Alzheimer's disease has been studied in 68 patients with Alzheimer's disease, diagnosed according to recognized criteria and paired for age and sex with non-demented controls (37). Aluminium speciation was assessed using established standard analytical protocols along with quality control procedures (total aluminium, total dissolved aluminium, monomeric organic aluminium, monomeric inorganic aluminium, polymeric aluminium, Al^{3+}, AlOH, AlF, $AlH_3SiO_4^{2+}$, $AlSO_4$). The results suggested a possible association between monomeric aluminium exposition and Alzheimer's disease. In contrast to the results of earlier studies, this association was observed in a geographical environment characterized by low aluminium concentrations and a high pH.

However, others have suggested that the theory that aluminium plays a role in the pathogenesis of Alzheimer's disease has been largely discarded, as our understanding of the pathogenic mechanisms of Alzheimer's disease has advanced (38).

Sensory systems

Tissue lesions can be caused by local deposition of aluminium, for example in the eye (39)

- A 76-year-old man with a history of multiple melanomas noticed a gradually enlarging pigmented mass in his right eye. He had had successful pneumatic cryopexy of a retinal tear in the temporal region of the right eye 4 years before with no reported complications. Slit lamp examination showed a 4 × 2 mm elevated darkly pigmented conjunctival mass surrounding the insertion site of the lateral rectus. An excisional biopsy showed multiple foci of fine, jet-black, granular pigmentation in a perivascular distribution, with additional deposition throughout the conjunctival stroma. There were no melanocyte abnormalities or cellular atypia. Energy dispersive analysis of X-rays showed spectral peaks corresponding to heavy aluminium deposition with trace amounts of silicone.

Aluminium is often incorporated in cryoprobe tips for ophthalmic use, providing a possible source of local

© 2006 Elsevier B.V. All rights reserved.

deposition. Other possibilities include a metallic foreign body and occupational exposure.

Mineral balance

The ability of aluminium gels to bind phosphate can result in clinical significant hypophosphatemia, which usually presents as myalgia, weakness, and bone pain, but can have more extreme consequences; one report described rickets with hypercalciuria after prolonged use, though the subject was an immobilized boy with spastic quadriplegia which can itself have affected the skeleton (40). Even relatively small doses of commonly used aluminium-containing liquid antacids (90–120 ml/day) can lead to adverse effects on calcium and phosphorus metabolism. During long-term therapy, a considerable loss of calcium may occur, resulting in skeletal demineralization (41). Collagen synthesis and matrix mineralization can be so seriously affected that a vitamin D-resistant osteomalacia develops (42). The adverse effects of aluminium overload on the bones respond to reduction in aluminium exposure, whether this has resulted from oral intake or use of aluminium in dialysis (43).

Metal metabolism

Severe copper deficiency has followed the intake of a gel containing bismuth, aluminium, magnesium, and sodium in a patient with pyloric stenosis (44).

Hematologic

Aluminium overload in uremic patients can lead to a microcytic hypochromic anemia (45). The mechanism is unknown, but it appears to involve inhibition of heme synthesis, either by inhibition of enzyme activity or by interference with the incorporation or utilization of iron. Exposure for 3 months is sufficient to reduce hematological values and cause significant increases in serum and urinary aluminium (46). The anemia can be reversed by lowering the aluminium intake or by chelation therapy with deferoxamine.

Gastrointestinal

Aluminium hydroxide can cause constipation, or even intestinal obstruction. Severe bowel dysfunction developed in 25 of 945 patients receiving long-term hemodialysis during 10 years (47). There was colonic perforation in 12 patients, six of whom died with peritonitis. In 10 other patients there was prolonged, severe, adynamic ileus that progressed to colonic pseudo-obstruction in eight. All had regularly taken aluminium hydroxide gel and had had chronic constipation before presentation.

Large doses of aluminium can be associated with fecal impaction and the development of intestinal obstruction in uremic patients (48). Impacted tablets have in some cases caused obstruction (SEDA-16, 417).

Aluminium hydroxide can have an aggravating effect on *Helicobacter pylori*-associated gastritis in patients with duodenal ulceration (49).

Liver

The histology and metal content of the liver have been studied in a patient with Wilson's disease (50). Copper and aluminium contents of the biopsied liver were measured simultaneously by neutron activation analysis. The copper content was markedly increased (814 μg/g dry weight) and there was an extremely high aluminium content (479 μg/g). On the other hand, macroscopically and histologically there was no evidence of cirrhosis, although there was mild fibrosis or inflammation of the liver. It is likely that toxic metals, such as aluminium, copper, and manganese, might be implicated in the pathogenesis of Wilson's disease.

Animal experiments suggest that aluminium may play a role in the pathogenesis of parenteral nutrition-induced hepatobiliary dysfunction (51).

Urinary tract

A patient who grossly overused an antacid containing aluminium and magnesium developed nephrolithiasis and bilateral ureteric obstruction as well as asymptomatic hypophosphatemia (SEDA-16, 417).

Irrigation of the urinary bladder with alum successfully controls vesical hematuria, but it can cause bladder spasm (52).

Skin

Aluminium causes histological changes at injection sites, and these stain with hematoxylin and eosin (53). Of four patients studied, one had a sclerosing lipogranuloma-like reaction with unlined cystic spaces containing crystalline material. Another presented as a large symptomatic subcutaneous swelling, which microscopically showed diffuse and widespread involvement of the subcutaneous tissues by a lymphoid infiltrate with prominent lymphoid follicles.

Contact allergy to topically applied aluminium compounds is rare but skin sensitization has been described (54). In one case the use of a cream for acne and hyperpigmentation was followed by dermatitis, and patch tests were positive to both aluminium sulfate and aluminium chloride. A more typical antecedent of sensitization is the injection of aluminium-adsorbed vaccines, and such patients may present with a granulomatous nodule at the site. Mixed contact sensitivity to nickel and aluminium has been reported to respond to antihistamine therapy (55).

Persistent skin lesions occurred in three patients after the administration of aluminium hydroxide-containing vaccines.

- A 19-year-old woman presented with multiple itchy nodules on the outer aspects of the upper arms at the sites of previous vaccine injections (56). There were several nodules, ranging from a few millimeters to 1 cm in diameter, some with overlying hyperpigmented skin. She had been receiving hyposensitization vaccines to treat recurrent extrinsic asthma and rhinitis for the previous 4 years. A skin biopsy showed a normal epidermis and upper dermis. There were multifocal unencapsulated granulomatous infiltrates in the deep dermis and subcutaneous tissues, disrupting the normal architecture of the latter. The infiltrate was predominantly composed of histiocytes with foreign body giant cells. There were also fibroblasts, fibrosis, and perivascular

© 2006 Elsevier B.V. All rights reserved.

lymphocytes and plasma cells, with a few eosinophils. There was a granular basophilic material within the cytoplasm of some histiocytes. However, patch tests with aluminium chloride, nickel sulfate, and potassium dichromate were all negative. She was treated with potent topical corticosteroids and oral antihistamines, with some relief, but the nodules persisted 2 years later.

- A 37-year-old woman with a 5-year history of multiple itchy nodules on the outer aspects of the upper parts of the arms at sites of previous vaccine injections had been receiving hyposensitization vaccines to treat recurrent extrinsic asthma and rhinitis for 10 years (56). Physical examination and a biopsy of one of the nodules were identical to those of the previous case. Patch tests with aluminium chloride were negative. Symptomatic relief was obtained with topical corticosteroids and oral antihistamines. The nodules persisted for at least 3 years.
- A 52-year-old woman, allergic to wasp venom, was hyposensitized with a vaccine containing wasp venom precipitated on aluminium hydroxide (57). Each subcutaneous injection of the extract was followed by cooling of the acute local reaction at the injection site for about 1 hour. As soon as 24 hours after the second maintenance dose, she developed tender, erythematous, ill-demarcated, indurated plaques at the injection sites on both the lateral thighs. The lesions resolved spontaneously after several weeks, leaving residual hyperpigmentation and subcutaneous atrophy. They reappeared with each treatment, even after the vaccine was changed to a lyophilized, aluminium-free extract. No further lesions occurred when the injection sites were not cooled, even though the aluminium hydroxide vaccine was continued. Patch tests with the vaccine, aluminium hydroxide, human albumin, phenol, and aluminium chloride hexahydrate were all negative. A biopsy of the skin lesions showed lobular panniculitis, with lipocyte necrosis and a mixed cellular infiltrate of neutrophils, lymphocytes, and histiocytes. Ultrasound examination of the atrophic areas showed significantly thinner subcutaneous tissue than in the normal contralateral skin. Rechallenge with an ice pack alone on the upper arm caused a similar skin lesion to appear within 24 hours.

Various mechanisms were postulated to explain these persistent lesions, such as a non-allergic direct toxic effect of aluminium and a delayed hypersensitivity reaction to aluminium.

Four cases have been reported of persistent subcutaneous nodules at sites of hepatitis B vaccination due to aluminium sensitization (58). Symptoms included pruritic, sore, erythematous, and in two cases hyperpigmented, subcutaneous nodules, persisting for 8 months to 2 years. All the patients were positive for aluminium salts in patch tests, while immunization against hepatitis B was successful.

Musculoskeletal

Macrophagic myofasciitis has been reported in relation to immunization with an aluminium-based vaccine (59).

- A 5-year-old boy with chronic intestinal pseudo-obstruction required nighttime parenteral nutrition. He had abnormal pupillary reflexes and urinary retention, suggesting diffuse dysautonomia. A 3-year-old child had developed delay and hypotonia. Both children had received age-appropriate immunizations. Quadriceps muscle biopsies showed the typical patchy, cohesive, centripetal infiltration of alpha-1-antitrypsin+, alpha-antichymotrypsin+, CD68+, PAS+, CD1a–, S-100–, factor XIII– granular macrophages with adjacent atrophy of myofibers, dilated blood vessels, and mild endomysial and perimysial fibrosis. There was no myonecrosis and no discrete granulomas. There was a single aluminium peak on energy dispersive X-ray microanalysis. Most infectious causes leading to macrophage activation were ruled out, thus implicating aluminium. Both patients improved gradually with time.

Heavy chronic use of antacids containing aluminium and magnesium hydroxide can cause serious skeletal impairment (60).

- A 39-year-old female pharmacist who self-medicated with high doses of a potent antacid containing aluminium and magnesium hydroxide for peptic ulcer disease consumed over 18 kg of elemental aluminium and 15 kg of elemental magnesium over 8 years. This resulted in severe osteomalacia, due to profound phosphate depletion. Bone biopsy showed stainable aluminium deposits along 28% of the total bone surface, which is a unique observation in a patient with normal renal function. Treatment included withdrawing the antacid and supplementation with phosphate, calcium, and vitamin D. This produced marked subjective and objective improvement, including a striking increase in her bone mineral density over the next 2 years.

Osteomalacia due to aluminium-containing antacids has been associated with stainable bone aluminium in patients with normal renal function (61).

- A 39-year-old woman who took high doses of aluminium and magnesium hydroxide for peptic ulcer disease (over 18 kg of elemental aluminium and 15 kg of elemental magnesium over 8 years) developed severe osteomalacia due to profound phosphate depletion (60). Bone biopsy showed stainable aluminium deposits along 28% of the total bone surface, a unique observation in a patient with normal renal function. Treatment included withdrawal of the antacid and supplementation with phosphate, calcium, and vitamin D. Her bone mineral density increased over the next 2 years.

Unexpected persistent aluminium-related bone disease occurred after renal transplantation following earlier use of aluminium hydroxide (62).

- A 59-year-old man presented with end-stage renal insufficiency. While on hemodialysis he had used aluminium hydroxide as a phosphate binder but then used calcium lactate instead after total parathyroidectomy. Oral vitamin D was discontinued after the parathyroidectomy. However, after he had received a renal transplant he developed aluminium-related bone disease and was treated with infusions of deferoxamine.

This is the first report of worsening aluminium-related bone disease after renal transplantation.

© 2006 Elsevier B.V. All rights reserved.

Hyperparathyroidism and aluminium hydroxide lead to aluminium-related bone disease; however, total parathyroidectomy does not lead to failure of aluminium mobilization after renal transplantation. This man had satisfactory graft function, and the aluminium excretion that was achieved by deferoxamine suggests that the renal transplant was not the limiting factor for the mobilization of aluminium. The most likely explanation was that he developed adynamic bone through a combination of vitamin D deficiency, hypoparathyroidism, and aluminium deposition. Vitamin D supplementation failed to prevent the osteodystrophy on its own. When aluminium chelation therapy was used, bone healing occurred and his symptoms improved.

Immunologic

Aluminium has a non-specific immunosuppressive action, which results in a lower incidence of transplant rejection in patients with high aluminium concentrations in the tissues; in the first instance one might consider this a reason for seeking to maintain a particularly high aluminium concentration in transplant patients. However, there are good reasons not to do so. Firstly, should infection occur, this immunosuppressive effect can lead to increased risk and higher mortality; work in dialysis patients has confirmed that an increased aluminium load raises the risk of infections (63). Secondly, after transplantations there already is a high aluminium concentration because of mobilization of aluminium from the storage pool. Aluminium loading before transplantation should therefore be avoided and excessive concentrations countered (64).

Aluminium salts are currently the only widely used adjuvants in human vaccines (65). Developments in the understanding of the structure, composition, and preparation of immunostimulating complexes (ISCOMs) have been reviewed and compared.

Susceptibility Factors

Renal disease

In many patients with severe renal disease there is a double risk: they are exposed to aluminium as a part of their treatment (in agents given for the control of serum phosphate concentrations, in aluminium-containing dialysis fluids and, in one case, in the form of bladder irrigation with alum) (66), and at the same time they have a reduced ability to eliminate it. Aluminium-containing phosphate binders are especially risky if used in combination with an alkalinizing citrate solution (Shohl's solution) (67,68); due to the formation of an aluminium citrate complex in the gastrointestinal tract, aluminium is absorbed more readily. In addition, aluminium citrate complex has a synergistic inhibitory action on bone growth and thus exacerbates aluminium-associated osteomalacia in chronic renal failure. Children with impaired renal function may be particularly susceptible to aluminium intoxication solely from oral aluminium loading (69).

When aluminium is used as a phosphate binder in patients on renal dialysis, absorption and accumulation can occur. Phosphate depletion accompanied by increased bone resorption and hypercalciuria (with a risk of osteomalacia) can result (70). Low phosphate diets exacerbate this risk. Concurrent use of oral citrate solutions may increase absorption of aluminium from aluminium hydroxide, resulting in high blood concentrations, especially when renal function is impaired (71).

Encephalopathy due to high serum aluminium concentrations has been reported in acute renal insufficiency (SEDA-17, 273) (72). Unsuspected intake of citrate from other sources has apparently promoted the occurrence of aluminium encephalopathy in renal insufficiency (73). Most reported instances of encephalopathy after alum irrigation have occurred in patients with compromised renal function.

- A 70-year-old man with advanced obstructive nephropathy began to hemorrhage from the bladder after decompression with a Foley catheter (74). He developed an encephalopathy after continuous irrigation with 1% alum for 2 days, associated with raised serum aluminium concentrations. Repeated treatment with deferoxamine and hemodialysis removed some aluminium, but he succumbed to bronchopneumonia. At autopsy his brain aluminium content was not excessive.

Prolonged exposure to aluminium in patients with chronic renal insufficiency can be involved in the pathogenesis of uremic pruritus, and increased calcium phosphate production seems to be an additional predisposing factor (75); certainly the incidence and intensity of pruritus in these uremic patients have been found to be related to the circulating concentrations of aluminium.

Slow accumulation of aluminium during long-term hemodialysis can cause osteomalacia (76), bone and joint pain and muscular weakness (77), iron-resistant microcytic anemia (78), and neurological disorders (79).

In 33 patients on hemodialysis, who were exposed to moderately high serum aluminium concentrations for less than 4 months, even moderately high aluminium concentrations produced significant hematological alterations and depletion of body iron stores before clinical manifestations were evident (80).

In all patients with chronic renal insufficiency, strict supervision of total aluminium intake is vital. The administration of aluminium should be stopped as soon as the serum concentration exceeds 150 μg/ml or at the appearance of the first symptoms of encephalopathy (81). According to current recommendations, dialysate solutions should contain less than 10 μg/l of aluminium (82). There is some controversy about the view that aluminium-containing medications used to control serum phosphate concentrations in uremic subjects should be replaced by calcium-containing phosphate binders (83). Another approach used to reduce the toxic risks of aluminium hydroxide may be to tailor doses to the phosphate concentration in serum, that is individualizing aluminium gel therapy (SED-12, 515).

Drug Administration

Drug overdose

Of 195 patients hospitalized after aluminium phosphide poisoning (84), 115 died. Death was related to the dose

© 2006 Elsevier B.V. All rights reserved.

but not to the time between ingestion and arrival at the hospital. The non-survivors had more severe hypotension and metabolic acidosis than the survivors, who had more severe vomiting. Aluminium phosphide is highly toxic, with a fatal dose as low as 1.5 g. The dominant clinical feature in such cases is severe hypotension, and severe gastrointestinal derangement and cardiorespiratory failure can occur within a day of exposure (85).

Drug–Drug Interactions

Citrate

Citrate is included in many effervescent or dispersible tablets, and increased absorption of aluminium from the gastrointestinal tract has been reported (86–88).

Deferoxamine

Although deferoxamine is effective in treating aluminium overload, case reports have shown that it can induce an exacerbation of aluminium encephalopathy (89), possibly due to increased aluminium concentrations in the cerebrospinal fluid (90,91). During treatment with deferoxamine, plasma aluminium concentrations should be monitored, as concentrations exceeding 800–1000 μmol/l can exacerbate encephalopathy.

Diflunisal

Aluminium reduced the systemic availability of diflunisal by about 40% in healthy volunteers (92).

Prednisone

In five healthy volunteers and 12 patients with chronic active liver disease, antacids containing aluminium hydroxide and magnesium hydroxide significantly reduced the C_{max} and AUC of prednisone when administered with antacids. The systemic availability was reduced by up to 43% (93).

Silicon

Aluminium has a close chemical affinity with silicon, which may have a role in protecting against aluminium toxicity (94). Serum aluminium and silicon concentrations were measured in hemodialysis patients from four different centers. Although there was no relation across all centers combined, in one center there was a reciprocal relation in patients on home hemodialysis (who did not require reverse osmosis). Median (range) aluminium concentrations were higher, 2.2 (0.4–9.6) μmol/l when serum silicon was less than 150 μmol/l, and lower, 1.1 (0.2–2.8) μmol/l when serum silicon was greater than 150 μmol/l. In patients treated by hemodialysis without reverse osmosis, high serum silicon concentrations were associated with lower serum aluminium concentrations. Further work is needed to confirm a preventive role for silicon in the accumulation and subsequent toxicity of aluminium in dialysis patients.

Tetracyclines

The laboratory finding that aluminium hydroxide binds a variety of drugs, thus forming poorly absorbable salts or complexes, has led to a general rule of thumb that other drugs should not be taken within 1–2 hours of aluminium compounds. In most cases such interactions are clinically insignificant, but caution is advisable. The absorption of tetracyclines under these conditions can be reduced by as much as 90% (95).

Amantadine

General Information

Amantadine is a symmetrical C10 tricyclic amine with an unusual structure (1-adamantanamine hydrochloride). It interferes with virus uncoating (1) by blocking the M2 ion channel, which is needed to affect a pH change that helps to initiate the uncoating process. Most consistent antiviral activity has been observed against influenza A virus, but amantadine has little or no activity against influenza B virus (2). However, influenza A virus can become rapidly resistant to amantadine in vitro (3). Amantadine also promotes the release of dopamine from nerve endings, but may also delay its reuptake into synaptic vesicles.

Doses of 100–200 mg/day are often used and are usually well tolerated. The best-documented adverse reactions are nausea, psychotic episodes (mania,

© 2006 Elsevier B.V. All rights reserved.

hallucinations, agitation, confusion), restless legs, and convulsions. Minor adverse reactions often resemble those caused by anticholinergic agents, for example blurred vision, dryness of the mouth, insomnia, lethargy, and rash. In rare cases, photosensitization has been described. Oral or aerosol administration can be accompanied by gastrointestinal or minor neurological symptoms, such as insomnia, light-headedness, concentration difficulties, nervousness, dizziness, and headache in individuals taking 200 mg/day (4). These symptoms disappear on withdrawal. More severe but rare complications include convulsions and coma (5,6). Local nasal adverse effects of the aerosolized form can mimic the symptoms of upper respiratory tract infection. In Parkinson's disease, in which doses of 200 mg/day or more have been used, minor adverse effects resembling those caused by anticholinergic agents (for example blurred vision, dry mouth, as well as livedo reticularis, rash, and photosensitization, can occur (SED-13, 874) (7,8).

Organs and Systems

Cardiovascular

Reversible congestive cardiac failure has been attributed to amantadine (9).

Nervous system

Insomnia is common with amantadine (10).

Myoclonus, especially vocal, can occur (11).

- A 48-year-old woman with a 17-year history of Parkinson's disease developed a sensorimotor peripheral neuropathy after taking amantadine 300 mg/day for 8 years (12). She had livedo reticularis after only 1 year of treatment and this had become increasingly extensive. Attempts to withdraw the drug resulted in worsening Parkinsonian symptoms. However, after the neuropathy had been diagnosed, amantadine was withdrawn, with improvement of the neurological symptoms within 6 weeks and complete resolution after 6 months. However, the livedo reticularis was still present 18 months after withdrawal.

This is the first description of peripheral neuropathy in these circumstances, but it suggests that chronic livedo reticularis may be a forerunner of more severe problems.

Three Japanese women aged 78–87 years who had taken amantadine 100–200 mg/day for 1 month to 5 years, in two cases together with co-careldopa, developed multifocal myoclonus and two were confused (13). Amantadine concentrations were high in the two patients in whom they were measured, at over 3000 ng/ml; a concentration over 1000 ng/ml is regarded as toxic. Amantadine was withdrawn and the myoclonus disappeared within 1–2 weeks and did not recur. Cortical myoclonus has also been described with levodopa and bromocriptine, but the mechanism is not known.

Sensory systems

Rarely, amantadine causes visual impairment due to corneal abrasions, local edema, and superficial keratitis (14).

Psychological, psychiatric

The risk of mental complications seems to increase substantially if doses of 200 mg or more are given (15). Amantadine can cause mania and is contraindicated in patients with bipolar affective disorder (16).

- While taking amantadine, an elderly man developed the Othello syndrome, a severe delusion of marital infidelity, as described in Shakespeare's plays *Othello* and *A Winter's Tale*; it abated with drug withdrawal (SEDA-17, 170).
- Amantadine and phenylpropanolamine may have caused intense recurrent déjà vu experiences in a healthy 39-year-old within 24 hours of starting both drugs for influenza (17).

Fluid balance

Resistant edema of the ankles in the absence of cardiac disease has repeatedly been described and well documented by rechallenge (18).

Skin

Livedo reticularis has been stated to occur in as many as 90% of patients; it is very common in female patients especially those with antiphospholipid antibodies (19).

Long-Term Effects

Drug withdrawal

On withdrawal of amantadine after long-term therapy, acute delirium with confusion, disorientation, agitation, and paranoia occurred in three patients (20). Reintroduction of the drug returned the patients to the baseline status.

In four patients, amantadine withdrawal was associated with delirium and confusion (21). The patients, three of them women, were aged 70–83 years and all but one were considered to have early dementia. Amantadine exposure was 1–5 years and the symptoms occurred within a week of drug withdrawal. In all cases they were reversed by reintroduction. The mechanism of the withdrawal reaction is unknown, but it should obviously be borne in mind, especially in elderly patients with long exposure to the drug and with already impaired cognitive function.

Neuroleptic malignant syndrome can occur on withdrawal of amantadine (22,23).

Susceptibility Factors

Renal disease

In a case of end-stage renal insufficiency, amantadine caused coma, though drug plasma concentrations were not greatly increased (SEDA-18, 160).

Amaranthaceae

See also Herbal medicines

General Information

The genera in the family of Amaranthaceae (Table 1) include cotton flower and rockwort.

Pfaffia paniculata and ginseng

Ginseng is an ambiguous vernacular term that can refer to *Panax* species such as *Panax ginseng* (Asian ginseng) and *Panax quinquefolius* (American ginseng), *Eleutherococcus senticosus* (Siberian ginseng), and *Pfaffia paniculata* (Brazilian ginseng). See ginseng in the monograph on Araliaceae.

Adverse effects

Respiratory

Asthma occurred in a patient who had been exposed to *Pfaffia paniculata* root powder used in the manufacturing of Brazil ginseng capsules (1). Airway hyper-reactivity was confirmed by a positive bronchial challenge to methacholine and sensitivity to the dust was confirmed by immediate skin test reactivity, a positive bronchial challenge (immediate response), and the presence of a specific IgE to an aqueous extract detected by ELISA. The bronchial response was inhibited by sodium cromoglicate. Unexposed subjects did not react to this ginseng extract with any of the tests referred to above. The same study performed with Korean ginseng (*Panax ginseng*) was negative.

Table 1 The genera of Amaranthaceae

Amfebutamone (bupropion)

See also Antidepressants, second-generation

General Information

Amfebutamone is an amphetamine-like drug. It is structurally and pharmacologically distinct from other antidepressants, and apparently enhances both dopamine and noradrenaline function in the brain (SEDA-8, 18) (SEDA-10, 20).

Amfebutamone is used to encourage smoking cessation and in some countries as an antidepressant. In some respects its adverse effects profile is similar to that of the SSRIs: insomnia, agitation, tremor, and nausea are most often reported.

Randomized controlled trials have shown that amfebutamone is less likely to cause sexual dysfunction than SSRIs (1,2), unlike SSRIs, which gives it an important advantage in some patients.

Amfebutamone has been used as an antidepressant for many years in the USA and Canada and is now licensed in Europe for smoking cessation. There has been concern about the number of serious adverse reactions associated with amfebutamone, with particular emphasis on the risk of seizures. Deaths have also been reported from myocarditis and liver failure (3). A problem in determining the role of amfebutamone in these adverse effects is that it is prescribed for heavy smokers who are at risk of serious co-morbid disorders, particularly cardiovascular and respiratory disease. However, it has been clear for some time that the use of amfebutamone is associated with an increased risk of seizures, though this is less with the modified-release formulation (SEDA-23, 20).

Organs and Systems

Cardiovascular

The UK Committee on Safety of Medicines has received over 200 reports of chest pain in patients taking amfebutamone, and a case of myocardial infarction has been reported.

- A 43-year-old man who had smoked up to 20 cigarettes daily for several years and had a family history of heart disease was given amfebutamone and stopped smoking after reaching the recommended dose (300 mg/day) (4). Three days later he developed central chest and arm pain and 1 day later stopped taking amfebutamone. Three days after this he developed classical symptoms of acute inferoposterolateral myocardial infarction. He was treated with thrombolytic therapy and discharged taking secondary prevention therapy.

It is difficult to know how far amfebutamone might have contributed to this acute cardiac event. However, continuing vigilance and case-control studies are warranted.

Nervous system

The main concern with the use of amfebutamone is that in higher dosages it is associated with a risk of seizures (0.4%). Early in 1986, advertising began to appear in advance of the expected release of amfebutamone in the USA. Abruptly, in March, distribution was halted because of reports of seizures in patients with bulimia. Although the risk is greater than that seen with SSRIs (about 0.1%), data have suggested that amfebutamone has approximately the same seizure potential as the tricyclic compounds (SEDA-8, 30). However, a higher seizure risk for amfebutamone than for tricyclic antidepressants has been reported in patients taking amfebutamone in doses over 450 mg/day (SEDA 17, 21). Furthermore, the manufacturers have noted an increased risk of seizures in patients taking over 600 mg/day in combination with lithium or antipsychotic drugs (SEDA-10, 20).

Of 279 patients who presented to a hospital emergency service between 1994 and 1998 with a first tonic-clonic seizure, 17 (6.1%) had seizures that were thought to be drug-related (5). The most common drug-induced causes were cocaine intoxication (6/17) and benzodiazepine withdrawal (5/17) followed by amfebutamone use (4/17). While one amfebutamone-associated seizure occurred in a 26-year-old woman without any other risk factors, the three other patients (all women) had additional risk factors, such as concomitant treatment with antidepressants that also lower seizure threshold and a history of bulimia nervosa. These results suggest that amfebutamone is not an infrequent cause of de novo seizures. However, because of the time frame of the study, many of the patients would have been taking standard-release amfebutamone. It would be of interest to repeat the study now that modified-release amfebutamone is available.

Amfebutamone lowers the seizure threshold and can cause paresthesia (6).

- A 38-year-old woman who was taking olanzapine 10 mg/day and lamotrigine 200 mg/day for a schizoaffective disorder started to take amfebutamone for a depressive mood swing. After 4 weeks the dose of amfebutamone was increased to 300 mg/day, at which point she complained of a twitching pain on the left side of her face. There was hypesthesia of two branches of the left trigeminal nerve, the ophthalmic and maxillary branches, and a reduced left corneal reflex. The amfebutamone was withdrawn and the neurological signs and symptoms disappeared within 8 days. Four weeks later, because of persisting depression, the amfebutamone was reintroduced; at a dosage of 300 mg/day identical neurological symptoms recurred.

The reason for this unusual reaction is not clear. Amfebutamone may potentiate dopamine neurotransmission, and dopamine D_2 receptors modulate trigeminal nerve function (7).

© 2006 Elsevier B.V. All rights reserved.

Amfebutamone has been reported to mimic transient ischemic attacks (8).

- A 67-year-old man with a strong history of ischemic heart disease, who had been smoking 20 cigarettes a day for many years, started to take amfebutamone (100 mg tds) as an aid to smoking cessation. One week later he had episodes of disorientation, a tingling sensation over his body, and roaring sounds in his ears. MRI scanning and angiography showed evidence of previous strokes. His current episodes were ascribed to transient ischemic attacks. He had stopped taking amfebutamone while in hospital and then restarted it 2 days after discharge, when the same symptoms recurred. He then stopped taking amfebutamone completely and over the next 9 months had no further neurological episodes.

It is possible that these symptoms were entirely due to amfebutamone, but more probably the amfebutamone interacted in some way with the patient's established cerebrovascular disease.

Acute dystonia is a recognized complication of treatment with antipsychotic drugs and it can also occur with SSRIs and the anxiolytic drug buspirone.

- A 44-year-old man took amfebutamone 300 mg/day and buspirone 45 mg/day for depression (9). Over 2–3 weeks he developed increasing neck stiffness, with tightening and spasm of the jaw muscles and pain in the left temporomandibular joint. He stopped taking his medications, and all his symptoms resolved over the next 3 weeks. Rechallenge with buspirone (45 mg/day) failed to reproduce the dystonic symptoms. The buspirone was withdrawn and amfebutamone 150 mg/day was started; the dystonic symptoms did not recur. However, 24 hours after the dose of amfebutamone was increased to 300 mg/day there was a return of neck stiffness and jaw spasm.

Amfebutamone has dopaminergic properties, which seem to have played a part in this dystonia. Whether the effect was initiated by concomitant buspirone therapy is unclear, but subsequently amfebutamone alone was sufficient to produce the dystonic symptoms.

Cases of visual hallucinations and tinnitus have been reported in patients taking amfebutamone (SEDA-17, 21).

Psychological, psychiatric

Amfebutamone potentiates dopamine neurotransmission and at higher doses can cause toxic delirium and psychosis, particularly in patients with a history of psychosis and those taking other dopaminergic medications (SEDA-8, 31).

- A 79-year-old man developed a paranoid psychosis with auditory hallucinations during treatment with amfebutamone (100 mg tds) (10). The symptoms remitted with reduction of the dose of amfebutamone and the introduction of haloperidol 5 mg/day.

Paranoid ideas and hallucinations can occur during the course of a severe depressive episode, but in this case the patient's mood was gradually improving, so a link with amfebutamone seems more likely. It seems prudent to dose amfebutamone conservatively in elderly patients.

In an open trial, two of 16 patients became psychotic and were withdrawn from the study (11). A more detailed report of this adverse effect described four of 13 patients who became psychotic during a trial of amfebutamone; three had a history of psychosis, but none had previously had this response to other antidepressants (12). The usual dosage range of amfebutamone is 300–750 mg/day, and the psychotic symptoms occurred at dosages of 300–500 mg/day. In two cases psychotic symptoms were absent at lower dosages, but in one case the dose was therapeutically inadequate.

Other reports of psychotic reactions and a manic syndrome associated with amfebutamone have appeared (SEDA-16, 10) (SEDA-17, 21). In two of these cases a possible drug interaction with fluoxetine, with inhibition of the metabolism of amfebutamone, could not be excluded.

Hematologic

Eosinophilia reportedly developed in a 72-year-old woman shortly after she was given amfebutamone. The eosinophil count fell rapidly after all medications (including glibenclamide and tolmetin) were withdrawn (13).

Skin

Adverse skin reactions, such as rash, urticaria, and pruritus, have been reported in 1–4% of patients taking amfebutamone (14).

Immunologic

Two cases of serum sickness-like reactions have been reported in association with amfebutamone when used as an aid to smoking cessation (15,16). Both patients developed localized swellings of the fingers and hands, urticaria, and arthralgia. In both cases treatment with antihistamines and corticosteroids produced rapid relief of symptoms.

In three other patients (two women, one man) a serum sickness-like reaction developed 6–21 days after the start of amfebutamone treatment (14). The symptoms, arthralgia, pruritus, and tongue swelling, abated within 2 weeks of treatment with oral corticosteroids. Serum sickness reactions to drugs are rare, and it will be important to find out whether amfebutamone carries an increased risk of this unusual reaction.

Death

Amfebutamone has been linked to 41 deaths (17). From the reports of suspected adverse events received by the Netherlands Pharmacovigilance Foundation, it appears that more than half concerned patients at risk of smoking-related diseases. In 15 cases there had been simultaneous use of amfebutamone with another antidepressant (10 patients), theophylline (1 patient), or insulin (4 patients). These combinations may lead to an increase in the risk of seizures. Furthermore, two patients reported having taken antiepileptic drugs, despite the fact that amfebutamone is contraindicated in patients with seizure disorders. These results suggest that the guidelines described in the product information are not being adhered to in some cases.

© 2006 Elsevier B.V. All rights reserved.

Drug Administration

Drug formulations

A modified-release formulation of amfebutamone has been marketed (18). There are insufficient data yet on the risk of seizures with higher doses of the modified-release formulation, but preliminary indications suggest that it is likely to be lower than that seen with the immediate-release formulation (18).

Drug overdose

Seizure is a significant risk in amfebutamone overdose.

- An 18-year-old man attempted suicide by taking amfebutamone 7.5 g (50 × 150 mg tablets) (19). On assessment 90 minutes later he was agitated and aggressive, with a resting pulse of 160 beats/minute and a blood pressure of 142/63 mmHg. He quickly developed a persistently low blood pressure (65/40 mmHg), followed by three generalized tonic-clonic seizures, which were controlled by diazepam. He was ventilated and a metabolic acidosis was corrected with sodium bicarbonate. Despite this, his blood pressure remained persistently low (70/40 mmHg) with a sinus tachycardia (150 beats/minute). Dopamine was ineffective and adrenaline was required. After 24 hours he was extubated and made a full recovery over the next 3 days.
- A 14-year-old boy took 1.5–3.0 g of amfebutamone and had a persistent tachycardia, seizures, and brief agitation and aggression (20). He also had visual hallucinations, disorientation, and confusion but recovered about 24 hours after ingestion.

These cases show that overdose of amfebutamone can be serious.

Drug–Drug Interactions

SSRIs

Amfebutamone is sometimes used to augment the action of other antidepressant drugs, but there are few data on the pharmacokinetic effects of this strategy. In an open study in 19 consecutive patients (7 men and 12 women), amfebutamone (150 mg/day for 8 weeks) did not alter plasma concentrations of paroxetine or fluoxetine (21). Plasma concentrations of venlafaxine increased, but concentrations of its active metabolite, O-desmethylvenlafaxine, fell. Overall tolerability was good and there was a significant reduction in depression rating scales. Sexual function, particularly orgasmic function in women, improved. These data suggest that adding amfebutamone to SSRI treatment does not alter plasma concentrations of SSRIs. The addition of amfebutamone to venlafaxine seems unlikely to cause pharmacokinetic problems in practice, because the increase in plasma concentration of the parent compound was offset by a reduction in the concentration of its major active metabolite. However, there is scope for an interaction of venlafaxine with amfebutamone and the effects in individual patients might be hard to predict. This study also supports clinical suggestions that the addition of amfebutamone to SSRI treatment can enhance antidepressant efficacy and improve sexual function. However, controlled trials are needed to confirm this view.

Amfepramone (diethylpropion)

See also Anorectic drugs

General Information

Reports on the frequency of adverse reactions to amfepramone are not entirely consistent. The number of adverse effects reported by patients taking amfepramone closely paralleled the number in those taking placebo in one study in 90 obese individuals. In another 16-week controlled study in 95 subjects who took amfepramone 25 mg tds, the main adverse effect was nervousness. In 121 obese patients who took a shorter-acting form for an average of 4.4 months, adverse effects occurred in under 9%. They were nausea, vertigo in two patients, and nervousness and palpitation in another two; treatment was discontinued in three cases because of nausea, insomnia, and paresthesia (1). With long-acting amfepramone in a double-blind 16-week crossover study in 102 Austrian patients, adverse effects included nervousness, tension, nausea, dizziness, light-headedness, and dry mouth [SED-9, 14]. The main unwanted effects in a double-blind trial of modified-release amfepramone (Tenuate Dospan) in 50 pregnant women were euphoria, sweating, irritability, and palpitation. Nervousness and insomnia were reported in another controlled study in 75 pregnant women [SEDA-8, 17]. In neither of the last two studies were the adverse reactions serious enough to justify withdrawal.

Organs and Systems

Nervous system

Altogether the effects of amfepramone on the central nervous system are much less common than those of dexamphetamine; for example, 78 patients who had to stop treatment with amphetamine and benzfetamine were able to continue therapy with amfepramone. Even insomnia is uncommon if the drug is taken early in the day.

Long-Term Effects

Drug dependence

There have been some reports of addiction and psychotic manifestations with amfepramone (2) but these are much less frequent than are those associated with amphetamine or phenmetrazole.

Drug–Drug Interactions

Diazepam

In a comparative study using a fixed combination of amfepramone 75 mg plus diazepam 10 mg the adverse effects were milder than those found with other anorexigenic drugs [SED-9, 14]. However, there were mild adverse effects (dry mouth, nervousness, and depression) in about half of the patients.

Amikacin

See also Aminoglycoside antibiotics

General Information

Amikacin is a semisynthetic derivative of kanamycin with similar pharmacokinetic properties and dosages. It is resistant to many of the bacterial R factor-mediated enzymes that inactivate kanamycin and gentamicin. Noteworthy is its effect against *Pseudomonas aeruginosa* and against most Gram-negative aerobes that are resistant to gentamicin and tobramycin. There are strains of *Staphylococcus aureus* that inactivate amikacin by phosphorylation and adenylation. Ticarcillin or azlocillin plus amikacin is considered one of the most efficacious empiric antibiotic combinations in febrile granulocytopenia in patients with cancer. On a weight basis amikacin is less active than gentamicin, and so the usual dose is 10–20 mg/kg/day. Wherever possible, peak concentrations of 40 μg/ml and troughs of 10 μg/ml should not be exceeded during twice-daily dosing.

Organs and Systems

Respiratory

Amikacin may have been the causative agent in an apneic episode in an infant on peritoneal dialysis (1).

Sensory systems

- A 43-year-old man, who was receiving hemodialysis through a permanent catheter developed severe irreversible sensorineural hearing loss after using an amikacin–heparin lock for 16 weeks (2). He suddenly developed a high-frequency sensorineural hearing loss of 40 decibels. His condition progressed over 1 week, despite immediate withdrawal of the amikacin–heparin lock, and he developed severe irreversible hearing loss below 80 decibels for both high and low frequencies.

Retinal toxicity can occur when aminoglycosides are given intravitreally for endophthalmitis.

- Preretinal hemorrhages developed in a 58-year old man who was treated with two intravitreal injections of amikacin (0.4 mg) and cefazolin (2.25 mg) 48 hours

© 2006 Elsevier B.V. All rights reserved.

apart for postoperative endophthalmitis following routine extracapsular cataract extraction (3).
- Macular toxicity followed the use of intravitreal amikacin 0.2 mg for postoperative endophthalmitis in a 69-year-old white woman (4).

Ototoxicity was observed in three of 195 patients who received amikacin (15 mg/kg/day) with either cefepime (2 g bd) or ceftazidime (2 g tds) (5). Two patients had severe loss of hearing, which persisted after drug withdrawal and resulted in permanent disability. The other had mild ototoxicity that required no action and resolved spontaneously.

Urinary tract

After administration of the recommended doses of amikacin for 10 days, renal damage probably occurs in less than 10% of cases. Limited data support the view that amikacin is less nephrotoxic than other aminoglycosides, possibly because of lower binding affinity to proximal tubular cells or reduced potential to cause phospholipidosis (SEDA-20, 236). In several prospective randomized studies the liability of amikacin to cause nephrotoxicity was no greater than that of gentamicin or tobramycin (6–8). In a prospective study there was significantly lower nephrotoxicity with amikacin 15 mg/kg/day (4% toxicity) compared with netilmicin 7 mg/kg/day (12%) (9). As with other aminoglycosides, renal toxicity is reversible in most cases (10).

Nephrotoxicity occurred in five of 195 patients who received amikacin (15 mg/kg/day) with either cefepime (2 g bd) or ceftazidime (2 g tds) (5). In two patients the deterioration in renal function was mild and resolved without withdrawal of amikacin. In the three other patients, renal insufficiency necessitated drug withdrawal; two of these patients recovered, but one died with sepsis, and renal function was still abnormal at the time of death.

Long-Term Effects

Drug tolerance

In Spain, an epidemic strain of *Acinetobacter baumannii* with resistance to amikacin was isolated in eight different hospitals (11).

Susceptibility Factors

In an open study in eight young healthy Japanese women, the pharmacokinetics of amikacin were affected by the phase of the menstrual cycle (12). In patients with hematological malignancies, bodyweight, renal function, acute myeloblastic leukemia, and hypoalbuminemia were the most important co-variates for the interindividual variability in amikacin pharmacokinetics (13).

Drug Administration

Drug formulations

The pharmacokinetics and toxicity of liposomal amikacin have been investigated in a patient treated for advanced pulmonary multidrug-resistant tuberculosis (14). The serum concentrations of amikacin obtained with the liposomal formulation were considerably greater than those obtained with the conventional formulation. Liposomal amikacin was well tolerated and led to clinical improvement, but the patient's sputum remained smear- and culture-positive during the treatment period and for 9 months.

Drug administration route

Amikacin has been tested for compatibility with a chlorhexidine-bearing central venous catheter, the ARROWg+ard Blue Plus, and did not cause a substantial increase in chlorhexidine delivery (15). The amount of amikacin sulfate that was delivered was slightly less than the amount in the infusion solution (92%), but this was considered acceptable.

Drug–Drug Interactions

Penicillins

Amikacin may be inactivated by penicillins. This inactivation occurs not only with a mixture of the agents in solution but also in vivo, particularly in patients with renal insufficiency. Amikacin offers, at least in vitro, the advantage of being much less inactivated than tobramycin or gentamicin (16).

Amiloride

See also Diuretics

General Information

Amiloride is a potassium-sparing diuretic that acts in the distal convoluted tubule independently of the action of aldosterone, inhibiting sodium channels. It is a relatively safe drug with few reported adverse effects.

Patients with congenital nephrogenic diabetes insipidus are often treated with a combination of a thiazide and a potassium-sparing diuretic, without consensus on the preferred potassium-sparing diuretic. A Japanese adult was systematically studied to determine the renal effects of hydrochlorothiazide plus amiloride and hydrochlorothiazide plus triamterene (1). The combination with amiloride was superior to that with triamterene in preventing excessive urinary potassium loss, hypokalemia, and metabolic alkalosis. These results suggest that amiloride is the preferred add-on therapy to hydrochlorothiazide in nephrogenic diabetes insipidus.

Organs and Systems

Cardiovascular

An isolated report (2) suggests that amiloride may have prodysrhythmic potential in a small proportion of patients with inducible sustained ventricular tachycardia.

Electrolyte balance

Amiloride has a specific effect on sodium flux in the renal tubules; severe hyponatremia has been reported with the combination of a thiazide diuretic and amiloride.

As a potassium-sparing diuretic, amiloride can cause hyperkalemia (3), even in patients who are taking a potassium-wasting diuretic (4). This effect can be enhanced by concomitant therapy with ACE inhibitors or angiotensin-II receptor antagonists. In five patients with diabetes mellitus over 50 years of age who were taking an ACE inhibitor the serum potassium rose markedly 8–18 days after the addition of amiloride (5). All but one had some degree of renal impairment. In four cases potassium concentrations were between 9.4 and 11 mmol/l.

Skin

Rashes with diarrhea and eosinophilia have been reported (6).

Immunologic

Sweden's National Adverse Reaction Monitoring System called the attention of physicians to a case in which a 73-year-old woman developed anaphylactic shock after taking only a single tablet of Moduretic (7). The National System had received three other reports on anaphylactic reactions to this combination, and by 1988 the WHO center in Uppsala had received eight others from other countries. Except for mild skin reactions, hypersensitivity reactions to hydrochlorothiazide alone are highly unusual and not of this type.

Drug–Drug Interactions

ACE inhibitors

Co-administration of potassium-sparing diuretics with ACE inhibitors can cause severe hyperkalemia (SED-14, 674). In a retrospective study, five patients developed extreme hyperkalemia (9.4–11 mmol/l) within 8–18 days of starting combination therapy with co-amilozide (amiloride + hydrochlorothiazide) and an ACE inhibitor (5).

Amphotericin

Amiloride is a therapeutic option in reducing potassium losses in patients receiving amphotericin. When it was given to 19 oncology patients with marked amphotericin-induced potassium depletion mean serum potassium concentrations increased in the 5 days before and after administration (from 3.4 to 3.9 mmol/l) (8). There was also a trend toward reduced potassium supplementation (48 versus 29 mmol/day). Adverse reactions were limited to hyperkalemia in two patients who took amiloride 20 mg/day and a high potassium intake.

Carbenoxolone

Amiloride inhibits the ulcer-healing properties of carbenoxolone (9).

Lithium

Although amiloride may reduce the renal clearance of lithium, it appears to be free of the troublesome interaction with lithium that complicates the use of thiazides and loop diuretics.

© 2006 Elsevier B.V. All rights reserved.

Pentamidine

Pentamidine is structurally similar to amiloride and can cause severe hyperkalemia if co-prescribed with potassium-sparing diuretics (10). This is a particularly important interaction in patients with AIDS.

Trimethoprim

Trimethoprim (SED-14, 675) is structurally similar to amiloride and can cause severe hyperkalemia if co-prescribed with potassium-sparing diuretics (10). This is a particularly important interaction in patients with AIDS.

Interference with Diagnostic Tests

Creatinine clearance

Amiloride does not alter renal function (11), but it does block the tubular secretion of creatinine, leading to falsely high measurements of creatinine clearance; inulin clearance is not affected similarly (6).

Amineptine

See also Tricyclic antidepressants

General Information

Amineptine is a tricyclic antidepressant that selectively reduces the dopamine reuptake without affecting the uptake of noradrenaline or serotonin (5-HT) (1). In vivo, it increases striatal homovanillic acid concentrations without affecting the concentrations of other metabolites of dopamine, 3,4,dihydroxyphenylacetic acid (DOPAC) and 3-methoxytyramine. However, high doses of amineptine reduced the extracellular DOPAC concentration in the nucleus accumbens but not in the striatum. Long-term treatment with amineptine causes down-regulation of beta-adrenoceptors.

Amineptine has a seven-membered carbon side-chain and is reported to have more stimulant and fewer sedative effects than other tricyclic compounds, possibly owing to differential actions on dopaminergic rather than serotonergic mechanisms. Amineptine appears to have an unusual propensity for causing hepatocellular damage, which may limit its clinical use (2).

Amineptine increases the release and reduces the re-uptake of dopamine, and it is therefore not surprising that an amphetamine-like drug dependence has been reported (3–5). A withdrawal syndrome occurs and can be improved by clonidine (SEDA-16, 8).

Organs and Systems

Liver

Of all the tricyclic antidepressants, amineptine appears to be the most likely to cause liver damage. More than 26 cases of toxic hepatitis have been reported in France (6). In most cases, hepatitis occurred within the usual dosage range and recurred on rechallenge. However, in several instances it was reported after overdosage. There are other reports of hepatotoxicity associated with amineptine (7,8).

Skin

Amineptine has been reported (9) to cause particularly active acne, occurring beyond the usual distribution on the body and beyond the usual age, especially in women. The remedy recommended is withdrawal of amineptine.

A rosacea-like eruption on the face of a 76-year-old woman was associated with amineptine; the association was confirmed by re-challenge (10).

Long-Term Effects

Drug dependence

Dependence on amineptine in a patient also taking midazolam has been reported (11).

Aminocaproic acid

General Information

During normal fibrinolysis, inactive circulating plasminogen binds to fibrin through an active site that binds lysine. The bound plasminogen is then converted to plasmin by activators (such as tissue plasminogen activator, t-PA) and converted to plasmin, which breaks down the fibrin. Aminocaproic acid (ε-aminocaproic acid, EACA, 6-aminohexanoic acid, Amicar) and tranexamic acid (Cyklokapron) are structural analogues of lysine, which bind irreversibly to the lysine-binding sites on plasminogen, inhibiting binding to fibrin and thus the whole process of fibrinolysis (1,2). These agents inhibit the natural degradation of fibrin and so stabilize clots.

Aminocaproic acid was the first such agent to be used widely, but it has largely been superseded in clinical practice by tranexamic acid, which is about 10 times more potent. *Para*-aminomethylbenzoic acid (PAMBA) is similar to aminocaproic acid, but is about three times more active in inhibiting plasminogen activators (3). However, it is no longer used despite the fact that it is well tolerated.

Uses

Antifibrinolytic agents are of benefit in the treatment of primary menorrhagia (4–7), recurrent epistaxis (8), oral bleeding in patients with congenital and acquired coagulation disorders (9,10), hemorrhage associated with thrombolytic therapy, and to reduce blood loss associated with surgery (especially cardiac surgery, joint replacement, and orthotopic liver transplantation) (11–14). Antifibrinolytic therapy can be of value in other conditions as well (15–21). It is effective in the bleeding diathesis that can accompany acute promyelocytic leukemia (22,23), but it does not improve outcome after subarachnoid hemorrhage (24).

General adverse effects

Some adverse effects are associated with all antifibrinolytic agents, reflecting their effect on clot stability. Dissolution of extravascular blood clots may be resistant to physiological fibrinolysis. These drugs should not to be used to treat hematuria due to blood loss from the upper urinary tract, as this can provoke painful clot retention and even renal insufficiency associated with bilateral ureteric obstruction (25–31).

Well-controlled studies on aminocaproic acid in a limited number of patients showed no serious adverse effects. Minor unwanted effects have been reported in 10–20% of patients and include headache, nasal congestion, conjunctival suffusion, nausea, vomiting, diarrhea, and transient hypotension (32). Skin rashes have also been associated with aminocaproic acid, including maculopapular and morbilliform eruptions. Rarer dermatological reactions reported include purpuric rashes (33), bullous eruptions (34), and contact dermatitis with positive patch tests (35–37). Treatment with a high dose (the maximum daily dose is 36 g/day) can result in an osmotic diuresis (38).

Miscellaneous adverse reactions attributed by the authors of single case reports have included a psychotic reaction (39), convulsions after intravenous administration of aminocaproic acid in a 60-year-old man treated for bleeding esophageal varices (40), and renal insufficiency due to glomerular capillary thrombosis (31).

Aminocaproic acid used during cardiopulmonary bypass reduced mediastinal blood losses by about one-third, while transfusion requirements were unchanged (41). In one series of over 950 patients, not a single thromboembolic complication could be ascribed to aminocaproic acid. However, a few cases of muscle necrosis and rhabdomyolysis with renal insufficiency have been reported with aminocaproic acid (42,43).

Organs and Systems

Cardiovascular

Aminocaproic acid has been reported to cause acute right heart failure (44).

© 2006 Elsevier B.V. All rights reserved.

Acid–base balance

Metabolic acidosis associated with a high anion gap has been reported after the administration of aminocaproic acid to a woman with renal insufficiency (45).

Hematologic

Inhibition of plasminogen by tranexamic acid and aminocaproic acid could theoretically facilitate the development of thrombosis, but whether it actually does so has been the subject of contradictory reports. Episodes of venous and arterial thrombosis have been reported in association with treatment using either tranexamic acid or aminocaproic acid. These include thrombosis at unusual sites such as mesenteric thrombosis (46), aorta (47), retinal artery occlusion (48), and intracranial arterial thrombosis (49–51), as well as deep vein thrombosis in the legs (52).

- Massive pulmonary thromboembolism was reported in a 62-year-old woman seven days after treatment with high doses for subarachnoid hemorrhage (53).

Caution should also be taken in the administration of antifibrinolytic agents in disseminated intravascular coagulation (54).

Prophylactic use of histamine H_1 and H_2 receptor antagonists, aminocaproic acid, and hyposensitization have all been proposed as means of preventing idiosyncratic reactions to radiological contrast media. Aminocaproic acid was formerly used prophylactically in France, but carried a risk of massive intravascular coagulation (SEDA-17, 536).

Skin

- A 70-year-old man taking aminocaproic acid developed dermatitis with eosinophilia and positive patch tests on days 2 and 4 (55).

Musculoskeletal

Myopathy has occasionally been reported in association with aminocaproic acid therapy in both adults and children (42,56–64).

- Myonecrosis developed in a 22-year-old man who presented with dark smoky urine and calf tenderness, with progressive weakness and difficulty in walking, after treatment with aminocaproic acid for several weeks for traumatic hematuria; after withdrawal he recovered over 3 weeks (61).

A review of published cases confirmed that this complication is very rare and is usually associated with the administration of high doses for several weeks (43). The myopathy is often painful, and associated with raised creatine kinase activity and even myoglobinuria. Full resolution can be expected once the drug is withdrawn.

Susceptibility Factors

Renal disease

Two different case reports have dealt with previously unreported adverse effects of aminocaproic acid in patients with renal insufficiency.

- A patient with underlying chronic renal insufficiency, who underwent coronary bypass artery grafting and was treated with intravenous aminocaproic acid, developed hyperkalemia (6.7 mmol/l) (65). There was no other obvious cause for the acute increase in serum potassium.

The authors suggested that the structural similarity between aminocaproic acid and lysine and arginine underlies the mechanism of hyperkalemia; intravenous arginine can cause hyperkalemia (66,67). Furthermore, aminocaproic acid infusion in anephric dogs caused a rapid rise in serum potassium (68).

Aminoglycoside antibiotics

See also Individual agents

General Information

Eleven aminoglycosides have been, or are still, important in medical practice: amikacin (rINN), gentamicin (pINN), isepamicin (rINN), kanamycin (rINN), neomycin (rINN), netilmicin (rINN), paromomycin (rINN), sisomicin (rINN), streptomycin (rINN) and dihydrostreptomycin (rINN), and tobramycin (rINN). The following aminoglycosides are also covered in separate monographs: amikacin, gentamicin, isepamycin, kanamycin, and tobramycin.

Being chemically similar, the aminoglycosides have many features in common, in particular their mechanism of antibacterial action, a broad antibacterial spectrum, partial or complete cross-resistance, bactericidal action in a slightly alkaline environment, poor absorption from the gastrointestinal tract, elimination by glomerular filtration, nephrotoxicity, ototoxicity, a potential to cause neuromuscular blockade, and partial or complete cross-allergy (1). Aminoglycosides have a moderate capacity for diffusion into bone tissue (2).

The aminoglycosides have probably more than one mechanism of action on bacterial cells. They cause misreading of the RNA code and/or inhibition of the polymerization of amino acids.

All the aminoglycosides have similar patterns of adverse reactions, although there are important differences with regard to their frequency and severity (Table 1).

Strategies for minimizing aminoglycoside toxicity include early bedside detection of cochlear and vestibular dysfunction, which should lead to prompt withdrawal, use of short periods of treatment, dosing intervals of at least 12 hours, monitoring of serum concentrations, and awareness of relative contraindications, such as renal or hepatic dysfunction, old age, hearing impairment, and previous recent aminoglycoside exposure (3).

Observational studies

In an open, randomized, comparative study of the efficacy, safety, and tolerance of two different antibiotic regimens in the treatment of severe community-acquired or nosocomial pneumonia, 84 patients were analysed (4). Half were treated with co-amoxiclav (amoxicillin 2 g and clavulanic acid 200 mg) every 8 hours plus a single-dose of 3–6 mg/kg of an aminoglycoside (netilmicin or gentamicin), and half with piperacillin 4 g and tazobactam 500 mg every 8 hours. The patients were treated for between 48 hours and 21 days. Clinical cure was achieved in 65% of patients with co-amoxiclav/aminoglycoside and in 81% of patients with piperacillin/tazobactam. Cure or improvement was observed in 84 and 90% respectively. Treatment failures were recorded in 14 versus 7%. One patient in each group relapsed. There was only one fatal outcome in the piperacillin/tazobactam group compared with six in the co-amoxiclav/aminoglycoside group. The adverse event rate was non-significantly lower in the

Table 1 Relative adverse effects of aminoglycoside antibiotics on eighth nerve function, the nervous system, and neuromuscular function

Aminoglycoside[1]	Usual parenteral dose (mg/kg/day)[2]	Site of adverse effect[3]			
		Vestibular function	Cochlear function	Nervous system	Neuromuscular function
Amikacin	10–15	+	++	++	+
Gentamicin	3–6	++	++	++	+
Kanamycin	10–20	+	+++	++	+
Netilmicin	3–6	+	+	++	+
Sisomicin	2–4	++	++	++	+
Streptomycin	10–20	+++	+	+	++
Dihydrostreptomycin	10–20	+	+++	+++	++
Tobramycin	3–6	++	++	++	+

[1] Neomycin and paromomycin: only accidental absorption after topical or gastrointestinal use.
[2] In general, older patients require lower doses. Low doses are required during therapy of infectious endocarditis when an aminoglycoside is given with a penicillin. Monitoring serum concentrations should be considered, particularly when using dosing regimens that involve more than one dose a day and high doses for several days.
[3] The number of signs (+) indicates the relative clinical importance of each reaction.

piperacillin/tazobactam group. In one patient given piperacillin/tazobactam, there were raised transaminases. In the co-amoxiclav/aminoglycoside group, acute renal insufficiency developed in two patients and possibly drug-related fever in one. Bacteriological efficacy was comparable (92% versus 96%). The authors concluded that piperacillin/tazobactam is highly efficacious in the treatment of severe pneumonia in hospitalized patients and compares favorably with the combination of co-amoxiclav plus an aminoglycoside.

General adverse effects

The main adverse reactions of aminoglycosides consist of kidney damage (often presenting as non-oliguric renal insufficiency) and ototoxicity, including vestibular and/or cochlear dysfunction. Neuromuscular transmission can be inhibited. Hypersensitivity reactions are most frequent after topical use, which should be avoided. Anaphylactic reactions can occur. Tumor-inducing effects have not been reported.

Pharmacoeconomics

The pharmacoeconomic impact of adverse effects of antimicrobial drugs is enormous. Antibacterial drug reactions account for about 25% of adverse drug reactions. The adverse effects profile of an antimicrobial agent can contribute significantly to its overall direct costs (monitoring costs, prolonged hospitalization due to complications or treatment failures) and indirect costs (quality of life, loss of productivity, time spent by families and patients receiving medical care). In one study an adverse event in a hospitalized patient was associated on average with an excess of 1.9 days in the length of stay, extra costs of $US2262 (1990–93 values), and an almost two-fold increase in the risk of death. In the outpatient setting, adverse drug reactions result in 2–6% of hospitalizations, and most of them were thought to be avoidable if appropriate interventions had been taken. In a review, economic aspects of antibacterial therapy with aminoglycosides have been summarized and critically evaluated (5).

Organs and Systems

Cardiovascular

Anecdotal reports refer to tachycardia, electrocardiographic changes, hypotension, and even cardiac arrest (6). In practice, effects on the cardiovascular system are unlikely to be of any significance.

Respiratory

Severe respiratory depression due to neuromuscular blockade has been observed (7). Bronchospasm can occur as part of a hypersensitivity reaction.

Neuromuscular function

The aminoglycosides have a curare-like action, which can be antagonized by calcium ions and acetylcholinesterase inhibitors (8). The mechanisms include reduced release of acetylcholine prejunctionally and an interaction with the postjunctional acetylcholine receptor-channel complex. While neomycin interacts with the open state of the receptor, streptomycin blocks the receptor (9).

Aminoglycoside-induced neuromuscular blockade can be clinically relevant in patients with respiratory acidosis, in myasthenia gravis, and in other neuromuscular diseases. Severe illness, the simultaneous use of anesthetics, for example in the immediate postoperative phase, and application of the antibiotic to serosal surfaces are predisposing factors (10).

With regard to this effect, neomycin is the most potent member of the group. Several deaths and cases of severe respiratory depression due to neomycin have been reported (11). Severe clinical manifestations are rare in patients treated with aminoglycosides that are administered in low doses, such as gentamicin, netilmicin, and tobramycin. In some cases the paralysis was reversed by prostigmine.

Sensory systems

Eyes

Collagen corneal shields pre-soaked with antibiotics are used as a means of delivering drug to the cornea and anterior chamber of the eye. Gentamicin damages the primate retina, particularly by macular infarction, and amikacin can have a similar effect; a subconjunctival injection of tobramycin causes macular infarction (SEDA-19, 245). This potentially devastating consequence suggests that care must be exercised when contemplating instillation of aminoglycosides directly into the eye. Allergic contact dermatitis causing conjunctivitis and blepharitis has been reported with topical ophthalmic tobramycin (12).

Ears

Ototoxicity is a major adverse effect of aminoglycoside antibiotics (13). They all affect both vestibular and cochlear function, but different members of the family have different relative effects (Table 1).

Differences between different aminoglycosides

Ototoxicity due to amikacin is primarily cochlear; however, in comparisons with equipotent dosages, ototoxicity was of the same order as that caused by gentamicin (14–16).

In 40 patients tobramycin had little effect on audiometric thresholds, but produced a change in the amplitude of the distortion products, currently considered an objective method for rapidly evaluating the functional status of the cochlea (17). In one case, tobramycin caused bilateral high-frequency vestibular toxicity, which subsequently showed clinical and objective evidence of functional recovery (18).

In a quantitative assessment of vestibular hair cells and Scarpa's ganglion cells in 17 temporal bones from 10 individuals with aminoglycoside ototoxicity, streptomycin caused a significant loss of both type I and type II hair cells in all five vestibular sense organs (19). The vestibular ototoxic effects of kanamycin appeared to be similar to those of streptomycin, whereas neomycin did not cause loss of vestibular hair cells. There was no significant loss of Scarpa's ganglion cells.

© 2006 Elsevier B.V. All rights reserved.

Incidence

The incidence of ototoxicity due to aminoglycosides varies in different studies, depending on the type of patients treated, the methods used to monitor cochlear and vestibular function, and the aminoglycoside used (20). Clinically recognizable hearing loss and vestibular damage occur in about 2–4% of patients, but pure-tone audiometry, particularly at high frequencies, and electronystagmography show hearing loss and/or vestibular damage in up to 26 and 10% respectively, despite careful dosage adjustment (21). In patients with *Pseudomonas* endocarditis receiving prolonged high-dose gentamicin, auditory toxicity was found in 44% (22,23).

A review of nearly 10000 adults suggested rates of 14% for amikacin, 8.6% for gentamicin, and 2.4% for netilmicin. Aminoglycoside toxicity is markedly lower in infants and children, with an incidence of 0–2%. A long duration of treatment and repeated courses or high cumulative doses appear to be critical for ototoxicity, which occurs in high frequency hearing beyond the range of normal speech.

There is a discrepancy between clinical observations, in which very few patients receiving aminoglycosides actually complain of hearing loss, and the reported incidences of ototoxicity in studies of audiometric thresholds. A major reason for this discrepancy relates to the fact that aminoglycosides cause high-frequency hearing loss well before they affect the speech frequency range in which they can be detected by the patient (21).

Gentamicin also damages the vestibular apparatus at a rate of 1.4–3.7%, resulting in vertigo and impaired balance. This effect is reversible in only about 50% from 1 week to 6 months after administration.

In a retrospective study in 81 men and 29 women, hearing loss of 15 decibels at two or more frequencies, or at least 20 decibels at at least one frequency, was found in 18% of patients treated with aminoglycosides (amikacin, kanamycin, and/or streptomycin) (24). In those treated with kanamycin the rate was 16%. Age, sex, treatment duration, total aminoglycoside dose, and first serum creatinine concentration were not associated with hearing loss.

Dose-relatedness

Hearing loss was attributed to repeated exposure to aminoglycosides in 12 of 70 patients with cystic fibrosis (one child) (25). There was a non-linear relation between the number of courses of therapy and the incidence of hearing loss. The severity of loss was not related to the number of courses. Assuming that the risk of hearing loss was independent of each course, the preliminary estimate of the risk was less than 2 per 100 courses.

Presentation

Clinically, cochlear ototoxicity is more frequent and easier to detect than vestibular toxicity; combined defects are relatively rare. Symptoms of cochlear damage include tinnitus, hearing loss, pressure, and sometimes pain in the ear. The manifestations of vestibular toxicity are dizziness, vertigo, ataxia, and nystagmus. These are often overlooked in severely ill, bed-ridden patients.

Symptoms of ototoxicity can occur within 3–5 days of starting treatment, but most patients with severe damage have received prolonged courses of aminoglycosides. In some cases, hearing loss progresses after the administration of the causative drug has been interrupted. The ototoxicity is reversible in only about 50% of patients. Permanent deafness is often seen in patients with delayed onset of symptoms, progressive deterioration after withdrawal of treatment, and hearing loss of over 25 db (21).

There are interesting differences in the toxicity patterns of aminoglycosides in animals. Gentamicin and tobramycin affect the cochlear and vestibular systems to a similar extent, while amikacin, kanamycin, and neomycin preferentially damage the cochlear and streptomycin the vestibular system. Netilmicin appears to be the least toxic (26,27).

In man, differences in the ototoxic risks of the currently used aminoglycosides are difficult to evaluate (20). There have been no prospective comparisons of more than two drugs using the same criteria in similar patient populations. However, several controlled comparisons of two aminoglycosides are available and provide some information. A survey of 24 such trials showed the following mean frequencies of ototoxicity: gentamicin 7.7%, tobramycin 9.7%, amikacin 13.8%, netilmicin 2.3% (28). There was also a lower incidence of netilmicin-induced inner ear damage compared with tobramycin in two studies (29,30).

Of 20 patients with Dandy's syndrome, 15 had previously been treated with aminoglycosides (13 with gentamicin and 2 with streptomycin), of whom 10 had symptoms of pre-existing chronic nephrosis or transitory renal insufficiency. In all 13 patients who had gentamicin, peripheral vestibular function was destroyed or severely damaged, whereas there was no hearing loss (31).

Mechanism

The mechanism of ototoxicity by aminoglycosides is still not fully clarified. Most of the experimental data have been gained in the guinea-pig model, which seems to resemble man.

Animal studies

Traditionally, toxic damage is considered to be the consequence of drug accumulation in the inner ear fluids (32,33). After a period of reversible functional impairment, destruction of outer hair cells occurs in the basilar turn of the cochlear duct and proceeds to the apex. Similar changes are found in the hair cells of the vestibular system. Gentamicin was detected in the outer hair cells in the cochlea of animals receiving non-ototoxic doses of the drug and continued to increase for several days after withdrawal (34). This was followed by a third and very much slower phase of elimination (estimated half-life 6 months), and in the absence of ototoxicity gentamicin could still be detected in the outer hair cells 11 months after treatment. This may explain why patients who receive several courses of aminoglycosides in a year may be more susceptible to ototoxicity, and suggests that the cumulative dose (and by implication the duration of therapy) is the more important determinant of cochlear damage. However, it has been questioned whether

© 2006 Elsevier B.V. All rights reserved.

ototoxicity correlates with plasma perilymph or whole-tissue concentrations of aminoglycosides (33).

The effects of aminoglycosides on the medial efferent system have been assessed in awake guinea-pigs (35,36). The ensemble background activity and its suppression by contralateral acoustic stimulation was used as a tool to study the medial efferent system. A single intramuscular dose of gentamicin 150 mg/kg reduced or abolished the suppressive effect produced by activation of the olivocochlear system by contralateral low-level broadband noise stimulation. This effect was dose-dependent and could be demonstrated ipsilaterally on the compound action potential, otoacoustic emissions, and ensemble background activity of the eighth nerve. Long-term gentamicin treatment (60 mg/kg for 10 days) had no effect, at least before the development of ototoxicity. Single-dose intramuscular netilmicin 150 mg/kg displayed blocking properties similar to gentamicin, although less pronounced, while amikacin 750 mg/kg and neomycin 150 mg/kg had no effect. With tobramycin 150 mg/kg and streptomycin 400 mg/kg a decrease in suppression was usually associated with a reduction of the ensemble background activity measured without acoustic stimulation, which may be a fist sign of alteration to cochlear function. There was no correlation between specificity and degree of aminoglycoside ototoxicity and their action on the medial efferent system.

Possible mechanisms and preventive strategies have also been investigated in pigmented guinea-pigs (37–39). Animals that received alpha-lipoic acid (100 mg/kg/day), a powerful free radical scavenger, in combination with amikacin (450 mg/kg/day intramuscularly) had a less severe rise in compound action potential threshold than animals that received amikacin alone. In a similar study in pigmented guinea-pigs, the iron chelator deferoxamine (150 mg/kg bd for 14 days) produced a significant protective effect against ototoxicity induced by neomycin (100 mg/kg/day for 14 days). The spin trap alpha-phenyl-tert-butyl-nitrone also protected against acute ototopical aminoglycoside ototoxicity in guinea-pigs. These studies have provided further evidence for the hypothesis that aminoglycoside ototoxicity is mediated by the formation of an aminoglycoside-iron complex and reactive oxygen species.

Aminoglycoside-induced ototoxicity may be in part a process that involves the excitatory activation of cochlear NMDA receptors (40). In addition, the uncompetitive NMDA receptor antagonist dizocilpine attenuated the vestibular toxicity of streptomycin in a rat model, further stressing that excitotoxic mechanisms mediated by NMDA receptors also contribute to aminoglycoside-induced vestibular toxicity (41). In two studies in guinea-pigs, nitric oxide and free radicals, demonstrated by the beneficial effect of the antioxidant/free radical scavenger alpha-lipoic acid, have been suggested to be involved in aminoglycoside-induced ototoxicity (38,42). In contrast, insulin, transforming growth factor alpha, or retinoic acid may offer a protective potential against ototoxicity caused by aminoglycosides. However, they do not seem to promote cochlear hair cell repair (43). In guinea-pigs, brain-derived neurotrophic factor, neurotrophin-3, and the iron chelator and antioxidant 2-hydroxybenzoate (salicylate), at concentrations corresponding to anti-inflammatory concentrations in humans, attenuated aminoglycoside-induced ototoxicity (44,45). In rats, concanavalin A attenuated aminoglycoside-induced ototoxicity, and kanamycin increased the expression of the glutamate-aspartate transporter gene in the cochlea, which might play a role in the prevention of secondary deaths of spiral ganglion neurons (46,47). Finally, 4-methylcatechol, an inducer of nerve growth factor synthesis, enhanced spiral ganglion neuron survival after aminoglycoside treatment in mice (48).

In hatched chicks repeatedly injected with kanamycin, afferent innervation of the regenerated hair cells was related more to the recovery of hearing than efferent innervation (49).

Human studies

There is evidence that the site of ototoxic action is the mitochondrial ribosome (50,51). In some countries, such as China, aminoglycoside toxicity is a major cause of deafness. Susceptibility to ototoxicity in these populations appears to be transmitted by women, suggesting mitochondrial inheritance. In Chinese, Japanese, and Arab-Israeli pedigrees a common mutation was found. A point mutation in a highly conserved region of the mitochondrial 12S ribosomal RNA gene was common in all pedigrees with maternally inherited ototoxic deafness (50). A mutation at nucleotide 1555 has been reported to confer susceptibility to aminoglycoside antibiotics, and to cause non-syndromic sensorineural hearing loss. Outside these susceptible families, sporadic cases also have this mutation in increased frequency. In patients bearing this mitochondrial mutation hearing loss was observed after short-term exposure to isepamicin sulfate (52). These findings might create a molecular baseline for preventive screening of patients when aminoglycosides are to be used (SEDA-18, 1) (50).

Differences between sera from patients with resistance or susceptibility to aminoglycoside ototoxicity have been described in vitro (53). Sera from sensitive but not from resistant individuals metabolized aminoglycosides to cytotoxins, whereas no sera were cytotoxic when tested without the addition of aminoglycosides. This effect persisted for up to 1 year after aminoglycoside treatment.

Susceptibility factors

Several factors predispose to ototoxic effects (Table 2). Drug-related toxicity is influenced by the quality of prescribing. Overdosage in patients with impaired renal function, unnecessary prolongation of treatment, and the concomitant administration of other potentially ototoxic agents should be avoided. The exact mechanism of

Table 2 Factors that increase susceptibility to the adverse effects of aminoglycosides

Patient factors	Drug-related factors
Prior renal insufficiency	High temperature
Prior abnormal audiogram	Dose (blood concentration exceeding the usual target range)
Age (mainly older patients)	Total cumulative dose
Septicemia	Prolonged duration of therapy (2–3 weeks)
Dehydration	Prior aminoglycoside exposure

© 2006 Elsevier B.V. All rights reserved.

increased toxicity in patients with septicemia and a high temperature is not clear; the possible relevance of additive damage by bacterial endotoxins has been discussed (54). Dehydration with hypovolemia is probably the main reason for the increased toxicity experienced when aminoglycosides are given with loop diuretics, but furosemide itself does not seem to be an independent risk factor (55,56). Attempts have been made in animals to protect against ototoxicity by antioxidant therapy (for example glutathione and vitamin C), as well as iron chelators and neurotrophins (57).

Hereditary deafness is a heterogeneous group of disorders, with different patterns of inheritance and due to a multitude of different genes (58,59). The first molecular defect described was the A1555G sequence change in the mitochondrial 12S ribosomal RNA gene. A description of two families from Italy and 19 families from Spain has now suggested that this mutation is not as rare as was initially thought (60,61). The A1555G mutation is important to diagnose, since hearing maternal relatives who are exposed to aminoglycosides may lose their hearing. This predisposition is stressed by the fact that 40 relatives in 12 Spanish families and one relative in an Italian family lost their hearing after aminoglycoside exposure. Since the mutation can easily be screened, any patient with idiopathic sensorineural hearing loss may be screened for this and possible other mutations.

In an Italian family of whom five family members became deaf after aminoglycoside exposure, the nucleotide 961 thymidine deletion associated with a varying number of inserted cytosines in the mitochondrial 12S ribosomal RNA gene was identified as a second pathogenic mutation that could predispose to aminoglycoside ototoxicity (62). Molecular analysis excluded the A1555G mutation in this family.

The A1555G mutation in the human mitochondrial 12S RNA, which has been associated with hearing loss after aminoglycoside administration (63) and has been implicated in maternally inherited hearing loss in the absence of aminoglycoside exposure in some families, can be identified by a simple and rapid method for large-scale screening that uses one-step multiplex allele-specific PCR (64).

Using lymphoblastoid cell lines derived from five deaf and five hearing individuals from an Arab-Israeli family carrying the A1555G mutation, the first direct evidence has been provided that the mitochondrial 12S rRNA carrying the A1555G mutation is the main target of the aminoglycosides (65). This suggests that they exert their detrimental effect through altering mitochondrial protein synthesis, which exacerbates the inherent defect caused by the mutation and reduces the overall translation rate below the minimal level required for normal cellular function.

A second pathogenic mutation that could predispose to aminoglycoside ototoxicity has been identified in an Italian family, of whom five members became deaf after aminoglycoside exposure (62). In the mitochondrial 12S ribosomal RNA gene, the deletion of nucleotide 961 thymidine was associated with a varying number of inserted cytosines. Transient evoked otoacoustic emission has been suggested as a sensitive measure for the early effects of aminoglycosides on the peripheral auditory system and may be useful as a tool for the prevention of permanent ototoxicity (66).

In a case-control study in 15 children under 33 weeks gestation with significant sensorineural hearing loss and 30 matched controls, the children with sensorineural hearing loss had longer periods of intubation, ventilation, oxygen treatment, and acidosis, and more frequent treatment with dopamine or furosemide (67). However, neither peak nor trough aminoglycoside concentrations, nor duration of jaundice or bilirubin concentration varied between the groups. At 12 months of age, seven of the children with sensorineural hearing loss had evidence of cerebral palsy compared with two of the 30 controls. Therefore, preterm children with sensorineural hearing loss required more intensive care in the perinatal period and developed more neurological complications than controls, and the coexistence of susceptibility factors for hearing loss may be more important than the individual factors themselves.

Diagnosis

To recognize auditory damage at an early stage and avoid severe irreversible toxicity, repeated tests of cochlear and vestibular function should be carried out in all patients needing prolonged aminoglycoside treatment. Pure-tone audiometry at 250–8000 Hz and electronystagmography with caloric testing are the standard methods. The first detectable audiometric changes usually occur in the high-tone range (over 4000 Hz) and then progress to lower frequencies. Hearing loss of more than 15 db is usually considered as evidence of toxicity. Brainstem auditory-evoked potentials have been recommended as a means of monitoring ototoxicity in uncooperative, comatose patients (68,69). This technique is time-consuming and requires some expertise, but may become a useful tool for detecting damage at an early stage. It also provides information on pre-existing changes, which is otherwise rarely available in intensive care patients (69).

Prevention

In rats, ototoxicity caused by gentamicin or tobramycin was ameliorated by melatonin, which did not interfere with the antibiotic action of the aminoglycosides (70). The free radical scavenging agent alpha-lipoic acid has previously been shown to protect against the cochlear adverse effects of systemically administered aminoglycoside antibiotics, and in a recent animal study it also prevented cochlear toxicity after the administration of neomycin 5% directly to the round window membrane over 7 days (71).

Loss of spiral ganglion neurons can be prevented by neurotrophin 3, whereas hair cell damage can be prevented by *N*-methyl-D-aspartate (NMDA) receptor antagonists. In an animal study, an NMDA receptor antagonist (MK801) protected against noise-induced excitotoxicity in the cochlea; in addition, combined treatment with neurotrophin 3 and MK801 had a potent effect in preserving both auditory physiology and morphology against aminoglycoside toxicity induced by amikacin (72).

Metabolism

Aminoglycosides can stimulate the formation of reactive oxygen species (free radicals) both in biological and cell-free systems (73,74).

© 2006 Elsevier B.V. All rights reserved.

Electrolyte balance

Aminoglycoside-induced proximal tubular dysfunction, which causes some manifestations of Fanconi's syndrome, including electrolyte abnormalities, is rare.

- A 72-year-old man was treated with ceftriaxone (2 g bd) and gentamicin (80 mg tds) for a severe urinary tract infection (75). On day 5 his serum potassium concentration was 3 mmol/l with a normal serum creatinine and urine examination. Despite treatment with oral potassium chloride plus a high potassium diet, his serum potassium fell to 2.3 mmol/l 4 days later, accompanied by inappropriate kaliuresis, hypouricemia with inappropriate uricosuria, and hypophosphatemia with inappropriate phosphaturia. There was no bicarbonate wasting, but there was proteinuria 1.2 g/day, with a predominance of low molecular weight proteins; in contrast, serum creatinine was normal and creatinine clearance was 78 ml/minute. The aminoglycoside was withdrawn with subsequent progressive improvement in renal proximal tubular function, which normalized 9 days later.

Mineral balance

Hypomagnesemia is a well-recognized adverse effect of treatment with various drugs, including aminoglycosides (SEDA-16, 279). Gentamicin-induced magnesium depletion is most likely to occur in older patients when large doses are used over long periods of time (76). Under these circumstances, serum concentrations and urinary electrolyte losses should be monitored.

Metal metabolism

Aminoglycosides can cause renal magnesium wasting and hypomagnesemia, usually associated with acute renal insufficiency. However, animal studies have shown frequent renal magnesium wasting, even in the absence of renal insufficiency and abnormalities of renal tubular morphology. In 24 patients with cystic fibrosis, treatment with amikacin plus ceftazidime for exacerbation of pulmonary symptoms by *Pseudomonas aeruginosa* resulted in mild hypomagnesemia due to renal magnesium wasting, even in the absence of a significant rise in circulating creatinine and urea concentrations (77).

In five healthy volunteers gentamicin 5 mg/kg caused immediate but transient renal calcium and magnesium wasting (78).

Reversible hypokalemic metabolic alkalosis and hypomagnesemia can occur with gentamicin, and routine monitoring has been recommended (79).

The results of an in vitro study on immortalized mouse distal convoluted tubule cells have suggested that aminoglycosides act through an extracellular polyvalent cation-sensing receptor and that they inhibit hormone-stimulated magnesium absorption in the distal convoluted tubule (80).

In children with cystic fibrosis, aminoglycosides can cause hypomagnesemia due to excessive renal loss (81).

Hematologic

In an in vitro study both gentamicin sulfate and netilmicin sulfate showed competitive inhibition of glucose-6-phosphate dehydrogenase from human erythrocytes, whereas streptomycin sulfate showed non-competitive inhibition (82).

Liver

Certain aminoglycosides affect liver function tests. Increases in alkaline phosphatase after gentamicin and tobramycin have been described.

Urinary tract

Impairment of kidney function is a major adverse effect of the aminoglycoside antibiotics. In a survey of the use of antibiotics in a surgical service, aminoglycosides were given to 26 patients, of whom four developed nephrotoxicity (83).

In patients undergoing peritoneal dialysis, intraperitoneal or intravenous aminoglycosides can increase the rapidity of the fall in residual renal function. In an observational, non-randomized study, 72 patients on peritoneal dialysis were followed for 4 years (84). Patients who had been treated for peritonitis with intraperitoneal or intravenous aminoglycosides for more than 3 days had a more rapid fall in renal creatinine clearance and a more rapid fall in daily urine volume than patients without peritonitis or patients treated for peritonitis with antibiotics other than aminoglycosides. However, the use of other nephrotoxins or agents that may improve renal function was not quantified.

Incidence

Impairment of kidney function in different studies is highly variable. It depends on the study population and the definition of toxicity, and can range from a few percent to more than 30% in severely ill patients (85,86).

In a retrospective study, the rate of nephrotoxicity at the end of treatment with aminoglycosides was 7.5% (kanamycin 4.5%) (24). Patients who developed nephrotoxicity had a longer duration of treatment and received larger total doses.

Susceptibility factors

As in the case of ototoxicity, certain susceptibility factors have been identified for nephrotoxicity (87,88). Total dose, age, abnormal initial creatinine clearance, the 1-hour post-dose and trough aminoglycoside serum concentrations, duration of treatment, and co-existent liver disease were predictors of subsequent kidney damage. However, the clinical significance and utility of predictive nomograms based on such risk factors have been challenged (89). Other factors, such as dehydration, hypovolemia, potassium and magnesium depletion, and sepsis are also important. Gentamicin nephrotoxicity is increased in biliary obstruction (SEDA-20, 235). Nephrotoxicity is potentiated by ACE inhibitors, cephalosporins, ciclosporin, cisplatin, loop diuretics (secondary to volume depletion), methoxyflurane, non-steroidal anti-inflammatory drugs, and any basic amino acid such as lysine. Additional factors, such as previous aminoglycoside exposure, metabolic acidosis, female sex, and diabetes mellitus, are less clearly associated with renal damage (90,91).

In a prospective, non-interventional surveillance study of 249 patients receiving a once-daily aminoglycoside

© 2006 Elsevier B.V. All rights reserved.

(17% amikacin and 83% gentamicin), serum creatinine increased by more than 50% in 12%; none developed oliguric renal insufficiency (92). Renal damage correlated significantly with: a high aminoglycoside trough concentration (over 1.1 μg/ml); a hemoglobin concentration below 10 g/dl; hospital admission for more than 7 days before aminoglycoside treatment; and aminoglycoside treatment for more than 11 days.

Mechanism

The mechanism of nephrotoxicity has been studied in vitro, in animals, and in man. The data suggest that accumulation of aminoglycosides in the renal cortex is an important reason for functional damage. In addition, aminoglycoside-induced alterations of glomerular ultrastructure have been described (93). Tissue uptake is predominantly mediated by proximal tubular reabsorption of the filtered drug. The degree of renal injury caused by an aminoglycoside correlates with the amount of drug that accumulates in the renal cortex. However, intrinsic toxicity differs among the aminoglycosides. Endotoxins can increase intracortical accumulation (94). After the drug binds to an amino acid receptor site, there is pinocytotic entry into the tubular cells. Once the drug is within the cell, it persists there for a long time and is liberated only slowly, with a half-life of several days (95,96). Direct toxicity to tubular cells is mainly explained by inhibition of lysosomal activity, with accumulation of lamellar myeloid bodies consisting of phospholipids. Inhibition of lysosomal phospholipids can also be shown in purified liposomes in vitro (97). In renal biopsy specimens, vacuolization of the proximal tubular epithelium, clumped nuclear chromatin, and swollen mitochondria are seen. Patchy tubular cell necrosis, desquamation, and luminal obstruction are found at later stages.

The uptake of aminoglycosides into proximal renal tubular epithelial cells is limited to the luminal cell border and is saturable. Less frequent administration of doses larger than needed for saturation of this uptake may therefore reduce drug accumulation in the renal cortex (98). In vitro and in vivo data have provided evidence that partially reduced oxygen metabolites (superoxide anion, hydrogen peroxide, and hydroxyl radical), which are generated by renal cortical mitochondria, are important mediators of aminoglycoside-induced acute renal insufficiency (99).

A lipopeptide, daptomycin, which has bactericidal activity against Gram-positive bacteria by inhibition of the synthesis of lipoteichonic acid, prevents tobramycin-induced nephrotoxicity in rats. Fourier transformed infrared spectroscopy has been used to monitor the hydrolysis of phosphatidylcholine phospholipase A_2 in the presence of different aminoglycosides and/or daptomycin (100). Among the various aminoglycosides investigated there were major differences, directly related to chemical structure. The number of charges, the size, and the hydrophobicity of the substituents of an aminoglycoside determined the influence on the lag phase, on the maximal rate, and on the final extent of hydrolysis. Daptomycin alone eliminated the initial latency period, and reduced the maximal extent of hydrolysis. When daptomycin was combined with any of the aminoglycosides, the latency period also disappeared, but the phospholipase activity was higher than with the lipopeptide alone. The strongest activation of phospholipase A_2 activation was observed when daptomycin was combined with gentamicin.

Stress proteins seem to be actively involved in aminoglycoside-induced renal damage. In a study in Wistar rats, subcutaneous gentamicin caused tubular necrosis, followed by tubular regenerative changes and interstitial fibrosis (101). Both the regenerated and phenotypically altered tubulointerstitial cells were found to express heat-shock protein 47 in and around the fibrosis. Increased shedding of tubular membrane components, followed by rapid inductive repair processes with overshoot protein synthesis, can be detected by analysis of tubular marker protein in the urine of rats after administration of aminoglycosides (102).

Prevention

In a prospective, randomized, double-blind study of once-daily versus twice-daily aminoglycoside therapy in 123 patients (of whom 83 received treatment for over 72 hours), once-daily administration of aminoglycosides had a predictably lower probability of causing nephrotoxicity than twice-daily administration. In a Kaplan–Meier analysis, once-daily dosing provided a longer time of administration until the threshold for nephrotoxicity was met. The risk of nephrotoxicity was modulated by the daily AUC for aminoglycoside exposure, and the concurrent use of vancomycin significantly increased the probability of nephrotoxicity and shortened the time to its occurrence (98). In another study, once-daily aminoglycoside in 200 patients was prospectively compared with a retrospectively evaluated group of 100 patients treated with individualized traditional dosing. Patients with a baseline creatinine clearance below 40 ml/minute, meningitis, burns, spinal cord injury, endocarditis, or enterococcal infection were excluded. Clinical and microbial outcome was similar in the two groups. Nephrotoxicity occurred in 7.5% of the patients treated with once-daily aminoglycosides compared with 14% of the others. The cumulative AUC was significantly larger in patients on traditional dosing. Minimum serum concentrations, length of aminoglycoside therapy, and AUC over 24 hours were related to nephrotoxicity. Whereas vancomycin and concurrent nephrotoxic agents were independently related to toxicity, sex and age were not (103).

Careful tailoring of the dose can prevent nephrotoxicity. In 89 critically ill patients with a creatinine clearance over 30 ml/minute who were treated with gentamicin or tobramycin 7 mg/kg/day independent of renal function, with subsequent doses chosen on the basis of the pharmacokinetics of the first dose, signs of renal impairment occurred in 14%; in all survivors renal function recovered completely and hemofiltration was not needed (104).

Presentation and diagnosis

Nephrotoxicity can present as acute tubular necrosis or, more commonly, as gradually evolving non-oliguric renal failure. The time-course of toxicity is variable, but it usually develops only after several days of treatment. Early diagnosis is difficult, since there can be a reduction in glomerular filtration before a significant rise in serum

© 2006 Elsevier B.V. All rights reserved.

creatinine concentration occurs (105). An increased number of casts in the urinary sediment can also precede the increase in serum creatinine (106). Measurement of phospholipids and urinary enzymes, such as beta$_2$-microglobulin or alanine aminopeptidase, has been proposed as a means of detecting early toxicity (107–109). However, data on these enzymes are not very useful, since they can be increased for various other reasons and raised concentrations do not reliably predict pending renal toxicity. Fortunately, recovery of renal function nearly always follows the withdrawal of aminoglycosides, although serum creatinine concentrations can continue to rise for several days after the last dose.

There is an increase in the urinary output of tubular marker proteins after aminoglycoside administration (102). Determination of *N*-acetyl-beta-D-glucosaminidase activity in the urine may be used as a screening test to facilitate early detection of the nephrotoxic effect of aminoglycosides (110). Urine chemiluminescence may aid in the detection of neonatal aminoglycoside-induced nephropathy (111).

Relative potency of different aminoglycosides

The nephrotoxicity of the various aminoglycosides has been compared in many animal experiments. The order of relative nephrotoxicity is as follows: neomycin > gentamicin > tobramycin > amikacin > netilmicin (112,113). However, in man conclusive data on the relative toxicity of the various aminoglycosides is still lacking. An analysis of 24 controlled trials showed the following average rates for nephrotoxicity: gentamicin 11%; tobramycin 11.5%; amikacin 8.5%; and netilmicin 2.8% (28). In contrast to this survey, direct comparison in similar patient groups showed no significant differences between the various agents in most trials (14,15,114–118). In fact, the relative advantage of lower nephrotoxicity rates observed with netilmicin in some studies may be limited to administration of low doses. In a prospective study there was significantly lower nephrotoxicity with amikacin 15 mg/kg/day (4% toxicity) compared with netilmicin 7 mg/kg/day (12%) (119). One prospective trial showed a significant advantage of tobramycin over gentamicin (120). However, these findings were not subsequently confirmed (121). Nephrotoxicity is a serious risk with all the currently available aminoglycoside antibiotics, and no drug in this series can be regarded as safe.

Skin

It is generally accepted that antibiotics that are important for systemic use should not be administered topically. This rule applies particularly to the aminoglycoside antibiotics. Even though neomycin and streptomycin are no longer often used systemically, the frequency of sensitization after topical administration of these drugs is particularly high.

Contact dermatitis due to arbekacin has been reported (122). The risk of sensitization by topically administered gentamicin seems to be smaller. Nevertheless, and in order to avoid resistance, topical use should be restricted to life-endangering thermal burns and to severe skin infections in which strains of *Pseudomonas* resistant to other antibiotics are involved.

Immunologic

In a prospective study of the results of skin patch testing in 149 patients who were scheduled for ear surgery, 14% of the patients had a positive skin reaction to one of the aminoglycosides (13% for gentamicin, 13% for neomycin) (123). In 16% of the patients with chronic otitis media and 6.7% of the patients with otosclerosis there was allergy to one of the aminoglycosides commonly found in antibiotic ear-drops. Patients who had previously received more than five courses of antibiotic ear-drops had a greater tendency to develop allergy to the aminoglycosides (35%).

Cross-reactivity between aminoglycoside antibiotics has long been known. Aminoglycoside antibiotics can be categorized in two groups, depending on the aminocycolitol nucleus: streptidine (streptomycin) and deoxystreptamine (neomycin, kanamycin, gentamicin, paromomycin, spectinomycin, and tobramycin). Another antigenic determinant is neosamine, a diamino sugar present in neomycin and, with minor changes, also in paromomycin, kanamycin, tobramycin, amikacin, and isepamicin. Streptomycin shares no common antigenic structures with the other aminoglycoside antibiotics, and cross-sensitivity with streptomycin has not been reported. Acute contact dermatitis was described in a 30-year-old man after rechallenge with gentamicin 80 mg; a patch test was positive for gentamicin, neomycin, and amikacin (124).

Occasional cases of anaphylactic shock have been reported, most of which have been due to streptomycin; other aminoglycosides have rarely been implicated, such as gentamicin (125,126) and neomycin (127).

Long-Term Effects

Drug resistance

During treatment of infections with either Gram-negative or Gram-positive bacteria, resistant subpopulations emerge, unless the peak to MIC ratio is high enough to reduce the bacterial inoculum drastically within a few hours (128). Similarly, rapid emergence of resistant subpopulations has been reported during aminoglycoside treatment in neutropenic animals. The virulence and clinical relevance of the relatively slow-growing resistant subpopulations (small colony variants) have been documented in both animal and clinical studies (129,130). Resistant subpopulations can be detected only by direct plating of specimens on aminoglycoside-containing agar plates, since resistance may be lost within one subculture. Combination therapy of an aminoglycoside plus a beta-lactam antibiotic has been successfully used to prevent selection of resistant subpopulations (131).

In a prospective surveillance study in France, the development of resistance to aminoglycosides and fluoroquinolones among Gram negative bacilli was assessed in 51 patients with a second infection due to Gram negative organisms at least 8 days after a first Gram negative infection (132). Treatment of the first infection with a beta-lactam antibiotic plus an aminoglycoside significantly reduced the susceptibility to amikacin (the most prescribed antibiotic). When the first infection was

© 2006 Elsevier B.V. All rights reserved.

treated with a beta-lactam plus a fluoroquinolone, susceptibility to ciprofloxacin, pefloxacin, netilmicin, and tobramycin, but not gentamicin and amikacin, fell significantly.

A multidrug efflux system that appears to be a major contributor to intrinsic high-level resistance to aminoglycosides and macrolides has been identified in *Burkholderia pseudomallei* (133).

Out of 1102 consecutive clinical Gram negative blood isolates from Belgium and Luxembourg, 157 were "not susceptible" to aminoglycosides (134). The resistance levels were 5.9% for gentamicin, 7.7% for tobramycin, 7.5% for netilmicin, 2.8% for amikacin, and 1.2% for isepamicin. In a large European multinational study on 7057 Gram negative bacterial isolates, resistance levels were 0.4–3% for amikacin, 2–13% for gentamicin, and 2.5–15% for tobramycin among Enterobacteriaceae; 75% of *Staphylococcus aureus* isolates, but only 21% of enterococcal strains were susceptible to gentamicin (135). In a study from Spain, 9% of 1014 clinical *P. aeruginosa* isolates were resistant to amikacin or tobramycin (136). In the same country, resistance to amikacin rose from 21% to 84% and to tobramycin from 33% to 72% between 1991 and 1996 (137).

In a leading cancer center in Houston, 24% of 758 Gram negative clinical isolates were resistant to tobramycin and 12% were resistant to amikacin (138). In 3144 bacterial isolates causing urinary tract infections in Chile, 74% were identified as *Escherichia coli*; 4.2% of these strains were resistant to gentamicin, and 1.3% were resistant to amikacin (139). In contrast, the resistance levels were 30% and 17% respectively, in the other enterobacterial strains. In Brazil, all isolates of methicillin-resistant *S. aureus* were also resistant to gentamicin, amikacin, kanamycin, neomycin, and tobramycin (140), and 97% of such strains from Spain were resistant to tobramycin (141).

In mice, the bacterial neomycin phosphotransferase gene, which confers resistance to aminoglycoside antibiotics, prevented the loss of hair cells after neomycin treatment (142).

In in vitro susceptibility studies on 99 clinical isolates of *S. aureus*, 68 of 73 strains of methicillin-resistant *S. aureus* (MRSA) and two of 26 strains of methicillin-susceptible *S. aureus* were gentamicin-resistant (143). However, the combination of arbekacin plus vancomycin produced synergistic killing against 12 of 13 gentamicin-resistant MRSA isolates. Combinations of meropenem and aminoglycosides may be effective against strains of *P. aeruginosa* that are resistant to meropenem at clinically relevant concentrations; synergistic effects were observed in combinations that included arbekacin or amikacin (144).

Second-Generation Effects

Teratogenicity

During pregnancy the aminoglycosides cross the placenta and might theoretically be expected to cause otological and perhaps nephrological damage in the fetus. However, no proven cases of intrauterine damage by gentamicin and tobramycin have been recorded. In 135 mother/child pairs exposed to streptomycin during the first 4 months of pregnancy, there was no increase in the risk of any malformation (145). However, streptomycin and dihydrostreptomycin have caused severe otological damage (146).

Using the population-based dataset of the Hungarian Case-Control Surveillance of Congenital Abnormalities (1980–96), which includes 38 151 pregnant women who had newborn infants without any defects and 22 865 pregnant women who had fetuses or newborns with congenital abnormalities, no teratogenic risk of parenteral gentamicin, streptomycin, tobramycin, or oral neomycin was discovered when restricted to structural developmental disturbances (147).

Susceptibility Factors

Age

In a prospective study on the prevalence of hearing impairment in a neonatal intensive care unit population (a total of 942 neonates were screened), aminoglycoside administration did not seem to be an important risk factor for communication-related hearing impairment (148). In almost all cases, another factor was the more probable cause of the hearing loss (dysmorphism, prenatal rubella or cytomegaly, a positive family history of hearing loss, and severe perinatal and postnatal complications).

Other features of the patient

The main susceptibility factors are summarized in Table 2. The most important factors are renal insufficiency, high serum drug concentrations, and a long duration of treatment (54).

Drug Administration

Drug dosage regimens

Twice-daily or thrice-daily administration was for a long time standard in aminoglycoside therapy of systemic bacterial infections in patients with normal renal function. However, in vitro, in vivo, and clinical studies have suggested that once-daily dosing of the same total daily dose might be more beneficial with respect to both efficacy and toxicity (SEDA-21, 265) (149–152).

Less frequent administration of higher doses results in higher peak concentrations. Owing to the pronounced concentration dependence of bacterial killing, higher peaks potentiate the efficacy of the aminoglycosides. The importance of a high ratio of peak concentration to the minimal inhibitory concentration (MIC) has been shown in vitro for both bactericidal activity and prevention of the emergence of resistance (153). Clinically the predictive value of the peak to MIC ratio has been documented for aminoglycoside therapy of Gram-negative bacteremia (154). Although once-daily dosing can result in prolonged periods of subinhibitory concentrations, bacterial regrowth does not occur immediately after the aminoglycoside concentration drops below the MIC. The term "post-antibiotic effect" has been suggested to describe this hit-and-run effect, in which there is persistent suppression of bacterial regrowth after cessation of

© 2006 Elsevier B.V. All rights reserved.

exposure of bacteria to an active antibiotic. This phenomenon has been observed both in vitro and in vivo (155).

Various in vivo models have been used to study the effect of the dosage regimen on aminoglycoside nephrotoxicity and ototoxicity. Renal uptake of aminoglycosides is not proportional to serum concentration, because of saturation at the high concentrations achieved with once-daily regimens. The degree of renal injury increases the more often the aminoglycoside is given in humans, dogs, rabbits, guinea-pigs, and rats, as long as the total daily dose is kept constant (156,157). Early auditory alterations also occur more often, or to a greater extent, the more often the aminoglycoside is given.

Once-daily regimens have been compared with multiple-daily regimens in at least 27 randomized clinical trials and eight meta-analyses and in a mega-analysis of meta-analyses (158). In all the studies, extended-interval dosing was at least as efficacious as multiple-daily dosing, and may have been slightly better; it was no more toxic, and may have been less nephrotoxic. Extended dosing is also less expensive than multiple-daily dosing and markedly reduces costs. An analysis of 24 randomized clinical trials of amikacin, gentamicin, and netilmicin, including 3181 patients, showed superior results with once-daily regimens with respect to clinical efficacy (90 versus 85%) and bacteriological efficacy (89 versus 83%) (151). There were no statistically significant differences for toxicity. Nevertheless, both nephrotoxicity and ototoxicity occurred less often during once-daily dosing (4.5 versus 5.5% and 4.2 versus 5.8% respectively). Finally, once-daily dosing is more economical, since less nursing time and infusion material are required and drug monitoring can be reduced. In conclusion, amikacin, gentamicin, and netilmicin can be given once a day.

In a randomized trial in 249 patients with suspected or proven serious infections, the safety and efficacy of gentamicin once-daily compared with three-times-a-day was assessed in 175 patients who were treated with ticarcillin–clavulanate combined with gentamicin once-daily or three times daily or with ticarcillin–clavulanate alone (159). The achievement of protocol-defined peak serum gentamicin concentrations was required for evaluability. There were no significant differences between treatment regimens with respect to clinical or microbiological efficacy; the incidence of nephrotoxicity was similar in the three groups. In a post-hoc analysis, renal function was better preserved in those treated with gentamicin once a day plus ticarcillin + clavulanate than ticarcillin + clavulanate only.

Once-daily amikacin was as effective and safe as twice-daily dosing in a prospective randomized study in 142 adults with systemic infections (160).

In 43 patients, once-daily tobramycin (4 mg/kg/day) was at least as effective and was no more and possibly even less toxic than a twice-daily regimen (161).

The pharmacokinetics of once-daily intravenous tobramycin have been investigated in seven children with cystic fibrosis (162). All responded well. There was one case of transient ototoxicity but no nephrotoxicity.

In a prospective study, only increasing duration of once-daily aminoglycoside therapy was recognized as risk factor for toxicity in 88 patients aged 70 years and over (163).

In controlled trials of once-daily aminoglycoside regimens patients with endocarditis have often been excluded, and therefore few clinical data are available on this topic. Based on pharmacokinetic data in experimental endocarditis and integrative computer modeling, it has been hypothesized that drug penetration into vegetations would be enhanced by once-daily aminoglycoside administration, resulting in a long residence time in the vegetations and a beneficial effect in providing synergistic bactericidal action in combination with another antibiotic (164). With the exception of two early studies using enterococci, results from animal studies have been promising in once-daily aminoglycoside treatment of endocarditis. Only two human studies of once-daily aminoglycoside therapy in streptococcal endocarditis were identified. The regimen was efficacious and safe. The authors concluded that there appeared to be sufficient promising evidence to justify large trials to further investigate once-daily aminoglycoside in the treatment of endocarditis due to viridans streptococci, whereas more preliminary investigations were needed for enterococcal endocarditis.

Once-daily dosing regimens of aminoglycosides are routinely used in critically ill patients with trauma, although there is a marked variability in pharmacokinetics in these patients, eventually leading to prolonged drug-free intervals, and individualized dosing on the basis of at least two serum aminoglycoside concentrations can be recommended when once-daily dosing regimens are chosen (165).

Not all populations of patients have been included or extensively studied in published trials. Therefore, conventional multiple-daily aminoglycoside dosing with individualized monitoring should be used in neonates and children, in patients with moderate to severe renal insufficiency (creatinine clearance below 40 ml/minute), serious burns (over 20% of body surface area), ascites, severe sepsis, endocarditis, and mycobacterial disease, in pregnancy, in patients on dialysis, in invasive *P. aeruginosa* infection in neutropenic patients, and with concomitant administration of other nephrotoxic agents (for example amphotericin, cisplatin, radiocontrast agents, and NSAIDs). Extended-interval aminoglycoside dosing may be safe and efficacious in patients with mild to moderate renal insufficiency (over 40 ml/minute) and febrile neutropenia, especially where the prevalence of *P. aeruginosa* is low. In other serious Gram-negative infections warranting aminoglycoside treatment, extended-interval dosing is strongly suggested (166).

Drug administration route

Intraocular

Aminoglycosides are often used in ophthalmology to treat or to prevent bacterial infections, and they can be toxic to retinal structures if high concentrations are reached in the vitreous. Retinal ultrastructure was examined at various intervals after a single intravitreal injection of 100–4000 μg of gentamicin into rabbit eyes. Three days after injection of 100–500 μg, numerous abnormal lamellar lysosomal inclusions were observed in the retinal pigment epithelium and in macrophages in the subretinal space. These changes were typical of drug-induced lipid storage and were comparable to inclusions reported in kidney and

© 2006 Elsevier B.V. All rights reserved.

other tissues as manifestations of gentamicin toxicity. One week after similar injections, focal areas of retinal pigment epithelium necrosis and hyperplasia with disruption of outer segments appeared, but the inner segments and the inner retina were intact. Doses of 800–4000 μg produced a combined picture of lipidosis of the retinal pigment epithelium and macrophages within the first 3 days, with increasing superimposed inner retinal necrosis (167).

Intratympanic

Intratympanic gentamicin therapy has gained some popularity in the treatment of vertigo associated with Menière's disease, as it offers some advantages over traditional surgical treatment. However, although the vestibulotoxic effect of gentamicin is well documented, there is no general agreement about the dose needed to control attacks of vertigo without affecting hearing. In 27 patients treated with small doses of gentamicin delivered via a microcatheter in the round window niche and administered by an electronic micropump, vertigo was effectively controlled; however, the negative effect on hearing was unacceptable (168,169).

Intraperitoneal

Bolus intraperitoneal gentamicin or tobramycin (5 mg/kg ideal body weight) is safe, achieves therapeutic blood concentrations for extended intervals, causes no clinical ototoxicity or vestibular toxicity, is cost-effective, and is convenient for patients and nurses (170).

Drug overdose

Although aminoglycoside antibiotics are dialysable, peritoneal dialysis may not remove aminoglycosides from the blood after overdosage (171). However, hemodialysis is effective (172). In one study in eight patients hemodiafiltration removed more netilmicin than conventional hemodialysis (173).

Drug–Drug Interactions

Cephalosporins

There are many reports of acute renal insufficiency from combined treatment with gentamicin (or another aminoglycoside) and one of the cephalosporins (174–176). The potential nephrotoxic effect of the combinations seems to be related mainly to the nephrotoxic effect of the aminoglycosides. In contrast, there is some evidence, both experimental (177) and clinical (178), that ticarcillin may attenuate the renal toxicity of the aminoglycosides.

Cisplatin/carboplatin

The nephrotoxic and ototoxic effects of cisplatin and carboplatin can be potentiated by concurrent administration of aminoglycosides, as shown in animals (179).

Loop diuretics

Among the agents that promote the nephrotoxic effects of the aminoglycosides, the loop diuretics furosemide and etacrynic acid are often mentioned. However, this interaction is by no means clearly established (26). These agents are not nephrotoxic in themselves. This supposed interaction may only be a consequence of sodium and volume depletion. Other types of diuretics, such as mannitol, hydrochlorothiazide, and acetazolamide, do not produce this interaction (26).

- A 60-year-old white woman developed ototoxicity after only 5 days of gentamicin therapy (500 mg, 6.8 mg/kg/day) and one dose of furosemide 20 mg (180).

Loop diuretics greatly potentiate the cochleotoxic effects of aminoglycosides (181). In pigmented guinea-pigs the effects of high-dose topical (10 μl of a 100 mg/ml solution directly on to the round window) or single-dose systemic (100 mg/kg) gentamicin and intracardiac administration of the loop diuretic etacrynic acid (40 mg/kg) on cochlear function have been studied (182). Compound action potentials were elicited at 8 kHz. All animals that received etacrynic acid had an immediate and profound rise in hearing threshold, irrespective of the method of gentamicin administration. The maximum threshold shift occurred within 30 minutes. Animals that received topical gentamicin recovered after etacrynic acid treatment; by day 20 the mean threshold shift was 7 dB. This group did not differ statistically from animals that received etacrynic acid alone. In contrast, animals that received systemic gentamicin initially recovered within 2 hours after etacrynic acid, but subsequently deteriorated over the next 24 hours. The mean threshold shift was 70 dB at day 20. Animals that received topical gentamicin had a temporary shift that resolved within 24–48 hours; by day 20, the mean threshold shift was 7 dB. Animals treated with systemic gentamicin alone did not have hearing loss. This study suggests that the potentiating effect of etacrynic acid on aminoglycoside ototoxicity is only after systematic and not topical aminoglycoside administration. This may be due to an etacrynic acid-induced increase in leakiness of the stria vascularis, thereby facilitating diffusion of aminoglycosides from the systemic circulation into the endolymphatic fluid.

Neuromuscular blocking drugs

The aminoglycosides have a curare-like action, which can be antagonized by calcium ions and acetylcholinesterase inhibitors (8). In patients who require general anesthesia, the effect of muscle relaxants, such as D-tubocurarine, pancuronium, and suxamethonium, can be potentiated by aminoglycosides (183).

Penicillins

There is an in vitro interaction between aminoglycoside antibiotics and carbenicillin or ticarcillin, leading to a significant loss of aminoglycoside antibacterial activity if these antibiotics are mixed in the same infusion bottle (184). The extent of inactivation depends on the penicillin concentration, the contact time, and the temperature. Azlocillin and mezlocillin inactivate aminoglycosides in a similar manner to that described for carbenicillin (185,186). Aminoglycosides should not be mixed with penicillins or cephalosporins in the same infusion bottle.

However, the clinical significance of the presence of both types of antibiotics in the patient is debatable. In

© 2006 Elsevier B.V. All rights reserved.

patients who received a combination of gentamicin and carbenicillin the measured serum gentamicin concentrations were lower than the pharmacokinetically predicted values (187). This interaction may be especially important in patients with severe renal impairment, in whom long in vivo incubation of these drug combinations takes place before supplemental doses of the aminoglycoside drugs are given.

Vancomycin

Combined use of vancomycin and an aminoglycoside can increase the risk of toxicity (188–190).

Monitoring Therapy

Serum concentrations have often been monitored during multiple-daily dosing of aminoglycosides, particularly when high doses are used and also during prolonged therapy. The main goals of individual dosing and monitoring are to reach high bactericidal drug concentrations and to avoid drug accumulation in the serum, to minimize the risk of toxicity. Since both goals are much more likely to be met with once-daily dosing it may be feasible to reduce monitoring efforts during such dosing regimens. However, more clinical experience needs to be accumulated to establish solid guidelines for monitoring once-daily dosing regimens. Although more clinicians are nowadays switching to once-daily dosing of aminoglycosides, some continue to use multiple-daily regimens. Therefore, two separate concepts of aminoglycoside monitoring have to be considered, depending on the dosing schedule.

In a retrospective case-control study, 2405 patients received aminoglycosides in doses that were decided either by individualized pharmacokinetic monitoring or by the physician (191). Those who received individualized pharmacokinetic monitoring were significantly less likely to develop aminoglycoside-associated nephrotoxicity. Women were also less likely to develop nephrotoxicity. Age 50 years and above, high initial aminoglycoside trough concentration, long duration of therapy, and concurrent therapy with piperacillin, clindamycin, or vancomycin increased the risk.

Monitoring multiple-daily dosing regimens

Peak serum concentrations of gentamicin and tobramycin over 5–7 μg/ml and of amikacin over 20–28 μg/ml are associated with improved survival in patients with septicemia and pneumonia caused by Gram-negative bacteria (192,193). On the other hand, excessive peak concentrations (over 10–12 μg/ml) and trough concentrations (over 2 μg/ml) of gentamicin and tobramycin increase the risk of ototoxicity and nephrotoxicity (194). Dosage requirements to obtain aminoglycoside concentrations in the target range can differ considerably, even in patients with normal renal function (195). Owing to the great individual variability in pharmacokinetics, dosage adjustments with the commonly used nomograms often result in suboptimal or potentially toxic aminoglycoside concentrations (196). An individualized treatment based on serum concentration monitoring is therefore necessary to achieve maximum bactericidal efficacy without a concomitant high risk of adverse reactions. Measurements of peak and trough serum concentrations should be carried out during the first 24–48 hours in all patients and repeated after 3–5 days to detect any tendency to abnormal drug accumulation. However, one must realize that close monitoring alone cannot completely eliminate the danger of ototoxicity and nephrotoxicity, since aminoglycoside drug concentrations progressively increase in renal tissue and in the inner ear with repeated administration, even if optimum serum concentrations are maintained.

The relation between serum concentration of aminoglycosides and the two clinically important adverse effects, ototoxicity and nephrotoxicity, has been debated for many years. Whereas some authors have found a definite relation between the frequency of adverse effects and serum concentrations, others have not (194). This controversy can be partly explained by the pharmacokinetic behavior common to all aminoglycosides, which leads to drug accumulation in deep compartments, particularly in the renal cortex. Assuming that the extent of accumulation is a factor that relates to the frequency of adverse effects, it is not surprising to find a correlation between serum concentrations and toxicity in one group of patients but not in another. The amount accumulated depends not only on the dosing schedule and the serum concentration achieved during treatment, but also on the duration of drug administration. The same concentration in the same patient can be associated with a significantly different amount of drug in the body, depending on whether it was sampled during the second or the tenth day after the beginning of treatment.

In a survey of aminoglycoside treatment in 2022 patients in Saudi Arabia, 8.8%, 18%, and 12% had trough concentrations considered toxic for amikacin, gentamicin, and tobramycin respectively, whereas there were peak serum drug concentrations in the subtherapeutic range in 53%, 50%, and 57% respectively (197). Toxic concentrations were noticed mainly in patients aged over 60 years and in patients in the intensive care unit, coronary care unit, and burn unit.

Monitoring once-daily dosing regimens

In general, both peak and trough concentrations are determined during monitoring of multiple-daily dosing regimens, and doses are subsequently adjusted to achieve the target concentrations. However, peak and trough concentrations do not necessarily offer the most valuable information for dosage adjustments during once-daily dosing. The indication and frequency of monitoring and the timing of serum concentrations within the interval, along with their target ranges, have yet to be established. Different targets have been proposed and used clinically (198–200), including mid-dosage interval plasma concentration monitoring as an estimate of the AUC (201).

In one prospective study 8-hour concentrations have been considered for monitoring as an alternative to the measurement of peaks and troughs (202). In 51 adult patients given an average dose of 400 mg once a day, doses were adjusted during therapy if 8-hour concentrations were not within the target range of 1.5–6.0 μg/ml. Concentrations above or below this target range

© 2006 Elsevier B.V. All rights reserved.

correlated significantly with nephrotoxicity, 24-hour trough concentrations, and AUCs. Determination of 8-hour concentrations was therefore useful for identifying patients with either low AUCs or an increased risk of nephrotoxicity. In other studies, aminoglycoside serum concentrations were determined in the second half of the dosing interval (198,200,203–205). However, trough concentrations do not allow for extrapolations of concentrations achieved in the period after infusion. Thus, patients with very low peak concentrations due to unusually high volumes of distribution cannot be identified. Similarly, very rapid elimination, as frequently happens in patients with burns or children, may not be noticed.

Depending on the goals of drug monitoring, peak 8-, 12- or 24-hour concentrations might be more important (151). Correlations of efficacy with high peak concentrations, high ratios of peak to MIC, and high AUCs suggest that drug concentrations should be determined during the first part of the dosing interval. In order to minimize toxicity, drug accumulation should be avoided. Therefore early detection of increased trough concentrations is of importance. It has been strongly suggested that the threshold values for troughs during once-daily dosing should be lowered, compared with multiple-daily dosing (203,206). To reduce the cost of aminoglycoside therapy, the indications for and frequency of monitoring serum concentrations should be minimal. Instead, serum creatinine concentrations might be used to monitor renal function. The strategy selected for monitoring aminoglycoside therapy must take a number of factors into account, including the type and severity of infection, the duration of therapy, or the presence of factors associated with increased risk of toxicity. In addition, local factors should be considered for the timing of blood samples, including the sensitivity of the drug assay available (207) and the time required for processing the specimens, in order to modify the subsequent dose, if necessary.

Major considerations in determining the appropriate dose of an aminoglycoside are its volume of distribution and rate of clearance. Concern has been raised regarding the use of the Cockcroft–Gault equation with either actual or ideal body weight, resulting in systematic errors, especially in malnourished patients (208). However, even extended-interval dosing should not obviate the need for monitoring drug concentrations. Even in patients with normal renal function in whom treatment is necessary for over 3 days, mid-interval or trough drug concentrations should be obtained once or twice a week to optimize the dosing regimen (166,209).

Economics of serum concentration monitoring

The economic impact of aminoglycoside toxicity and its prevention through therapeutic drug monitoring have been investigated in a cost-effectiveness study. It was estimated that to offset the cost of providing high-level drug monitoring, that is serum drug concentration monitoring with assessment and consultation by trained personnel using computerized resources to determine individualized pharmacokinetic parameters, for the purpose of achieving an optimum dosage regimen, by cost saving due to reducing nephropathy, the service should reduce the risk of nephrotoxicity by 6.6%. Therefore, high-level therapeutic drug monitoring is only cost-justified in populations in which high rates of nephrotoxicity would be expected. Risk factors for a high rate of nephrotoxicity include age, duration of therapy, high drug concentrations, the presence of ascites or liver disease, and the concomitant use of nephrotoxic drugs (210). The economic significance of aminoglycoside peak concentrations has been assessed in 61 febrile neutropenic patients with hematological malignancies. Since the clinical outcome and average infection-related costs depended significantly on peak aminoglycoside concentration, it was concluded that successful pharmacokinetic intervention may save money (211).

A pharmacy-based active therapeutic drug monitoring service has been examined in a prospective study (63). In the patients that were not monitored, the gentamicin dosage regimen was determined by the physician; in the patients that were monitored, the regimen was calculated using a population model and measured serum gentamicin concentrations. This resulted in significantly different mean dosage intervals: 19 hours in the monitored patients and 14 hours in the others. Active monitoring resulted in higher peak concentrations of aminoglycosides, lower trough concentrations, a reduction in the length of hospitalization, a reduced duration of aminoglycoside therapy, reduced nephrotoxicity, and a trend toward reduced mortality that was significant for patients with an infection on admission. Costs were lower with active monitoring. Although all patients treated with an aminoglycoside profited from active monitoring, it was most beneficial in patients who were admitted to the hospital with a suspected or proven Gram negative infection.

Aminophenazone

General Information

Aminophenazone (amidopyrine) is the most toxic and most dangerous anti-inflammatory analgesic. Blood dyscrasias have been documented beyond any doubt, perhaps due to a hypersensitivity mechanism. The Committee on the Safety of Drugs of the Japanese Pharmaceutical Affairs Bureau has ordered its withdrawal because of its serious adverse effects (SEDA-12, 82) and it has been withdrawn in most developed countries. However, aminophenazone is still used in some developing countries (1).

© 2006 Elsevier B.V. All rights reserved.

Organs and Systems

Hematologic

Aminophenazone causes severe bone marrow depression, usually with a fulminant course and a high mortality (SED-9, 146) (2,3). Specific antibodies and leukoagglutinins are sometimes found (4). Agranulocytosis is caused by arrest of maturation at the metamyelocyte stage (5).

Fatal thrombocytopenia has been reported in a breastfeeding infant after the administration of aminophenazone suppositories (6).

Gastrointestinal

Gastrotoxicity with aminophenazone is less common than with other analgesic/anti-inflammatory drugs, probably because of its weaker anti-inflammatory effect.

Liver

Aminophenazone is not hepatotoxic, but liver damage can occur in the course of a general hypersensitivity reaction (7).

Urinary tract

Albuminuria, hematuria, and acute renal insufficiency have been observed, and aminophenazone causes direct renal damage even at therapeutic doses. It can also contribute to analgesic nephropathy (SED-8, 211) (8,9).

Skin

Toxic epidermal necrolysis, exfoliative dermatitis, and Stevens–Johnson syndrome have been described (SED-8, 210) (10–13).

Immunologic

A range of allergic skin reactions, acute anaphylactic shock, acute bronchospasm (in predisposed patients), and cross-sensitivity to aspirin have been reported (14).

Long-Term Effects

Tumorigenicity

Aminophenazone and its derivatives may be metabolized to carcinogenic nitrosamines. The clinical importance of this is not clear (SEDA-2, 389) (15).

Drug Administration

Drug overdose

In overdose, aminophenazone mainly affects the central nervous system, causing coma and convulsions, and the liver (16). Fatal intoxication has occurred in infants (17).

Aminorex

See also Anorectic drugs

General Information

Aminorex is an amfetamine analogue that was used as an anorectic agent, but was withdrawn from the market over 20 years ago because of its association with pulmonary hypertension, which sometimes proved fatal. Its adverse effects have been attributed predominantly to the release of noradrenaline and other catecholamines.

© 2006 Elsevier B.V. All rights reserved.

Organs and Systems

Respiratory

Aminorex can cause primary pulmonary hypertension, which can be fatal (1,2). The fulminant character and rapid development of the disease (characterized by dyspnea, dysrhythmias, peripheral edema, dizziness, cyanosis, chest pain, and syncope, in the absence of usual causes of pulmonary vascular disease) suggested the possibility of its being drug-induced. Long-term follow-up of aminorex-induced primary pulmonary hypertension showed that the syndrome has a chronic course, with long-term survival possible (3). Two cases of supposedly delayed reactions to aminorex have been described (4). Both concerned pulmonary hypertension, one in a subject who had taken aminorex 6 years before. In the other there was a reaction of limited duration 8 years after aminorex treatment.

In 16 patients polymorphic hydroxylation of debrisoquine was not related to the risk of aminorex-induced pulmonary hypertension (5).

Despite the withdrawal of aminorex, work to identify the mechanism of the pathogenic effect has continued, in view of the risk that other agents might behave similarly. In smooth muscle cells taken from the small resistance pulmonary arteries of the rat lung aminorex inhibited potassium current and in isolated, perfused rat lung, it caused a dose-related increase in perfusion pressure (6). However, long-term administration of aminorex fumarate to rats failed to cause hypertensive pulmonary vascular disease (7), although in dogs there was an increase in pulmonary pressure (8).

Aminosalicylates

General Information

The aminosalicylates that are currently available are:

- mesalazine (rINN; 5-aminosalicylic acid mesalamine);
- sulfasalazine (rINN), a compound of mesalazine and sulfapyridine, the two compounds being linked by a diazo bond that is hydrolysed by intestinal bacteria; mesalazine is therapeutically effective in inflammatory bowel disease and sulfapyridine causes adverse effects;
- olsalazine (rINN), a compound of two molecules of mesalazine, linked by a diazo bond that is hydrolysed by intestinal bacteria;
- balsalazide (rINN), a prodrug of mesalazine linked to 4-amino-benzolylanine by an azo bond that is hydrolysed by intestinal bacteria.

Mesalazine can be administered using carriers that deliver it to the large bowel or on its own in the form of a modified-release formulation (1).

The pharmacological properties of aminosalicylates and their potential value in the treatment of inflammatory bowel disease have been reviewed (2). Aminosalicylates are the drugs of first choice in the acute treatment of ulcerative colitis and in maintaining remission. Their value in Crohn's disease is more modest. The variability in clinical results is at least partly caused by the different formulations and dosages of the drug used, as well as the high variation in drug disposition and topical availability of the active drug. The popularity of aminosalicylates is most likely due to the low incidence of adverse effects and good overall safety record.

Observational studies

Mesalazine caused apoptosis and reduced cell proliferation in the colorectal mucosa in 17 patients with sporadic polyps of the large bowel (3). This may be clinically relevant in lowering the rate of polyp recurrence after polypectomy, thereby contributing to chemoprevention of sporadic colonic carcinoma.

Comparative studies

In a randomized, double-blind study, balsalazide 3 g/day and mesalazine 1.2 g/day effectively maintained remission in 99 patients with ulcerative colitis (4). Adverse events were equally common in the two groups, the most common being headache, abdominal pain and diarrhea, respiratory infections, body pains, and flu-like symptoms.

In a 12-week trial in 168 patients with mild to moderate ulcerative colitis, olsalazine 3 g/day was as effective as mesalazine 3 g/day in inducing a remission (5). There were more adverse effects in patients taking olsalazine (41 of 88) than mesalazine (29 of 80). Most of the adverse effects related to bowel disturbances: diarrhea, vomiting, abdominal discomfort, heartburn, flatulence, and nausea. Diarrhea was more common in patients taking olsalazine. One patient taking mesalazine developed a lupus-like syndrome.

The effects of mesalazine and olsalazine in delivering active mesalazine to the colon and in producing a systemic load as a basis for potential long-term toxicity have been compared in a single-blind, randomized, crossover study in 15 patients with ulcerative colitis (6). The patients took either olsalazine 500 mg bd or mesalazine 500 mg tds, with a crossover after 7 days. Plasma and urine concentrations of mesalazine and acetylmesalazine were assayed. Olsalazine caused loose stools in one patient and diarrhea in two, whereas mesalazine caused diarrhea in one. The systemic load of active mesalazine was significantly higher after mesalazine than olsalazine, based on both therapeutically recommended doses and when calculated on an equimolar basis. Some patients treated with mesalazine had very high plasma and urinary concentrations of mesalazine and acetylmesalazine, which may have long-term safety implications.

The relapse-preventing effects and safety profiles of balsalazide 1.5 g bd, balsalazide 3 g bd, and mesalazine 0.5 g tds have been studied in a multicenter, randomized, double-blind trial in 133 patients with ulcerative colitis in remission (7). High-dose balsalazide was significantly more effective in maintaining remission compared with the other two treatments. All three treatments were well tolerated.

In a double-blind, multicenter study in 182 patients with active Crohn's disease affecting the ileum and/or ascending colon, a modified-release formulation of budesonide 9 mg/day was more effective in inducing remission than mesalazine 2 g bd (8). Adverse events were similar in the two groups. Mild abnormalities of adrenal function tests were slightly more common with budesonide, but the clinical significance of these was unclear.

In a randomized, multicenter study in 94 patients, mesalazine 4 g/day for 12 weeks in a microgranular formulation was as effective as a standard dose of a glucocorticoid (6-methylpredisolone 40 mg/day) in mild to moderate Crohn's ileitis (Crohn's Disease Activity Index 180-350) (9). The group treated with methylpredisolone had a higher number of adverse events than those given mesalazine. The only adverse effect related to mesalazine was acute pancreatitis, which resolved on withdrawal.

Short-chain fatty acids, especially butyrate, are a preferred source of energy for the colonic epithelium. There is evidence to suggest that butyrate enemas are effective in the treatment of ulcerative colitis. The seeds of *Plantago ovata* (a source of fermentable dietary fiber) increase fecal concentrations of butyrate and acetate. In a randomized, open, parallel-group, multicenter study in 105 patients with ulcerative colitis, *P. ovata* seeds 10 mg bd were as effective as mesalazine 500 mg tds in maintaining remission over 12 months (10). Adverse effects were similar in the two groups, and included constipation, flatulence, nausea, and diarrhea.

Placebo-controlled studies

In an 18-month, double-blind, randomized, placebo-controlled trial in 318 patients, mesalazine 4 g/day did not significantly affect the postoperative course of Crohn's disease compared with placebo (11). There was some relapse-preventing effect in patients with isolated small bowel disease. The overall incidence of adverse effects was similar with mesalazine and placebo. Of the serious adverse effects reported, only one case of alopecia

© 2006 Elsevier B.V. All rights reserved.

was considered to be possibly or probably related to mesalazine.

In a double-blind, placebo-controlled, multicenter trial in 65 patients with ulcerative proctitis in clinical and endoscopic remission, mesalazine in suppositories 500 mg/day as sole treatment was effective, well tolerated, and safe for maintenance of remission over 24 months (12). The incidence of adverse effects was similar with mesalazine and placebo. The most frequent adverse effects with mesalazine were rectal disorders, abdominal pain, and headache.

Daily mesalazine 4 g orally plus placebo enema and mesalazine 2 g orally plus mesalazine 2 g rectally as a liquid enema have been compared in the treatment of mild to moderate ulcerative colitis in a multicenter, randomized, double-blind trial in 130 patients (7). The two treatments were equally effective in inducing disease remission. Both were well tolerated, and the frequencies of adverse effects were similar in the two groups.

In a randomized, double-blind, placebo-controlled trial in 328 patients with quiescent Crohn's disease, olsalazine 2 g/day given for 52 weeks was not superior to placebo in maintaining remission (13). Gastrointestinal adverse effects were significantly more frequent in the olsalazine group; diarrhea was the most commonly reported adverse effect.

General adverse effects

Adverse reactions with sulfasalazine are frequent, and the withdrawal rate for this reason can be as high as 30% (SEDA-16, 426). Common adverse effects related to sulfapyridine include headache, nausea, anorexia, and malaise. Other allergic or toxic adverse effects include fever, rash, hemolytic anemia, hepatitis, pancreatitis, paradoxical worsening of colitis, and reversible sperm abnormalities (14). Sulfasalazine appears to cause frequent severe adverse effects in adult-onset Still's disease and systemic-onset juvenile rheumatoid arthritis, as suggested by a long-term, follow-up study of 41 patients with adult-onset Still's disease and 109 consecutive patients with rheumatoid arthritis (15). Adverse effects included abdominal pain, nausea and vomiting, urticaria, facial flushing, high fever, hypotension, severe myelosuppression, and fulminant hepatitis, which resulted in death in one patient.

Skin reactions are common with sulfasalazine, and general sensitization can occur, as with other sulfa derivatives. The clinical features, besides skin rash, include granulomatous liver disease, positive lupus phenomenon, hypocomplementemia, and fever (16). More serious skin conditions can also occur. In the case of mild reactions, patients can often be desensitized by giving small (and then progressively increasing) doses. Various complex autoimmune syndromes can occur (SEDA-17, 423); in long-term studies of the use of sulfasalazine in rheumatoid arthritis, 12–20% of evaluable patients developed antinuclear antibodies during treatment (SEDA-16, 426) (SEDA-18, 375). Tumor-inducing effects have not been described.

The role of mesalazine in the acute and long-term treatment of ulcerative colitis has been reviewed (17). Mesalazine is equivalent to or better than sulfasalazine and better than placebo in inducing remission of acute disease, and comparable to sulfasalazine and better than placebo for long-term maintenance of remission. Adverse effects are uncommon, but include idiosyncratic worsening of colitis and renal toxicity. Mesalazine is safe during pregnancy and breastfeeding. In maintenance therapy, it may reduce the risk of developing colorectal carcinoma.

Crossover studies have shown that mesalazine has about a 10-fold lower potential than sulfasalazine for inducing allergic reactions or causing intolerance. Adverse effects with all aminosalicylates include (generally more frequent with sulfasalazine) headache, nausea, abdominal pain, dyspepsia, fatigue, rash, fever, rarely exacerbation of the disease, pancreatitis, pericarditis, pneumonitis, liver disease, nephritis, and bone marrow depression. Watery diarrhea is an adverse effect unique to olsalazine, while anorexia, folate malabsorption, hemolysis, neutropenia, agranulocytosis, male infertility, and neuropathy are unique to sulfasalazine.

The adverse effects of sulfasalazine 2–3 g/day and mesalazine 1.2–2.4 g/day in 685 patients have been reviewed for a median follow-up period of 7 and 5 years respectively (18). Adverse effects were observed overall in 20% of patients taking sulfasalazine and 6.5% of those taking mesalazine. The commonest adverse effects due to sulfasalazine (reported by more than 10% of patients) were dyspepsia, rash, and headache, while the commonest due to mesalazine were rash, diarrhea, headache, fever, abdominal pain, impaired renal function, dyspepsia, and edema. Fertility was affected in all 42 male patients taking sulfasalazine who were assessed, but improved when they changed to mesalazine.

A pharmacovigilance report from France reported 128 adverse events during 15.6 million days of therapy with Pentasa in 1993 and 1994. Adverse events with a high likelihood of causality included diarrhea, pancreatitis, liver abnormalities, blood dyscrasias, renal insufficiency, and cardiac disorders, including myocarditis. Most of these rare adverse events did not appear to be dose-related in the therapeutic range (SEDA-21, 364) A meta-analysis of studies of the effectiveness of mesalazine in maintaining remission in Crohn's disease showed an adverse effect frequency of 14% in patients taking mesalazine and 15% in patients taking placebo. The most frequent adverse effect attributable to mesalazine was diarrhea (SEDA-22, 394).

The dose response relation of oral mesalazine in inflammatory bowel disease has been briefly reviewed (19). Higher doses (3 g/day) are more effective in inducing and maintaining remission than lower doses (1.5 g/day). None of the known adverse effects of mesalazine is clearly dose-related in the therapeutic range of doses.

An analysis of suspected serious adverse reactions reported to the Committee on Safety of Medicines in the UK in 1991–98 has failed to show a safety advantage for mesalazine over sulfasalazine in the treatment of inflammatory bowel disease (20). Pancreatitis and interstitial nephritis were significantly more common with mesalazine.

The adverse effects of olsalazine would be expected to be those of mesalazine, and this is largely the case. However, diarrhea has been sufficiently common to suggest that it may be a particular problem with olsalazine,

© 2006 Elsevier B.V. All rights reserved.

with an incidence of some 13%; it is probably a small-intestinal secretory diarrhea (SEDA-17, 425) (21). Similarly, cholestatic hepatitis, confirmed on rechallenge, did not recur with mesalazine in similar doses (SEDA-16, 428). In one case there was a marked hypersensitivity reaction in a man previously intolerant of sulfasalazine, but the circumstances suggested a reaction to mesalazine rather than to the double molecule (SEDA-18, 376).

Organs and Systems

Cardiovascular

A single Scandinavian case report has reliably attributed a fatal myocarditis to mesalazine (22).

The time between the start of treatment and the onset of mesalazine-associated pericarditis usually ranges from a few days to 7 months. However, the delay can be longer.

- A 53-year-old man with Crohn's disease, who had taken mesalazine 500 mg/day for the past 8 years, developed pericarditis with an effusion (23). The pericarditis resolved rapidly on drug withdrawal. Investigations excluded other common causes of pericarditis.
- Pericarditis in a 16-year-old boy with inflammatory bowel disease taking mesalazine resolved on withdrawal, but recurred after starting sulfasalazine 500 mg tds (24).
- Acute pericarditis has been reported in a 17-year-old man with severe ulcerative colitis who had taken mesalazine 1.5 g/day for 2 weeks (25). The pericarditis resolved on withdrawal and recurred on rechallenge with a low dose (62.5 mg) of mesalazine 3 weeks later.
- Constrictive pericarditis has been reported in a 37-year-old woman with chronic ulcerative colitis who had taken mesalazine 2 g/day for 2 weeks (26). She recovered after radical pericardiectomy.

Bradycardia has been attributed to mesalazine.

- Severe symptomatic bradycardia has been reported in a 29-year-old woman with ulcerative colitis who was taking mesalazine (27). The bradycardia resolved on withdrawal. Six weeks later mesalazine was restarted for a relapse of her colitis, and symptomatic bradycardia recurred. Again this resolved on withdrawal.

Chest pain has been attributed to mesalazine (28).

- A 37-year-old man with ulcerative colitis developed severe retrosternal chest pain with non-specific ST–T wave changes in the inferolateral leads of the electrocardiogram after taking mesalazine 800 mg qds for 1 week. Cardiac enzymes, coronary angiography, left ventricular function, and pulmonary angiography were normal. Mesalazine was omitted and glucocorticoids were tapered. He recovered completely and his electrocardiogram normalized. Two weeks later he was given mesalazine 800 mg qds and again developed retrosternal chest pain with T wave inversion in the lateral leads. Mesalazine was withdrawn and his symptoms resolved within 24 hours. His chest pain did not recur over an 18 month follow-up period while not taking mesalazine.

Raynaud's phenomenon has been attributed to sulfasalazine (29,30).

Respiratory

"Sulfasalazine lung," fibrosing alveolitis, and eosinophilic pleurisy are variants on a well-recognized although unusual lung complication. Most commonly it presents with cough, fever, eosinophilia, dyspnea, and pulmonary infiltrates (SEDA-15, 309) (31). Sputum production, a history of allergy, rash, chest pain, and weight loss are inconsistent findings. The disease usually develops 1–9 months after the start of treatment and the fibrosing alveolitis can be fatal (32). The lung pathology is variable, the commonest change being an eosinophilic pneumonia with peripheral eosinophilia and interstitial inflammation with or without fibrosis. In case reports, the majority of patients with suspected sulfasalazine-induced lung disease improved within weeks of drug withdrawal (33). Whether the salicylate or the sulfa moiety is responsible is unclear; both can cause pulmonary eosinophilia. Differentiation from lung disease simply associated with ulcerative colitis can be difficult, particularly because the drug-induced form sometimes causes an interstitial pneumonitis without evidence of an allergic reaction (34) and rechallenge can be dangerous (SEDA-16, 427).

Peripheral lung infiltrates with blood eosinophilia are rare effects of sulfasalazine. Sulfasalazine-induced hypersensitivity lung disease with simultaneous *Legionella pneumophila* infection has been reported for the first time (35).

- A 32-year-old woman with ulcerative colitis developed bilateral pulmonary infiltrates with peripheral eosinophilia 2 weeks after starting to take sulfasalazine and mesalazine enemas, and both drugs were withdrawn. Based on a high antibody titer, legionnaires' disease was diagnosed and empirical therapy with a macrolide antibiotic was started; she improved within a few days. Three months later sulfasalazine was restarted, followed 3 days later by acute pulmonary symptoms (bilateral confluent opacities) and blood eosinophilia. The abnormalities resolved completely after drug withdrawal and prophylactic antibiotic therapy.

Various adverse respiratory effects of mesalazine have been reported.

- A patient who took mesalazine for 2 years had a symptomatic bilateral lung reaction, with interstitial infiltrates and impaired function; the condition developed insidiously but recovered within 8 months after drug withdrawal (36). The condition was not necessarily identical to the lung reaction seen with sulfasalazine.
- Pleural effusion with pulmonary infiltration has been reported in a 72-year-old woman with ulcerative colitis taking mesalazine 800 mg tds (37). The lung pathology resolved after drug withdrawal.
- An eosinophilic pleural effusion has been reported in a 35-year-old male non-smoker who had taken mesalazine 2.4 g/day orally for 2 weeks for a diarrheal illness (38). He recovered after mesalazine was withdrawn.
- A 35-year-old woman with ulcerative colitis who had taken mesalazine 1.5 g/day for about 40 days developed a low-grade fever with bilateral eosinophilic pulmonary infiltrates (confirmed by transbronchial lung biopsy) (39). Spontaneous clinical and radiological resolution

© 2006 Elsevier B.V. All rights reserved.

occurred on withdrawal. A drug lymphocyte stimulation test was positive for mesalazine.

- A 29-year-old woman with ulcerative colitis taking mesalazine 1 g tds developed respiratory distress (40). Her respiratory symptoms (chest pain and respiratory distress, especially exertional dyspnea) occurred 48 hours after she started to take mesalazine and disappeared immediately on withdrawal. Similar symptoms recurred on rechallenge 3 weeks later in a lower dose of 500 mg bd. Chest X-ray and white cell count a day later were normal.
- Bronchiolitis obliterans has been reported in an 18-year-old female non-smoker with ulcerative colitis, 3 months after reintroduction of mesalazine 1.6 g/day orally (41). She recovered after mesalazine withdrawal and treatment with glucocorticoids.
- Interstitial pulmonary disease (lymphocytic alveolitis and mild interstitial pulmonary fibrosis) has been reported in a 70-year-old woman with ulcerative colitis who had taken mesalazine 2.4 g/day for 3 months (42). Halving the dose of mesalazine to 1.2 g/day led to resolution of her lung disorder without relapse of ulcerative colitis.

A limited form of Wegener's granulomatosis with a bronchiolitis obliterans organizing pneumonia-like variant has been reported in a 19-year-old man, a non-smoker, with ulcerative colitis, 6 months after the introduction of mesalazine 2.25 g tds orally (43). He recovered after mesalazine withdrawal and treatment with glucocorticoids.

Nervous system

An unusual but not unique case of transverse myelitis was reported in 1991, and other published case reports suggest links with chorea and ataxia (SEDA-16, 427).

Individual cases of other adverse effects on the nervous system have appeared.

- Vivid dreams and daytime hallucinations occurred in a woman taking sulfasalazine (44).
- Aseptic meningitis occurred in a patient with pre-existing Sjögren's syndrome; and the drug link was confirmed by positive rechallenge (45).
- In a slow acetylator, an axonal sensorimotor neuropathy could have been due to sulfasalazine (SEDA-17, 424).

Seizures with acute encephalopathy have been reported in a woman taking sulfasalazine for polyarthritis (46).

Hematologic

In a randomized, double-blind, placebo-controlled trial, 70 patients with established ankylosing spondylitis and a mean disease duration of 17 years were investigated in two centers for 26 weeks, comparing sulfasalazine 3 g/day with placebo. In the treatment group there were significantly more cases of anemia, leukopenia, eosinophilia, and thrombocytopenia (47).

Sulfasalazine causes Heinz body anemia in patients with abnormal hemoglobin and hemolysis in patients with glucose-6-phosphate dehydrogenase deficiency (48).

- A 79-year-old woman who had been taking sulfasalazine for ulcerative colitis for 5 years developed a positive Coombs' test and a hemoglobin of 8.2 g/dl. Agglutination occurred when a mixture of sulfasalazine and the patient's serum was added to normal erythrocytes treated with the endopeptidase ficin, but there was no reactivity when control serum was used or when sulfasalazine was omitted. Preincubation of sulfasalazine with normal erythrocytes gave negative results on addition of the patient's serum, excluding the possibility of a penicillin-like reaction. The patient had normal glucose-6-phosphate dehydrogenase activity and there were no Heinz bodies in a blood smear.

However, about 1.7% of patients with ulcerative colitis develop immune hemolytic anemia, even in the absence of sulfasalazine, so cause and effect is not always possible to determine.

Agranulocytosis is very unusual but well described with sulfasalazine, and can occur suddenly and very early in treatment (49). The risk in sulfasalazine users with arthritic disorders (6/1000 users) was about 10 times higher than that in users with inflammatory bowel disease (0.6/1000 users) (SEDA-20, 320). Agranulocytosis is supposedly more common in slow acetylators (50). However, in one study the risk of agranulocytosis was not increased in slow acetylators (50). Leukopenia occurred in a patient taking mesalazine after a similar reaction to sulfasalazine (SEDA-17, 425).

Sulfasalazine reduces folic acid absorption, but rarely to a clinically significant extent, although megaloblastic anemia has rarely been documented (51,52).

Methemoglobinemia can occur in slow acetylators of sulfapyridine (53).

Thrombocytopenia has occasionally been attributed to mesalazine (54–56) and olsalazine (57).

- A possible association between mesalazine and pancytopenia has been reported in a 23-year-old man with Crohn's disease (58). The pancytopenia resolved after withdrawal.

Gastrointestinal

Nausea and vomiting, taste disturbances (SEDA-17, 424), anorexia, stomatitis, flatulence (59), and abdominal discomfort can occur in patients taking sulfasalazine and mesalazine. They are particularly common in slow acetylators, but symptoms remit with dosage reduction. Diarrhea is more common with olsalazine than with sulfasalazine.

Five cases of severe persistent diarrhea following the use of mesalazine in doses of 2.4–4.8 g/day have been reported (60). The diarrhea was made worse by increasing doses of the drug. Symptoms resolved on withdrawal or dosage reduction.

- Severe diarrhea that mimicked the effects expected with the use of non-steroidal anti-inflammatory drugs, associated with changes in fecal eicosanoid content, has been reported in a 57-year-old man with non-granulomatous enterocolitis who took mesalazine 4 g/day (61). The diarrhea resolved dramatically on withdrawal.

Exacerbation of existing colitis is rare but well recognized with sulfasalazine and it can also cause colitis de novo; pseudomembranous colitis with *Clostridium difficile* was reported in 1991, as was fatal neutropenic colitis with no

© 2006 Elsevier B.V. All rights reserved.

evidence of *C. difficile* infection (SEDA-17, 424). Reports of exacerbation of colitic symptoms caused by intolerance of mesalazine are infrequent. Diarrhea, rectal bleeding, and weight loss have been described in three patients (aged 13, 14, and 17 years) with ulcerative colitis who were taking mesalazine 2–4 g/day (62). Their symptoms resolved dramatically after mesalazine withdrawal.

The finding of *Escherichia coli* on rectal swabs, with a range of resistance extending beyond the sulfa drugs, is difficult to evaluate. The clinical relevance is doubtful.

Liver

Exceptionally, fulminant hepatic failure with massive necrosis has been seen in patients taking sulfasalazine (63). Two fatal cases were reported in 1992 (SEDA-17, 424).

Cases of hepatitis have been observed in patients taking mesalazine; one such case was observed in a series of 103 patients taking mesalazine, and two further cases in another series of 44 patients (SEDA-20, 320).

- Severe hepatic injury with biopsy-proven cholestasis was reported in a man who had taken mesalazine in a dose of 4 g/day for 4 months (SEDA-22, 394) (64).

Mesalazine-induced chronic hepatitis and liver fibrosis, with raised serum IgG concentrations and autoantibodies, has been reported (65).

- A 57-year-old man with an unspecified abdominal complaint (later confirmed not to be inflammatory bowel disease), who was also taking simvastatin, developed abnormal liver function tests and antinuclear and anti-smooth muscle antibodies 13 months after starting to take mesalazine. Simvastatin hepatotoxicity was suspected and that drug was withdrawn, but there was no improvement in liver function. Mesalazine was withdrawn 21 months after the start of therapy, with rapid normalization of liver enzymes and serum IgG concentrations and disappearance of the autoantibodies.

Pancreas

Pancreatitis has several times been ascribed to sulfasalazine and may well be the expression of an allergic reaction; cases with positive rechallenge are on record.

Pancreatitis has been noted with mesalazine often enough to be taken seriously (66); it usually occurs within a short time of starting treatment, has occurred in children as well as adults, and has sometimes been confirmed by rechallenge (SEDA-18, 375).

- A 29-year-old man with Crohn's disease who had taken mesalazine 2 g/day for 3 days developed acute pancreatitis (67). Clinical and biochemical improvement occurred on drug withdrawal. Acute pancreatitis recurred on rechallenge.
- A 23-year-old man with ulcerative colitis developed acute pancreatitis after taking mesalazine 1.5 g/day for 4 days (68). Resolution occurred on withdrawal but rechallenge was not performed.
- A 10-year-old boy with ulcerative colitis developed acute pancreatitis 1 day after the dose of mesalazine was increased from 400 mg bd (which he has taken for 5 months without any adverse effect) to 800 mg bd for a mild relapse (69). He became asymptomatic 3 days after drug withdrawal.
- A 34-year-old woman with colitis developed pancreatitis 1 week after starting mesalazine 1 g tds; she recovered after drug withdrawal (70). She was admitted 15 months later with a relapse of colitis and was given oral prednisolone 50 mg/day and mesalazine enemas (2 g bd). Although the colitis regressed, 10 days later she again developed acute pancreatitis. She recovered 3 days after prednisolone and mesalazine enemas were withdrawn. Symptoms of pancreatitis did not recur when prednisolone was restarted.
- A patient developed pancreatitis after taking mesalazine 2 g bd; the symptoms resolved when the drug was withdrawn, but recurred when azathioprine was given (71).

Two unusual cases of delayed-onset pancreatitis occurring 3 months and 2 years after starting mesalazine have been described (SEDA-22, 394) (72).

Urinary tract

Two patients with long-standing ulcerative colitis developed what seemed to be a drug-induced chronic interstitial nephritis after taking sulfasalazine for several years, with no other detectable cause (73); the same problem has arisen with mesalazine. However, in a long-term study (mean treatment time 10 years) in 36 patients taking sulfasalazine for ulcerative colitis, there was no nephrotoxicity (74).

Proximal renal tubular proteinuria is a possible complication in patients treated with high doses of mesalazine, and it is clearly important to monitor renal function in these patients (SEDA-22, 394) (75). Two studies in 21 (76) and 95 (77) patients with ulcerative colitis and Crohn's disease have shown that proteinuria of tubular marker proteins is common and is related to disease activity rather than to treatment with mesalazine. Thus, tubular proteins are not useful predictors of an adverse renal response to the drug. Nephrotic syndrome with minimal change nephropathy has been described with sulfasalazine and mesalazine (SEDA-16, 427).

Interstitial nephritis has been well documented in patients taking mesalazine (SEDA-17, 425) (8,78–81).

- Interstitial nephritis occurred in a 29-year-woman with ulcerative colitis and a 48-year-old woman with Crohn's disease who were taking mesalazine (82).

There have been three other reports of interstitial nephritis associated with mesalazine in patients with inflammatory bowel disease, two with ulcerative colitis and one with Crohn's disease (83–85). One patient continued to be dialysis-dependent and in two patients withdrawal of the drug and treatment with glucocorticoids resulted in partial improvement in renal function.

- Acute tubular necrosis has been reported in a 49-year-old man with Crohn's disease who had taken mesalazine 4 g/day for 1 month (86). Renal function normalized rapidly after withdrawal of mesalazine.

In addition, there has been a report of a possible association between mesalazine and nephrotic syndrome due to

© 2006 Elsevier B.V. All rights reserved.

minimal change nephropathy, which resolved after withdrawal (87).

Serious renal impairment occurs in under 1 in 500 recipients of enteric-coated mesalazine (88), and early recognition and withdrawal (after up to 10 months of administration) has been reported to have resulted in complete recovery of renal function in five out of six patients. Monitoring renal function in patients taking mesalazine formulations is recommended. Oral enteric-coated mesalazine should not be used in patients with renal sensitivity to sulfasalazine, a history of hypersensitivity to salicylates, severe renal impairment, and children under 2 years old.

- A 23-year-old student with ulcerative colitis who took mesalazine 1.5 g/day for 15 days developed asymptomatic renal insufficiency (89). Renal function rapidly normalized after drug withdrawal.

Two other cases of interstitial nephritis have been reported in children with Crohn's disease who were taking mesalazine (90).

Nephrotoxicity has been described during treatment with olsalazine (SEDA-21, 364). To assess the effects of 9 months of treatment with oral mesalazine 1.2 g/day and olsalazine 1 g/day on renal function, a randomized trial has been performed in 40 patients with ulcerative colitis in complete remission (91). Neither drug had a significant effect on glomerular filtration rate. Adverse effects (all mild to moderate) were more common in the mesalazine group; they included abdominal pain and distension, dyspepsia, nausea, and diarrhea.

Skin

Simple rashes are not uncommon in patients taking sulfasalazine, including maculopapular rash, pruritus, urticaria, angioedema, eczematous dermatitis, photosensitivity, skin discoloration, and oral ulceration. Raynaud's phenomenon and toxic epidermal necrolysis associated with erythroid hypoplasia and agranulocytosis have occurred; in one case of toxic epidermal necrolysis there was marked immunosuppression (SEDA-18, 375).

- Acute generalized exanthematous pustulosis occurred in a 28-year-old man with ulcerative colitis taking sulfasalazine (92). A patch test was negative, but the lymphocyte stimulation assay for sulfasalazine showed a stimulation index of 541% (controls were not mentioned).

A rare case of skin hyperpigmentation (apparently a phototoxic reaction) has been associated with sulfasalazine lung (93).

Rashes have not generally proved an important problem with mesalazine, but two cases of oral and cutaneous lichen planus which had developed during sulfasalazine treatment recurred when the patients later took mesalazine (SEDA-17, 425).

Hair

Hair loss is rare in patients taking sulfasalazine (SEDA-16, 427).

Sexual function

Erectile impotence has often been described in patients taking sulfasalazine, sometimes with positive rechallenge (94).

Immunologic

The causes of ANCA-positive vasculitis with high titers of antimyeloperoxidase antibodies in 30 new patients have been reviewed (95). The findings illustrate that this type of vasculitis is predominantly drug-induced. Only 12 of the 30 cases were not related to a drug. The most frequently implicated drug was hydralazine ($n = 10$); the others were propylthiouracil ($n = 3$), penicillamine ($n = 2$), allopurinol ($n = 2$), and sulfasalazine ($n = 1$).

Treatment with sulfasalazine was associated with lupus-like symptoms and systemic lupus erythematosus-related autoantibody production in 10% of patients with early rheumatoid arthritis; risk factors included a systemic lupus erythematosus-related HLA haplotype, increased serum interleukin-10 concentrations, and a speckled pattern of antinuclear antibodies (96).

Sulfasalazine-induced angioimmunoblastic lymphadenopathy has been reported in a patient with juvenile chronic arthritis (97).

A Kawasaki-like syndrome has been reported in a patient taking sulfasalazine, who later reacted in the same way to mesalazine (SEDA-16, 427).

The possibility of allergic reactions to mesalazine has been suggested, but they may be rather less of a problem than with sulfasalazine.

- Angioedema has been reported in a 23-year-old man with inflammatory bowel disease 48 hours after he was given mesalazine 4 g/day (98).

A lupus-like syndrome has been described on several occasions (SEDA-15, 400) (99).

Second-Generation Effects

Fertility

Oligospermia, with reduced motility and a high frequency of abnormal forms, and male infertility are well documented in patients taking sulfasalazine. Oral and rectal treatments have the same effects, which reverse on withdrawal. Male infertility caused by sulfasalazine can be reversed by switching to mesalazine.

Pregnancy

Pregnant colitic patients generally fare better if they continued to take aminosalicylates. Though sulfasalazine crosses the placenta, competes for albumin-binding sites with bilirubin, and can be detected in breast milk, no adverse effects on offspring have been detected.

Lactation

Even in women taking large doses, only very small amounts of mesalazine enter the breast milk; toxic effects are unlikely but allergic effects can occur (SEDA-18, 376).

© 2006 Elsevier B.V. All rights reserved.

Susceptibility Factors

Genetic factors

Because sulfonamides are subject to polymorphic metabolism by *N*-acetyltransferase (NAT2), some of the adverse effects of sulfasalazine are more common in slow acetylators. Gastrointestinal adverse reactions occur more commonly in slow acetylators, and they should use lower doses.

Glucose-6-phosphate dehydrogenase deficiency can be associated with a tendency to hemolysis in patients taking sulfasalazine.

When chronic inflammatory bowel disease co-exists with acute intermittent porphyria, the bowel condition itself brings with it an increased risk of acute attacks of porphyria; sulfasalazine can trigger such an attack in this condition (SEDA-17, 425).

Drug Administration

Drug formulations

Oral enteric-coated mesalazine consists of ethylcellulose-coated microgranules from which mesalazine is released in the small and large intestines in a diffusion-dependent manner.

The use of oral enteric-coated mesalazine, which releases mesalazine in the terminal ileum and colon, has been reviewed (88,100). Dose-related improvements in clinical and endoscopic parameters have been reported with prolonged-release mesalazine 2–4 g/day in trials in patients with mild to moderately active ulcerative colitis. About 74% of patients with mild to moderate ulcerative colitis improve with enteric-coated mesalazine 2.4–4.8 g/day. There is a trend toward a better response with higher doses. Oral enteric-coated mesalazine 0.8–4.4 g/day appears to be as effective as sulfasalazine 2–4 g/day, modified-release mesalazine 1.5 g/day, and balsalazide 3 g/day in maintaining remission in ulcerative colitis.

Prolonged-release mesalazine also reduced disease activity in patients with mild to moderately active Crohn's disease. In Crohn's disease, mesalazine was more effective in preventing relapse in patients with isolated small bowel disease than in those with colonic involvement. Prolonged-release mesalazine appears to be as well tolerated as placebo, and the incidence of adverse effects does not appear to be dose related. Nausea/vomiting, diarrhea, abdominal pain, and dyspepsia are the most commonly reported. Reports of nephrotoxicity with this formulation are rare.

In a randomized, open trial in 227 patients with mild to moderate ulcerative colitis, mesalazine 4 g/day given as prolonged-release granules bd and qds was as effective as prolonged-release tablets given qds (101). All the treatments were well tolerated and the frequencies of adverse effects were similar in the treatment groups. The patients preferred twice-daily dosing.

In a 4-week, randomized trial in 103 patients with mild to moderate left-sided ulcerative colitis or proctosigmoiditis, mesalazine gel enema 2 g/day was as effective as mesalazine foam enema 2 g/day in inducing remission (102). Patients in the foam group had significantly more difficulty in retention and more abdominal bloating and discomfort during administration of the drug.

In an open, randomized trial in 266 patients with active distal ulcerative colitis, mesalazine foam enema 2 g/day was as effective as mesalazine standard liquid enema 4 g/day (103). The number of adverse effects attributable to medication was higher in the foam group than in the liquid enema group (14 versus 4). The most commonly reported adverse effect was flatulence.

Oral enteric-coated mesalazine is well tolerated in children aged 4–19 years and in adults who are intolerant of sulfasalazine. The most common adverse effects are headache, gas, nausea, diarrhea, and dyspepsia. The adverse effects can be severe enough to require withdrawal of the drug in up to 11% of patients.

Drug–Drug Interactions

Azathioprine and mercaptopurine

In a prospective, parallel-group study in 34 patients with Crohn's disease taking azathioprine or mercaptopurine, co-administration of mesalazine 4 g/day, sulfasalazine 4 g/day, or balsalazide 6.75 g/day for 8 weeks resulted in an increase in whole blood 6-thioguanine nucleotide concentrations and a high frequency of leukopenia (104). In 16 patients with quiescent Crohn's disease taking a stable dose of azathioprine plus sulfasalazine or mesalazine, mean 6-thioguanine nucleotide concentrations fell significantly after aminosalicylate withdrawal without significant changes in thiopurine methyltransferase activity (105).

Thiopurines are metabolized by thiopurine methyltransferase, whose activity is controlled by a common genetic polymorphism in the short arm of chromosome 6. Patients with low or intermediate activity who take azathioprine or 6-mercaptopurine are at risk of myelosuppression caused by excess accumulation of the active thiopurine metabolite 6-thioguanine nucleotide. Benzoic acid derivatives, such as mesalazine and its precursors, and prodrugs (sulfasalazine, olsalazine, and balsalazide) inhibit thiopurine methyltransferase activity in vitro. This action could explain the increase in whole blood concentrations of 6-thioguanine nucleotide, leading to leukopenia.

Digoxin

Sulfasalazine reduces the systemic availability of digoxin (106).

Ferrous sulfate

Ferrous sulfate interferes with the absorption of sulfasalazine, possibly by chelation (107). The significance of this phenomenon is doubtful, given that the beneficial effect of sulfasalazine depends on the release of mesalazine in the large intestine.

Warfarin

An interaction of mesalazine with warfarin has been reported (108).

- A 55-year-old woman taking warfarin 5 mg/day for deep venous thrombosis was also given mesalazine

© 2006 Elsevier B.V. All rights reserved.

800 mg tds for a solitary cecal ulcer. Four weeks later she developed worsening of her venous thrombosis. Her serum warfarin concentrations were undetectable and the INR was 0.9. Mesalazine was withdrawn; her INR rose to 1.8 on the following day and was 2.1 five days later.

The mechanism of this interaction is not known.

Interference with Diagnostic Tests

Iron

Sulfasalazine interferes with coulometry of serum iron (109).

Amiodarone

See also Antidysrhythmic drugs

General Information

Amiodarone is highly effective in treating both ventricular and supraventricular dysrhythmias (1). Its pharmacology, therapeutic uses, and adverse effects and interactions have been extensively reviewed (2–14).

General adverse effects

Amiodarone prolongs the QT interval and can therefore cause dysrhythmias; there have also been reports of conduction disturbances. Abnormalities of thyroid function tests can occur without thyroid dysfunction, typically increases in serum T4 and reverse T3 and a reduction in serum T3. However, in up to 6% of patients frank thyroid dysfunction can occur (either hypothyroidism or hyperthyroidism). Several of the adverse effects of amiodarone are attributable to deposition of phospholipids in the tissues. These include its effects on the eyes, nerves, liver, skin, and lungs. Almost all patients develop reversible corneal microdeposits, which can occasionally interfere with vision. There are reports of peripheral neuropathy and other neurological effects. Changes in serum activities of aspartate transaminase and lactate dehydrogenase can occur without other evidence of liver disease, but liver damage can occur in the absence of biochemical evidence. Skin sensitivity to light occurs commonly, possibly due to phototoxicity. There may also be a bluish pigmentation of the skin. Interstitial pneumonitis and alveolitis have been reported and may be fatal. Lung damage due to amiodarone may be partly due to hypersensitivity. Tumor-inducing effects have not been reported.

Studies in the prevention of dysrhythmias

In a study of the use of implantable defibrillators or antidysrhythmic drugs (amiodarone or metoprolol) in 288 patients resuscitated from cardiac arrest, the defibrillator was associated with a slightly lower rate of all-cause mortality than the antidysrhythmic drugs (15). However, the small difference was not statistically significant. There was hyperthyroidism in three of those given amiodarone. Drug withdrawal was required in nine of those given amiodarone and 10 of those given metoprolol. There were deaths in five patients fitted with a defibrillator and two patients given amiodarone. There was crossover to the other therapy in 6% in each group, usually because of recurrence of the dysrhythmia. When sudden cardiac death was analysed, the reduction in mortality with defibrillation was much larger (61%). There were no differences in all-cause mortality and sudden death rates between those given amiodarone and those given metoprolol.

Amiodarone and carvedilol have been used in combination in 109 patients with severe heart failure and left ventricular ejection fractions of 0.25 (16). They were given amiodarone 1000 mg/week plus carvedilol titrated to a target dose of 50 mg/day. A dual-chamber pacemaker was inserted and programmed in back-up mode at a basal rate of 40. Significantly more patients were in sinus rhythm after 1 year, and in 47 patients who were studied for at least 1 year the resting heart rate fell from 90 to 59. Ventricular extra beats were suppressed from 1 to 0.1/day and the number of bouts of tachycardia over 167 per minute was reduced from 1.2 to 0.3 episodes per patient per 3 months. The left ventricular ejection fraction increased from 0.26 to 0.39 and New York Heart Association Classification improved from 3.2 to 1.8. The probability of sudden death was significantly reduced by amiodarone plus carvedilol compared with 154 patients treated with amiodarone alone and even more so compared with 283 patients who received no treatment at all. However, the study was not randomized, and this vitiates the results. The main adverse effect was symptomatic bradycardia, which occurred in seven patients; two of those developed atrioventricular block and four had sinoatrial block and/or sinus bradycardia; one patient developed slow atrial fibrillation.

A meta-analysis of 13 randomized trials has shown that both total mortality and sudden death or dysrhythmic death was less common over 24 months after randomization to amiodarone than in control subjects (17).

Studies in atrial fibrillation

Cardiac glycosides such as digoxin are commonly used to treat uncomplicated atrial fibrillation. In those in whom digitalis is not completely effective or in whom symptoms (for example bouts of palpitation) persist despite adequate digitalization, a calcium antagonist, such as verapamil or diltiazem, can be added, or amiodarone used as an alternative.

The use of oral amiodarone in preventing recurrence of atrial fibrillation, for preventing recurrence after cardioversion or for pharmacological cardioversion of atrial fibrillation, has been reviewed (18). There is insufficient evidence to support its use as a first-line drug for

© 2006 Elsevier B.V. All rights reserved.

preventing recurrence of atrial fibrillation or in preventing paroxysmal atrial fibrillation.

In 186 patients randomized equally to amiodarone 200 mg/day, sotalol 160–480 mg/day, or placebo, the incidence of atrial fibrillation after 6 months was higher in those taking placebo compared with amiodarone and sotalol and higher in those taking sotalol compared with amiodarone (19). Of the 65 patients who took amiodarone, 15 had significant adverse effects after an average of 16 months. There were eight cases of hypothyroidism, four of hyperthyroidism, two of symptomatic bradycardia, and one of ataxia. There were minor adverse effects in 9% of the patients, including gastrointestinal discomfort, nausea, photosensitivity, and eye problems. These patients had recurrent symptomatic atrial fibrillation. In contrast, only two patients using sotalol developed symptomatic bradycardia and one had severe dizziness.

In 208 patients with atrial fibrillation of various duration, including 50 with chronic atrial fibrillation, randomized to amiodarone or placebo, 80% converted to sinus rhythm after amiodarone compared with 40% of those given placebo (20). Amiodarone was given as an intravenous loading dose of 300 mg for 1 hour and 20 mg/kg for 24 hours, followed by 600 mg/day orally for 1 week and 400 mg/day for 3 weeks. Those who converted to sinus rhythm had had atrial fibrillation for a shorter duration and had smaller atria than those who did not convert. The shorter the duration of fibrillation and the smaller the atria the sooner conversion occurred. There was significant hypotension in 12 of the 118 patients who received amiodarone during the first hour of intravenous administration, but in all cases this responded to intravenous fluids alone. There was phlebitis at the site of infusion in 17 patients, and the peripheral catheter was replaced by a central catheter. There were no dysrhythmic effects.

In 40 patients with atrial fibrillation, some with severe heart disease (including cardiogenic shock in eight and pulmonary edema in 12), amiodarone 450 mg was given through a peripheral vein within 1 minute, followed by 10 ml of saline; 21 patients converted to sinus rhythm, 13 within 30 minutes and another 8 within 24 hours (21). There were two cases of hypotension, but in those that converted to sinus rhythm there was a slight increase in systolic blood pressure. There were no cases of thrombophlebitis. Efficacy is hard to judge from this study, because it was not placebo-controlled.

In 72 patients with paroxysmal atrial fibrillation randomized to either amiodarone 30 mg/kg or placebo, those who received amiodarone converted to sinus rhythm more often than those given placebo (22). The respective conversion rates were about 50 and 20% at 8 hours, and 87 and 35% after 24 hours. The time to conversion in patients who converted did not differ. One patient developed slow atrial fibrillation (35/minute) with a blood pressure of 75/55 mmHg. Three other patients who received amiodarone had diarrhea and one had nausea. In the control group two patients had headache, one had diarrhea, one had nausea, and two had episodes of sinus arrest associated with syncope during conversion to sinus rhythm; the last of these was thought to have sick sinus syndrome.

In a single-blind study 150 patients with acute atrial fibrillation were randomized to intravenous flecainide, propafenone, or amiodarone (23). At 12 hours there was conversion to sinus rhythm in 45 of 50 patients given flecainide, 36 of the 50 given propafenone, and 32 of the 50 given amiodarone. Thus, flecainide and propafenone were both more effective than amiodarone. There were no differences between the groups in the incidences of adverse effects; there was one withdrawal in each group, due to cerebral embolism in a patient given amiodarone, heart failure in a patient given propafenone, and atrial flutter in a patient given flecainide. There were no ventricular dysrhythmias during the study.

Amiodarone and magnesium have been compared in a placebo-controlled study to reduce the occurrence of atrial fibrillation in 147 patients after coronary artery bypass graft surgery (24). Amiodarone was given as a infusion of 900 mg/day for 3 days and magnesium by infusion of 4 g/day for 3 days. The cumulative occurrences of atrial fibrillation with placebo, amiodarone, and magnesium were 27, 14, and 23% respectively. These differences were not significant. Amiodarone delayed the onset of the first episode of dysrhythmia significantly, but the slight benefit was associated with a longer period of invasive monitoring and was not considered worthwhile. Patients who were more likely to develop atrial fibrillation were older and had a plasma magnesium concentration at 24 hours of under 0.95 mmol/l. Patients who were given amiodarone had a slightly higher rate of adverse events, including hypotension, atrioventricular block, and bradycardia; adverse events led to withdrawal in four cases.

Amiodarone, sotalol, and propafenone have been compared for the prevention of atrial fibrillation in 403 patients who had had at least one episode of atrial fibrillation within the previous 6 months; the study was not placebo-controlled (25). The rate of recurrence of atrial fibrillation was significantly higher in those given sotalol or propafenone than in those given amiodarone. During the study nine patients given amiodarone died, compared with eight given sotalol or propafenone. Four deaths were thought to be dysrhythmic, three in patients given amiodarone. There were major non-fatal adverse events in 36 of the 201 patients given amiodarone and in 35 of the 202 patients given propafenone or sotalol. These included one case of torsade de pointes in a patient who received propafenone, and congestive heart failure in 11 patients given amiodarone and nine given sotalol or propafenone. There were strokes and intracranial hemorrhages in one patient given amiodarone and nine patients given sotalol or propafenone, of whom most were taking warfarin at the time. In all, 68 of the patients who were given amiodarone and 93 of those given sotalol or propafenone withdrew from the study; 17 of those taking amiodarone withdrew because of lack of efficacy compared with 56 of those taking sotalol or propafenone; 36 of those who took amiodarone withdrew because of adverse events compared with 23 of those who took sotalol or propafenone, and this was almost statistically significant.

Amiodarone, propafenone, and sotalol have also been compared in the prevention of atrial fibrillation in 214 patients with recurrent symptomatic atrial fibrillation. They were randomized to amiodarone 200 mg/day, propafenone 450 mg/day, or sotalol 320 mg/day. There was recurrence of atrial fibrillation in 25 of the 75 patients who took amiodarone compared with the 51 of 75 who took sotalol and 24 of the 64 who took propafenone. There

© 2006 Elsevier B.V. All rights reserved.

were adverse effects requiring withdrawal of treatment in 14 patients who took amiodarone, five who took sotalol and one who took propafenone while they were in sinus rhythm. These effects included symptomatic bradycardia in three patients, hyperthyroidism in six, hypothyroidism in four, and ataxia in one patient who took amiodarone. In those taking sotalol the adverse effects were bradycardia in three and severe dizziness in two. In the one patient in whom propafenone was withheld the reason was symptomatic bradycardia. Thus, amiodarone and propafenone were both more effective than sotalol, but amiodarone also caused more adverse effects requiring withdrawal (26).

In a meta-analysis of five randomized, placebo-controlled trials of amiodarone 200–1200 mg/day for 2–7 days in the treatment of postoperative atrial fibrillation and flutter in 764 patients, the incidence of adverse events with amiodarone was no greater than with placebo (27).

In a meta-analysis of five randomized, placebo-controlled trials of intravenous amiodarone about 500–2200 mg over 24 hours in the treatment of recent-onset atrial fibrillation in 410 patients, the incidence of adverse events was 27% with amiodarone and 11% with placebo (28). Intravenous amiodarone was significantly more effective than placebo in producing cardioversion. The most common adverse effects of intravenous amiodarone were phlebitis, bradycardia, and hypotension; most of these effects were not considered to be dose-limiting.

Of 85 patients with persistent atrial fibrillation after balloon mitral valvotomy given amiodarone (600 mg/day for 2 weeks and 200 mg/day thereafter), 33 converted to sinus rhythm (29). Of the other 52 patients, who underwent DC cardioversion at 6 weeks, 41 converted to sinus rhythm. Six patients had adverse effects attributable to amiodarone. Five had mild gastrointestinal symptoms, such as abdominal discomfort and nausea. One developed hypothyroidism after 3 months, which resolved when the dosage of amiodarone was reduced to 100 mg/day.

In 83 patients (27 women, 56 men; mean age 61 years) disopyramide, propafenone, or sotalol were used to prevent recurrence after elective electrical cardioversion for persistent atrial fibrillation (30). If there was recurrence cardioversion was repeated and the patient was given one of the other antidysrhythmic drugs. If there was further recurrence, amiodarone was used, a third cardioversion was performed, and, if sinus rhythm was restored, amiodarone 100–200 mg/day was continued. Patients in whom the initial cardioversion was not successful were given amiodarone and underwent repeated cardioversion. The follow-up duration was 12 months. The first electrical cardioversion was effective in 44 (53%) patients, and after 1 year 23 (52%) of them were still in sinus rhythm. None of the patients who underwent a second cardioversion and received a second antidysrhythmic drug stayed in sinus rhythm. Amiodarone as a third antidysrhythmic agent was effective in 10 (48%) patients. After 12 months of antidysrhythmic drug therapy sinus rhythm was maintained in 75% of patients in whom the first cardioversion had been effective, accounting for 40% of all the patients selected for cardioversion. In the 83 patients, sequential antidysrhythmic treatment effectively maintained sinus rhythm in 54 (65%), of whom 31 (57%) took amiodarone. The authors concluded that repeated electrical cardioversion and antidysrhythmic drug therapy enabled maintenance of sinus rhythm in 68% of patients for 1 year, that there was limited efficacy of the first antidysrhythmic drug given after a first effective electrical cardioversion, regardless of the drug used, excluding amiodarone, and that when atrial fibrillation recurred, a second antidysrhythmic drug, other than amiodarone, was completely ineffective. There were very few adverse events in this study. One patient taking amiodarone developed hyperthyroidism and two had symptomatic bradycardia.

Amiodarone 30 mg/kg orally for the first 24 hours plus, if necessary, 15 mg/kg over 24 hours has been compared with propafenone 600 mg in the first 24 hours plus, if necessary, 300 mg in the next 24 hours in 86 patients with recent onset atrial fibrillation (31). Conversion to sinus rhythm occurred faster with propafenone (2.4 hours) than amiodarone (6.9 hours). However, by 24 hours and 48 hours the same proportions of patients were in sinus rhythm; one patient given amiodarone had a supraventricular tachycardia and one a non-sustained ventricular tachycardia.

Studies in atrial flutter

Antidysrhythmic drugs have been compared with radiofrequency ablation in 61 patients with atrial flutter (32). Drug treatment was with at least two drugs, one of which was amiodarone. Of the 30 patients who took drug therapy, 19 needed to come into hospital one or more times, whereas after radiofrequency ablation that happened in only seven of 31 cases. In those who took the antidysrhythmic drugs the mean number of drugs was 3.4 and the range of drugs used was very wide. Quality-of-life and symptoms scores improved significantly in those in whom radiofrequency ablation was used, but not in those who took the antidysrhythmic drugs, apart from the symptom of palpitation, which improved in both groups, but to a greater extent in the non-drug group. Adverse effects were not discussed in this study, but it is clear that it suggests that radiofrequency ablation is to be preferred in these patients.

Studies in ventricular dysrhythmias

The effects of amiodarone in 55 patients with sustained ventricular tachycardia after myocardial infarction have been assessed in a long-term follow-up study (33). The patients underwent programmed ventricular stimulation after having been loaded with amiodarone. They were divided into those in whom ventricular tachydysrhythmias could be induced or not, and all were then given amiodarone 200 mg/day. In 11 cases a cardioverter defibrillator was implanted, because the first episode of ventricular tachycardia had been poorly tolerated or had caused hemodynamic instability. A defibrillator was also implanted in five other cases during follow-up, because of recurrence of dysrhythmias. There was a non-significant trend to a difference between the cumulative rates of dysrhythmias during long-term follow-up, with more events in those in whom a dysrhythmia had been inducible after loading. However, mortality rates in the two groups did not differ, and was around 25% at a mean follow-up of 42 months. Survival was significantly higher in patients with a left ventricular ejection fraction over 0.4, and the lower the left ventricular ejection fractions the higher the mortality. Amiodarone was withdrawn in six patients after a

© 2006 Elsevier B.V. All rights reserved.

mean of 34 months because of neuropathy ($n = 1$), hypothyroidism ($n = 1$), prodysrhythmia with incessant ventricular tachycardia ($n = 2$), and non-specific adverse effects ($n = 2$). There was no pulmonary toxicity and no cases of torsade de pointes. In two patients there was evidence of hypothyroidism, mild neuropathy, and skin discoloration, but these events did not lead to withdrawal. In two patients the doses of amiodarone was reduced to 100 mg/day because of sinus bradycardia.

In a comparison of amiodarone ($n = 23$) with sotalol ($n = 22$) in patients with spontaneous sustained ventricular tachydysrhythmias secondary to myocardial infarction, sotalol was much more effective, 75% of those taking it remaining free of dysrhythmias compared with 38% of those taking amiodarone (34). Adverse effects requiring withdrawal occurred in 17% of those taking amiodarone at a median time of 3.5 months. The adverse effects included malaise, rash, headaches, flushing, and dyspnea due to pulmonary fibrosis.

Studies in myocardial infarction and heart failure

There have been reviews of the results of major trials of amiodarone after myocardial infarction (35) and in chronic heart failure (36).

- In the Basel Antiarrhythmic Study of Infarct Survival (BASIS) amiodarone significantly reduced all-cause mortality from 13 to 5%, compared with no antidysrhythmic drug therapy (37).
- In the Polish Arrhythmia Trial (PAT) amiodarone reduced all-cause mortality from 10.7 to 6.9% compared with placebo and cardiac mortality from 10.7 to 6.2% (38).
- In the Spanish Study of Sudden Death (SSD) amiodarone reduced all-cause mortality from 15.4 to 3.5% compared with metoprolol; however, the mortality in those receiving no antidysrhythmic drugs at all was only 7.7%, and in those the effect of amiodarone was not significant (39).
- In the European Myocardial Infarction Arrhythmia Trial (EMIAT) amiodarone reduced the risk of dysrhythmic deaths from 8.5 to 4.1% compared with placebo (40).
- In the Canadian Amiodarone Myocardial Infarction Arrhythmia Trial (CAMIAT) amiodarone reduced dysrhythmic deaths from 6.0 to 3.3% compared with placebo; non-dysrhythmic deaths were not affected (41).

In a meta-analysis of 10 studies of the use of amiodarone in patients with heart failure, the overall odds ratio for mortality with amiodarone compared with placebo was 0.79 (95% CI = 0.68, 0.92). The corresponding odds ratio for adverse effects was 2.29 (1.97, 2.66) (36). The benefit to risk ratio of the use of amiodarone in these patients is not yet clear. The dosage of amiodarone in these studies varied from 50 to 400 mg/day, with an average of around 250 mg/day.

Organs and Systems

Cardiovascular

The incidence of cardiac dysrhythmias with amiodarone is under 3% (42), lower than with many other antidysrhythmic drugs, and several randomized controlled trials have failed to show any prodysrhythmic effect (43).

Other cardiac effects that have been reported include sinus bradycardia, atrioventricular block, infra-His block, asystole, and refractoriness to DC cardioversion (SEDA-10, 147).

There is a risk of hypotension and atrioventricular block when amiodarone is given intravenously.

Cardiogenic shock has been reported in 73-year-old woman with a dilated cardiomyopathy who had digitalis and amiodarone toxicity (44).

Ventricular dysrhythmias

Amiodarone can prolong the QT interval, and this can be associated with torsade de pointes, although this is uncommon. This effect is potentiated by hypokalemia (45).

Ventricular dysrhythmias due to drugs can be either monomorphic or polymorphic. The class Ia drugs are particularly likely to cause polymorphic dysrhythmias, as is amiodarone (although to a lesser extent). In contrast, the class Ic drugs are more likely to cause monomorphic dysrhythmias (46).

- A 40-year-old woman developed torsade de pointes within the first 24 hours of intravenous administration of amiodarone 150 mg followed by 35 mg/hour (47). The association with amiodarone was confirmed by subsequent rechallenge.
- Three boys with congenital cardiac defects developed polymorphous ventricular tachycardia after having been given intravenous amiodarone; two died (48).
- An 8-day-old boy was given intravenous amiodarone 5 mg/kg over 60 minutes followed by 10 mg/kg/day for a postoperative junctional ectopic tachycardia after a cardiac operation. He developed ventricular fibrillation 12 hours later, but recovered with defibrillation and internal cardiac massage. His serum amiodarone concentration was 1–2.5 mg/l, within the usual target range.
- A 3-month-old boy underwent a cardiac operation and 6 hours later developed a junctional ectopic tachycardia. He was given amiodarone as a continuous intravenous infusion of 10 mg/kg/day for 3 hours and developed ventricular fibrillation, from which he was not resuscitated. The serum amiodarone concentration was 0.3 mg/l.
- A 3-month-old boy developed a postoperative junctional ectopic tachycardia 48 hours after operation and was given a continuous intravenous infusion of amiodarone 10 mg/kg/day. After 2 hours he developed ventricular fibrillation and was not resuscitated. His serum amiodarone concentration was in the target range.

It is not clear that the dysrhythmias in these cases were due to amiodarone, particularly since the doses had been very low and the serum concentrations no higher than the usual target range; QT intervals were not reported.

- A 79-year-old woman took amiodarone 4800 mg over 6 days and developed a polymorphous ventricular tachycardia; the associated precipitating factors were a prolonged QT interval and hypokalemia (49).
- A 71-year-old Japanese man with bouts of sustained monomorphic ventricular tachycardia, in whom non-sustained polymorphic ventricular tachycardia was induced by rapid pacing during electrophysiological studies, was given amiodarone and developed three different types of sustained monomorphic ventricular

© 2006 Elsevier B.V. All rights reserved.

tachycardia, with slightly different cycle lengths, induced and terminated by rapid pacing (50).

The authors proposed that amiodarone had modulated the threshold of induction and/or termination of ventricular tachycardia.

Of 189 patients, five had torsade de pointes and all five had prolonged QT intervals (51). Two of the five, all women, also had raised blood glucose concentrations, and the authors suggested that hyperglycemia is a risk factor for torsade de pointes. However, the number of cases reported in this series was too small to justify such a conclusion.

It has been suggested that women are more likely to develop torsade de pointes than men in response to antidysrhythmic drugs (52), and this has been confirmed in the case of amiodarone in a study of 189 patients given intravenous amiodarone (51). This is also reminiscent of the finding that prolongation of the QT interval due to quinidine is greater in women than in men at equivalent serum concentrations (53).

T wave alternans is an occasional presentation, in association with ventricular dysrhythmias (SEDA-18, 201).

- A 65-year-old man with atrial fibrillation was given intravenous amiodarone 450 mg over 30 minutes followed by 900 mg over 24 hours (54). He reverted to sinus rhythm, but the electrocardiogram showed giant T wave alternans with a variable QT interval (0.52–0.84 seconds). He had a short bout of torsade de pointes and was given magnesium. Two days later the electrocardiogram was normal.
- In a 62-year-old man with dilated cardiomyopathy and an implantable cardioverter defibrillator for ventricular tachycardia, microvolt T wave alternans differed when amiodarone was added (55). The onset heart rate with T wave alternans was lower and the alternans voltage higher with amiodarone than without it.

The effects of amiodarone appeared to be related to exacerbations of ventricular tachycardia and an increased defibrillation threshold.

Atrial dysrhythmias

Amiodarone has been reported to cause atrial flutter in 10 patients who had been given it for paroxysmal atrial fibrillation (56). In nine of those the atrial flutter was successfully treated by catheter ablation. However, during a mean follow-up period of 8 months after ablation, atrial fibrillation occurred in two patients who had continued to take amiodarone; this was a lower rate of recurrence than in patients in whom atrial flutter was not associated with amiodarone. The authors therefore suggested that in patients with atrial flutter secondary to amiodarone given for atrial fibrillation, catheter ablation allows continuation of amiodarone therapy.

Amiodarone can sometimes cause atrial flutter, even though it is also used to treat it (SEDA-25, 180). There has been a report of seven cases (six men and one woman, aged 34–75 years) of 1:1 atrial flutter with oral amiodarone (57). Four of them had underlying cardiac disease; none had hyperthyroidism. The initial dysrhythmia was 2:1 atrial flutter ($n = 4$), 1:1 atrial flutter ($n = 2$), or atrial fibrillation ($n = 1$). One patient was taking amiodarone 200 mg/day and one was taking 400 mg/day plus carvedilol. The other five all received loading doses of 9200 (sd 2400) mg over 10 (sd 4) days. There was an adrenergic trigger factor (exertion, fever, esophageal stimulation, or a beta-adrenoceptor agonist aerosol) in five patients. One required emergency cardioversion.

Of 136 patients with atrial fibrillation treated with either amiodarone ($n = 96$) or propafenone ($n = 40$), 15 developed subsequent persistent atrial flutter, nine of those taking amiodarone and six of those taking propafenone (58). In all cases radiofrequency ablation was effective. It is not clear to what extent these cases of atrial flutter were due to the drugs, although the frequency of atrial flutter in previous studies with propafenone has been similar. Atrial enlargement was significantly related to the occurrence of persistent atrial flutter in these patients.

Bradycardia

Bradycardia has been reported to occur in about 5% of patients taking amiodarone (SEDA-20, 176).

Of 2559 patients admitted to an intensive cardiac care unit over 3 years, 64 with major cardiac iatrogenic problems were reviewed (59). Of those, 58 had dysrhythmias, mainly bradydysrhythmias, secondary to amiodarone, beta-blockers, calcium channel blockers, electrolyte imbalance, or a combination of those. Amiodarone was implicated in 19 cases, compared with 44 cases attributed to beta-blockers and 28 to calcium channel blockers. Of the 56 patients with sinus bradycardia, 10 were taking a combination of amiodarone and a beta-blocker, six were taking amiodarone alone, and three were taking amiodarone plus a calcium channel blocker.

Heart block

- In a 66-year-old woman taking amiodarone 1200 mg/week there was marked prolongation of the QT interval, to 680 ms; the succeeding P waves fell within the refractory period of the preceding beat and were unable to institute conduction (60). This resulted in 2:1 atrioventricular block. Amiodarone was withdrawn and the QT interval normalized with a time-course consistent with the long half-life of amiodarone. A subsequent rechallenge with intravenous amiodarone caused further prolongation of the QT interval.

The authors hypothesized that this patient had a silent mutation in one of the genes coding for the two major potassium channel proteins (IK_r or IK_s) that are involved in the mode of action of amiodarone. However, they did not present any genetic studies to support this hypothesis.

Respiratory

There have been reviews of the lung complications of amiodarone toxicity (61,62) and of its mechanisms (63).

Frequency

The risk of lung toxicity is about 5–6% (64) and is greatest during the first 12 months of treatment and among patients over 40 years of age. The mortality rate in those who develop respiratory involvement is about 9% (about 0.5% of the total).

© 2006 Elsevier B.V. All rights reserved.

Mechanism

Amiodarone causes lung damage either by direct deposition of phospholipids in the lung tissue or by some immunologically mediated reaction. Other mechanisms have also been proposed, including oxidant-mediated damage, a direct detergent effect, and a direct toxic effect of iodide (SEDA-15, 168).

It has been suggested that the serum activity of lactate dehydrogenase (LDH) may be related to the occurrence of amiodarone-induced pneumonitis, as occurred in a 72-year-old woman in whom the serum LDH activity rose from a baseline of around 750 U/l to around 1500 U/l during acute pneumonitis and resolved with resolution of a clinical condition after withdrawal of amiodarone (65). The LDH activity in bronchoalveolar lavage fluid was also increased. The proposed mechanism was leakage of lactate dehydrogenase from the pulmonary interstitial cells into the blood. Of course, a rise in the serum LDH activity is highly non-specific, and it is not clear whether it might also rise in bronchoalveolar lavage fluid in other conditions.

Presentation

The commonest form of lung damage is an interstitial alveolitis, although pneumonitis and bronchiolitis obliterans have also been reported, as have solitary localized fibrotic lesions, non-cardiac pulmonary edema, pleural effusions, acute respiratory failure, acute pleuritic chest pain, and adult respiratory distress syndrome (SEDA-17, 220) (SEDA-18, 201) (66–68). Amiodarone has also been reported to cause impairment of lung function, even in patients who do not develop pneumonitis (69), and pre-existing impairment of lung function may constitute a contraindication to amiodarone.

Lung damage due to amiodarone usually develops slowly, but it can occasionally have a rapid onset, particularly in patients who are given high concentrations of inspired oxygen, and there is experimental evidence that amiodarone enhances the toxic effects of oxygen on the lungs (70).

- Adult respiratory distress syndrome occurred very rapidly in a 66-year-old man who took amiodarone 200 mg/day for a few weeks only (71).
- Pulmonary infiltrates occurred in a 72-year-old man after treatment with amiodarone (total dose 6800 mg) for only 7 days (72).
- Two patients with dilated cardiomyopathy developed pneumonitis after 6 weeks and 8 months while taking amiodarone 400 and 200 mg/day respectively (73).

Some cases of amiodarone-induced lung toxicity, some in patients who took very large doses, illustrate the wide variety of possible presentations.

- A 77-year-old man without a history of lung disease was given amiodarone 7 days after bypass surgery because of supraventricular dysrhythmias and non-sustained ventricular tachycardia (74). He had taken 1600 mg/day for a week followed by a maintenance dosage of 400 mg/day, and 15 days later became pale, sweaty, febrile, and tachypneic. His blood pressure was 100/60 and his heart rate 100/minute. There were reduced breath sounds and crackles throughout the lung fields. A chest X-ray showed diffuse interstitial and alveolar infiltrates and small bilateral pleural effusions. A high-resolution CT scan of the chest showed diffuse ground-glass attenuation and patchy peripheral opacities, consistent with an acute hypersensitivity pneumonitis, and other diagnoses were ruled out. He responded to gluco-corticoids.
- A 72-year-old man developed hypoxemic respiratory failure while taking amiodarone 300 mg/day (74). He had no history of lung disease. His CT scan was similar to that of the first patient. He responded to treatment with corticosteroids.
- In a 79-year-old man with emphysema taking amiodarone 200 mg/day, the diagnosis of amiodarone-induced lung toxicity was complicated by the fact that emphysema has the opposite effect on lung volumes and spirometry from interstitial lung disease (75). His FEV_1, which had been reduced, became normal and then increased. However, the combination of emphysema with amiodarone-induced lung disease led to worsening dyspnea, and a chest X-ray showed patchy mixed interstitial and airspace disease, most marked in the mid to upper lung zones bilaterally, and ground-glass opacification in the left lower lobe, suggesting an acute alveolitis. He responded to prednisone after withdrawal of amiodarone. His carbon monoxide diffusing capacity, which had fallen, returned to normal. A CT scan showed marked bullous emphysema and ground-glass interstitial changes. The FEV_1 almost doubled, from being severely reduced to within the reference range.
- A 77-year-old man who had taken amiodarone 400 mg/day for 11 months developed crackles at the lung bases and scattered respiratory wheeze (76). His leukocyte count was raised at 13.5 × 109/l and he had progressive reduction in carbon monoxide diffusing capacity, serially measured. A chest X-ray showed bilateral opacities in the upper zones, peripheral in distribution, and a CT scan showed dense bilateral lung parenchymal opacities. The symptoms of dyspnea on exertion, cough with minimal sputum, pleuritic chest pain, and low-grade fever abated after withdrawal, and the upper lobe densities resolved.
- A 62-year-old man took amiodarone 400 mg bd and developed several adverse effects, including bilateral apical opacities with left hilar lymphadenopathy (77). Amiodarone was withdrawn and he was given glucocorticoids, with good effect; there was dramatic radiographic resolution within 3 weeks and he was no longer breathless with 1 week. The lung biopsy showed typical foamy macrophages. He had fibrosis of the bronchioles and interstitium, foci of obliterative bronchiolitis, and thickening of the alveolar walls. He had an accompanying peripheral neuropathy, which improved after withdrawal, and impaired visual acuity, about which no further information was given. Biopsy of the right vastus lateralis muscle showed type II atrophy with vacuolization, which the authors suggested supported the suspicion of amiodarone toxicity.

Amiodarone can occasionally cause isolated lung masses (SEDA-15, 168). One case was associated with a vasculitis; the lesions resolved completely 4 months after amiodarone withdrawal (78). In another case an isolated mass

© 2006 Elsevier B.V. All rights reserved.

was associated with multiple small nodules in both lungs; the lesions resolved completely 6 months after amiodarone withdrawal (79).

Diagnosis

Diagnosis of amiodarone-induced lung damage can be difficult. The clinical symptoms and signs, the changes on chest radiography, and abnormalities of lung function tests are all non-specific. The presence of lymphocytes and foamy macrophages in bronchial lavage fluids and of phospholipidosis in lung biopsies are all suggestive. Measurement of the diffusing capacity of carbon monoxide has been used, but is unreliable.

The sialylated carbohydrate antigen KL-6 has been reported to be a serum marker of the activity of interstitial pneumonitis in seven patients with amiodarone-induced pulmonary toxicity (80,81). The dosages of amiodarone were 200–800 mg as an oral loading dose followed by 75–200 mg/day. Pulmonary complications occurred at 17 days to 48 months of treatment. In two patients with severe dyspnea and interstitial shadows on chest X-ray the KL-6 concentrations were very high (2100 and 3000 U/ml). In one of these the concentration increased from 695 to 2100 U/ml at a time when the interstitial changes on the CT scan worsened. In contrast, in two patients in whom pneumonia resolved with antibiotic treatment and without withdrawal of amiodarone, the serum KL-6 concentrations were lower (120 and 330 U/ml). In a patient in whom congestion of the lungs due to congestive cardiac failure had been confused with interstitial shadows the KL-6 concentration was only 190 U/ml. In two patients with lung cancers the concentrations were 260 and 360 U/ml. The authors proposed that a KL-6 concentration above the reference range (more than 520 U/ml) might be useful in differentiating patients with amiodarone-induced pneumonitis from patients with similar features not associated with amiodarone.

In 25 patients, three had proven interstitial pneumonitis and KL-6 serum concentrations of 414, 848, and 1217 U/ml; in contrast, all of the other 22 patients had normal CT scans and normal KL-6 concentrations (under 500 U/ml) (82). In the same study the limitations of carbon monoxide diffusing capacity in the diagnosis of amiodarone-induced lung disease (SEDA-15, 168) were again demonstrated.

Several scanning techniques have been used in the diagnosis of amiodarone-induced lung damage.

Computed tomography

Computed tomography may show a typical pattern of basal peripheral high-density pleuroparenchymal linear opacities, although these may be absent (83). It has also been suggested that high-resolution CT scanning may be able to detect iodine deposition from the drug (84). Of 16 patients taking long-term amiodarone, eight had severe respiratory and other symptoms and eight either had no symptoms or had only mild or chronic respiratory symptoms. All eight controls had negative high-resolution CT scans with no areas of high attenuation, while all eight cases had a least one high-attenuation lesion.

^{67}Gallium scintigraphy

^{67}Gallium scintigraphy has been used to diagnose amiodarone-induced lung damage (SEDA-15, 168).

- A 75-year-old man, who had taken amiodarone 200 mg/day for 4 years, developed acute dyspnea, chest pain, fever, and sweats (85). The chest X-ray showed diffuse alveolar and interstitial infiltrates, particularly at the lung bases. No pathogenic organisms were isolated and antibiotics had no effect. There was no evidence of sarcoidosis. Pulmonary ^{67}gallium scintigraphy showed extensive uptake of tracer throughout both lungs, consistent with amiodarone pneumonitis on a background of asbestosis with interstitial fibrosis. Treatment with corticosteroids after withdrawal of amiodarone resulted in marked clinical improvement.

The authors said that the extensive changes on gallium scanning, not present on the chest X-ray, had helped them to make the diagnosis, although a high-resolution CT scan had also shown widespread changes.

^{99m}Technetium-diethylene triamine penta-acetic acid (DPTA) aerosol scintigraphy

Another scanning technique, ^{99m}Tc-diethylene triamine penta-acetic acid (DPTA) aerosol scintigraphy, has been compared with ^{67}Ga scanning in 26 patients, seven with amiodarone-induced lung damage, eight taking amiodarone without lung damage, and 11 healthy controls (86). ^{67}Ga scintigraphy was positive in four of the seven patients with lung damage but normal in the others. There was a positive correlation between ^{99m}Tc-DTPA clearance and the cumulative dose of amiodarone. The mean clearance values were 2%/minute in those with amiodarone-induced lung damage, 1.3%/minute in those without lung damage, and 0.9%/minute in the controls. The authors concluded that ^{67}Ga lung scintigraphy is useful for detecting amiodarone-induced lung damage but that ^{99m}Tc-DTPA aerosol scintigraphy is better.

Management

Although early reports suggested that glucocorticoids might be beneficial in management, this has not been subsequently confirmed (87).

Nervous system

The most common forms of neurological damage attributed to amiodarone are tremor, peripheral neuropathy, and ataxia (88). Other effects that have been reported include delirium (89), Parkinsonian tremor (90), and pseudotumor cerebri (91). Acute myolysis has recently been described at high dose (92). The peripheral neuropathy is probably due to intracellular lipidosis (93).

- Periodic ataxia has been attributed to amiodarone in a 67-year-old man taking amiodarone 200 mg/day (94). The ataxia responded to acetazolamide and eventually to withdrawal of amiodarone. It recurred with rechallenge.

Amiodarone-induced neuromyopathy has been studied in three patients by a review of their records, electromyography, and histopathology of muscle and nerve (95). Two patients had a slightly asymmetric, mixed, but primarily

© 2006 Elsevier B.V. All rights reserved.

demyelinating sensorimotor polyneuropathy and the third had an acute neuropathy resembling Guillain–Barré syndrome. Creatine kinase activity did not correlate with clinical or electromyographic evidence of myopathy. In the peripheral nerves there was demyelination, some axon loss, and a variable number of characteristic lysosomal inclusions. Muscle specimens from two patients showed evidence of a vacuolar myopathy. After withdrawal of amiodarone, two patients improved and one died with a cardiac dysrhythmia.

Benign orgasmic headache has been associated with amiodarone (96).

- A 52-year-old man, who had taken amiodarone 800 mg/day for 7 months, developed acute, severe, throbbing headaches precipitated by coitus and occasionally other forms of exertion. An MRI scan of the brain was normal. When the dose of amiodarone was reduced to 200 mg/day the headaches diminished in frequency and severity. When the dose was increased again to 400 mg/day they increased in frequency and severity. The amiodarone was withdrawn and the headaches resolved.

Amiodarone was originally developed as a vasodilator, and that may have been the cause of headaches in this case.

Sensory systems

The adverse effects of amiodarone on the eyes have been reviewed (97). The most common effect is corneal microdeposits. In some cases chronic blepharitis and conjunctivitis have been reported (98), but the relation of these to amiodarone is not clear.

Keratopathy

In almost all patients (99,100) corneal microdeposits of lipofuscin occur secondary to the deposition of amiodarone. These are generally of no clinical significance, but occasionally patients complain of haloes around lights, particularly at night, photophobia, blurring of vision, dryness of the eyes, or lid irritation. Occasionally amiodarone can cause anterior subcapsular deposits, which are usually asymptomatic. In 22 patients taking long-term amiodarone there were corneal drug deposits in all of the eyes, slight anterior subcapsular lens opacities in 22%, and dry eyes in 9% (101).

Verticillate epithelial keratopathy due to amiodarone, in which there is whorl-shaped pigmentation of the cornea, has been proposed to be worsened by soft contact lenses (SEDA-15, 171). Two patients with hard contact lenses and amiodarone-associated keratopathy both complained of increased sensitivity to sunlight and were fitted with ultraviolet light-blocking lenses instead, as a precaution against further corneal damage; however, the authors did not think that the contact lenses had contributed to the damage (102).

The eyes of 11 patients (eight men and three women) taking amiodarone have been compared with those of 10 healthy sex- and age-matched controls by confocal microscopy (103). All those taking amiodarone had bright, highly reflective intracellular inclusions in the epithelial layers, particularly in the basal cell layers. In eyes with advanced keratopathy there were bright microdots in the anterior and posterior stroma and on the endothelial cell layer. Keratocyte density in the anterior stroma was lower in the treated subjects than in the controls, and there was marked irregularity of the stromal nerve fibers. The authors concluded that in some patients taking long-term amiodarone corneal damage may penetrate deeper than has previously been suspected.

Color vision disturbances

Amiodarone can cause impaired color vision associated with keratopathy (SEDA-12, 153) (104). Of 22 patients taking long-term amiodarone, two who had otherwise healthy eyes had abnormal blue color vision (101). Otherwise, color vision, contrast sensitivity, and visual fields were normal or could be explained by eye diseases such as cataract.

Optic neuropathy

A more serious effect of amiodarone on the eye is an optic neuropathy (105) (SEDA-15, 171). Although this resolves on withdrawal there can be residual field defects (106,107). Blindness has been attributed to bilateral optic neuropathy in a patient taking amiodarone (108). The incidence of optic neuropathy with amiodarone (SEDA-23, 199) has been estimated at 1.8% (SEDA-13, 141). There has been a recent review of 73 cases of optic neuropathy associated with the use of amiodarone, including 16 published case reports and 57 other reports from the National Registry of Drug-Induced Ocular Side Effects, the US FDA, and the WHO (109). Amiodarone-induced optic neuropathy is of insidious onset, with slow progression, bilateral visual loss, and protracted disc swelling, which tends to stabilize within several months of withdrawal. These features all distinguish it from non-arteritic ischemic optic neuropathy. The pathology of amiodarone-induced optic neuropathy is associated with lipid deposition, as with other forms of adverse effects of amiodarone.

- A 51-year-old man developed blurred vision after having taken amiodarone 600 mg/day for 3 months and 400 mg/day for 5 months (110). There was mild optic disc palor and edema on the right side, with a nearby flame-shaped hemorrhage; the optic disc on the left side was normal. There were accompanying corneal opacities in both eyes. Amiodarone was withdrawn and the optic neuropathy and corneal opacities improved.
- A 48-year-old man developed bilateral blurred vision and visual field changes after having taken amiodarone 400 mg/day for 2 months; 3 weeks after withdrawal of amiodarone his symptoms improved (111). There was no optic disc edema.

Other effects

The absence of optic disc edema in the last case is unusual; most cases are accompanied by some form of swelling of the optic disc.

Rare effects include raised intracranial pressure with papilledema (SEDA-12, 153) (112), retinal maculopathy (113), and retinopathy (97).

Multiple chalazia have been reported on the eyelids, due to lipogranulomata that contained a lot of amiodarone (114).

© 2006 Elsevier B.V. All rights reserved.

Sicca syndrome has occasionally been reported (9,115–117).

Brown discoloration of implanted lenses has been attributed to amiodarone (118).

- A 66-year-old woman, who had had two silicone intraocular lenses inserted because of cataract, developed progressive brown discoloration of the lens while taking amiodarone (dosage not stated). The discoloration progressed markedly after vitrectomy, suggesting that it was due to leakage of the drug into the eye. She also had an amiodarone-induced keratopathy.

Psychological, psychiatric

Delirium has rarely been reported with amiodarone (SEDA-13, 140).

- A 54-year-old man with no previous psychiatric history took amiodarone 400 mg bd (119). After a few days he became depressed and paranoid, suffered from insomnia, and had rambling speech. The dosage of amiodarone was reduced to 200 mg bd and he improved. However, 3 days later he became confused, with tangential thinking, labile effect, and a macular rash on the limbs. His serum sodium was reduced at 127 mmol/l and his blood urea nitrogen was raised. A CT scan of the head was normal. Amiodarone was withdrawn and 4 days later he was alert and oriented. About a week later he started taking amiodarone again and within 4 days became increasingly agitated, confused, and paranoid. He once more recovered after withdrawal of amiodarone.
- Depression has been attributed to amiodarone in a 65-year-old woman who was taking amiodarone (dosage not stated) (120). Because the mode of presentation was atypical in onset, course, duration, and its response to antidepressant drugs, amiodarone was withdrawn, and she improved rapidly. There was no evidence of thyroid disease.

Endocrine

Testes

Amiodarone can cause endocrine testicular dysfunction, as judged by increases in serum concentrations of FSH and LH and hyper-responsiveness to GnRH (121).

Syndrome of inappropriate ADH secretion

Amiodarone-induced hyponatremia, due to the syndrome of inappropriate secretion of antidiuretic hormone, is rare (SEDA-21, 199) (122). The mechanism is unknown. Unlike other adverse effects of amiodarone, it seems to occur rapidly and to resolve rapidly after withdrawal.

- A 63-year-old man reduced his dietary sodium intake to combat fluid retention and was taking furosemide 40 mg/day, spironolactone 50 mg/day, and enalapril 2.5 mg/day (123). He then took amiodarone 800 mg/day for 7 days and his serum sodium concentration fell to 119 mmol/l; his plasma vasopressin concentration was raised at 2.6 pmol/l. The dose of amiodarone was reduced to 100 mg/day, with fluid restriction; his sodium rose to 130 mmol/l and his vasopressin fell to 1.4 pmol/l.
- An 87-year-old man reduced his dietary sodium intake to combat fluid retention and was taking furosemide 40 mg/day and spironolactone 25 mg/day (123). He then took amiodarone 200 mg/day for 7 days and 100 mg/day for 8 days and his serum sodium concentration fell to 121 mmol/l; his plasma vasopressin concentration was raised at 11 pmol/l. Amiodarone was continued, with fluid restriction; his sodium rose to 133 mmol/l and his vasopressin fell to 2.4 pmol/l.
- A 67-year-old man, who had taken amiodarone 200 mg/day for 3 months, developed hyponatremia (serum sodium concentration 117 mmol/l) (124). He was also taking furosemide 20 mg/day, spironolactone 25 mg/day, and lisinopril 40 mg/day. His urine osmolality was 740 mosmol/kg with a normal serum osmolality. Fluid restriction was ineffective, but when amiodarone was withdrawn the sodium rose to 136 mmol/l.
- A 62-year-old woman with paroxysmal atrial fibrillation who had taken amiodarone 300 mg/day had a serum sodium concentration of 120 mmol/l with a normal serum potassium and a reduced serum osmolality (240 mmol/kg); the urinary sodium concentration was 141 mmol/l and the urine osmolality 422 mmol/kg (122). There was no evident cause of inappropriate secretion of ADH and within 5 days of withdrawal of amiodarone the serum sodium concentration had risen to 133 mmol/l and rose further to 143 mmol/l 14 days later. There was no rechallenge and no recurrence of hyponatremia during the next 6 months.

In some of these cases other factors may have contributed to the hyponatremia that amiodarone seems to have caused.

Thyroid gland

The effects of amiodarone on thyroid function tests and in causing thyroid disease, both hyperthyroidism and hypothyroidism, have been reviewed in the context of the use of perchlorate, which acts by inhibiting iodine uptake by the thyroid gland (125), and there have been several other reviews (126–130).

Effects on thyroid function tests

Amiodarone causes altered thyroid function tests, with rises in serum concentrations of T4 and reverse T3 and a fall in serum T3 concentration. This is due to inhibition of the peripheral conversion of T4 to T3, causing preferential conversion to reverse T3. These changes can occur in the absence of symptomatic abnormalities of thyroid function.

Hyperthyroidism

DoTS classification

Dose-relation: collateral effect
Time-course: delayed
Susceptibility factors: genetic (unoperated or palliated cyanotic congenital heart disease; beta-thalassemia major); sex (conflicting results); altered physiology (iodine intake, conflicting results)

© 2006 Elsevier B.V. All rights reserved.

Frequency

Apart from its effects on thyroid function tests, amiodarone is also associated with both functional hyperthyroidism and hypothyroidism, in up to 6% of patients. The frequency of thyroid disease in patients taking amiodarone has been retrospectively studied in 90 patients taking amiodarone 200 mg/day for a mean duration of 33 months (131). Hypothyroidism occurred in five patients and hyperthyroidism in 11. Hyperthyroidism became more frequent with time and was associated with recurrent supraventricular dysrhythmias in four of the 11 patients.

In a nested case-control analysis of 5522 patients with a first prescription for an antidysrhythmic drug and no previous use of thyroid drugs, cases were defined as all patients who had started a thyroid-mimetic or antithyroid drug no sooner than 3 months after the start of an antidysrhythmic drug and controls were patients with a comparable follow-up period who had not taken any thyroid drugs during the observation period (132). There were 123 patients who had started antithyroid drugs and 96 who had started a thyroid-mimetic drug. In users of amiodarone there was an adjusted odds ratios of 6.3 (95% CI = 3.9, 10) for hyperthyroidism compared with users of other antidysrhythmic drugs. Patients who were exposed to a cumulative dose of amiodarone over 144 g had an adjusted odds ratio of 13 (6, 27) for hyperthyroidism.

Mechanisms

Amiodarone causes two different varieties of hyperthyroidism (SEDA-23, 199), one by the effects of excess iodine in those with latent disease (so-called type 1 hyperthyroidism), the other through a destructive thyroiditis in a previously normal gland (so-called type 2 hyperthyroidism). The two varieties can be distinguished by differences in radio-iodine uptake by the gland: in type 1 hyperthyroidism radio-iodine uptake is normal or increased, whereas in type 2 it is reduced. In type 1 hyperthyroidism, thyroid ultrasound shows a nodular, hypoechoic gland of increased volume, whereas in type 2 the gland is normal.

Iodine intake may be important in determining the type of amiodarone-induced thyroid disease. In 229 patients taking long-term amiodarone hyperthyroidism was more common (9.6 versus 2%) in West Tuscany, where dietary iodine intake is low, and hypothyroidism more common (22 versus 5%) in Massachusetts, where iodine intake is adequate (SEDA-10, 148) (133). However, other factors may play a part. In a retrospective inter-regional study in France there was a greater incidence of amiodarone-induced hyperthyroidism in the maritime areas Aquitaine and Languedoc–Roussillon, and a greater incidence of amiodarone-induced hypothyroidism in Midi–Pyrenees, a non-maritime area, in which iodine intake is lower than in Languedoc–Roussillon (134).

There have also been reports of painful thyroiditis associated with amiodarone (SEDA-15, 170).

Susceptibility factors

There has been a retrospective study of the frequency of amiodarone-associated thyroid dysfunction in adults with congenital heart disease (135). Of 92 patients who had taken amiodarone for at least 6 months (mean age 35, range 18–60 years), 36% developed thyroid dysfunction—19 became hyperthyroid and 14 hypothyroid. The mean dosage was 194 (100–300) mg/day, and the median duration of therapy was 3 (0.5–15) years. Female sex (OR = 3) and unoperated or palliated cyanotic congenital heart disease (OR = 7) were significant susceptibility factors for thyroid dysfunction. The risk was also dose-related. Although the authors conceded that they may have over-estimated the risk of thyroid dysfunction, because of the selected nature of the population they studied, the risks were markedly higher than in previous studies of older patients with acquired heart disease, despite a lower maintenance dosage of amiodarone.

In contrast, it has been suggested that men are more susceptible to hyperthyroidism due to amiodarone (136). Of 122 600 patients in 12 practices in the West Midlands in the UK, 142 men and 74 women were taking amiodarone and 27 (12.5%) had thyroid disease. Of those, 11 men (7.7%) and 4 women (5.4%) had hypothyroidism, a non-significant difference; however, 12 men (8.5%) had hyperthyroidism compared with no women. This difference is particularly striking because hyperthyroidism is usually more common in women.

Patients with beta-thalassemia major have an increased risk of primary hypothyroidism. In 23 patients with beta-thalassemia amiodarone was associated with a high risk of overt hypothyroidism (33 versus 3% in controls) (137). This occurred at up to 3 months after starting amiodarone. The risk of subclinical hypothyroidism was similar in the two groups. In one case overt hypothyroidism resolved spontaneously after withdrawal, but the other patients were given thyroxine. After 21–47 months of treatment three patients developed thyrotoxicosis, with remission after withdrawal. There were no cases of hyperthyroidism in the controls. The authors proposed that patients with beta-thalassemia may be more susceptible to iodine-induced hypothyroidism, related to an underlying defect in iodine in the thyroid, perhaps associated with an effect of iron overload.

Presentation

Many examples of hyperthyroidism due to amiodarone have been published.

- A 72-year-old woman with dilated cardiomyopathy was given amiodarone for fast atrial flutter and 6 months later developed abnormal thyroid function tests, with a suppressed TSH and a raised serum thyroxine. The autoantibody profile was negative and a thyroid uptake scan showed reduced uptake (138).

Despite the fact that she was clinically euthyroid, the authors suggested that this patient had amiodarone-induced hyperthyroidism. However, amiodarone inhibits the peripheral conversion of thyroxine to triiodothyronine; it can therefore increase the serum thyroxine and suppress the serum TSH, as in this case. On the other hand, the reduced uptake by the thyroid gland is consistent with type 2 amiodarone-induced hyperthyroidism. The authors did not report the serum concentrations of free thyroxine and triiodothyronine.

- A 67-year-old man took amiodarone 200 mg/day for 20 months, after which it was withdrawn; 8 months later his serum TSH was suppressed and the free thyroxine and

© 2006 Elsevier B.V. All rights reserved.

free triiodothyronine were both raised; there were no thyroid antibodies and an ultrasound scan showed a diffuse goiter with a nodule in the right lobe and reduced iodine uptake (139). Histological examination of the nodule showed a papillary cancer.

The authors attributed these changes to an effect of amiodarone, but it is not clear that amiodarone-induced changes would have taken so long to become manifest after withdrawal. However, the diagnosis of type 2 amiodarone-induced hyperthyroidism was supported by a poor response to prednisone, potassium perchlorate, and methimazole. Lithium produced temporary benefit, but thyroidectomy was required.

- In five patients who presented in Tasmania during 1 year, all of whom were taking amiodarone 200 mg/day, serum TSH was undetectable and the free thyroxine and triiodothyronine concentrations were raised (140). In one case there was a low titer of TSH receptor antibodies and in another a high titer of antithyroid peroxidase antibodies. In all cases the hyperthyroidism was severe and occurred after at least 2 years of treatment with amiodarone. In one of two patients in whom it was measured the serum concentration of interleukin-6 was raised, as has been previously shown (SEDA-19, 193). In two cases the hyperthyroidism was refractory to treatment with propylthiouracil, lithium, and dexamethasone; in these cases thyroidectomy was required. Two patients responded to propylthiouracil, lithium, and dexamethasone, and one responded to carbimazole.

Amiodarone-induced hyperthyroidism can occasionally be fatal (141).

- A 62-year-old man took amiodarone for 2 years and developed hyperthyroidism; carbimazole 40 mg/day, prednisolone, lithium, and colestyramine were ineffective and he died with hepatic encephalopathy and multiorgan failure.
- A 55-year-old man took amiodarone for 4 years and developed hyperthyroidism; carbimazole 60 mg/day, prednisolone, and lithium were ineffective and he died with septicemia and multiorgan failure.

In three other cases reported in the same paper, severe hyperthyroidism responded severally to treatment with carbimazole, carbimazole plus lithium, or propylthiouracil. In one case amiodarone therapy was restarted after prophylactic subtotal thyroidectomy.

Diagnosis

The diagnosis of amiodarone-induced thyroid disorders can be difficult, because amiodarone often alters thyroid function tests without disturbing clinical thyroid function. Although radio-iodine uptake by the thyroid gland is not helpful in making a diagnosis, the discharge of iodine from the thyroid gland in response to perchlorate is reduced in patients with hypothyroidism (142). The test is not abnormal in patients with hyperthyroidism and it is not clear how helpful it is in hypothyroidism.

Since the measurement of serum T3 and T4 concentrations may not be helpful, an alternative would be to measure metabolic status. Measurement of the serum concentration of co-enzyme Q10 may distinguish patients with clinical thyroid dysfunction from those who simply have abnormalities of thyroid function tests (143), but the value of this test remains to be established.

Color-flow Doppler sonography of the thyroid and measurement of serum interleukin-6 (IL-6) have been studied as diagnostic tools in a retrospective case-note study of patients with amiodarone-associated hyperthyroidism (144). There were 37 patients with amiodarone-associated hyperthyroidism (mean age 65, range 20–86 years), and 25 underwent color-flow Doppler sonography. Of those, 10 were classified as type 1 (based on increased vascularity) and 10 as type 2 (based on patchy or reduced vascularity); 5 were indeterminate. In those with type 1 hyperthyroidism, free serum thyroxine tended to be lower (52 versus 75 pmol/l), free serum triiodothyronine was lower (8.8 versus 16 pmol/l), the cumulative amiodarone dose was lower (66 versus 186 g), and less prednisolone was used (because the diagnosis of type 1 disease encouraged steroid withdrawal); however, carbimazole doses were not different and the time to euthyroidism was the same in the two groups (81 versus 88 days). IL-6 was raised in two patients with type 1 and in one patient with type 2 hyperthyroidism. The authors proposed that color-flow Doppler sonography could be used to distinguish the two subtypes, confirming an earlier report (145), but that IL-6 measurement was unhelpful.

Management

The treatment of amiodarone-induced hyperthyroidism is difficult. It often does not respond to conventional therapy with carbimazole, methimazole, or radio-iodine. However, corticosteroids and the combination of methimazole with potassium perchlorate have been reported to be effective (146), even if amiodarone is continued (147). Other regimens that have been used include combinations of corticosteroids with carbimazole (148), corticosteroids and benzylthiouracil (149), or propylthiouracil (SEDA-15, 170). Potassium perchlorate has also been used (SEDA-21, 199). Other forms of treatment that have been successful have been plasma exchange and in very severe cases subtotal thyroidectomy (150) or total thyroidectomy (SEDA-15, 170) (SEDA-17, 220) (151).

It has been suggested that potassium perchlorate should be used in the treatment of type 1 hyperthyroidism and glucocorticoids in the treatment of type 2 (SEDA-21, 199). Since hypothyroidism due to amiodarone tends to occur in areas in which there is sufficient iodine in the diet, it has been hypothesized that an iodinated organic inhibitor of hormone synthesis is formed and that the formation of this inhibitor is inhibited by perchlorate to a greater extent than thyroid hormone iodination is inhibited, since the iodinated lipids that are thought to be inhibitors require about 10 times more iodide than the hormone. However, there is a high risk of recurrence after treatment with potassium perchlorate, and it can cause serious adverse effects (SED-13, 1281).

When five patients with type 2 amiodarone-induced hyperthyroidism were treated with a combination of an oral cholecystographic agent (sodium ipodate or sodium iopanoate, which are rich in iodine and potent inhibitors of 5′-deiodinase) plus a thionamide (propylthiouracil or methimazole) after amiodarone withdrawal, all improved substantially within a few days and became euthyroid or hypothyroid

© 2006 Elsevier B.V. All rights reserved.

in 15–31 weeks (152). Four of the five became hypothyroid and required long-term treatment with levothyroxine.

In another study, three patients with type 1 disease, two of whom had not responded to methimazole plus perchlorate, were successfully treated with a short course of iopanoic acid 1 g/day, resulting in a marked reduction in the peripheral conversion of T4 to T3 (153). Euthyroidism was restored in 7–12 days, allowing uneventful thyroidectomy. The patients were then treated with levothyroxine for hypothyroidism and amiodarone was safely restarted. The authors suggested that iopanoic acid is the drug of choice for rapid restoration of normal thyroid function before thyroidectomy in patients with drug-resistant type 1 amiodarone-induced hyperthyroidism.

However, others have suggested that the differentiation of amiodarone-induced hyperthyroidism into two types is not helpful in determining suitable therapy (154). Of 28 consecutive patients there was spontaneous resolution of hyperthyroidism in 5 and 23 received carbimazole alone as first-line therapy. Long-term euthyroidism was achieved in 11, 5 became hypothyroid and required long-term thyroxine, and 5 relapsed after withdrawal of carbimazole and became euthyroid with either long-term carbimazole ($n = 3$) or radioiodine ($n = 2$). Four were intolerant of carbimazole and received propylthiouracil, with good effect in three. One was resistant to thionamides and responded to corticosteroids. There was no difference in presentation or outcome between those in whom amiodarone was continued or stopped or between possible type 1 or type 2 disease (defined clinically and by serum IL-6 measurement). The authors concluded that continuing amiodarone has no adverse effect on the response to treatment of hyperthyroidism and that first-line therapy with a thionamide alone, whatever the type of disease, is appropriate in iodine-replete areas, thus avoiding potential complications of other drugs. However, it is not clear how good their differentiation of types 1 and 2 disease was. A previous prospective study in 24 patients showed that differentiation predicted response to treatment (155).

It is generally recommended that amiodarone should be withdrawn. However, in some cases (156,157) worsening of thyrotoxic symptoms and heart function has been reported after withdrawal of amiodarone. When withdrawal of amiodarone is not an option, near-total thyroidectomy may be preferred. If surgery is not possible plasmapheresis can be helpful.

The use of local anesthesia for total thyroidectomy in patients with amiodarone-induced hyperthyroidism and cardiac impairment has been reviewed in the context of six patients (158).

Hypothyroidism

Amiodarone-induced hypothyroidism has been reviewed in the light of a case of 74-year-old woman (148).

In a nested case-control analysis of 5522 patients with a first prescription for an antidysrhythmic drug and no previous use of thyroid drugs, cases were defined as all patients who had started a thyroid-mimetic or antithyroid drug no sooner than 3 months after the start of an antidysrhythmic drug and controls were patients with a comparable follow-up period who had not taken any thyroid drugs during the observation period (132). There were 123 patients who had started antithyroid drugs and 96 who had started a thyroid-mimetic drug. In users of amiodarone there was an adjusted odds ratios of 6.6 (3.9, 11) for hypothyroidism compared with users of other antidysrhythmic drugs.

The risk of amiodarone-induced hypothyroidism may be greater in patients who have pre-existing thyroid autoimmune disease (159). There is some evidence that the risk of hypothyroidism due to amiodarone is increased in elderly patients (160), but the data are not conclusive.

In amiodarone-induced hypothyroidism the simplest method of treatment is to continue with amiodarone and to add thyroxine as required.

Metabolism

Amiodarone can cause altered serum lipid concentrations (161). Serum cholesterol rises, as can blood glucose and serum triglyceride concentrations. The mechanisms of these effects are not known; nor is it known to what extent they are due to changes in thyroid function.

Hematologic

Although phospholipid inclusion bodies commonly occur in the neutrophils of patients taking amiodarone (162), adverse hematological effects have rarely been attributed to amiodarone. However, there have been reports of thrombocytopenia (163) and of impaired platelet aggregation, associated with gingival bleeding and ecchymoses of the legs (164). Coombs'-positive hemolytic anemia has also been reported (165).

Bone marrow granulomata have rarely been reported in patients taking amiodarone (166).

- A 53-year-old woman developed leukoerythroblastosis with giant thrombocytes in the peripheral blood and was subsequently given amiodarone. The bone marrow became hypocellular with atypical megakaryocytes and several granulomata.
- A 78-year-old woman with a raised erythrocyte sedimentation rate, a mild anemia, and a polyclonal gammopathy on serum immunoelectrophoresis. The bone marrow became hypocellular with atypical megakaryocytes and several granulomata.

In the first case amiodarone was given after the onset of the peripheral blood film abnormalities and the only change in the bone marrow was the occurrence of the granulomata. The authors proposed that the granulomata had occurred because of phospholipid accumulation.

- Bone marrow biopsy in a patient taking amiodarone 100 mg/day showed multiple non-caseating epithelioid granulomata, which resolved 3 months after the withdrawal of amiodarone in a 67-year-old man (167). Similar granulomas were found in a 77-year-old woman who had taken amiodarone 100 mg/day for many years and had thrombocytopenia; the bone marrow contained an increased number of megakaryocytes. Her platelet count normalized 1 month after

© 2006 Elsevier B.V. All rights reserved.

amiodarone had been withdrawn, and after 3 months there were fewer granulomata in the bone marrow.

- A 76-year-old man, who had taken amiodarone for an unspecified time, developed a monoclonal gammopathy with bone marrow granulomata (168). After another 2 years he developed hepatic granulomata and the amiodarone was withdrawn. The bone marrow granulomata resolved within a few months. Infections were excluded and there was no evidence of sarcoidosis.

The mechanism of this effect is unknown.

Liver

Amiodarone often causes rises in the serum activities of aspartate transaminase and lactate dehydrogenase to about twice normal, without changes in alkaline phosphatase or bilirubin, and without clinical evidence of liver dysfunction (169). Changes of this kind were originally reported to be transient and dose-related, returning to normal when the dose was reduced (170).

However, amiodarone can also cause liver damage, which usually takes the form of a hepatitis associated with phospholipid deposition, and there can be changes similar to those of alcoholic hepatitis (171–173). In some cases there is progression of cirrhosis (174). The risk of hepatic impairment in patients taking amiodarone is not known, but relatively severe liver damage can occur even in the absence of symptoms and with only minor associated changes in liver function tests.

- A 40-year-old man who had taken amiodarone 400 mg/day for 6 weeks developed an acute hepatitis accompanied by clusters of light brown granular cells, which were identified as macrophages (175). There were phospholipid inclusions in the macrophages and hepatocytes.

The authors proposed that the granular macrophages represented an early marker of amiodarone-induced hepatotoxicity. Their unusual color was attributed to the deposition of a combination of phospholipid, lipofuscin, and bile breakdown products.

Other forms of liver damage that have been reported include a syndrome resembling Reye's syndrome (176). Severe hepatitis at low dosage and thought to be immunologically based has been described (177).

Chronic liver damage with amiodarone is much more common than acute hepatitis, but cholestatic jaundice is one of the relatively rare presentations (SEDA-19, 193) (178,179).

- An 84-year-old woman, who had taken amiodarone 400 mg/day for 4–5 years, developed weakness, fatigue, anorexia, and abnormal liver function tests, with an aspartate transaminase activity of 234 U/l, alanine transaminase 154 U/l, and alkaline phosphatase 316 U/l (180). She had a normal serum bilirubin and the serum concentrations of amiodarone and desethylamiodarone were both within the usual target ranges. Apart from gallstones, endoscopic retrograde cholangiography and abdominal ultrasound showed a normal biliary tree. After withdrawal of amiodarone her liver function tests improved, but 4 months later she developed a rapidly rising serum bilirubin concentration (142 mmol/l), her serum albumin concentration fell to 30 g/l, and her serum cholesterol concentration was high (11 mmol/l). She had bilirubin and urobilinogen in the urine and there was no evidence of viral or immunological hepatitis. Abdominal ultrasonography was normal, as was a liver scan, but a CT scan of the abdomen showed a diffusely hyperdense liver consistent with the effects of amiodarone. Liver biopsy also showed findings consistent with amiodarone-induced cholestatic liver damage, with distorted architecture, portal fibrosis, pericellular sinusoidal fibrosis, and focally irregular lobular sinusoidal fibrosis, but without bridging fibrosis or cirrhosis. There was ductal proliferation and a mild lymphocytic infiltrate but no cholangitis. Electron microscopy showed lamella inclusions compatible with phospholipidosis.

If amiodarone was responsible in this case, it is hard to reconcile the improvement after amiodarone withdrawal with the cholestasis that occurred 4 months later. The patient was also taking felodipine, furosemide, potassium chloride, aspirin (500 mg/day), and cisapride, but the authors argued that the changes were not consistent with liver damage due to any of those drugs. In particular they thought that the felodipine was unlikely to have caused cholestasis, although that has been previously reported, because of the presence of Mallory bodies in the liver biopsy; however, Mallory bodies have previously been reported with felodipine, and although cholestatic liver injury caused by felodipine has not been reported before, that seems as likely a candidate in this case as amiodarone.

Acute hepatitis with liver failure can occur after intravenous administration and may be due to the solvent, polysorbate (SEDA-14, 149) (SEDA-16, 178) (SEDA-18, 202) (SEDA-22, 206) (181).

- A 69-year-old man was given amiodarone intravenously 1500 mg for multiple coupled ventricular extra beats and 24 hours later developed acute hepatitis, with a 50-fold increase in serum transaminase activities and simultaneous increases in lactate dehydrogenase, gamma-glutamyl transferase, bilirubin, and prothrombin time; there was a moderate leukocytosis and mild renal insufficiency (182). No further amiodarone was given and there was full recovery within 2 weeks. Other causes of acute hepatitis were excluded.

The mechanism of this effect is not known, but the histology includes Mallory bodies, steatosis, intralobular inflammatory infiltrates, and fibrosis; electron microscopy suggests phospholipidosis.

It has been suggested that liver injury due to amiodarone is either due to a direct biochemical action or perhaps metabolic idiosyncrasy. Because there have been cases in which oral administration has not led to a recurrence, it has also been suggested that the vehicle in which amiodarone is usually dissolved, polysorbate (Tween) 80, is responsible rather than the amiodarone itself (SEDA-18, 202).

Pancreas

There have been two reported cases of pancreatitis and in one the patient died of progressive liver failure (183,184). Whether this was a direct effect of amiodarone is unclear.

© 2006 Elsevier B.V. All rights reserved.

Urinary tract

Increases in serum creatinine concentrations, correlated with serum amiodarone concentrations, have been reported (185).

Skin

Amiodarone commonly causes phototoxicity reactions (186,187). The risk of phototoxicity increases with the duration of the exposure. Window glass and sun screens do not give protection, although zinc or titanium oxide formulations and narrow band UVB photo therapy can help (188–190). For most patients this adverse effect will be no more than a nuisance, and the benefit of therapy may be worthwhile. However, in a few cases treatment may have to be withdrawn. Histological examination of skin biopsies shows intracytoplasmic inclusions of phospholipids (191). There has been a single report of a severe case of photosensitivity in conjunction with a syndrome resembling porphyria cutanea tarda, resulting in bullous lesions (192).

Amiodarone can cause a cosmetically annoying bluish pigmentation of the skin (SEDA-15, 171) (SEDA-22, 207) (SEDA-23, 199) (193).

- A 54-year-old man who took the drug for 1 year developed bluish-gray discoloration of the face (194). The discoloration almost completely resolved within 9 months of withdrawal.
- A 55-year-old woman who had taken amiodarone 250 mg/day for about 10 years developed bluish-gray discoloration of the face (195). The pigmentation responded to treatment with a Q-switched ruby laser at an energy of 8 J/cm^2 and a wave length of 694 mm.

The authors suggested that the ruby laser had damaged pigment-containing cells. However, the amiodarone was continued, so presumably the laser also destroyed lipofuscin in situ.

- A 69-year-old white man who had taken amiodarone 400 mg/day for 3 years developed blue–gray discoloration of the face and other exposed areas (196). Areas that had been protected from the sun (the forehead by a broad-brimmed hat and the skin under his wrist watch) were not affected.
- A 70-year-old man developed grey–blue pigmentation on sun-exposed areas of his skin after taking amiodarone for 10 years and minocycline for 4 years (197).

Minocycline can also cause skin pigmentation and it is not clear in this last case what the interaction of amiodarone with minocycline was.

Grey–blue discoloration of the skin during amiodarone therapy has been presumed to be due to lipofucsin deposition. However, it has also been suggested that amiodarone may block the maturation of melanosomes, in view of a case of discoloration associated with a reduced number of mature melanosomes and an increased number of premelanosomes in sun-exposed areas of the skin, but normal numbers in non-exposed areas (198).

It has been suggested that the skin and mucosal toxicity of amiodarone may be enhanced by radiotherapy (SEDA-16, 178) (SEDA-17, 221). However, in a retrospective review of 10 patients who took amiodarone when having external beam radiation therapy there were no unexpected acute sequelae (199).

Other skin reactions that have been reported include iododerma (200), erythema nodosum, psoriasis (201), and exfoliative dermatitis (202).

Amiodarone can increase the risk of mucosal and skin toxicity due to radiotherapy and rarely causes hair loss (SEDA-17, 221) and vasculitis (203).

The severe form of erythema multiforme known as toxic epidermal necrolysis has rarely been attributed to amiodarone (204).

- A 71-year-old woman, who had taken amiodarone 200 mg/day for 3 months and diltiazem for 8 months, developed extensive erythema, blistering, and erosions affecting 50% of the body surface area, with a maculopapular rash on the limbs (205). She developed bilateral pneumonia and septicemia and died after 7 days.

Musculoskeletal

A proximal myopathy has occasionally been reported in patients taking amiodarone (69) and there has been a report of an acute necrotizing myopathy (206).

Sexual function

Epididymitis has been reported in patients taking high dosages of amiodarone, resolving with dosage reduction or withdrawal (SEDA-18, 203).

Reproductive system

Non-infective epididymitis has occasionally been reported in patients taking amiodarone (SEDA-10, 148) (SEDA-18, 203).

- A 25-year-old man who had taken amiodarone 200 mg bd for 1 year developed epididymitis, which resolved within 3 months of withdrawal of amiodarone and recurred within 2 months of its reintroduction (207).

This case was unusual in that it involved both testes. The mechanism of this effect is not known, but it has been reported to be dose-dependent, although anti-amiodarone antibodies have also been reported (208). The incidence is not known, but has been reported to be as high as 11%. The author of one very brief report (209) claimed to have seen 20 cases of epididymitis, some of which were bilateral, since the late 1980s. He claimed that withdrawal produced dramatic resolution of symptoms within 10–20 days, and that amiodarone in a dose of 200 mg/day did not usually cause symptoms, even in patients who had had epididymitis at higher dosages.

Immunologic

Lupus-like syndrome has rarely been attributed to amiodarone.

- A 71-year-old woman, who had been taking amiodarone 200 mg bd for 2 years, developed malaise, intermittent fever, arthralgia, and weight loss (210). She had a malar rash and hypoventilation at both lung bases. Her erythrocyte sedimentation rate was markedly raised (90 mm/hour), there was a mild normochromic

© 2006 Elsevier B.V. All rights reserved.

normocytic anemia (10 g/dl), a slight lymphopenia, and otherwise normal routine tests. Her rheumatoid factor was raised in a titer of 1:320, and circulating complexes of IgG-C1q were positive. Antinuclear antibody was positive (1:640), but all other antibodies were negative. There was progressive improvement on withdrawal of amiodarone and all the biochemical tests returned to normal.

- A 59-year-old man, who had taken amiodarone 200 mg/day for 2 years, developed fever, pleuritic chest pain, dyspnea at rest, a non-productive cough, malaise, and joint pains (211). He had a verrucous endocarditis and a pleuropericardial effusion. He had raised titers of antinuclear antibodies (1:320) with anti-Ro specificity. Serum complement was normal and there were no circulating immune complexes, no cryoglobulins, and no anti-dsDNA, anti-La, anti-U1 ribonucleoprotein, anti-Sm, anti-Sc1, 70, anti-Jo 1, antihistone, antiphospholipid, anticentromere, anticardiolipin, or anticytoplasmic antibodies. Within 7 days of withdrawal of amiodarone the signs and symptoms started to resolve, and he recovered fully with the addition of prednisolone.

Angioedema has been reported in a 70-year-old woman who had taken amiodarone 200 mg/day for 8 years (212). The amiodarone was withdrawn and the symptoms disappeared. Rechallenge produced facial flush and facial angioedema within 20 minutes of a 200 mg dose.

Death

The effect of intravenous and oral amiodarone on morbidity and mortality has been studied in 1073 patients during the first hours after the onset of acute myocardial infarction (213). The patients were randomized to receive amiodarone or placebo for 6 months. The interim analysis showed an increased mortality, albeit not significant, with high-dose amiodarone (16 versus 10%) and the dose was therefore reduced from 400 to 200 mg/day. Low-dose amiodarone was associated with a reduced death rate (6.6 versus 9.9%). There were non-fatal adverse events in 108 patients taking amiodarone and 73 taking placebo. The only non-fatal adverse effect that occurred significantly more often with amiodarone was hypotension during the initial intravenous loading phase, a well-known effect. In the context of this study, it should be remembered that in several previous studies amiodarone has been shown to reduce mortality after myocardial infarction (SEDA-23, 198) (SEDA-24, 206) (214).

Second-Generation Effects

Teratogenicity

There are no major teratogenic effects of amiodarone (215).

Fetotoxicity

Exposure to amiodarone in utero has only occasionally been described.

Cardiovascular

There have been reports of sinus bradycardia (SEDA-8, 179) (SEDA-20, 176) (216,217) and prolongation of the QT interval (215).

Nervous system

Congenital nystagmus has been described (SEDA-20, 176).

Psychological

In one child there was evidence of mental delay, hypotonia, hypertelorism, and micrognathia (SEDA-20, 176), although the authors thought that the link between amiodarone and neurotoxicity was speculative. However, there has also been a retrospective study of 10 children who were exposed to amiodarone during pregnancy, compared with matched controls (218). There was no change in IQ score, but the children who had been exposed to amiodarone had impaired expressive language skills and one child had global developmental delay. However, most of the mothers were not concerned about their children's development, and so any effect of amiodarone on neurological development was probably small. One child had transient neonatal hypothyroidism, which responded to a short course of thyroxine; another had mild transient neonatal hyperthyroidism; in neither case was there any difference in development from the other children who had been exposed to amiodarone. One child was born with a congenital jerk nystagmus and had relatively poor reading and comprehension skills for both words and passages, low scores on several of the verbal subtests of the WISC-R test for information, arithmetic, and vocabulary, and below average spelling.

Endocrine

The major adverse effect on the fetus is altered thyroid function (SEDA-13, 141) (SEDA-14, 149) (SEDA-19, 194) (SEDA-20, 176). There have been individual reports of neonatal hyperthyroxinemia (219), goiter (216), and hypothyroidism (220). In the patient with goiter there was associated hypotonia, bradycardia, large fontanelles, and macroglossia (216).

Two neonates who had been given intravenous amiodarone as fetuses at 26 and 29 weeks and whose mothers had also taken it orally developed hypothyroidism (221). The authors suggested that low dietary iodine intake by the mothers may have contributed, by enhancing the Wolff–Chaikoff effect.

Susceptibility Factors

Age

The safety and efficacy of amiodarone for supraventricular tachycardia have been studied in 50 infants (mean age 1.0 month, 35 boys) (222). They had congenital heart disease (24%), congestive heart failure (36%), or ventricular dysfunction (44%). Six, who were critically ill, received a loading dose of intravenous amiodarone 5 mg/kg over 1 hour, and all took 20 mg/kg/day orally for 7–10 days, followed by 100 mg/day; if this failed to control the dysrhythmia, oral propranolol (2 mg/kg/day) was added. Follow-up was for an average of 16 months. Rhythm control was achieved in all patients. Growth and

© 2006 Elsevier B.V. All rights reserved.

development were normal. The higher dose of amiodarone was associated with an increase in the QT_c interval to over 0.44 seconds, but there were no dysrhythmias. Two infants had hypotension during intravenous loading, as has previously been reported in infants (SEDA-19, 194). Aspartate transaminase and alanine transaminase activities and thyrotropin (TSH) concentrations all increased, but remained within their reference ranges. There were no adverse effects that necessitated drug withdrawal.

Young patients are more likely to develop adverse effects in the skin (223).

In children under 10 years of age the risk of adverse effects is less than in adults (224,225). It is not clear whether older children are at greater or lesser risks of adverse effects than are adults.

The safety of antidysrhythmic drugs in children has not been thoroughly studied. However, the risk of prolongation of the QT interval seems to be considerably less than that in adults (226), although it has been reported with quinidine, disopyramide, amiodarone, sotalol, and diphemanil.

Other features of the patient

Amiodarone-induced liver damage is more common in those with reduced left ventricular function (223).

Anesthesia and surgery

It has been reported that there is an increased risk of adverse reactions to amiodarone in patients undergoing anesthesia (SEDA-15, 171). However, in a retrospective survey of 12 patients who underwent anesthesia for urgent thyroidectomy due to amiodarone there were no anesthetic complications or deaths (227).

There is an increased risk of some of the adverse effects of amiodarone (including dysfunction of the liver and lungs) in patients who have had or who are having surgery (228). In addition the perioperative mortality in these patients is higher than in controls (229). The factors that increase the risks of amiodarone-associated adverse cardiovascular effects during surgery (230) include pre-existing ventricular dysfunction, too rapid a rate of intravenous infusion, hypocalcemia, and an interaction between amiodarone and both the general anesthetics used and other drugs with negative inotropic or chronotropic effects. It has therefore been recommended (230) that serum concentrations of calcium, amiodarone, and digoxin should be within the reference or target ranges before operation, and that other drugs with negative inotropic or chronotropic effects should be withdrawn before surgery.

The use of amiodarone in the prevention of atrial fibrillation after cardiac surgery has been reviewed (231). When an intravenous loading dose of amiodarone was used, bradycardia was a common adverse effect but was rarely severe enough to warrant withdrawal. When only oral amiodarone was used there were no serious adverse reactions.

Drug Administration

Drug formulations

The steady-state plasma concentrations of amiodarone and desethylamiodarone in 77 patients taking two different formulations, a new generic formulation and Cordarone, were comparable (232).

Drug administration route

In contrast to its effects during oral administration, the therapeutic and short-term unwanted effects of amiodarone during intravenous administration arise within minutes or hours (2). The reason for this is not clear; plasma concentrations after single oral and intravenous doses of 400 mg are very similar (2), but that does not rule out a pharmacokinetic explanation for the paradox. The possible role of the solvent used in the intravenous formulation, polysorbate (Tween) 80, has not been fully elucidated. Amiodarone certainly has different electrophysiological effects when it is given intravenously. For example, intravenous amiodarone prolongs the AH interval, while oral amiodarone prolongs atrial and ventricular refractory periods and the HV interval (233). Furthermore, the blocking effects of amiodarone on sodium and calcium channels and its beta-adrenoceptor blocking action occur earlier than its Class III action (234). An anecdotal report of torsade de pointes after both intravenous and oral administration of amiodarone on different occasions has underlined this difference.

- A 70-year-old woman with dilated cardiomyopathy, ventricular tachydysrhythmia, and a QT_c interval of 0.49 seconds was given intravenous amiodarone 240 mg over 15 minutes, and 30 minutes later developed a junctional escape rhythm (48/minute) with QT_c prolongation to 0.68 seconds; 8 hours later she developed torsade de pointes (235). A few years later she was given oral amiodarone 100 mg/day and 7 weeks later presented with congestive heart failure. Her QT_c interval was prolonged (0.50 seconds) and increased further to 0.64 seconds after the addition of dopamine 3 micrograms/kg/minute; torsade de pointes again developed. Amiodarone was withdrawn and the QT_c interval shortened, but she continued to have recurrent episodes of sustained ventricular tachycardia.

The authors suggested that torsade de pointes induced by intravenous amiodarone depended on heart rate during a bout of bradycardia, while that after oral amiodarone depended on increased sympathetic nervous system activity, and that therefore different electrophysiological mechanisms had been at play. However, it is by no means clear from their description of this case that that was so. They did not report plasma concentrations of amiodarone or desethylamiodarone, its active metabolite.

After rapid intravenous administration hypotension, shock, and atrioventricular block can occur and can be fatal (2). The rate of infusion should not exceed 5 mg/minute. Other adverse effects reported during intravenous infusion include sinus bradycardia (236), facial flushing, and thrombophlebitis (236–239). The risk of this last complication can be reduced by infusing the drug into as large a vein as possible and preferably via a central venous catheter, or perhaps by using a very dilute solution of the drug (240).

The use of intravenous amiodarone for atrial fibrillation has been reviewed (241). The most commonly reported adverse effects in all studies have been hypotension and bradycardia. Other effects include worsening of heart failure, thrombophlebitis at the site of infusion, non-sustained ventricular tachycardia, facial rash, and nightmares.

© 2006 Elsevier B.V. All rights reserved.

A few studies have also reported the effects and adverse effects of intravenous amiodarone in patients with atrial fibrillation. Of 67 patients with atrial fibrillation, of whom 33 received amiodarone and 34 received placebo, conversion to sinus rhythm occurred in 16 of the patients who received amiodarone and in none of those who received placebo (242). In five patients the systolic blood pressure fell significantly during the first trial of intravenous drug administration. There were no cardiac dysrhythmias. Thrombophlebitis occurred in 12 patients who received amiodarone.

In a randomized, placebo-controlled trial of 100 patients with paroxysmal atrial fibrillation, intravenous amiodarone 125 mg/hour was compared with placebo (243). There were no serious adverse effects; five patients given amiodarone developed significant sinus bradycardia, in all cases after conversion to sinus rhythm. In this series there were no significant episodes of hypotension. Thrombophlebitis occurred in eight patients who received amiodarone.

Drug overdose

The features of amiodarone overdose and its management have been reviewed (244).

- There has been a report of acute self-poisoning with 8 g of amiodarone orally (245). Initially the only abnormal physical sign was profuse sweating; the electrocardiogram showed sinus rhythm with a normal QT_c interval and the blood pressure was normal. No active measures were taken. The QT_c interval subsequently lengthened on the third and fourth days after overdosage, and there was sinus bradycardia between the second and fifth days. Over 3 months of follow-up there were no effects on thyroid or liver function and no evidence of lung, skin, or corneal involvement.

Drug–Drug Interactions

Anesthetics

The risks of cardiovascular adverse effects in patients undergoing surgery may be partly related to an interaction of amiodarone with anesthetics, either directly or via some interaction with the catecholamines that are released during anesthesia (246). The risk of hypotension during cardiopulmonary bypass in patients taking amiodarone can be increased by the concurrent administration of an ACE inhibitor. There is a high incidence of lung complications when patients treated with amiodarone are ventilated with 100% oxygen, including acute adult respiratory distress syndrome.

Beta-blockers

The combination of amiodarone with beta-adrenoceptor antagonists can be beneficial in the treatment of refractory ventricular tachycardia, especially when low doses of the beta-blockers are used. However, there have also been reports of adverse interactions in these circumstances, and various correspondents have commented on the possibility that beta-blockers may enhance the effects of amiodarone in reducing mortality in patients who have had a myocardial infarction or are in heart failure (190,247,248).

In a systematic review, the beneficial interaction has been confirmed (249). Four groups of patients who had been studied in EMIAT and CAMIAT (SEDA-21, 198) were defined: patients who had taken amiodarone plus beta-blockers, patients who had taken beta-blockers or amiodarone alone, and patients who had taken neither. The relative risks for all-cause mortality and all forms of cardiac death or resuscitated cardiac arrest were lower in the patients who had taken amiodarone plus beta-blockers than in the other three groups. The results of this post hoc analysis should be regarded with caution, but in view of previous similar reports they are suggestive of a beneficial interaction of amiodarone with beta-blockers in patients who have had a previous myocardial infarction. The interaction was statistically significant for cardiac deaths and for dysrhythmic deaths or resuscitated cardiac arrest. In all other cases the relative risk was reduced, although not significantly. The risk was not affected by heart rate. This interaction has been reviewed (250).

Budesonide

The corticosteroid budesonide undergoes a high degree of first-pass elimination in the liver after oral administration, and therefore causes few systemic adverse effects. It was therefore surprising that Cushing's syndrome occurred in an 81-year-old man taking oral budesonide 9 mg/day and amiodarone 100 mg/day (251). When amiodarone was withdrawn the clinical effects of Cushing's syndrome disappeared. The authors suggested that amiodarone had inhibited the metabolism of budesonide by hepatic CYP3A.

Ciclosporin

Amiodarone can increase the blood concentrations of ciclosporin and thus impair renal function.

- A 66-year-old developed a ventricular tachycardia after kidney transplantation and was given amiodarone. Maintenance immunosuppression included prednisone, azathioprine, and ciclosporin. Ciclosporin concentrations before amiodarone initiation were stable (range 100–150 ng/ml). During amiodarone therapy, the ciclosporin concentration increased more than two-fold.

The authors proposed that changes in protein binding or metabolism might have explained this interaction.

Class I antidysrhythmic drugs

Amiodarone can potentiate the dysrhythmogenic actions of some Class I antidysrhythmic drugs (SEDA-18, 203), particularly because of the risk of QT interval prolongation (SEDA-19, 194). In 26 patients taking mexiletine plus amiodarone for 1 month and 155 taking mexiletine alone, there was no significant difference in the apparent oral clearance of mexiletine (252). However, the lack of a pharmacokinetic interaction does not reduce the risk that dangerous QT interval prolongation may occur with a combination such as this.

© 2006 Elsevier B.V. All rights reserved.

Cyclophosphamide

Both amiodarone and cyclophosphamide can cause lung damage.

- Interstitial pneumonitis has been reported in a 59-year-old man, who had taken amiodarone for 18 months, 18 days after a single dose of cyclophosphamide; 1 year before he had also received six cycles of chemotherapy containing cyclophosphamide, vincristine, and prednisone, followed by four cycles of cisplatin, cytarabine, and dexamethasone (253).

The authors suggested that the lung damage had been due to the cyclophosphamide, enhanced by the presence of amiodarone, but in view of the fact that previous similar exposure on six occasions had not resulted in the same effect, it is perhaps more likely that this was a long-term adverse effect of amiodarone alone. The presence of foamy histiocytes in the lung biopsy was consistent with this interpretation (SEDA-15, 168). It is true, however, that lung damage due to amiodarone is usually of a more insidious onset than was reported in this case, although a more rapid onset can occur in patients who are given high concentrations of inspired oxygen. On the other hand, lung damage has occasionally been reported to occur rapidly (71).

Digoxin

Amiodarone reduces both the renal and non-renal clearances of digoxin and prolongs its half-life, without changing its apparent volume of distribution. It has also been suggested that amiodarone increases the extent of absorption of digoxin (SEDA-10, 144) (SEDA-12, 150). Digoxin dosages should be halved as soon as amiodarone is introduced. This interaction may also occur with acetyldigitoxin (254).

Diltiazem

Sinus arrest with hypotension has been reported in a patient with a congestive cardiomyopathy when diltiazem was added to amiodarone (255).

Indinavir

Indinavir inhibits CYP3A4, which is responsible for the de-ethylation of amiodarone to desethylamiodarone.

- A 38-year-old man, who had taken amiodarone 200 mg/day for more than 6 months, was given postexposure prophylaxis for HIV infection after a needle injury; this included zidovudine, lamivudine, and indinavir (256). During the 4 weeks of therapy his serum amiodarone concentration rose from 0.9 to 1.3 mg/l, with only a small rise in the serum concentration of desethylamiodarone from 0.4 to 0.5 mg/l. After withdrawal of the prophylactic therapy the plasma amiodarone concentration gradually fell to the pretreatment value, and there was no further change in the concentration of desethylamiodarone.

No adverse effects of this interaction were reported.

Meglumine antimoniate

A pharmacodynamic interaction has been described between amiodarone and meglumine antimoniate, both of which prolong the QT interval; the interaction resulted in torsade de pointes (257).

- A 73-year-old man with visceral leishmaniasis was given meglumine antimoniate intramuscularly 75 mg/kg/day. At that time his QT_c interval was normal at 0.42 seconds. Three weeks later his QT_c interval was prolonged to 0.64 seconds and he was given methyldigoxin 0.4 mg and amiodarone 450 mg intravenously over 8.25 hours; 12 hours later he had a cardiac arrest with torsade de pointes, which was cardioverted by two direct shocks of 300 J and lidocaine 100 mg in two bolus injections. Because he had frequent episodes of paroxysmal atrial fibrillation, he was given amiodarone 100 mg over the next 40 hours, and developed recurrent self-limiting episodes of torsade de pointes associated with QT_c interval prolongation, which responded to intravenous magnesium 1500 mg. After withdrawal of amiodarone there was no recurrence and a week later the QT_c interval was 0.48 seconds. The plasma potassium concentration was not abnormal in this case.

In view of this report it is probably wise to avoid coadministration of these two drugs.

Phenazone (antipyrine)

The clearance of phenazone (antipyrine) is reduced by amiodarone (258).

Phenytoin

Amiodarone increases the plasma concentrations of phenytoin, probably by inhibiting its metabolism (259,260), while phenytoin increases the metabolism of amiodarone and perhaps also of its metabolite desethylamiodarone (261).

Rifampicin

- In a 33-year-old woman taking amiodarone 400 mg/day the addition of rifampicin 600 mg/day resulted in paroxysms of atrial fibrillation and atrial flutter, with a very low serum amiodarone concentration and an undetectable concentration of desethylamiodarone (262). This was attributed to induction of the metabolism of amiodarone and desethylamiodarone, and after withdrawal of rifampicin the concentrations of the two compounds rose to within the target ranges.

This interaction has been demonstrated in human liver microsomes (263).

Warfarin

That amiodarone can potentiate the action of warfarin by inhibiting its metabolism is well known (SEDA-11, 156). However, potentiation of the action of warfarin has been attributed to amiodarone-induced thyrotoxicosis (264). A metabolic interaction in this case was unlikely, because the patient had taken both drugs together for 2 years before the increase in response to warfarin, coincident with the emergence of thyrotoxicosis.

In a study of this interaction in 43 patients who took both amiodarone and warfarin for at least 1 year, the interaction peaked at 7 weeks and the mean dosage of warfarin fell by 44% from 5.2 to 2.9 mg/day (265). The dosage of warfarin correlated inversely with the maintenance dose of

© 2006 Elsevier B.V. All rights reserved.

amiodarone. There were minor bleeding episodes in five patients. The authors recommended reducing the daily warfarin dose by about 25, 30, 35, and 40% in patients taking amiodarone 100, 200, 300, and 400 mg/day respectively.

Interference with Diagnostic Tests

Serum creatinine

Amiodarone has been reported to cause a small and reversible increase in serum creatinine concentration (266). It is not clear whether this effect is due to true renal impairment, or to some effect on either the kinetics of creatinine or its measurement in the blood.

Thyroid function tests

Amiodarone causes altered thyroid function tests, with rises in serum concentrations of T4 and reverse T3 and a fall in serum T3 concentration (267). This is due to inhibition of the peripheral conversion of T4 to T3, causing preferential conversion to reverse T3. These changes can occur in the absence of symptomatic abnormalities of thyroid function.

Blood urea nitrogen

Amiodarone has also been reported to cause a small and reversible increase in blood urea nitrogen concentration (266). It is not clear whether this effect is due to true renal impairment, or to some effect on either the kinetics of urea or its measurement in the blood.

Diagnosis of Adverse Drug Reactions

The differences in the rates of onset of effects of amiodarone after oral and intravenous administration in the face of similar plasma concentrations suggest that there can be no simple relation between the plasma concentrations of amiodarone and its therapeutic effects. Matters are further complicated by metabolism of amiodarone to desethylamiodarone, which has pharmacological activity. However, evidence (2,268) suggests that a plasma amiodarone concentration of around 1.0–2.5 mg/ml is associated with a high likelihood of therapeutic efficacy in patients with dysrhythmias. However, adverse effects can still occur when the plasma concentration is within this range, and there is no clear limit to the concentration above which toxicity starts to become important. Similarly, the therapeutic range of concentrations for desethylamiodarone is unclear, although it has been suggested to be around 0.5–1.0 mg/ml (SEDA-10, 146).

In one careful study EC_{50} values for certain effects of amiodarone were calculated (269). The respective concentrations of amiodarone and desethylamiodarone that were associated with effects were as follows: reduction in heart rate 1.2 and 0.5 mg/ml; QT_c prolongation 2.6 and 1.4 mg/ml; corneal microdeposits 2.2 and 1.1 mg/ml.

Because amiodarone prolongs the QT_c interval, it has been suggested that this might be a useful measure of its efficacy. The percentage prolongation of the QT_c interval correlates well with both daily dose and the plasma and myocardial concentrations of amiodarone (270), although this is not a universal finding during long-term administration (237,271), and the QT_c interval is not prolonged after short-term intravenous use (2).

Since amiodarone inhibits the peripheral conversion of thyroxine (T4) to tri-iodothyronine (T3), there is an increase in serum concentrations of reverse tri-iodothyronine (rT3). However, there have been conflicting results in studies of the relation between serum concentrations of rT3 and the therapeutic and adverse effects of amiodarone (SEDA-15, 172).

Amiphenazole

General Information

Amiphenazole is a respiratory stimulant. It increases ventilation by accelerating the frequency at increased CO_2 partial pressures above 6 kPa (45 mmHg) (1).

Its adverse effects include restlessness, prolonged and forced expiration, nausea and vomiting, sweating, and skin reactions; the last include rashes (2), occasionally oral lichenoid eruptions (3), and ulceration (4). Muscle twitching and mental disorientation can also occur in the elderly. With large doses, convulsions can occur (5).

In a double-blind randomized study in 30 women in the recovery room a single intravenous bolus injection of amiphenazole 150 mg was compared with placebo; amiphenazole did not improve ventilation (6). However, in a double-blind study amiphenazole reversed respiratory depression and analgesia due to morphine (7).

Amisulpride

See also Neuroleptic drugs

General Information

Amisulpride is an atypical antipsychotic drug, a benzamide derivative, which may have a low propensity to cause extrapyramidal symptoms (SEDA-22, 55).

Amisulpride 600–1200 mg/day for 3 months was effective and well tolerated in 445 patients with schizophrenia aged 18–45 years (1). During this time, 124 patients (28%) dropped out of the study; 21% reported adverse events, neurological (35%), psychiatric (15%), or endocrine (9.1%). Seven adverse events were assessed as serious: two suicides, two suicide attempts, one neuroleptic malignant syndrome, one somnolence, and one worsening of arteritis.

A lower dose of amisulpride (50 mg) has been tested in 20 healthy elderly volunteers (aged 65–79 years) (2). There were no serious adverse events, but one subject reported a moderate headache for 18 hours, a second subject vomited 9 hours after dosing, and a further subject complained of mild somnolence for 12 hours starting 4 hours after dosing; however, there were no extrapyramidal symptoms, clinically significant hemodynamic variations, or electrocardiographic abnormalities.

Comparisons with placebo and other antipsychotic drugs

In a randomized double-blind study, there were no differences in the numbers of patients with at least one adverse effect with amisulpride 100 mg (24%; $n = 18$), amisulpride 50 mg (25%; $n = 21$), or placebo (33%; $n = 27$) (3). Few patients had endocrine symptoms (2 out of 160 in the amisulpride groups).

Two narrative reviews of amisulpride have been published (4,5). The authors emphasized that amisulpride in low dosages (below 300 mg/day) causes a similar incidence of adverse effects to placebo; nevertheless, at higher dosages (400–1200 mg/day), the overall incidence of adverse events in those taking amisulpride was similar to that in patients taking haloperidol, flupenthixol, or risperidone. The most commonly reported adverse events associated with higher dosages of amisulpride were extrapyramidal

© 2006 Elsevier B.V. All rights reserved.

symptoms, insomnia, hyperkinesia, anxiety, increased body weight, and agitation. The incidence of extrapyramidal symptoms was dose-related. In elderly people, amisulpride can cause hypotension and sedation. There are no systematic published data on efficacy in children aged under 15 years.

In an extensive review of 19 randomized studies for the Cochrane Library ($n = 2443$), most of the trials were small and of short duration (6). The data from four trials with 514 participants with predominantly negative symptoms suggested that low-dose amisulpride (up to 300 mg/day) was more acceptable than placebo ($n = 514$; RR = 0.6; 95% CI = 0.5, 0.8).

A meta-analysis of 10 randomized controlled clinical trials of amisulpride in "acutely ill patients" ($n = 1654$) has been published, supported in part by a grant from Sanofi-Synthélabo, the marketing authorization holder (7). Amisulpride was significantly better than conventional antipsychotic drugs by about 11 percentage points on the Brief Psychiatric Rating Scale. In four studies in patients with "persistent negative symptoms," amisulpride was significantly better than placebo ($n = 514$), but there was no significant difference between amisulpride and conventional drugs (only three trials; $n = 130$). Low doses of amisulpride (50–300 mg/day) were not associated with significantly more use of antiparkinsonian drugs than placebo ($n = 507$), and usual doses caused fewer extrapyramidal adverse effects than conventional antipsychotic drugs ($n = 1599$). In studies in acutely ill patients, significantly fewer patients taking amisulpride dropped out compared with patients taking conventional drugs, mainly owing to fewer adverse events; there were no significant differences in dropout rates between amisulpride and conventional antipsychotic drugs (three small studies).

Comparisons with antidepressants

Amisulpride has been compared with amitriptyline ($n = 250$; 6 months) (8) and with amineptine ($n = 323$; 3 months) in randomized double-blind trials in the treatment of dysthymia (9). In both trials, amisulpride was more efficacious than placebo but equal to amineptine and amitriptyline. Endocrine symptoms (such as galactorrhea and menstrual disorders) and weight gain were more frequent with amisulpride. There was galactorrhea in 8.4% and 11% respectively. In one of the studies (8), serious adverse events occurred in 13 of 165 patients taking amisulpride (15 events). Sudden death, probably secondary to myocardial infarction, occurred in a patient taking amisulpride 7 days after withdrawal. In the other cases, admission to hospital was required for fracture (two cases) and gastric pain, neuralgia, hyperglycemia, eczema, an injury, and an erythematous rash (one case each).

In a randomized, double-blind, multicenter trial for 8 weeks in 278 patients with depression, there were no differences in efficacy or tolerability between amisulpride 50 mg and SSRIs (10).

Organs and Systems

Cardiovascular

QT interval prolongation has been attributed to amisulpride.

- Sinus bradycardia and QT interval prolongation occurred in a 25-year-old man taking amisulpride 800 mg/day (11). The dosage of amisulpride was reduced to 600 mg/day and the electrocardiogram normalized within a few days.

Psychological, psychiatric

In a randomized, double-blind, crossover study in 21 healthy volunteers who took amisulpride 50 mg/day, amisulpride 400 mg/day, haloperidol 4 mg/day, or placebo, amisulpride 400 mg had several adverse effects on psychomotor performance and cognitive performance, similar to those of haloperidol, at the end of the 5-day course of treatment; however, there were no signs of mental disturbances on clinical rating scales or during a structured psychiatric interview (12).

Amitriptylinoxide

See also Tricyclic antidepressants

General Information

Amitriptylinoxide, a metabolite of amitriptyline, has been compared with the parent drug (1). The antidepressant effects were comparable, but the metabolite was thought to have fewer adverse effects, especially cardiotoxic ones. This conclusion was based on the absence of cardiographic abnormalities in 15 patients, but this is a very small series on which to base such a conclusion.

Amlodipine

See also Calcium channel blockers

General Information

Amlodipine is a long-acting dihydropyridine calcium channel blocker. It has an adverse effects profile similar to those of other dihydropyridines, but at a lower frequency (1). Along with felodipine (2), but unlike other calcium channel blockers, it may also be safer in severe chronic heart failure when there is concurrent angina or hypertension (3).

The effects of amlodipine and isosorbide-5-mononitrate for 3 weeks on exercise-induced myocardial stunning have been compared in a randomized, double-blind, crossover study in 24 patients with chronic stable angina and normal left ventricular function (4). Amlodipine attenuated stunning, evaluated by echocardiography, significantly more than isosorbide, without difference in anti-ischemic action or hemodynamics. Amlodipine was better tolerated than isosorbide, mainly because of a lower incidence of headache (4).

Vasodilatory calcium channel blockers have been reported to improve exercise tolerance in some preliminary studies. A multicenter, randomized, placebo-controlled trial was therefore performed in 437 patients with mild to moderate heart failure to assess the effects of amlodipine 10 mg/day in addition to standard therapy (5). Over 12 weeks amlodipine did not improve exercise time and did not increase the incidence of adverse events.

Mental stress is a risk factor for cardiovascular disease. In 24 patients with mild to moderate hypertension, amlodipine reduced the blood pressure rise during mental stress compared with placebo, but increased plasma noradrenaline concentrations (6).

Hypertension leading to cardiac dysfunction is very frequent in patients with the inherited syndrome called Ribbing's disease, which is characterized by multiple epiphyseal dystrophy. In a randomized, double-blind comparison of amlodipine (10 mg/day) and enalapril (20 mg/day) in 50 patients for 6 months, both drugs significantly reduced blood pressure, but amlodipine increased heart rate and plasma concentrations of noradrenaline and angiotensin II (7). These undesired effects make ACE inhibitors a better choice for prevention of cardiac dysfunction.

Organs and Systems

Nervous system

- A 35-year-old woman with benign intracranial hypertension and high blood pressure was given amlodipine, with good control of her blood pressure (8). However, her headache worsened and she developed papilledema. The CSF pressure was 30 cm. Her symptoms disappeared shortly after amlodipine withdrawal.

Liver

Hepatitis has been attributed to amlodipine.

- A 77-year-old man took amlodipine for 1 month and developed jaundice and raised aspartate transaminase, alanine transaminase, and bilirubin (9). A liver biopsy suggested a drug-induced hepatitis and the amlodipine was withdrawn. His symptoms and laboratory values normalized. Other drugs (metformin, fluindione, and omeprazole) were not withdrawn.
- A 69-year-old hypertensive man who had taken amlodipine for 10 months abruptly developed jaundice, choluria, raised serum bilirubin, and increased transaminases (10). After amlodipine withdrawal he progressively recovered in a few weeks without sequelae or relapses. However, after several months he presented again with jaundice and an enlarged liver, having started to take diltiazem 5 months before. He recovered completely in a few weeks after drug withdrawal.

In the second case the authors hypothesized an idiosyncratic mechanism.

Skin

Recognized skin eruptions associated with amlodipine include erythematous and maculopapular rashes, skin discoloration, urticaria, dryness, alopecia, dermatitis, erythema multiforme, and lichen planus. A granuloma annulare-like eruption has been reported (11).

- A 64-year-old Caucasian woman, with a history of ankylosing spondylitis, hypertension, and osteoporosis, took amlodipine for 13 days and developed a rash on her lower legs. Amlodipine was withdrawn, but the rash progressed to involve both of her hands. The eruption consisted of multiple erythematous pruritic papules. Histology showed focal collagen degeneration and a significant interstitial histiocytic dermal infiltrate, suggestive of granuloma annulare. Within 3 months of withdrawal of amlodipine the reaction cleared and did not recur during follow-up for 3 years.

Amlodipine can cause generalized pruritus, which usually happens within 24 hours and resolves within 24 hours of withdrawal (12).

© 2006 Elsevier B.V. All rights reserved.

Photosensitivity presenting with telangiectasia can be caused by calcium channel blockers.

- A 57-year-old hypertensive man developed telangiectasia, initially on the forehead and rapidly extending to the upper back, shoulders, and chest, particularly during the summer (13). The eruption began 1 month after starting amlodipine and diminished considerably 3 months after withdrawal.
- A 3-year-old girl developed telangiectases on the cheeks and gingival hyperplasia while taking furosemide, captopril, and amlodipine for hypertension due to hemolytic–uremic syndrome (14). Both lesions disappeared on withdrawal of amlodipine.

Calcium channel blockers can cause lichen planus.

- A 56-year-old Nigerian woman, with a previous history of sickle cell trait, osteoarthritis, and non-insulin-dependent diabetes mellitus, took amlodipine 5 mg/day for hypertension for 2 weeks and developed a lichenoid eruption (15). Histological examination confirmed the diagnosis of lichen planus. Amlodipine was withdrawn and there was rapid symptomatic and clinical improvement after treatment with glucocorticoids and antihistamines.

Musculoskeletal

A patient presented with severe, generalized muscle stiffness, joint pain, and fatigue while taking amlodipine for hypertension and zafirlukast for asthma. Stopping zafirlukast did not change her symptoms; the dose of amlodipine was increased at different times up to 15 mg to control blood pressure better. The neurological symptoms worsened, in the absence of any evidence of immunological or neurological disorders, and so amlodipine was withdrawn: the symptoms disappeared within 4 days (16).

Second-Generation Effects

Pregnancy

Subcutaneous fat necrosis in a neonate has been attributed to maternal use of amlodipine during pregnancy (17).

- A boy weighing 4 kg was born by spontaneous normal delivery at 39 weeks to a 38-year-old Afro-Caribbean woman, whose pregnancy was complicated by essential hypertension treated with amlodipine. On day 1 the child developed firm, red, pea-sized nodular lesions on the face, buttocks, back, shoulders, and arms.

Subcutaneous fat necrosis of the newborn is relatively uncommon. It is said to be benign and painless and to resolve within a few weeks. However, in this case it was extremely painful and was relieved only by opiates. The skin changes persisted beyond the age of 6 months and remained extremely symptomatic until the age of 9 months, when the skin had become normal. Calcium abnormalities have often been reported in association with subcutaneous fat necrosis, and exposure to amlodipine during pregnancy may have resulted in impairment of enzyme systems dependent on calcium fluxes for their action; it may also have affected calcium homeostasis in the neonate. Since previous reports of teratogenicity in animals have been published, few women take calcium channel blockers during pregnancy and there are no reports to date of an association between these drugs and subcutaneous fat necrosis (17).

Drug Administration

Drug overdose

Amlodipine overdose has been reported (18).

- A 23-year-old woman took 60 tablets of amlodipine intentionally and developed tachycardia and severe hypotension. She did not improve with intensive therapy and developed left ventricular failure and oliguria and underwent hemodiafiltration. Her condition slowly improved over 4 days.

Drug–Drug Interactions

Chloroquine

A possible interaction of amlodipine with chloroquine has been reported (19).

- A 48-year-old hypertensive physician, who had optimal blood pressure control after taking oral amlodipine 5 mg/day for 3 months, developed a slight frontal headache and fever, thought that he had malaria, and took four tablets of chloroquine sulfate (total 600 mg base). Two hours later he became nauseated and dizzy and collapsed; his systolic blood pressure was 80 mmHg and his diastolic pressure was unrecordable, suggesting vasovagal syncope, which was corrected by dextrose–saline infusion.

There was no malaria parasitemia in this case, and hence the syncope may have resulted from the acute synergistic hypotensive, venodilator, and cardiac effects of chloroquine plus amlodipine, possibly acting via augmented nitric oxide production and calcium channel blockade. Since malaria fever is itself associated with orthostatic hypotension, this possible interaction may be unrecognized and unreported in these patients.

Ciclosporin

Ciclosporin increases the survival of allografts in man. However, it causes renal vasoconstriction and increases proximal tubular reabsorption, leading in some cases to hypertension (20). The concomitant use of calcium channel blockers can prevent most of these adverse effects of ciclosporin. However, some calcium channel blockers (verapamil, diltiazem, nicardipine) can increase plasma concentrations of ciclosporin up to three-fold through inhibition of cytochrome P450. Eight different studies have been performed on the combination of amlodipine and ciclosporin given for 1–6 months to kidney transplant recipients, and the results have been reviewed (21). In three studies, in a total of 41 patients, amlodipine increased ciclosporin concentrations, while in the others, a total of 85 patients, there was no evidence of an interaction.

In normotensive renal transplant recipients treated for 2 months with amlodipine there was a small but significant nephroprotective effect (22). Thus, amlodipine, in contrast to other calcium channel blockers, does not affect ciclosporin blood concentrations and can be safely added in transplant recipients.

© 2006 Elsevier B.V. All rights reserved.

Sildenafil

The effect of sildenafil on arterial pressure has been tested in 16 hypertensive men taking amlodipine 5–10 mg/day (23). Sildenafil did not affect amlodipine pharmacokinetics, but caused a further additive fall in blood pressure. Adverse events with the combination of sildenafil and amlodipine, headache, dyspepsia, and nausea, did not require drug withdrawal.

Ammonium chloride

General Information

Ammonium chloride, which is used as an expectorant in productive cough, can cause gastric irritation, acidosis, and hypokalemia in large doses (1).

Reference

Ammonium tetrathiomolybdate

General Information

Ammonium tetrathiomolybdate can be used as a chelator of copper in Wilson's disease.

Organs and Systems

Hematologic

Several reports suggest that ammonium tetrathiomolybdate can cause reversible hypoplastic anemia (1,2).

Amocarzine

General Information

Amocarzine is an antifilarial antihelminthic drug, derived from amoscanate, that is active against the adult worms of *Onchocerca volvulus*.

Although ivermectin is very effective in the treatment of onchocerciasis, a fully effective and safe macrofilaricidal drug is still lacking. In animal studies of filarial infections, amocarzine showed promise as a macrofilaricidal drug and was afterward extensively tried in humans. Promising results were obtained in the early 1990s in Ecuador with amocarzine 3 mg/kg bd for 3 days and with acceptable adverse effects, including dizziness, itching, and rash. There were reversible neurological symptoms, such as impaired coordination and a positive Romberg's sign, in 4–12% of patients (1). Amocarzine was later tried in Africa in higher doses, with less good results. In a study from Ghana (2), the combination of ivermectin and amocarzine was not more effective than ivermectin alone. Adverse effects were more severe with amocarzine alone compared with ivermectin alone or with amocarzine preceded by ivermectin. Mazzotti-type reactions, such as itching, rash, peripheral sensory phenomena, and swellings, were all more severe or frequent after amocarzine than after ivermectin. Pretreatment with ivermectin markedly reduced these adverse reactions but did not affect other symptoms, such as dizziness and gaze-evoked nystagmus, suggesting that these adverse effects were probably directly drug-related and not a reaction to dying worms.

Amodiaquine

General Information

Amodiaquine is a Mannich base derivative related to chloroquine. While it is generally considered equivalent to chloroquine, more recent studies have shown that amodiaquine is superior to chloroquine in tackling resistant strains of *Plasmodium falciparum*, although there may be cross-resistance to chloroquine (SEDA-20, 260).

Compared with chloroquine, amodiaquine was more effective and better tolerated in outpatients with uncomplicated malaria tropica in Kenya (SEDA-20, 260).

Because of its adverse effects, amodiaquine is no longer in use in the countries of the European Union or the USA, and was dropped from malaria control programs by the WHO in 1990 (SEDA-20, 260). However, it remains in use in other areas, including Africa and Oceania (SEDA-18, 287).

Organs and Systems

Cardiovascular

Prolongation of the QT interval is a recognized effect of 4-aminoquinolines. In 20 adult Cameroonian patients with non-severe falciparum malaria treated with amodiaquine (total dose 30 mg/kg or 35 mg/kg over 3 days) there was asymptomatic sinus bradycardia ($n = 16$) and prolongation of the PQ, QRS, and QT intervals at the time of maximum cumulative concentration of drug (day 2 of treatment) (1).

Sensory systems

Corneal and conjunctival changes, which included intralysosomal membranous and amorphous inclusions in the epithelial cells, as well as abnormal retinal test responses, were reported in a man who took amodiaquine for 1 year. Follow-up over the years after withdrawal showed a reduction in the abnormalities. There are no data on possible retinal changes similar to those seen with chloroquine.

In 69 children given 35 mg/kg over 3 days (SEDA-16, 306), parasitemia was cleared in all but one case. Tolerance was good, except that there was a fairly high incidence of conjunctival hyperemia.

Hematologic

The principal reason against recommending amodiaquine for malaria prophylaxis is the reporting of agranulocytosis, occasionally associated with hepatitis (SEDA-12, 241) (SED-12, 692). Since specific IgG antibodies, which lead to leukopenia, can be detected, all this suggests that the agranulocytosis is immune-mediated.

It takes substantial doses for a couple of weeks to cause the adverse hematological effects (SEDA-16, 692) (SEDA-17, 327). If this is correct, amodiaquine could still be of use for short intensive courses of treatment in areas of chloroquine resistance.

Gastrointestinal

Gastrointestinal complaints (nausea, vomiting, diarrhea, or constipation) are not uncommon with amodiaquine (SEDA-11, 587).

Skin

Abnormal pigmentation of the palate, nail beds, and the skin of the face and neck has been reported. The duration of such pigmentation after withdrawal is unknown. The effects on the nails resemble those seen with chloroquine (SEDA-12, 692) (SEDA-12, 241).

Nails

Abnormal pigmentation of nail beds has been reported. The duration of such pigmentation after withdrawal is unknown. The effects on the nails resemble those seen with chloroquine (SEDA-12, 692) (SEDA-12, 241).

Amopyroquine

General Information

Amopyroquine is a 4-aminoquinoline, structurally related to amodiaquine. It is not a new compound, but it is of renewed interest as a result of the extensive occurrence of resistance to chloroquine and the adverse effects of prophylactic amodiaquine. In a study in 152 patients with malaria, the efficacy of a 12 mg/kg, given as two intramuscular injections of 6 mg/kg 24 hours apart, was described as good (1). All the patients became apyrexial and there was clearance of parasites on day 7 in 143 cases; the nine who retained a low level of parasitemia were all children. In 50% of the cases, the parasite had been chloroquine-resistant. The drug was well tolerated, and there were no major adverse effects.

Amoxapine

See also Tricyclic antidepressants

General Information

In a major review of amoxapine and its pharmacology it was concluded that it is similar in efficacy and potency to standard tricyclic compounds, with a sedative action intermediate between amitriptyline and imipramine (1).

As previously noted (SEDA-4, 21) (SEDA-5, 17), amoxapine has a tricyclic nucleus with a modified piperazine side chain and is closely related to the neuroleptic drug loxapine. In animals, amoxapine has no antiserotonergic properties and less anticholinergic activity than prototype drugs. Peak plasma concentrations are achieved in less than 2 hours, and the half-lives of the parent drug and its two active metabolites are 8, 6, and 30 hours respectively.

Overall, amoxapine appears to have some advantage over other tricyclic antidepressants: possible earlier onset of action and relative freedom from serious cardiotoxic effects. Its major drawbacks are the potential for neuroleptic adverse effects, a high incidence of seizures, deaths in overdose (2), and the possibility of long-term neurological damage.

Amoxapine is less potent than other tricyclic antidepressants, with a therapeutic dosage range of 75–600 mg/day (usually 200–400 mg/day). Clinical effects have not been consistently correlated with plasma concentrations, but amoxapine has similar efficacy to other tricyclic antidepressants in heterogeneous populations of depressed patients. Controlled comparisons have shown that its clinical profile is very similar to that of imipramine (3) and that it is somewhat less sedative than amitriptyline (4–6). In two of these studies (4,6) the results confirmed the suggestion of a somewhat earlier onset of action.

Amoxapine appears to have the same common adverse effects as other tricyclic compounds, including those attributable to anticholinergic activity. Its structural similarity to the classic neuroleptic drugs appears to confer an additional hazard of adverse effects usually found in that category of drugs, such as galactorrhea and extrapyramidal disorders (SEDA-9, 20). In a study of its potential neuroleptic properties (7), using a radioreceptor assay in vivo and using plasma drawn from patients taking neuroleptic drugs or antidepressants, amoxapine and its metabolite, 7-hydroxyamoxapine, had potent neuroleptic activity. In patients taking amoxapine, there was neuroleptic activity comparable to that in patients taking loxapine, while none of the other tricyclic antidepressants (amitriptyline, nortriptyline, imipramine, and desipramine) had this property. Further reports of adverse effects attributable to its neuroleptic profile continue to appear, including tardive dyskinesia (8,9), acute torticollis (10), and malignant neuroleptic syndrome (SEDA-16, 9) (SEDA-17, 18) (11).

Organs and Systems

Metabolism

A further reminder of the structural resemblance of amoxapine to the neuroleptic drugs has been provided by an adverse effect reported with both amoxapine and its close congener, loxapine (12).

- A 49-year-old woman with no history of diabetes was admitted in unexplained hyperglycemic coma (blood glucose 26 mmol/l) while taking lithium 1500 mg/day and loxapine 150 mg/day. She responded to insulin, but insulin responses on testing were not delayed and suggested an iatrogenic rather than a diabetic cause. The fasting glucose fell to 4.2 mmol/l after withdrawal of loxapine but continuing lithium. Two weeks later amoxapine 150 mg/day was started and she became

© 2006 Elsevier B.V. All rights reserved.

acutely confused, with a serum glucose of 5.7 mmol/l. Two weeks after stopping amoxapine the serum glucose returned to normal.

The authors speculated that a common metabolite of both drugs, 7-hydroxyamoxapine, was responsible for the hyperglycemia, owing to its antidopaminergic properties.

Drug Administration

Drug overdose

A bleak picture has rapidly evolved for amoxapine with regard to its toxicity in overdosage. Over 18 months, 33 cases were reported from Washington, DC, and New Mexico Poison Centers (2). These cases included 5 patients who died and 12 who developed seizures. Thus, the mortality rate of 15% greatly exceeds that of 0.7% for other antidepressants in the same centers, and the seizure rate is 36% compared to 4.3%. The authors noted that "the striking CNS toxicity of amoxapine overdose with frequent, persistent, and poorly controlled seizure activity is disconcerting." In a retrospective comparison of deaths from antidepressant overdosage in Scotland, England, and Wales between 1987 and 1992, the number of deaths per million prescriptions of amoxapine was significantly higher than expected (13).

Renal damage has occurred in cases of amoxapine overdose.

- Acute renal insufficiency and rhabdomyolysis were reported in a 27-year-old man who took 1–2 g of amoxapine (14). The authors recommended aggressive volume expansion and diuresis with loop diuretics, because of the futility of hemodialysis.
- A 24-year-old man took 4 g of amoxapine and developed gross hematuria and a high serum uric acid concentration on the second day of hospitalization (15). As in previously reported cases, serum creatine phosphokinase was grossly raised. The patient remained obtunded and stuporose for 7 days but eventually recovered.

Amphetamines

See also Individual agents

General Information

Note on spelling

In International Non-proprietary Names the digraph -ph- is usually replaced by -f-, although usage is not consistent, and -ph- is used at the beginnings of some drug names (for example, compare fenfluramine and phentermine) or when a name that beings with a ph- is modified by a prefix (for example, chlorphentermine). For the amphetamines we have used the following spellings: amfetamine, benzfetamine, dexamfetamine, metamfetamine (methylamphetamine), and methylenedioxymetamfetamine (ecstasy).

Pharmacology and general adverse effects

Amfetamine is a sympathomimetic compound derived from phenylethylamine. However, the word amphetamines has become generic for the entire group of related substances, including benzfetamine, dexamfetamine, metamfetamine, and methylenedioxymetamfetamine (MDMA, ecstasy). Metamfetamine, a popular drug of abuse, is also known as "speed," "meth," "chalk," "crank," "ice," "crystal," or "glass." Other amfetamine-like drugs include fenfluramine (used as an appetite suppressant) and methylphenidate (used in narcolepsy and attention deficit hyperactivity disorder (ADHD)). When it was first introduced, one of the most frequent uses of amfetamine was as an anorexigenic agent in the treatment of obesity. A number of anorectic agents, many of them related to amfetamine, have since been manufactured. Most are stimulants of the central nervous system; in descending order of approximate stimulatory potency, they are

© 2006 Elsevier B.V. All rights reserved.

dexamfetamine, phentermine, chlorphentermine, mazindol, amfepramone (diethylpropion), and fenfluramine.

The amfetamine epidemic of the 1960s and early 1970s has now been superseded by cocaine abuse in the USA and many other Western countries. Realization of the risk of abuse and of dependence has led to the present attitude that there may be only a restricted place for amphetamines in medicine. Perhaps low-dose, short-term use in combating fatigue and altering depressed mood could be justified, but only for specific indications and under continuous medical supervision. However, in the USA there has been a resurgence of metamfetamine abuse on the West coast and in the Southwest and Midwest. This geographical distribution is thought to reflect the traffic from Mexico of ephedrine, a precursor for the synthesis of metamfetamine in the quick-bake method. Because primitive labs can be established in trailers, the spread to adjacent locals has been very rapid, resulting in escalation of migrating epidemics.

Adverse effects of "catecholaminergic stimulants," such as amfetamine and cocaine, fall into several categories, based on dose, time after dose, chronicity of use, and pattern of use/abuse (for example 4–5 day bingeing episodes). Adverse effects include not only responses during the period of use but also intermediate and long-term residual effects after withdrawal. For example, in some abusers once an amfetamine psychosis has developed with chronic abuse, only one or two moderate doses are required to induce the full-blown psychosis in its original form, even long after withdrawal (1). This is also evidenced by the precipitous slide to severe re-addiction in former abusers who are re-introduced to stimulants.

Even with therapeutic use of stimulants, usually in moderate doses, careful monitoring for emergent psychosis, agitation, and abuse is important. Periodic checks for monodelusional syndromes are important with doses in the mid-to-high range (2).

The use of amfetamine-type stimulants for depression, fatigue, and psychasthenia has fallen into disfavor since the early 1970s, because of the potential for abuse and the low rates of success, especially after tolerance is established. However, there have been reports and reviews of successes in carefully selected groups of patients (3–5). The underlying symptoms of patients who respond to stimulants are mild anhedonia, lack of mental and physical energy, easy fatiguability, and low self-esteem, but in the absence of the marked depressed mood disturbance, guilt, and hopelessness that are associated with major depression. Examples include patients with dysthymic disorders, medically ill patients (especially after a stroke), depressed patients, hospitalized cancer patients, and patients with significant cardiovascular disorders, all of whom can have anergia and easy fatiguability. HIV-related neuropsychiatric symptoms, including depression, respond to psychostimulants (4–6). Withdrawn apathetic geriatric patients without major dementia have positive responses (7). General adverse effects, such as tachycardia and agitation, are relatively mild and all reverse on withdrawal (SEDA-17, 1). The combination of stimulants with monoamine oxidase inhibitors in treatment-resistant depressed patients has been reported (8). However, this use should be restricted to patients in whom there is careful monitoring by specialists, because of the potential for hypertensive crisis.

The relative reinforcing effects or abuse potential of these drugs is thought to be related to their potency in releasing dopamine from nerve terminals, compared with serotonin release. Amfetamine, metamfetamine, and phenmetrazine are potent dopamine releasers with high euphoriant and stimulant properties, whereas the compounds with halide substitution in the phenol ring, for example chlorphentermine, are more potent releasers of serotonin and have greater sedative action in anorectic doses. Thus, in summary, those drugs with relatively strong serotonergic to dopaminergic releasing properties seem to provide anorectic effects without euphoria, except at high doses, and might be considered first in any patient who has potential for abuse (2,9,10).

In a study of extended treatment (15 months) of ADHD, amfetamine was clearly superior to placebo in reducing inattention, hyperactivity, and other disruptive behavioral problems. The treatment failure rate was considerably lower and the time to treatment failure was longer in the treated group; adverse effects were few and relatively mild (11).

There is an association between the illicit use of metamfetamine and traumatic accidents. A retrospective review of trauma patients in California showed that metamfetamine rates doubled between 1989 and 1994, while cocaine showed a minimal increase and alcohol a fall. Metamfetamine-positive patients were most likely to be Caucasian or Hispanic and were most commonly injured in motor vehicle collisions. The authors recommended intervention strategies, similar to those used for preventing alcohol consumption and driving, in order to minimize morbidity and mortality (12).

Traumatic shock can be complicated by metamfetamine intoxication (13). Identifying the cause of shock is a key step in the management of patients with severe injuries. This is a challenge, because shock is occasionally caused by more than one mechanism; among the many causes, metabolic derangement attributable to drug abuse should be considered, and masked metabolic acidosis may be a clue to metamfetamine intoxication (14). With the increased emergence of metamfetamine abuse, clinicians should consider it in the differential diagnosis of any patient exhibiting violence, psychosis, seizures, or cardiovascular abnormalities.

Organs and Systems

Cardiovascular

Tachycardia, dysrhythmias, and a rise in blood pressure have been described after the administration of centrally acting sympathomimetic amines. Amfetamine acutely administered to men with a history of amfetamine abuse enhanced the pressor effects of tyramine and noradrenaline, while continuous amfetamine led to tolerance of the pressor response to tyramine. As with intravenous amphetamines, cardiomyopathy, cardiomegaly, and pulmonary edema have been reported with smoking of crystal metamfetamine (15–17).

The cardiovascular response to an oral dose of *d*-amfetamine 0.5 mg/kg has been determined in 81 subjects with schizophrenia, 8 healthy controls who took amfetamine, and 7 subjects with schizophrenia

© 2006 Elsevier B.V. All rights reserved.

who took a placebo (18). Blood pressure increased in both amphetamine groups, whereas placebo had no effect. However, pulse rate did not change in the schizophrenic group and only increased after 3 hours in the controls. Intramuscular haloperidol 5 mg produced a more rapid fall in systolic blood pressure in six subjects, compared with 12 subjects who did not receive haloperidol. The authors concluded that increased blood pressure due to amfetamine may have a dopaminergic component. They also suggested that haloperidol may be beneficial in the treatment of hypertensive crises caused by high doses of amfetamine or metamfetamine.

Two cases of myocardial infarction after the use of amfetamine have been reported (19,20).

- A 34-year-old man who smoked a pack of cigarettes a day took amfetamine for mild obesity. He developed an acute myocardial infarction 1 week later. Echocardiography showed inferior left ventricular hypokinesia and a left ventricular ejection fraction of 50%. Coronary cineangiography showed normal coronary arteries but confirmed the inferior left ventricular hypokinesia. Blood and urine toxicology were positive only for amfetamine.
- A 31-year-old man developed generalized discomfort after injecting four doses of amfetamine and metamfetamine over 48 hours, but no chest pain or tightness or shortness of breath. Electrocardiography showed inverted T-waves and left bundle branch block. Echocardiography showed reduced anterior wall motion.

The authors reviewed other reported cases of myocardial infarction associated with amphetamines. The patients were in their mid-thirties and most were men. The interval from the use of amphetamines to the onset of symptoms varied from a few minutes to years. No specific myocardial site was implicated. Coronary angiography in most cases showed non-occlusion. The cause of myocardial ischemia in these cases was uncertain, even though coronary artery spasm followed by thrombus formation was considered the most likely underlying mechanism. Some have suggested that electrocardiographic and biochemical cardiac marker testing should be considered in every patient, with or without symptoms suggesting acute coronary syndrome, after the use of amphetamines. Others have suggested that calcium channel blockers may play an important role in the treatment of myocardial infarction due to amfetamine use or abuse. In one patient, administration of beta-blockers caused anginal pain, suggesting that they should be avoided. All the patients except one had a good outcome.

Vertebral artery dissection has been described in a previously healthy man with a 3-year history of daily oral amfetamine abuse (21).

- A healthy 40-year-old right-handed man presented with a 3-day history of an occipital headache and imbalance. He had a 3-year history of daily oral amfetamine abuse with escalating quantities, the last occasion being 12 hours before the onset of the symptoms. He had a history of "speed" abuse and a 20-pack-year history of tobacco use. He had mild right arm dysmetria without ataxia. His brain CT scan without contrast was normal. He then developed nausea, vomiting, visual loss, and progressive obtundation. He had hypertension (160/90 mmHg), bilateral complete visual loss, right lower facial weakness, mild dysarthria without tongue deviation, divergent gaze attenuated by arousal, bilateral truncal and appendicular dysmetria with inability to stand and walk, and generalized symmetrical hyperreflexia with extensor plantar reflexes. His urine screen was positive for metamfetamine. A brain MRI scan showed infarction of both medial temporal lobes, the left posteromedial thalamus, and the right superior and left inferior cerebellum. Magnetic resonance angiography and fat saturation MRI showed reduced flow in the left vertebral artery and a ring of increased signal within its lumen, consistent with hematoma and dissection. He was treated with anticoagulants and made a partial recovery.

Since this patient had no known risk factors for vertebral artery dissection and had abused amfetamine daily for 3 years with escalating amounts, an association between metamfetamine and vertebral artery dissection cannot be excluded. The local and systemic vascular impacts of amfetamine could have contributed to initial changes (along with smoking), resulting in dissection.

Of the other central stimulants, aminorex, doxapram, fenfluramine, and fenfluramine plus phentermine can cause chronic pulmonary hypertension, as can chlorphentermine, phentermine, phenmetrazine, and D-norpseudoephedrine (SED-9, 8). A genetic predisposition may be involved (SED-9, 8). Pulmonary hypertension may develop or be diagnosed a long time after the drug has been withdrawn.

Nervous system

Metamfetamine toxicity in infants can mimic scorpion (*Centruroides sculpturatus*) envenomation (22,23). However, the neurotoxic effect of envenomation can be distinguished from amfetamine-induced toxicity by the presence of cholinergic stimulation in scorpion envenomation, producing hypersalivation, bronchospasm, fasciculation of the tongue, purposeless motor agitation, involuntary and conjugate slow and roving eye movements, and often extraocular muscle dysfunction (24). Failure of the antivenin would bring scorpion neurotoxicity into great question (25).

Concentrations of metamfetamine and its metabolite amfetamine were measured in autopsied brain regions of 14 human metamfetamine abusers (26). There was no evidence of variation in the regional distribution of amphetamines in the brain. Post-mortem redistribution of metamfetamine in the heart and lung has been reported before, although peripheral blood concentrations appear to remain constant (27,28).

Stereotyped behavior

A type of automatic behavior, which can continue for hours, has been observed in addicts who inject large doses of central nervous system stimulants. Dyskinesias can occur, with strange facial and tongue movements or jerky motions of the arms and legs and a never-ending repetition of certain actions. Such stereotyped activity is induced in laboratory animals with high doses of amfetamine.

Amphetamines and brain damage

The question of whether amphetamines in large doses can cause permanent brain damage has repeatedly been raised by animal studies (29,30), but definitive studies in man have not been performed. Vasculitis of large elastic vessels, found in chronic animal studies, has been reported to involve the internal carotid artery in man (31); intravenous administration is secondarily implicated. In man and animals, behavioral changes continue for several months after withdrawal of amphetamines; chronic residual changes have been reported mainly in monoaminergic neurons or terminals, either as structural changes or as residual depletion of monoamines and synthesizing enzymes (32). In post-mortem studies (33,34) chronic metamfetamine abusers had significantly lower concentrations of dopamine, tyrosine hydroxylase, and dopamine transporters in the caudate and putamen. It has been suggested that the reduced dopamine concentrations (up to 50% of control), even if not indicative of neurotoxicity, are consistent with amotivational changes reported by metamfetamine abusers after withdrawal (33).

Metamfetamine-induced neurotoxicity in animals, especially involving effects on the mitochondrial membrane potential and electron transport chain and subsequent apoptotic cascade, has been comprehensively reviewed (35). Metamfetamine increases the activity of dopamine, mainly by inhibiting the dopamine transporter. However, this does not explain why psychosis persists even when the metamfetamine is no longer present in the body (36). Chronic metamfetamine use has been reported to reduce dopamine transporter density in the caudate/putamen and nucleus accumbens. However, previous studies have been criticized for not controlling for other drug use.

Dopamine transporter density in the brain has been investigated during a period of abstinence in 11 metamfetamine monodrug users and nine healthy subjects, all men (37). The dopamine transporter density of metamfetamine users was significantly lower in the caudate/putamen, nucleus accumbens, and prefrontal cortex than in the controls. The severity of psychiatric symptoms correlated with the duration of metamfetamine use. The reduction in dopamine transporter density in the caudate/putamen and nucleus accumbens was significantly associated with the duration of metamfetamine use and closely related to the severity of persistent psychiatric symptoms. The reduction in dopamine transporters may be long lasting, even if metamfetamine is withdrawn.

Only some metamfetamine users develop psychosis, not all (36). In laboratory animals, metamfetamine is toxic to dopamine terminals. In 15 subjects (six men and nine women, mean age 32 years), who met the criteria for metamfetamine abuse, and 18 healthy volunteers (12 men and six women), there was a significant reduction in the number of dopamine transporters in detoxified metamfetamine abusers compared with controls (mean values of 28% in the caudate and 21% in the putamen) (38). This was associated with poor motor and memory performance. The reductions in dopamine transporters in the metamfetamine abusers were smaller than those found in patients with Parkinson's disease and occurred in subjects who had been abstinent for 11 months. Since significant reductions in dopamine transporters occur with both age and metamfetamine use, it is possible that metamfetamine will be associated with a higher risk of parkinsonian symptoms in abusers later in life.

Glucose metabolism in the brain has been studied using positron emission tomography after administration of ^{18}F-fluorodeoxyglucose, to look for evidence of functional changes in regions other than those innervated by dopamine neurons in 15 detoxified metamfetamine abusers and 21 controls (39). Whole-brain metabolism in the metamfetamine abusers was 14% higher than in the controls. The difference was largest in the parietal cortex (20%), but there was significantly lower metabolism in the thalamus (17%) and striatum (12% caudate and 6% putamen). The authors suggested that metamfetamine, in doses abused by humans, causes long-lasting metabolic changes in brain regions connected with dopamine pathways, but also in areas that are not innervated by dopamine.

The effects of protracted abstinence on loss of dopamine transporters in the striatum in five metamfetamine abusers have been evaluated during short-term abstinence and then retested during protracted abstinence (12–17 months) (40). The dopamine transporters increased in number, providing hope for effective treatment; however, this regeneration was not sufficient to provide complete functional recovery, as measured by neuropsychological tests.

Chronic amfetamine abusers, chronic opiate abusers, and patients with focal lesions of the orbital prefrontal cortex or dorsal lateral/medial prefrontal cortex were subjected to a computerized decision-making task, in order to compare their capacity for making decisions (41). Chronic amfetamine abusers made suboptimal decisions (correlated with years of abuse) and deliberated significantly longer before making their choices. The opiate abusers had only the second of these behavioral changes. Both the suboptimal choices and the increased deliberation times were also evident in patients with damage to the orbital frontal prefrontal cortex but not other areas. These data are consistent with the hypothesis that chronic amfetamine abusers have similar decision-making deficits to those seen after focal damage to the orbital frontal prefrontal cortex.

The use of proton magnetic resonance scanning (^{1}H MRS) in detecting long-term cerebral metabolite abnormalities in abstinent metamfetamine users has been studied in 26 subjects (13 men) with a history of metamfetamine dependence (mean age 33 years) and 24 healthy subjects with no history of drug dependence (42). The neuronal marker *N*-acetylaspartate was reduced by 6% in the frontal white matter and by 5% in the basal ganglia of the abstinent metamfetamine users. *N*-acetylaspartate is a marker for mature neurons, and reduced *N*-acetylaspartate is thought to indicate reduced neuronal density or neuronal content. According to the authors, these findings suggest neuronal loss or persistent neuronal damage in the absence of significant brain atrophy in metamfetamine users. They speculated that these abnormalities may underlie the persistent abnormal forms of behavior, such as violence, psychosis, and personality changes, seen in some individuals months or even years after their last drug use. Metamfetamine users in the study also had increased concentrations of choline-containing

© 2006 Elsevier B.V. All rights reserved.

compounds and myoinositol in the frontal gray matter. Myoinositol is a glial cell marker, while the increase in choline-containing compounds reflects increased cell membrane turnover. Thus, these increases in the frontal cortex in drug users may have reflected glial proliferation (astrocytosis). The authors suggested that the finding of reduced *N*-acetylaspartate accompanied by increased myoinositol, which has been observed in many active brain disorders, indicated glial proliferation in response to neuronal injury. However, they noted that neurotoxicity may not be present in subjects who use amounts of the drugs that are much lower than the amounts used by the chronic abusers they studied. They suggested that future studies should observe whether treatments or long periods of abstinence could reverse these abnormalities.

These findings have given further support to an earlier observation of long-term neurotoxicity associated with MDMA (ecstasy) in animals (SEDA-14, 3). However, it is uncertain whether the reported abnormalities suggestive of neuronal damage are reversible despite continued treatment or beyond 21 months of abstinence.

Dyskinesias

Although controversial, there is a growing consensus that stimulants can provoke, cause, or exacerbate Gilles de la Tourette's syndrome (SEDA-7, 10), based on the observation that stimulants such as the amphetamines, methylphenidate, and pemoline facilitate dopamine retention in the synaptic cleft. There is much evidence that in children with ADHD vulnerable to Tourette's syndrome, stimulants exacerbate motor and phonic tics (43). These studies suggest that Tourette's syndrome and a family history of dyskinesias should be contraindications to stimulant use. However, there is virtually no evidence that stimulants in clinically appropriate doses provoke Tourette's syndrome, and it has been suggested that dyskinesias are a function of high doses (44). Nevertheless, patients taking stimulants should be carefully examined periodically for dyskinesias. It is not known whether structural changes in the central nervous system accompany stimulant-induced dyskinesias.

Stroke

Intracerebral hemorrhage associated with amfetamine has been reported for more than five decades. Eight cases were associated with amfetamine over a period of 3.5 years (45). All had undergone head CT scans and cerebral digital subtraction angiography. Seven had a parenchymal hematoma, three in the frontal lobe and one each in the parietal lobe, frontoparietal region, temporal lobe, and brain stem. One patient had a subarachnoid hemorrhage. The time from exposure to onset of symptoms ranged from less than 10 minutes to about 2 months (median 1 day). The authors reviewed the literature and found 37 other cases. They observed that young people, mean age 28 years, were at high risk. While most were repeat abusers, one-third claimed to be first time or infrequent users. Intracerebral hemorrhage was seen with all routes of drug use, 57% from oral use, 34% from intravenous use, and 5% after inhalation. Of those who had a CT scan, 84% had a proven intracerebral hemorrhage, three had a subarachnoid hemorrhage, and one had a brainstem hemorrhage. In one patient, with a negative CT scan, the diagnosis of subarachnoid hemorrhage was confirmed by lumbar puncture. In 35 patients who had angiography, 20 were normal or showed only mass effect from a hematoma, 16 had vasculitic beading, and 1 had an arteriovenous malformation. Seven patients died and only 14 had a good recovery.

- A previously healthy 16-year-old schoolboy had mesencephalic ischemia, most probably caused by vasospasm, after combined abuse of amfetamine and cocaine (46). There was a close temporal relation between intake of the drug and the onset of symptoms. Thus, combining these drugs, even in small amounts, may be harmful.

Psychological, psychiatric

Amphetamines release monoamines from the brain and thereby stimulate noradrenergic, serotonergic, and particularly dopaminergic receptors. Under certain circumstances this leads to psychosis and compulsive behavior, as well as auditory hallucinations similar to those experienced in paranoid schizophrenia. In addition, amphetamines cause an acute toxic psychosis with visual hallucinations, usually after one or two extremely large doses (47).

When an amfetamine is taken, even in a therapeutic dose, most people experience a sensation of enhanced energy or vitality, which, with repetitive administration, follows different patterns. Most often euphoria will develop, usually with a sense of heightened function or perception, and occasionally compulsive behavior as well as hallucinogenic delusions. Dysphoria occurs in some (especially older) individuals. The euphoric effect may enhance craving for amfetamine, and repeated reinforcement can lead to conditioned drug responses, which may facilitate dependence. Progression to severe dependence depends highly on individual vulnerability, the circumstances, the setting, the pattern of use, and especially escalation to high-dose patterns of use. Although most people probably use amphetamines for the original reason they were prescribed, and do not escalate the dosage, a significant proportion do, highlighting the abuse potential. The amphetamines are sometimes used recreationally for years in moderate doses. However, once inhalation and intravenous administration or higher doses are used, a "high-dose transition" into abuse usually occurs, and the capacity for low-dose occasional use is lost, presumably, forever (see the sections on Drug abuse and Drug dependence in this monograph).

Personality degeneration

In a double-blind, placebo-controlled, short-term study there was significant deterioration of personality in five of 26 children treated with dexamfetamine (48).

Phobias

Social phobia has been attributed to amfetamine (49).

- A 26-year-old woman reported flushing, sweating, palpitation, and shortness of breath, in a range of social situations. She was described as a confident and extroverted woman, with no history of psychiatric problems.

© 2006 Elsevier B.V. All rights reserved.

She reported daily oral consumption of street amfetamine 1.6 g. At the time of assessment, she had given up her work. Initially, she felt good while taking the drug, but more recently she had been using it to "get going"; there were no symptoms of psychosis or affective disorder.

The authors speculated that dopaminergic dysfunction, reported by some to underlie social phobia, could have resulted in this case from chronic amfetamine-related striatal dopamine depletion.

Psychoses

Psychotic reactions in people taking amphetamines were first reported many years ago and the question was posed whether it was due to the amphetamines or to co-existing and exacerbated paranoid schizophrenia. In one study, most of the psychotic symptoms remitted before the excretion of amines had fallen to its normal basal value (SED-9, 8). The psychotic syndrome was indistinguishable from paranoid schizophrenia, with short periods of disorientation, and could occur after a single dose (many had taken the equivalent of some 500 mg of amfetamine or metamfetamine orally) with or without simultaneous alcohol, and was most pronounced in addicts (SED-9, 9). Amfetamine psychosis was also seen in 14 people in Australia (1); the predominant hallucinations were visual, which is unusual for schizophrenia (SED-8, 11). Similarly, in contrast to schizophrenia, vision was the primary sensory mode in thinking disorders and body schema distortions in 25 amfetamine addicts (50).

In other studies, volunteers previously dependent on amphetamines were dosed to a level at which amfetamine psychosis was produced, in order to examine the mechanism of action and pharmacokinetics of amfetamine and its possible relation to schizophrenia (51,52). Psychosis was induced by moderately high doses of amfetamine and the psychotic symptoms were often a replication of the chronic amfetamine psychosis, raising the question of whether the establishment of chronic stimulant psychosis leaves residual vulnerability to psychosis precipitated by stimulants. The mechanism might be similar to that which operates in the reverse tolerance that has been seen in experimental animals (53). In some cases an underlying psychosis can be precipitated; an increase in schizophrenic symptoms (SED-8, 12) was observed in 17 actively ill schizophrenic patients after a single injection of amfetamine.

Amfetamine psychosis is relatively rare in children, even in hyperactive children taking large doses of amfetamine; amfetamine psychosis has been reported in an 8-year-old child with a hyperkinetic syndrome (SED-8, 12). Large doses of amfetamine can cause disruption of thinking, but amfetamine psychosis is not usually accompanied by the degree of disorganization normally seen in schizophrenia (SED-9, 8).

Increased sensitivity to stress may be related to spontaneous recurrence of metamfetamine psychosis, triggering flashbacks. Stressful experiences, together with metamfetamine use, induce sensitization to stress associated with noradrenergic hyperactivity, involving increased dopamine release (54,55). This hypothesis has been investigated by determining plasma noradrenaline metabolite concentrations in 26 flashbackers (patients with spontaneous recurrence of metamfetamine psychosis) (11 taking neuroleptic drugs before and during the study and 15 during the course of the study), 18 non-flashbackers with a history of metamfetamine psychosis, 8 with persistent metamfetamine psychosis, and 34 controls (23 metamfetamine users and 11 non-users). The 26 flashbackers had had stressful events and/or metamfetamine-induced, fear-related, psychotic symptoms during previous metamfetamine use. Mild psychosocial stressors then triggered flashbacks. During flashbacks, plasma noradrenaline concentrations increased markedly. Flashbackers with a history of stressful events, whether or not they had had fear-related symptoms, had a further increase in 3-methoxytyramine concentrations. Thus, robust noradrenergic hyperactivity, involving increased dopamine release in response to mild stress, may predispose to further episodes of flashbacks. The authors pointed out the limitations of their study: (a) plasma noradrenaline concentrations do not accurately reflect central monoamine neurotransmitter function; (b) raised noradrenaline concentrations may reflect heightened autonomic arousal secondary to stress or anxiety; (c) the neuroleptic drugs used may have altered the concentrations of noradrenaline and 3-methoxytyramine; and (d) the study was retrospective and carried out in women in prison.

A paranoid hallucinatory state similar to schizophrenia has been reported in women with a history of metamfetamine abuse in a study of flashbacks in 81 female inmates in Japan (56). Details of symptoms of initial metamfetamine psychosis, stressful experiences, and patterns of abuse were obtained. Plasma monoamine concentrations were also measured during flashback states and in control abusers who had never experienced them. The researchers reported that concreteness of abstract thought and impaired goal-directed thought characteristic of schizophrenia was not usually seen in metamfetamine-induced psychosis. Moreover, it was the use of metamfetamine and not a severe stressor that caused the initial psychotic state, but the flashbacks appeared to be due to mild environmental stressors. The authors described this pattern as "spontaneous psychosis due to previous metamfetamine psychosis." They also observed that plasma concentrations of noradrenaline were significantly higher in women with flashbacks both during flashbacks and during remissions. This suggests a possible role of noradrenergic hyperactivity in sensitivity to mild stress and susceptibility to flashbacks. Furthermore, these noradrenergic findings could be used to predict relapse to a paranoid hallucinatory state in schizophrenia.

Chlorpromazine has been used to treat amfetamine psychosis due to acute poisoning in children who did not respond to barbiturates (57).

Management

Reports have suggested that atypical antipsychotic drugs, such as risperidone (58–60) and olanzapine (61), can be effective in the treatment of acute and residual metamfetamine-induced psychosis. Moreover, adherence to olanzapine for about 8 weeks also effectively controlled cravings for metamfetamine. Rigorous controlled studies are needed to establish the therapeutic efficacy of atypical

antipsychotic drugs in the treatment of the psychosis and cravings of metamfetamine addiction.

- A 76-year-old woman, who had taken dexamfetamine since the age of 28 years for narcolepsy, developed an acute schizophreniform psychosis with paranoid delusions and auditory hallucinations. She was initially treated with sulpiride while continuing to take dexamfetamine. Five months later, sulpiride was withdrawn, and her psychotic symptoms recurred. She was given risperidone 3 mg/day and continued to take dexamfetamine 15 mg/day.
- A 24-year-old man, with a history of intravenous metamfetamine abuse since the age of 19 years, developed psychotic symptoms characterized by auditory hallucinations and persecutory delusions. He had no insight and was given haloperidol and levomepromazine. His symptoms disappeared after 4 months of treatment and he then stopped using metamfetamine. A year and a half later, "odd ideas" recurred, and he became anxious but had insight. He was treated with bromperidol 9 mg/day for 6 months, but the odd ideas persisted. On referral, he was found to fulfil the criteria for obsessive-compulsive disorder according to DSM-IV. No abused substances, including metamfetamine, were identified in his urine. Risperidone 2 mg/day was started and then increased to 5 mg/day. After 3 weeks, the intrusive thoughts and symptoms of "anxious-restless state" gradually subsided and eventually disappeared. His symptoms recurred within a week of stopping risperidone and resolved on reintroduction.

Metabolism

Amphetamines can cause retardation of growth (height and weight) in hyperactive children (SED-9, 9).

Hematologic

Acute myeloblastic leukemia occurred in a 24-year-old man who had taken massive doses of amfetamine for more than 2 years (SED-8, 13).

Mouth and teeth

Dental wear has been evaluated prospectively in metamfetamine users at an urban university hospital (62). Information was collected from 43 patients (26 men, 40 tobacco smokers), mean age 39 years, who admitted to having used metamfetamine for more than 1 year. Patients who regularly snorted metamfetamine had higher "tooth-wear" scores for anterior maxillary teeth than patients who injected, smoked, or ingested metamfetamine. The authors suggested that the anatomy of the blood supply to this area possibly explained the association of the regional differences in tooth wear with snorted metamfetamine. The anterior maxillary teeth and the nasal mucosa have a common blood supply. Thus, snorting may cause vasoconstriction, impairing the blood supply both to the nasal mucosa as well as the teeth.

Skin

The severe form of erythema multiforme known as toxic epidermal necrolysis has been attributed to a mixture of dexamfetamine and ephedrine (63).

- A 27-year-old woman developed peripheral target plaques, papules, blisters, and lip erosions, consistent with erythema multiforme, 9 days after using "speed" (dexamfetamine and ephedrine), and 3 days later developed widespread lesions with large areas of blistering affecting 40% of her body surface area. She was given intravenous ciclosporin and improved within 24 hours.

Musculoskeletal

There may be an association between metamfetamine abuse and rhabdomyolysis. In a retrospective review of 367 patients with rhabdomyolysis, 166 were positive for metamfetamine (64). They had higher mean initial and lower mean peak activities of creatine phosphokinase. There was no significant difference in the incidence of acute renal insufficiency. The authors suggested screening all patients with rhabdomyolysis of unclear cause for metamfetamine and measuring creatine phosphokinase activity.

Sexual function

Reports of the effects of amfetamine on sexual behavior refer variously to unchanged, reduced, mixed, and heightened sexual performance, but long-term abusers often have sexual dysfunction (SED-9, 9).

Immunologic

An anaphylactic reaction after the injection of crushed tablets equivalent to 45 mg of amfetamine occurred in a young woman; in others injected with the same solution and at the same time there were no adverse effects (SED-9, 8). The reaction may have involved amfetamine or excipients. Scleroderma is a potential consequence of various stimulants used for appetite control (65).

Infection risk

- A 34-year-old woman who had taken intranasal metamfetamine weekly for 15 years developed osteomyelitis of the frontal bone and a subperiosteal abscess. The authors proposed that this was due to chronic abuse of metamfetamine (66).

A rare case of Pott's puffy tumor, anterior extension of a frontal sinus infection that results in frontal bone osteomyelitis and subperiosteal abscess, has been associated with metamfetamine use (67).

- A 34-year-old woman presented with a 9-day history of fever, chills, photophobia, and neck pain. Nine months earlier, she had developed a swelling on her forehead, which enlarged and spontaneously drained pus. Over the next weeks, a fistula developed at the site of the swelling, accompanied by an intermittent bloody purulent drainage that lasted for about 9 months. She had either inhaled metamfetamine or had used it intranasally weekly for 15 years and reported continued use immediately before the development of the forehead lesion. She had a sinocutaneous fistula in the midline of the forehead, with seropurulent discharge but no local erythema or tenderness. A CT scan of the head showed complete opacification of all sinuses, with a 1 cm connection between the anterior frontal sinus and the skin. Cultures grew *Streptococcus milleri* and *Candida*

© 2006 Elsevier B.V. All rights reserved.

albicans. She responded to extensive medical and surgical treatment.

The authors proposed that intranasal metamfetamine had contributed to chronic sinus inflammation and subsequent complications. Furthermore, the vasoconstriction induced by metamfetamine in the mucosal vessels may have resulted in ischemic injury to the sinus mucosa, providing an environment conducive to bacterial growth.

Death

There has been a retrospective investigation of metamfetamine-related fatalities during a 5-year period (1994–1998) in Southern Osaka city in Japan (68). Among 646 autopsy cases, methamphetamine was detected in 15, most of whom were men in their late thirties. The cause and manner of death were methamphetamine poisoning ($n = 4$), homicide ($n = 4$), accidental falls and aspiration from drug abuse ($n = 4$), death in an accidental fire, myocardial infarction, and cerebral hemorrhage (one each). Blood metamfetamine concentrations were 23–170 μmol/l in fatal poisoning, 4.4–38 μmol/l in deaths from other extrinsic causes, and 14–22 μmol/l in cardiovascular and cerebrovascular accidents. The common complications were cardiomyopathy, cerebral perivasculitis, and liver cirrhosis/interstitial hepatitis. The general profile of patients reported in this series compares with that of a previous study from Taiwan (SEDA-24, 2).

Long-Term Effects

Drug abuse

The most important problem encountered with amphetamines is abuse and the development of dependence. The most rapid amfetamine epidemic occurred in Japan after World War II, where there had been little or no previous abuse (69). Although a high proportion of amfetamine users probably already have emotional and social difficulties, sustained abuse can result in serious psychiatric complications, ranging from severe personality disorders to chronic psychoses (70,71). Whereas signs of intense physical dependence are not thought to occur (SED-9, 9), withdrawal may be associated with intense depression (SED-9, 9) (72), and relapses in psychiatric disorders have often been noted. Some countries in which the problem became widespread banned amphetamines, and Australia restricted their use to narcolepsy and behavioral disorders in children. Amfetamine dependence developed into a serious problem in the USA (and to a lesser extent in the UK), where it followed the typical pattern of drug dependence (SED-9, 7, 10).

Continuing critical re-assessment of the usefulness versus the harmfulness of amphetamines has led to further restrictions in their use (SED-9, 10). They have been subjected to rigid legislative control in many countries, accompanied by recommendations that they should not be prescribed. The World Health Organization and the United Nations have also stressed the need for strict control of amphetamines (SED-9, 10) (73).

There is a high prevalence of the use of amfetamine-like drugs in Brazil, particularly among women, owing to the "culture of slimness as a symbol of beauty" (74). Of 2370 subjects in São Paulo and Brasilia, 72% had already undergone from one to more than 10 previous courses of treatment, usually with amfetamine-like anorectic drugs. Over half of them had taken amfetamine-like drugs in compound formulations containing four or more substances, such as benzodiazepines and/or laxatives, diuretics, and thyroid hormones. There were adverse reactions to the amfetamine-like drugs in 86% and 37% sought medical advice; 3.9% required hospitalization. The authors argued the need for more rigorous legislation and enforcement strategies to stop such misuse of drugs.

Further evidence concerning increased metamfetamine abuse has come from Taiwan (75). Between 1991 and 1996, of 3958 deaths with autopsies, 244 were related to metamfetamine (mean age 31 years, 73% men). The manner of death was natural (13%), accidental (59%), suicidal (11%), homicidal (14%), or uncertain (3%). Owing to the endemic problem and public hazard created by illicit metamfetamine abuse, the authors urged stronger antidrug programs.

Drug dependence

The role of dopamine in the addictive process has been explored (76). The authors raised the possibility that the orbitoprefrontal cortex is linked to compulsive drug abuse. They recruited 15 metamfetamine users and 20 non-drug user controls. The metamfetamine abusers had significantly fewer dopamine D_2 receptors than the controls. There was an association between lower numbers of dopamine D_2 receptors and metabolism in the orbitofrontal cortex in the metamfetamine users. These findings are similar to those observed in cocaine, alcohol, and heroin users. The authors suggested that D_2 receptor-mediated dysregulation of the orbitofrontal cortex could be a common mechanism underlying loss of control and compulsive abuse of drugs.

Second-Generation Effects

Pregnancy

In pregnant women who reported for prenatal care between 1959 and 1966 there was an excess of oral clefts in the offspring of mothers who had taken amphetamines in the first 56 days from their last menstrual period, but this was considered to be either a chance finding or one element in a multifactorial situation (SED-9, 9).

Teratogenicity

The possible neurotoxic effect of prenatal metamfetamine exposure on the developing brain has been studied using ^{1}H magnetic resonance spectroscopy in 12 metamfetamine-exposed children and 14 age-matched unexposed controls (77). There was an increased creatinine concentration in the striatum, with relatively normal concentrations of *N*-acetyl-containing compounds in children exposed to metamfetamine. These findings suggest that exposure to metamfetamine in utero causes abnormal

© 2006 Elsevier B.V. All rights reserved.

energy metabolism in the brain of children. However, there were no differences in reported behavioral problems among metamfetamine-exposed children compared with controls.

Susceptibility Factors

Genetic factors

A study in 93 unrelated metamfetamine-dependent subjects and 131 controls did not prove any association between metamfetamine dependence in Caucasians of Czech origin and TaqI A polymorphism of the DRD2 gene, I/D polymorphism of the ACE gene, or M235T polymorphism of the AGT gene (78).

Age

Special care should be taken when using amphetamines in elderly patients, in view of the likelihood of stimulation of adrenoceptors and in particular of cardiovascular and respiratory function. Periodic users especially need to be wary of acute use under circumstances of exercise and environmental heat, owing to the risk of heat stroke.

Other features of the patient

The existence of a previous neurological disorder may be a risk factor for treatment-resistant psychosis in metamfetamine abusers (79). It is of particular interest that most of these patients sustained their disorder during childhood. It is not uncommon for metamfetamine patients to continue with psychotic symptoms despite extended periods of abstinence (80). These patients often are labeled as being schizophrenic. This study has shown the importance of considering a history of neurological disorders, especially during childhood, in such patients.

Drug Administration

Drug administration route

Injection as a method of delivery of illicit drugs carries its own special risks. Metamfetamine-dependent subjects ($n = 427$) participated in a study to detect differences between injecting metamfetamine users (13%) and non-injecting users (87%) (81). The patients entered treatment at a center in California between 1988 and 1995. Injectors reported significantly more years of heavy use. Psychological problems were more common in the injectors, more of whom reported depression, suicidal ideation, hallucinations, and episodes of feeling that their body parts "disconnect and leave." Moreover, injectors reported more problems concerning sexual functioning and more episodes of loss of consciousness. The injectors were more commonly HIV-positive and they had more felony convictions and were on parole more often than other users. Although individuals who inject metamfetamine use it more often than non-injectors, the number of grams used per week did not differ between the groups. Thus, injectors use a smaller amount of drug per dose than non-injectors. Eighty percent of the injectors were unemployed, possibly reflecting the extent of impairment related to addiction in this group. The injectors, who had more psychiatric and medical morbidity, warrant special attention and carefully designed treatment plans.

Drug overdose

Overdosage of amphetamines can cause restlessness, dizziness, tremor, increased reflexes, talkativeness, tenseness, irritability, and insomnia; less common effects include euphoria, confusion, anxiety, delirium, hallucinations, panic states, suicidal and homicidal tendencies, excessive sweating, dry mouth, metallic taste, anorexia, nausea, vomiting, diarrhea, and abdominal cramps. Fatal poisoning is usually associated with hyperpyrexia, convulsions, coma, or cerebral hemorrhage. In addition, peripheral excitation of smooth muscle or blood vessels supplying skeletal muscle has been described. Excitatory actions can cause increased heart rate, palpitation, dysrhythmias, and metabolic effects, such as glycogenolysis in liver and adipose tissue.

The problem of fatal overdose is central to the problem of frequently repeated intravenous high-dose abuse of stimulants of unknown quality and quantity. Fatal overdose is less frequent among experienced chronic users than in naive or episodic high-dose users (82–84), in part because of the establishment of tolerance to hyperpyrexia and hypertension. Fatal hypertension can be potentiated by high ambient temperatures and vigorous exercise, as in the use of these drugs by athletes. Rare individuals have used up to 1–3 g/day of oral amfetamine for many years without problems of overdosing, yet acute toxic overdoses have been reported at 100–200 mg (53). Hyperpyrexia, seizures, hypertensive cerebrovascular hemorrhage, ventricular fibrillation, left ventricular failure, and complications of intravenous drug abuse have all been reported as causes of death (83–86). An autopsy study of amfetamine abusers in San Francisco showed that 54% died of drug toxicity, 10% of accidental trauma, 12% by suicide, and 10% by homicide (87).

Two deaths from metamfetamine overdose in drug dealers have been reported from Thailand, which has experienced an increase in metamfetamine abuse (88).

- A 43-year-old male drug dealer swallowed a number of metamfetamine tablets at the time of his arrest. When seen in the emergency room, he was comatose with reactive pupils. He died 6 hours after consuming the tablets. The autopsy findings were non-specific.
- Another 33-year-old female drug dealer, while at the police station, swallowed a number of metamfetamine pills that had been hidden in her undergarments. At the hospital, a gastric lavage was done but she died 10 hours after ingestion.

As described in these cases, there may be an increased risk of death in drug dealers who, in attempting to prevent arrest, may consume toxic amounts without anticipating the consequences.

Drug–Drug Interactions

Adrenergic neuron blocking drugs

Amphetamines and other stimulatory anorectic agents, apart from fenfluramine, would be expected to impair

© 2006 Elsevier B.V. All rights reserved.

the hypotensive effects of adrenergic neuron blocking drugs such as guanethidine. Not only do they release noradrenaline from stores in adrenergic neurons and block the reuptake of released noradrenaline into the neuron, but they also impair re-entry of the antihypertensive drugs (89).

Alcohol

Alcohol increases blood concentrations of amphetamines (SED-9, 9).

Barbiturates

Barbiturates can enhance amfetamine hyperactivity (SED-8, 9).

Benzodiazepines

Benzodiazepines can enhance amfetamine hyperactivity (SED-8, 9).

Estradiol

Preclinical studies (as well as anecdotal clinical reports) have shown that estrogens, through effects on the central nervous system, can influence behavioral responses to psychoactive drugs. In an unusual crossover study, the subjective and physiological effects of oral D-amfetamine 10 mg were assessed after pretreatment with estradiol (90). One group of healthy young women used estradiol patches (Estraderm TTS, total dose 0.8 mg), which raised plasma estradiol concentrations to about 750 pg/ml, and a control group used placebo patches. Most of the subjective and physiological effects of amfetamine were not affected by acute estradiol treatment, but the estrogen did increase the magnitude of the effect of amfetamine on subjective ratings of "pleasant stimulation" and reduced ratings of "want more." Estradiol also produced some subjective effects when used alone, raising ratings of "feel drug," "energy and intellectual efficiency," and "pleasant stimulation." Some limitations of the study were:

(a) plasma amfetamine concentrations were not measured, so an effect of estradiol on the pharmacokinetics of amfetamine cannot be ruled out;
(b) only single doses of amfetamine and estradiol were tested;
(c) the dose of amfetamine was relatively low and that of estradiol relatively high, maximizing the chances of detecting estradiol-dependent increases in two subjective effects of amfetamine.

Monoamine oxidase inhibitors

The amphetamines should not be used together with or within 14 days of any monoamine oxidase inhibitors; severe hypertensive reactions and on occasion confusional states (for example with fenfluramine) can occur (SED-9, 9).

Ritonavir

A fatal interaction between ritonavir and metamfetamine has been described (91).

- A 49-year-old HIV-positive Caucasian man had taken ritonavir (400 mg bd), saquinavir (400 mg bd), and stavudine (40 mg bd) for 4 months. His CD4 cell count was 617×10^6 cells/l and HIV-1 RNA less than 400 copies/ml. He had previously taken zidovudine for 7 months. He self-injected twice with metamfetamine and sniffed amyl nitrite and was found dead a few hours later. At autopsy, there was no obvious cause of death. Metamfetamine was detected in the bile (0.5 mg/l) and cannabinoids and traces of benzodiazepines were detected in the blood.

Nitric oxide formed from amyl nitrite inhibits cytochrome P450 (92) and ritonavir inhibits CYP2D6 (93), which has a major role in metamfetamine detoxification (94). This interaction could have led to fatal plasma concentrations of metamfetamine. It is therefore suggested that patients who take protease inhibitors are made aware of the potential risk of using any form of recreational drugs metabolized by CYP2D6, particularly metamfetamine.

SSRIs

A man taking long-term dexamfetamine had two episodes of serotonin syndrome while taking first venlafaxine and later citalopram (95).

- A 32-year-old man, who was taking dexamfetamine 5 mg tds for adult ADHD, developed marked agitation, anxiety, shivering, and tremor after taking venlafaxine for 2 weeks (75 mg/day increased after a week to 150 mg/day). His heart rate was 140/minute, blood pressure 142/93 mmHg, and temperature 37.3°C. His pupils were dilated but reactive. There was generalized hypertonia, hyper-reflexia, and frequent myoclonic jerking. Dexamfetamine and venlafaxine were withdrawn and cyproheptadine (in doses of 8 mg up to a total of 32 mg over 3 hours) was given. His symptoms completely resolved within a few hours.

Dexamfetamine was restarted 3 days later and citalopram was started a few days later. Two weeks later he reported similar symptoms and stopped taking citalopram. He was successfully treated again with cyproheptadine.

Tricyclic antidepressants

Tricyclic antidepressants increase blood concentrations of amfetamine (96,97).

Amphotericin

General Information

Having a broad-spectrum fungicidal activity, amphotericin remains the mainstay of treatment of most invasive fungal infections. Compared with conventional amphotericin B deoxycholate, other lipid formulations of amphotericin (amphotericin B colloidal dispersion, amphotericin B lipid complex, and liposomal amphotericin B) facilitate treatment in patients with suspected and proven invasive mycoses, who are intolerant of or refractory to conventional amphotericin.

Mechanism of action

The principal mechanism of action of amphotericin is based on its binding to lipids of the cell membrane of target cells, particularly to ergosterol, the predominant lipid in fungal cells, and cholesterol, the predominant lipid of the vertebrate cell membrane. The principle of selectivity is based on a higher affinity of amphotericin to ergosterol than cholesterol, but peroxidation of the membrane appears to be of equal importance (1–3).

Different formulations of amphotericin

Because of nephrotoxicity from amphotericin, which is common when amphotericin is given as the deoxycholate, lipid formulations have been developed. The formulations that are currently available are:

- amphotericin B deoxycholate (DAMB);
- amphotericin B colloidal dispersion (ABCD);
- amphotericin B lipid complex (ABLC);
- liposomal amphotericin B (L-Amb, AmBisome).

Pharmacokinetics

The pharmacokinetics of amphotericin are highly variable and depend on the formulation used and the infusion rate (4,5). Amphotericin, when administered as the deoxycholate complex, is highly bound to lipoproteins, mainly LDL and VLDL, and to a lesser extent to HDL (6,7) as well as to cell membranes of circulating blood cells. Binding is so avid that after spiking human plasma, no unbound amphotericin is detectable (7). Concentrations in peritoneal, pleural, and synovial fluids are usually less than half of those in serum, while cerebrospinal fluid concentrations range from undetectable to some 4% of the serum concentration, but over 40% in neonates (8). For DAMB the half-life is 1–2 days. Concentrations in bile are detectable for up to 12 days and in urine for 27–35 days. Clearance is faster and the volume of distribution smaller in neonates and infants (9) There is marked tissue storage of amphotericin, again depending on the formulation and the rate of infusion. Liver, spleen, kidneys, and lungs accumulate large amounts. Tissue storage plays a major role in the pharmacokinetics of amphotericin, which can be detected in tissues much more than a year after the completion of therapy (10–12). Up to 40% of amphotericin is ultimately excreted unchanged in urine. Elimination via the bile plays a lesser role, and metabolism appears to be unimportant. Elimination is so slow that dosages need not be altered in patients with renal insufficiency.

Lipid formulations of amphotericin have individually variable pharmacokinetics. The use of DAMB in 20% Intralipid results in marked changes, with lower antifungally active blood concentrations (13). Infusion of ABLC, ABCD, or L-Amb, AmBisome results in plasma amphotericin concentrations specific to the individual formulation. The half-life of amphotericin after lipid formulations is prolonged compared with the deoxycholate formulation (14): 4–10 days for ABCD (15) and about 5 days for ABLC (16). The importance of these differences is unknown, because they do not reflect the biologically active concentration of amphotericin, which also varies with formulation. On a weight for weight basis amphotericin in lipid formulations is less active than in the deoxycholate formulation, because of lower systemic availability (5). One factor that complicates the interpretation of blood concentrations is the sparse data

© 2006 Elsevier B.V. All rights reserved.

discriminating between amphotericin bound to the original lipid formula and to plasma lipoproteins, and the minute amount of unbound amphotericin not detectable by available analytical methods (7).

The interaction of amphotericin with serum lipoproteins (6) suggests that manipulations of blood lipids and blood lipoproteins might affect the pharmacokinetics of amphotericin, and therefore also alter its activity, including toxic effects, as suggested in animal studies (17).

Observational studies

Amphotericin is highly effective in the treatment of visceral leishmaniasis (18). In a prospective study of 938 patients from Bihar, India, who received the drug in a dosage of 1 mg/kg/day infused over 2 hours for 20 days, serum creatinine values over 177 μmol/l were noted in 6.3%, and acute renal insufficiency developed in three patients. Two patients died, possibly related to amphotericin, one with renal insufficiency and one with hypokalemia and cardiac arrest. Infusion-related chills occurred in 92% and fever in 40% of patients. The parasitological cure rate (no relapse within 6 months) exceeded 99%.

Amphotericin deoxycholate

The adverse effects of amphotericin deoxycholate have been reviewed in a retrospective analysis of 102 adult patients (median age 61 years) with a variety of underlying conditions who were admitted to a small community hospital in Honolulu and who received the drug for treatment of presumed or proven fungal infections that were mostly due to *Candida* species (19). The average total dose of amphotericin deoxycholate was comparatively low at 162 (range 10–840) mg. The initial dose averaged 16 (range 1–50) mg and the total duration of therapy was 8.3 (range 1–46) days. Chills, fever, and/or nausea were noted in 25% of the patients. Hypokalemia (a serum potassium concentration below 3.5 mmol/l) occurred in 19%, and nephrotoxicity (defined as a serum creatinine concentration of at least 141 μmol/l (1.6 mg/dl) with an increase of at least 44 μmol/l (0.5 mg/dl) during amphotericin deoxycholate therapy) in 15% of the patients. Nephrotoxicity increased with increasing total dose of amphotericin, while infusion-associated toxicity decreased with advancing age. The overall response rate to therapy with amphotericin deoxycholate was 83%.

Amphotericin colloidal dispersion

The safety and efficacy of amphotericin colloidal dispersion have been evaluated in 148 immunocompromised patients with candidemia (20). ABCD was given intravenously in a median daily dose of 3.9 (range 0.1–9.1) mg/kg for a median of 12 (range 1–72) days. In the safety analysis ($n = 148$ patients), nephrotoxicity occurred in 16% of the patients, with either doubling of the baseline serum creatinine concentration or an increase of 88 μmol/l (1.0 mg/dl) or a 50% fall in calculated creatinine clearance. Severe adverse events were believed to be probably or possibly related to ABCD in 36 patients (24%), including chills and fever (9.5%), hypotension and abnormal kidney function (4%), tachycardia, asthma, hypotension (3%), and dyspnea (2%). ABCD was withdrawn in 12% because of toxicity. The overall response rate in 89 evaluable patients was 66% with candidemia alone and 14% with disseminated candidiasis.

The safety and efficacy of ABCD have been studied in 133 patients with invasive fungal infections and renal impairment due to either amphotericin deoxycholate or pre-existing renal disease (21). The mean daily dose of ABCD was 3.4 (range 0.1–5.5) mg/kg, and the mean duration of therapy was 21 (range 1–207) days. Although individual patients had increases in serum creatinine concentrations, ABCD did not have an adverse effect on renal function: the mean serum creatinine concentration tended to fall slightly with days on therapy, and increases were not dose-related. Six patients discontinued ABCD therapy because of nephrotoxicity. Infusion-related adverse events occurred at least once in 74 patients (56%); however, while 43% of patients had infusion-related toxic effects on day 1, only 18% reported these events by day 7. There were complete or partial responses in 50% of the intention-to-treat population and in 67% of the 58 evaluable patients.

The safety of ABCD has been reviewed using data from 572 immunocompromised patients refractory to or intolerant of standard therapies enrolled in five phase I/II clinical trials (22). The mean daily dose of ABCD was 3.85 (median 3.8, range 0.1–9.1) mg/kg and the mean duration of treatment was 25 (median 16, range 1–409) days. Overall, the principal adverse events associated with ABCD therapy were chills (52%), fever (39%), and hypotension (19%). These infusion-related reactions were dose-related and were the dose-limiting adverse events, defining the maximum tolerated dosage at 7.5 mg/kg. ABCD did not adversely affect renal function, as measured by overall changes in serum creatinine from baseline to the end of therapy, even in patients with pre-existing renal impairment; only 3.3% of patients discontinued therapy because of nephrotoxicity. Complete or partial responses to treatment were reported in 149 of 260 evaluable patients (57%).

The safety and efficacy of ABCD have been studied in 220 bone marrow transplant recipients enrolled in the same five phase I or phase II studies (23). The median dose in this population was 4 (range 0.4–8.0) mg/kg, and the median duration of treatment was 16 (range 1–409) days. Overall, 37 (19%) of the patients had nephrotoxicity, defined as a doubling of serum creatinine from baseline, an increase of 88 μmol/l from baseline, or at least a 50% fall in calculated creatinine clearance. There were no significant changes in hepatic transaminases, alkaline phosphatase, or total bilirubin. Fever and chills were reported by 12 and 11% of patients respectively. Other acute, severe, infusion-related adverse events were hypoxia (4.1%), hypertension (2.7%), and hypotension (2.7%).

Mucormycosis has an exceedingly high mortality rate in immunocompromised patients. In five phase I and phase II studies of ABCD, 21 patients were given ABCD (mean dose 4.8 mg/kg per infusion for a mean duration of 37 days) on the basis of pre-existing renal insufficiency, nephrotoxicity during amphotericin B therapy, or refractory infections (24). Of 20 evaluable patients, 12 responded to ABCD, and there was no renal or hepatic toxicity. However, a previous randomized, comparative trial showed an at least similar if not increased frequency

© 2006 Elsevier B.V. All rights reserved.

and severity of infusion-related reactions compared with conventional amphotericin B (25).

Amphotericin lipid complex

The safety and efficacy of ABLC have been evaluated in 556 cases of proven or presumptive invasive fungal infection treated in an open, single-patient, US emergency-use study of patients who were refractory to or intolerant of conventional antifungal therapy (26). The daily dosage was either 5 mg/kg (87%) or 3 mg/kg. The investigators had the option of reducing the daily dosage as clinically warranted. Treatment was for 7 days in 540 patients (97%). During the course of ABLC therapy, serum creatinine concentrations in all patients fell significantly from baseline. In 162 patients with serum creatinine concentrations of at least 221 μmol/l (2.5 mg/dl) at baseline, the mean serum creatinine concentration fell significantly from the first week to the sixth week. The serum creatinine concentration increased from baseline to the end of therapy in 132 patients (24%). Hypokalemia (serum potassium concentration of less than 3 mmol/l) developed in 4.6%, and hypomagnesemia (serum magnesium concentration of less than 0.75 mmol/l) in 18%. There was a rise in serum bilirubin in 142/284 patients (33%); the overall increase was from 79 to 112 μmol/l (4.66–6.59 mg/dl) at the end of therapy. The mean alkaline phosphatase activity rose from 273 to 320 IU/l. There was no significant change overall in alanine transaminase activity, but the activity increased by the end of treatment in 16% of patients with initially normal values. There were complete or partial responses to therapy with ABLC in 167 of 291 mycologically confirmed cases evaluable for therapeutic response (57%).

The safety and efficacy of ABLC 5 mg/kg/day in patients with neutropenia and intolerance or refractoriness to amphotericin deoxycholate have been reported in two smaller series of 25 treatment courses from the UK. In one, the mean serum creatinine at the start of therapy was 139 μmol/l and at the end of therapy 132 μmol/l; there were no infusion-related adverse events (27). There was an increase in alanine transaminase activity in 12 of the 22 analysed treatment courses. In the other, there was an increase in serum creatinine in 5 of 18 courses (28%), and hypokalemia (less than 2.5 mmol/l) in two courses (11%); premedication for infusion-associated reactions was required in three courses (17%) (28). There were modest increases in serum alanine transaminase activities in five patients (30%).

In contrast to these reports, there was a high prevalence of adverse events with ABLC in the treatment of suspected or documented invasive fungal infections in 19 Scandinavian patients with mostly hematological malignancies (29). The mean starting dose of ABLC was 4.1 mg/kg/day, given for a median of 3 (range 1–19) days. ABLC was withdrawn because of adverse events in 14/19 patients (74%). These included rising creatinine concentrations ($n = 12$), increased serum bilirubin ($n = 7$), erythema ($n = 6$), increased alanine transaminase ($n = 6$), fever and chills ($n = 5$), hypoxemia ($n = 3$), hemolysis ($n = 2$), and back pain and increased serum alkaline phosphatase activity ($n = 1$ each). In patients with renal adverse effects, there were significantly increased serum creatinine concentration (from 85 to 199 mmol/l) and increased bilirubin concentration (from 17 to 77 μmol/l) in seven patients. The authors stated that while all the patients were very ill at the time of the start of ABLC therapy, in all cases the adverse effects had a direct and obvious correlation with the administration of ABLC. However, the reason for this unusual high rate of adverse events remains unclear.

Safety data have been published in a retrospective analysis of 551 patients with invasive fungal infections intolerant of or refractory to conventional antifungal therapy, 73 of whom received ABLC initially at 3 mg/kg/day instead of 5 mg/kg/day, as recommended in the protocol (30). There were no notable differences in adverse events (increased serum creatinine, infusion-related chills) between the two groups. Serum creatinine values were improved or stable at the end of therapy in 78 and 70% of patients respectively.

Two smaller series have addressed the safety of ABLC in immunocompromised patients (31,32). Each included about 30 patients who were treated with median dosages of 4.8 and 5.0 mg/kg for a median of 8 and 14 days. In contrast to a previous retrospective analysis that showed a 74% withdrawal rate, mostly due to infusion-related reactions (29), ABLC was well tolerated, with withdrawal rates of 6 and 0% and an overall trend for stable or improved serum creatinine values at the end of therapy. Similarly, 13 infusion-related reactions have been reported among 308 infusions in four of ten patients with hematological malignancies receiving ABLC 3 mg/kg/day (33). These reactions (fever, rigors, myalgias), occurred during the first infusions, were judged to be mild, and resolved during later infusions. ABLC was well tolerated by 30 persistently febrile neutropenic patients with hematological malignancies who received it in a low dosage of 1 mg/kg/day for a median of 7.5 (range 2–19) days (34). Seven patients (23%) had mild to moderate infusion-related reactions, and no patient had nephrotoxicity. In one patient, ABLC was discontinued owing to intolerable infusion-related fever and chills.

The safety and efficacy of low dose ABLC (1 mg/kg/day) for empirical treatment of fever and neutropenia have been studied in 69 episodes in 61 patients with hematological malignancies (35). The median duration of therapy was 8 (range 2–19) days and 13 patients had mild to moderate infusion-related adverse events. Creatinine concentrations remained stable in 42 cases, improved in 9, and deteriorated in 18. There were no other toxic effects. The response rate (resolution of fever during neutropenia and absence of invasive fungal infection) was 67%.

Fungal infection remains an important cause of morbidity and mortality in lung transplant patients. In a prospective non-comparative evaluation in lung or heart-lung transplant recipients, ventilated patients received undiluted aerosolized ABLC 100 mg, and extubated patients received 50 mg; in all, 381 treatments were given (98 in ventilated patients and 283 in extubated patients) (36). The treatment was administered by face mask jet nebulizer with compressed oxygen at a flow rate of 7–8 l/minute and inhaled over 15–30 minutes. Treatments were

© 2006 Elsevier B.V. All rights reserved.

delivered once every day for four consecutive days, then once a week for 2 months. In all, 381 treatments were given to 51 patients, and ABLC was subjectively well tolerated in 98%. Pulmonary function worsened by 20% or more in under 5% of all treatments. There were no significant adverse events.

Liposomal amphotericin

The safety, tolerance, and pharmacokinetics of liposomal amphotericin have been evaluated in an open, sequential dose escalation, multiple-dose phase I/II study in 36 patients with neutropenia and persistent fever requiring empirical antifungal therapy (37). The patients received doses of 1, 2.5, 5.0, or 7.5 mg/kg/day of liposomal amphotericin for a mean of 9.2 days. Liposomal amphotericin was well tolerated: infusion-related adverse effects (fever, chills, rigor) occurred in 15 (5%) of all 331 infusions, and only two patients (5%) required premedication (dyspnea and generalized flushing; facial urticaria). Hypotension (one infusion) and hypertension (three infusions) were infrequent. One patient each had sharp flank pain and dyspnea during one infusion; these symptoms did not recur during subsequent infusions. Serum creatinine, potassium, and magnesium concentrations were not significantly changed from baseline, and there were no net increases in serum transaminases. There was, however, a significant increase in serum alkaline phosphatase activity and increase in bilirubin concentration in the overall population as well as in individual dosage groups. One patient who received concomitant L-asparaginase had increases in serum lipase and amylase activities in association with symptoms of pancreatitis while receiving liposomal amphotericin; however, as he continued to receive the drug, the serum lipase and amylase returned to baseline. Liposomal amphotericin had non-linear pharmacokinetics consistent with reticuloendothelial uptake and redistribution. There were no breakthrough fungal infections during therapy.

The efficacy of two dosages of liposomal amphotericin in the treatment of proven or probable invasive aspergillosis in neutropenic patients with cancer or those undergoing bone marrow transplantation has been studied in a prospective, randomized, open, multicenter trial in 120 patients randomized to receive either 1 mg/kg/day or 4 mg/kg/day of liposomal amphotericin; 87 patients were available for evaluation (38). There was at least one toxic event during treatment in 15 of 41 patients given 1 mg/kg/day and 25 of 46 given 4 mg/kg/day, but the numbers of events per patient were similar. These events included headache, nausea, diarrhea, rash, liver toxicity, myalgia, dyspnea, fever, chills, and back pain. Renal toxicity definitely related to liposomal amphotericin occurred in 1/41 patients treated with 1 mg/kg/day and 5/46 patients treated with 4 mg/kg/day. Only in one case was treatment permanently discontinued because of toxicity related to liposomal amphotericin (4 mg/kg/day). No patient died from liposomal amphotericin toxicity. Overall, liposomal amphotericin was effective in 50–60% of patients; however, the number of cases with proven invasive aspergillosis was too small to allow a meaningful comparison of the two dosages regarding efficacy in this life-threatening disease.

The safety and efficacy of liposomal amphotericin have been compared with that of ABLC in a retrospective analysis of 59 adult patients with hematological malignancies who received 68 courses of either liposomal amphotericin ($n = 32$) or ABLC ($n = 36$) for a variety of presumed or confirmed invasive fungal infections (39). The median daily dosages were 1.9 (range 0.7–4.0) mg/kg for liposomal amphotericin and 4.8 (range 1.9–5.8) mg/kg for ABLC. There was no statistically significant difference in the overall outcome; febrile reactions were significantly more common with ABLC (36 versus 6%), but there were no significant differences in the median creatinine concentrations at baseline and at the end of therapy or in the number of patients with urinary loss of potassium or magnesium.

In an open, sequential phase II clinical study of three different regimens of liposomal amphotericin for visceral leishmaniasis (2 mg/kg on days 1–6 and on day 10; 2 mg/kg on days 1–4 and on day 10; 2 mg/kg on days 1, 5, and 10) in Indian and Kenyan patients in three developing countries, there were few infusion-associated adverse effects (40). Of 32 Brazilian patients (15 of whom received 2 mg/kg on days 1–10 because of poor responses to the first regimen, 37% had a fever with one or more infusions, 9% had chills, and 6% had back pain; in addition, three patients had respiratory distress and/or cardiac dysrhythmias. There were different response rates to the three regimens in the different countries, leading to the recommendation of 2 mg/kg on days 1–4 and day 10 in India and Kenya, and 2 mg/kg on days 1–10 in Brazil.

In order to determine the maximum tolerated dosage of liposomal amphotericin B, a phase I/II study was conducted in 44 adult patients with proven ($n = 21$) or probable ($n = 23$) infections due to *Aspergillus* species and other filamentous fungi (41). The dosages were 7.5, 10, 12.5, and 15 mg/kg/day. The number of infusions was 1–83 with a median duration of 11 days. The maximum tolerated dosage was at least 15 mg/kg. Infusion-related reactions included fever in 8 and chills and rigors in 5 of 43 patients. Three patients developed a syndrome of substernal chest tightness, dyspnea, and flank pain, which was relieved by diphenhydramine. Serum creatinine increased two times above baseline in 32% of patients, but this increase was not dose-related. Hepatotoxicity developed in one patient. Altogether, the most common adverse events included fever (48%), increased creatinine concentration (46%), hypokalemia (39%), chills (32%), and abdominal pain (25%), with no obvious dose-dependency. Nine patients (20%) stopped taking the drug because of an adverse event. The reasons included raised serum creatinine, renal insufficiency, pancreatitis, hyperbilirubinemia, hypotension associated with the infusion, cardiorespiratory failure, multiorgan failure, and relapse of the primary malignancy. The last three events were attributed to the underlying disease process. Discontinuation was unrelated to dosage. Pharmacokinetic analysis showed dose-related non-linear kinetics at dosages of 7.5 mg/kg/day and over.

Aerosolized amphotericin

In a prospective, randomized, multicenter trial, inhalation of aerosolized amphotericin (10 mg bd) has been investigated as prophylaxis against invasive aspergillosis

© 2006 Elsevier B.V. All rights reserved.

in 382 cancer patients with an anticipated duration of neutropenia of at least 10 days (42). While there was no difference in the incidence of invasive aspergillosis, infection-related mortality, and overall mortality, 31% of the patients discontinued amphotericin prophylaxis prematurely owing to adverse effects (55%; most commonly cough, bad taste, nausea), inability to cooperate further (30%), violation of the study protocol (11%), and non-adherence (4%).

Comparative studies

Comparisons of different formulations of amphotericin

Amphotericin deoxycholate in glucose versus amphotericin deoxycholate in Intralipid

The safety of two formulations of intravenous amphotericin deoxycholate has been investigated in a randomized, open comparison in neutropenic patients with refractory fever of unknown origin or pulmonary infiltrates (43). Amphotericin deoxycholate was given in a dose of 0.75 mg/kg/day either in 250 ml of a 5% glucose solution or mixed with 250 ml of a 20% lipid emulsion (Intralipid 20%) on eight consecutive days and then on alternate days as a 1–4 hour infusion. The mean number of days of treatment was 11.3 versus 9.9 days. There were no statistically significant differences between the two cohorts with respect to the incidence of infusion-related adverse events, such as fever and chills, renal impairment, or treatment failure. However, grade 3–4 acute dyspnea occurred slightly more often with the lipid emulsion formulation, and there were significantly more other severe respiratory events in patients receiving lipid emulsion, raising the possibility of a causal relation via fat overload or incompatibility between amphotericin deoxycholate and the lipid emulsion.

The efficacy and tolerability of amphotericin prepared in Intralipid 20% have been evaluated in 16 patients with HIV infection and esophageal candidiasis or cryptococcosis and compared with standard amphotericin in a matched group of 24 patients (44). While both formulations had apparently similar clinical and microbiological efficacy, fewer patients receiving the lipid emulsion formulation required premedication or symptomatic therapy for infusion-associated adverse events, and fewer patients were withdrawn because of adverse effects. Renal adverse effects (a rise in serum creatinine and/or electrolyte loss) were more common in patients who received the conventional formulation.

The efficacy and safety of amphotericin in Intralipid 20% or 5% glucose has been evaluated in a retrospective case analysis in 30 patients with AIDS and cryptococcal meningitis who received either formulation 1 mg/kg/day for 20 days with or without flucytosine ($n = 20$) or fluconazole ($n = 4$), followed by maintenance therapy with fluconazole 400 mg/day (45). Twenty patients received amphotericin deoxycholate in 500 ml 5% glucose over 5 hours, and 10 received amphotericin deoxycholate in 100 ml of 20% Intralipid given over 2 hours. Complete clinical resolution was obtained in 55 and 60% of the patients respectively. There were no differences regarding infusion-related adverse effects, nephrotoxicity, or anemia.

Amphotericin deoxycholate versus amphotericin B colloidal dispersion

Amphotericin colloidal dispersion has been compared with amphotericin deoxycholate in a prospective, randomized, double-blind study in the empirical treatment of fever and neutropenia in 213 patients (25). Patients were stratified by age and concomitant use of ciclosporin or tacrolimus and then randomized to receive ABCD (4 mg/kg/day) or amphotericin deoxycholate (0.8 mg/kg/day) for 14 days. Renal dysfunction was less likely to develop and occurred later with ABCD than with amphotericin deoxycholate. Likewise, the absolute and percentage fall in the serum potassium concentration from baseline to the end of therapy was greater with amphotericin deoxycholate than ABCD. However, probable or possible infusion-related hypoxia and chills were more common with ABCD than amphotericin deoxycholate. There was a therapeutic response in 50% of the patients who received ABCD and 43% of those who received amphotericin deoxycholate. Thus, ABCD was of comparable efficacy and less nephrotoxic than amphotericin deoxycholate, but infusion-related events were more common with ABCD.

Amphotericin deoxycholate versus liposomal amphotericin

Liposomal amphotericin 5 mg/kg/day and amphotericin deoxycholate 1 mg/kg/day have been compared in the treatment of proven or suspected invasive fungal infections in neutropenic patients in a randomized, multicenter study (46). Significantly more patients given amphotericin deoxycholate had a greater than 100% increase in baseline serum creatinine. Treatment was temporarily discontinued or the dosage reduced because of an increase in serum creatinine in 18/54 (33%) patients treated with amphotericin deoxycholate versus 2/51 (4%) treated with liposomal amphotericin. There was no statistically significant difference in the number of patients with infusion-related toxicity (fever/chills), hypokalemia, or increases in serum transaminases, alkaline phosphatase, or serum bilirubin. In 66 patients eligible for analysis of efficacy, there was a trend to an improved overall response rate and a significant difference in the rate of complete responses in favor of liposomal amphotericin; death rates were also lower in patients treated with liposomal amphotericin.

The results of a randomized, double-blind, multicenter comparison of liposomal amphotericin (3.0 mg/kg/day) with conventional amphotericin deoxycholate (0.6 mg/kg/day) for empirical antifungal therapy in patients with persistent fever and neutropenia have been reported (47). The mean duration of therapy was 10.8 days for liposomal amphotericin (343 patients) and 10.3 days for amphotericin deoxycholate (344 patients). While the composite rates of successful treatment were similar (50% for liposomal amphotericin and 49% for amphotericin deoxycholate), significantly fewer of the patients who received the liposomal preparation had

© 2006 Elsevier B.V. All rights reserved.

infusion-related fever (17 versus 44%), chills or rigors (18 versus 54%), or other reactions, including hypotension, hypertension, and hypoxia. Nephrotoxicity (defined by a serum creatinine concentration twice the upper limit of normal) was significantly less frequent among patients treated with liposomal amphotericin (19%) than among those treated with conventional amphotericin deoxycholate (34%).

Amphotericin lipid complex versus liposomal amphotericin

Liposomal amphotericin and ABLC have been compared in an open randomized study in 75 adults with leukemia and 82 episodes of suspected or documented mycosis (48). The median durations of treatment and dosages were 15 days at 4 mg/kg/day for liposomal amphotericin and 10 days at 3 mg/kg/day for ABLC. Acute but not dose-limiting infusion-related adverse events occurred in 36 versus 70%. Bilirubin increased to over 1.5 times baseline in 59 versus 38%. There was no difference in the effects of either agent on renal function and drug-related withdrawals. The overall response rate to therapy in documented fungal infections (29 and 30% respectively) was not different between the two drugs.

Amphotericin deoxycholate in glucose versus amphotericin in nutritional fat emulsion

The safety of DAMB prepared in nutritional fat emulsion (a non-approved mode of amphotericin administration) has been reviewed (SEDA-21, 282) (SEDA-22, 285). It is not clear whether it has a better therapeutic index than other formulations, and methods of preparing it have not been standardized. The adverse effects of amphotericin prepared in nutritional fat emulsion have been compared with those of amphotericin prepared in 5% dextrose in two studies. While one of the studies showed a significantly lower frequency of infusion-related reactions and hypokalemia in patients receiving the fat emulsion (49), there were no differences in safety and tolerance between the two formulations in the other study (50). The safety of amphotericin prepared in nutritional fat emulsions has been reviewed (SEDA-21, 282) (SEDA-22, 285). Because of stability concerns and lack of systematic safety data, this form of amphotericin cannot be recommended.

Comparisons of amphotericin with other antifungal drugs

Antifungal azoles

Fluconazole

There has been an open, randomized comparison of amphotericin deoxycholate 0.5 mg/kg/day intravenously versus fluconazole 400 mg/day orally for empirical antifungal therapy in neutropenic patients with cancer and fever refractory to broad-spectrum antibiotics (51). Patients with abnormal hepatic or renal function were excluded, as were those with proven or suspected invasive fungal infection. The mean duration of therapy was 8.3 days with amphotericin deoxycholate and 7.9 days with fluconazole. Altogether, 32/48 patients randomized to amphotericin deoxycholate and 19/52 randomized to fluconazole had adverse affects (67 versus 36%). Two patients developed immediate hypersensitivity reactions (flushing, hypotension, bronchospasm) to amphotericin deoxycholate and had to be withdrawn. Hypokalemia was noted in 25 patients (52%), and nephrotoxicity, defined as a rise in serum creatinine of 44 μmol/l (0.5 mg/dl) or more compared with the baseline value, in nine patients (19%). The corresponding frequencies with fluconazole were 23 and 6% respectively. Treatment success rates and mortality were similar (46 versus 56% and 33 versus 27% respectively).

Fluconazole and amphotericin as empirical antifungal drugs in febrile neutropenic patients have been investigated in a prospective, randomized, multicenter study in 317 patients randomized to either fluconazole (400 mg qds) or amphotericin deoxycholate (0.5 mg/kg qds) (52). Adverse events (fever, chills, renal insufficiency, electrolyte disturbances, and respiratory distress) occurred significantly more often in patients who were given amphotericin (128/151 patients, 81%) than in those given fluconazole (20/158 patients, 13%). Eleven patients treated with amphotericin, but only one treated with fluconazole, were withdrawn because of an adverse event. Overall mortality and mortality from fungal infections were similar in both groups. There was a satisfactory response in 68% of the patients treated with fluconazole and 67% of those treated with amphotericin. Thus, fluconazole may be a safe and effective alternative to amphotericin for empirical therapy of febrile neutropenic patients; however, since fluconazole is ineffective against opportunistic molds, the possibility of an invasive infection by a filamentous fungus should be excluded before starting empirical therapy. Similarly, patients who take azoles for prophylaxis are not candidates for empirical therapy with fluconazole.

Conventional amphotericin deoxycholate (0.2 mg/kg qds) and fluconazole (400 mg qds) have been compared in a prospective randomized study in 355 patients with allogeneic and autologous bone marrow transplantation (53). The drugs were given prophylactically from day 1 until engraftment. There was no difference in the occurrence of invasive fungal infections, but amphotericin was significantly more toxic than fluconazole, especially in related allogeneic transplantation, after which 19% of patients developed toxicity compared with none of those who received fluconazole.

Itraconazole

Amphotericin and itraconazole have been compared in a multicenter, open, randomized study in 277 adults with cancer and neutropenia (54). Itraconazole oral solution (100 mg bd, $n = 144$) was compared with a combination of amphotericin capsules and nystatin oral suspension ($n = 133$). Adverse events were reported in about 45% of patients in each group. The most frequent were vomiting (14 versus 12 patients), diarrhea (12 versus 9 patients), nausea (5 versus 12 patients), and rash (2 versus 13 patients). There were no differences in liver function

© 2006 Elsevier B.V. All rights reserved.

test abnormalities. Treatment had to be withdrawn because of adverse events (including death) in 34 patients who took itraconazole and 33 of those who took amphotericin plus nystatin; there were 17 deaths in each group and death was recorded as adverse event in 13 and nine patients respectively.

Intravenous amphotericin deoxycholate (0.7–1.0 mg/kg) and itraconazole (400 mg intravenously for 2 days, 200 mg intravenously for up to 12 days, then 400 mg/day orally) have been compared in 384 granulocytopenic patients with persistent fever in a randomized, multicenter trial (55). The median duration of therapy was 8.5 days. The incidence of drug-related adverse events (54 versus 5%) and the rate of withdrawal due to toxicity (38 versus 19%) were significantly higher with amphotericin. The most frequent reasons for withdrawal in patients taking itraconazole were nausea and vomiting (5%), rash (3%), and abnormal liver function tests (3%). Significantly more of the patients who received amphotericin had nephrotoxicity (24 versus 5%); however, fewer had hyperbilirubinemia (5 versus 10%). There was no difference in gastrointestinal adverse events between the two groups.

Amphotericin in capsules 500 mg qds has been compared with itraconazole elixir 2.5 mg/kg bd for the prophylaxis of systemic and superficial fungal infections in a double-blind, randomized, placebo-controlled, multicenter trial for 1–59 days (56). While itraconazole significantly reduced the frequency of superficial fungal infections, it was not superior in reducing invasive fungal infections or in improving mortality. Adverse events were reported in 222 patients taking itraconazole (79%) and in 205 patients taking amphotericin (74%). The commonest adverse events were gastrointestinal, followed by rash and hypokalemia, with no differences between the two regimens. In both groups, 5% of the adverse events were considered to be definitely drug-related. Comparable numbers of patients in the two groups permanently stopped treatment because of adverse events (including death), 78 (28%) in the amphotericin group and 75 (27%) in the itraconazole group. Nausea (11 and 9%) and vomiting (7 and 8%) were the most frequently reported adverse events that led to withdrawal. Biochemical changes were comparable in the two groups.

Echinocandins

In a randomized, double-blind comparison of amphotericin (0.5 mg/kg intravenously) and caspofungin acetate (35, 50, or 70 mg) once daily for 7–14 days in 140 patients with oropharyngeal and/or esophageal candidiasis, 63% had esophageal involvement and 98% were infected with HIV (57). Response rates were 63% with amphotericin and 74–91% with caspofungin. More patients receiving amphotericin had drug-related adverse effects (fever, chills, nausea, vomiting) than those receiving any dose of caspofungin. Two patients who took caspofungin 35 mg and one who was given amphotericin withdrew because of adverse effects. Drug-related laboratory abnormalities were also more common in patients who received amphotericin. The most common drug-related laboratory abnormalities in patients who received caspofungin were raised alanine transaminase, aspartate transaminase, and alkaline phosphatase, which were typically less than five times the upper limit of normal and resolved despite continued treatment. None of the patients receiving caspofungin and nine of those who received amphotericin developed drug-related increases in serum creatinine concentrations. No patient withdrew because of drug-related laboratory adverse effects.

Amphotericin has been compared with caspofungin in a multicenter, double-blind, randomized trial in 128 adults with endoscopically documented symptomatic *Candida* esophagitis (58). There was endoscopically verified clinical success in 63% of patients given amphotericin deoxycholate 0.5 mg/kg/day and in 74 and 89% of the patients who received caspofungin 50 and 70 mg/day respectively. Therapy was withdrawn because of drug-related adverse events in 24% of the patients who were given amphotericin and in 4 and 7% of those who were given caspofungin 50 and 70 mg/day respectively. More patients who received amphotericin had drug-related fever, chills, or nausea than those who received caspofungin. More patients who received amphotericin (91%) than caspofungin (61 and 32%) developed drug-related laboratory abnormalities. There were drug-related increases in blood urea–nitrogen concentrations in 15% of the patients who received amphotericin but none of those who received caspofungin. Likewise, serum creatinine concentrations increased in 16 patients who received amphotericin but in only one who received caspofungin. In summary, caspofungin was as effective as amphotericin but better tolerated in the treatment of esophageal candidiasis.

In a double-blind, randomized trial, amphotericin deoxycholate was compared with caspofungin for the primary treatment of invasive candidiasis (59). Patients who had clinical evidence of infection and a positive culture for *Candida* species from blood or another site were enrolled. They were stratified according to the severity of disease, as indicated by the presence or absence of neutropenia and the Acute Physiology and Chronic Health Evaluation (APACHE II) score, and were randomly assigned to receive either amphotericin (0.6–0.7 mg/kg/day or 0.7–1.0 mg/kg/day for patients with neutropenia) or caspofungin (50 mg/day with a loading dose of 70 mg on day 1). Of the 239 patients enrolled, 224 were included in the modified intention-to-treat analysis. Baseline characteristics, including the percentage of patients with neutropenia and the mean APACHE II score, were similar in the two treatment groups. The efficacy of amphotericin was similar to that of caspofungin, with successful outcomes in 62% of the patients treated with amphotericin and in 73% of those treated with caspofungin. There were significantly more drug-related adverse events (fever, chills, and infusion-related events) associated with amphotericin. Amphotericin caused more nephrotoxicity, as defined by an increase in serum creatinine of at least twice the baseline value or an increase of at least 88 μmol/l) (8.4 versus 25%). Only 2.6% of those who were given caspofungin were withdrawn because of adverse events, compared with 23% of those who were given amphotericin. Thus, caspofungin was at least as effective

© 2006 Elsevier B.V. All rights reserved.

as amphotericin for the treatment of mostly non-neutropenic patients with invasive candidiasis but significantly better tolerated.

Comparisons with antimonials

Amphotericin might be useful in the treatment of leishmaniasis, as suggested by a comparative study (amphotericin in 14 doses of 0.5 mg/kg infused in 5% glucose on alternate days) against sodium stibogluconate (20 mg/kg in two divided doses daily for 40 days). All 40 patients taking amphotericin were cured, whereas in the stibogluconate group 28 of the 40 showed an initial cure but only 25 a definite cure (60).

Placebo-controlled studies

In a small randomized, double-blind, placebo-controlled study, liposomal amphotericin (2 mg/kg three times weekly) was investigated as prophylaxis against fungal infections in 161 patients undergoing chemotherapy or bone marrow transplantation for hematological malignancies (61). There were no statistically significant differences between the two study arms in the incidences of the most frequently reported adverse events or in changes in renal and hepatic laboratory parameters. Despite a sizable rate of suspected or documented fungal infections in the placebo arm, prophylactic therapy with liposomal amphotericin did not lead to a significant reduction in fungal infections or the requirement for systemic antifungal therapy.

General adverse effects

Fever, rigors, nausea, vomiting, headaches, muscle pains, and joint pains are common. The incidence and severity of these reactions are highest with rapidly increasing blood concentrations, and are frequent during the start of therapy (62). Hypersensitivity reactions have been described in case reports. Reports of rashes have been rare. The UK Committee on Safety of Medicines received 20 reports of the occurrence of rash over a 17-year period (SEDA-16, 289). However, with increased use of lipid formulations this could change (63–65). Tumor-inducing effects have not been demonstrated in animals or humans.

Organs and Systems

Cardiovascular

Electrolyte disturbances (hyperkalemia, hypomagnesemia, renal tubular acidosis) due to renal toxicity can be additional factors that precipitate cardiac reactions.

Effects on blood pressure

Changes in blood pressure (hypotension as well as hypertension) have been reported (66,67).

- A 67-year-old man with multiple intraperitoneal and urinary fungal pathogens and a history of well-controlled chronic hypertension developed severe hypertension associated with an infusion of ABLC (68). He received a 5 mg test dose, which was tolerated without incident. About 60 minutes into the infusion (5 mg/kg), his blood pressure rapidly increased to 262/110 mmHg from a baseline of 150/80 mmHg. His temperature increased to 39.8°C, and tachycardia developed (up to 121/minute). The infusion was stopped, and he was given morphine, propranolol, and paracetamol. His blood pressure returned to baseline over the next 2 hours. Rechallenge with ABLC on the next day resulted in an identical reaction despite premedication with pethidine, diphenhydramine, and morphine. ABLC was permanently withdrawn, and the infection was managed with high dosages of fluconazole.

The etiology of amphotericin-associated hypertension has not been elucidated, but it may be related to vasoconstriction. Of note, the traditional test dose appears not to identify individuals predisposed to hypertensive reactions; four of six cases of amphotericin-associated hypertension received test doses without incident.

Cardiac dysrhythmias

In 6 of 90 children given intravenous amphotericin there was a significant fall in heart rate, and monitoring of heart rate was recommended in children with underlying heart disease (69). These immediate reactions follow intravenous administration and occur particularly with excessively rapid infusion of DAMB.

Ventricular dysrhythmias have been reported after rapid infusion of large doses of DAMB (70) in patients with hyperkalemia and renal insufficiency, but not in patients with normal serum creatinine and potassium concentrations, even if they have received the drug over a period of 1 hour. Slower infusion rates and infusion during hemodialysis have been advocated in patients with terminal kidney insufficiency, in order to avoid hyperkalemia.

Chest pain

Three cases of chest discomfort associated with infusion of L-AmB at a dosage of 3 mg/kg/hour for 1 hour have been reported (71).

- The first patient had chest tightness and difficulty in breathing and the second had dyspnea and acute hypoxia (PaO_2 55 mmHg; 7.3 kPa), both within 10 minutes of the start of the infusion. The third complained of chest pain 5 minutes after the start of two infusions. In all cases the symptoms resolved on terminating therapy. Two patients were later rechallenged with slower infusions and tolerated the drug well.

A review of the literature showed that similar reactions had been reported anecdotally in several clinical trials of L-AmB, with all other formulations, and with liposomal daunorubicin and doxorubicin. While the pathophysiology of such reactions is yet unclear, the authors recommended infusing L-AmB over at least 2 hours with careful monitoring of adverse events.

Myocardial ischemia

Rare instances of cardiac arrest have been reported (72).

Vascular effects

Phlebitis occurs in over 5% of patients receiving amphotericin deoxycholate through peripheral veins, which

© 2006 Elsevier B.V. All rights reserved.

limits the concentration advisable for this route of administration.

Raynaud's syndrome has been attributed to DAMB phenomenon (73).

Extravasation can cause severe local reactions, including tissue necrosis. Safe venous access, preferably via a central line is advisable. The recommendation to use sodium heparin or buffered dextrose is not supported by clinical data.

Respiratory

Inhaled DAMB, and to a lesser extent inhaled liposomal amphotericin, can provoke pulmonary reactions, including bronchospasm, cough, and dyspnea (74–77).

Original suggestions that DAMB in combination with granulocyte transfusions (78) result in pulmonary toxicity have subsequently not been confirmed in prospective observations (62,79). Pulmonary reactions, including dyspnea, hemoptysis, and new infiltrates, have also been suspected to be caused by the combined use of blood platelet transfusions and DAMB (SEDA-12, 227). It therefore appears advisable to space transfusions of blood products and amphotericin if possible (80).

Intravenous administration of DAMB has been associated with pulmonary reactions, including dyspnea, bronchospasm, fever, and chills; in contrast to rare reports of dyspnea after liposomal amphotericin (5), dyspnea was not associated with general toxic reactions. The possibility that liposome overload is the explanation of this reaction should be considered.

A life-threatening event has been reported after the use of ABLC in a patient previously treated with amphotericin deoxycholate (81).

- Tachycardia, tachypnea, dyspnea, and severe hypoxemia occurred 90 minutes after the start of the first dose of ABLC, with radiological evidence of bilateral interstitial infiltrates, and required transient mechanical ventilation. After the event, treatment was continued with amphotericin deoxycholate without undesirable effects.

Nervous system

Headache is common during the immediate infusion reaction. Neuropathy, convulsions, tremor, and paresis have also been attributed to amphotericin. It is difficult to assess these reports, because in systemic fungal infections, with the possibility of central nervous system involvement, the symptoms may be due to the underlying disease.

Reversible parkinsonism has been attributed to ABLC (82).

- A 10-year-old bone marrow recipient was given ABLC 7 mg/kg/day for prolonged periods of time. Ablation therapy before transplantation included cytosine arabinoside, cyclophosphamide, and total body irradiation. He developed progressive parkinsonian features; an MRI scan showed non-specific frontal cortex white matter abnormalities, and brain MR spectroscopy was consistent with significant neuronal loss in the left insular cortex, left basal ganglia, and left frontal white matter. He was given co-careldopa (carbidopa + levodopa) and made a slow recovery within 4 months. A follow-up MRI scan again showed frontal white matter changes, but repeat MR spectroscopy showed marked improvement in the areas previously examined.

This case shows that, regardless of the formulation of amphotericin, severe neurological adverse effects can occur, in particular in patients who receive large dosages of amphotericin after cranial irradiation. A clinical syndrome of akinetic mutism, incontinence, and parkinsonism has been described in patients who received large doses of amphotericin deoxycholate in association with central nervous system irradiation or infection (67).

Electrolyte balance

Selective distal tubular epithelial toxicity by amphotericin can cause hypokalemia, and hypokalemia can cause further tubular damage. There is some evidence that hypokalemia due to amphotericin is mitigated by both spironolactone (83) and amiloride (84).

Infusion of amphotericin deoxycholate can cause hyperkalemia, in particular in the setting of renal insufficiency (67). The primary mechanism is not known.

- Fatal cardiopulmonary arrest occurred in a 4-year-old boy with acute leukemia and disseminated invasive candidiasis after the third infusion of ABLC 5 mg/kg/day, infused over 1 hour (85). During resuscitation he had a serum potassium concentration of 16 mmol/l; there was no evidence of hemolysis or rhabdomyolysis and serum creatinine and potassium concentrations had been within the reference ranges earlier in the day. Autopsy showed numerous fungal abscesses, including several in the myocardium.
- Serum potassium concentrations were determined at the end of a 2-hour infusion of amphotericin deoxycholate (1 mg/kg/day) in a 2-year-old girl with systemic candidiasis receiving long-term hemodialysis for renal dysplasia (85). The potassium concentration was 6.7 mmol/l, despite dialysis against a 1.5 mmol/l potassium bath just before the infusion. The next dose was given during dialysis, and the serum potassium concentration was 2.6 mmol/l after the infusion.

When giving amphotericin to dialysed patients, it may be necessary to give it during dialysis in order to avoid hyperkalemia.

Hematologic

A normochromic, normocytic, usually mild anemia develops regularly during therapy with DAMB. The erythropoietin response to anemia appears to be blunted during DAMB therapy, and survival of erythrocytes may be reduced by toxic effects of amphotericin on the cell membrane (86).

Frank hemolysis has also been reported in rare instances, including, rarely, immune-mediated hemolysis (87,88).

Leukopenia has been reported (SED-12, 673).

Thrombocytopenia has been reported in several instances and also occurs with lipid formulations (89,90).

© 2006 Elsevier B.V. All rights reserved.

During amphotericin therapy, the response of platelet counts to thrombocyte transfusions was reduced, as was platelet survival (91,92).

Gastrointestinal

Anorexia, nausea, and vomiting are common effects of parenteral administration of amphotericin. Gastrointestinal complaints are markedly less common with liposomal amphotericin than with ABCD(5).

Liver

Cholestasis has been reported in infants treated with amphotericin for systemic *Candida* infections (SEDA-14, 230). Most of the above reports were incidental, and amphotericin cannot be regarded as a known cause of liver damage. This does not necessarily also apply to liposomal amphotericin and other lipid formulations. Therapy with L-Amb, AmBisome was associated with a rise in alkaline phosphatase in over a third of children treated with AmBisome (93) and with hepatic dysfunction in a little under 20% of adolescents and adults. In a small retrospective study, ABLC was withdrawn in 27% of patients because of rises in serum bilirubin and alkaline phosphatase, a finding confirmed in a larger prospective study. Cholestasis has also been observed with ABCD, in contrast to reports that L-AmB does not increase transaminases (5).

Acute hepatic damage has rarely been reported with DAMB. Asymptomatic increases in hepatic serum enzyme activities were seen in one case (94).

- A 26-year-old previously healthy man with life-threatening pulmonary blastomycosis developed increased hepatic transaminases to a maximum of ten times (aspartate transaminase) and 20 times (alanine transaminase), the upper limit of the reference ranges, 10 days after the addition of amphotericin (0.5 mg/kg) to his initial itraconazole therapy (200 mg bd) (95). The serum transaminase activities returned to normal within 4 days after withdrawal of amphotericin, and the blastomycosis was successfully treated with itraconazole alone. A liver biopsy showed mild focal fatty changes but no evidence of blastomycosis.

The authors speculated that amphotericin may have facilitated the uptake of itraconazole into mammalian cells by its membrane-damaging action, leading to increased interaction of itraconazole with CYP450 enzymes and hepatocellular damage.

Pancreas

In a retrospective analysis, 5 of 31 children with cancers, who had received liposomal amphotericin in dosages of 1–3 mg/kg/day, had an isolated transient rise in the serum lipase activity during or shortly after therapy with liposomal amphotericin (96). Three of these patients had signs of pancreatitis. While the exact pathogenesis is unclear, the authors proposed fat overload or toxic damage to the pancreas by the liposomes or amphotericin itself as potential mechanisms.

Urinary tract

Amphotericin can cause both glomerular and tubular damage. Lipid-based formulations (colloidal dispersion, lipid complex, and liposomal amphotericin) are less nephrotoxic than conventional amphotericin deoxycholate (97). However, several caveats have to be kept in mind in making such comparisons. For example, there are no defined equivalent doses for amphotericin deoxycholate and its lipid-based counterparts.

Presentation

The clinical and laboratory findings include reductions in glomerular filtration rate and renal plasma flow, proteinuria, cylindruria, and hematuria; the last three are frequent but usually discrete. The reductions in renal plasma flow and filtration fraction occur early. Changes in tubular function can cause increased excretion of uric acid (an effect that can be used to monitor the tubular damage). Excessive loss of potassium, magnesium, and bicarbonate result in hypokalemia, hypomagnesemia, and renal tubular acidosis (98,99). Severe hypokalemia is common, and requires parenteral potassium replacement. Acidosis can also be severe, requiring bicarbonate. Hypomagnesemia, which may be symptomatic, can cause secondary hypocalcemia, resulting in tetany (100–102).

Amphotericin can cause an inability to form a concentrated urine (hyposthenuria) although this rarely becomes clinically important (67).

Nephrogenic diabetes insipidus, resistant to vasopressin, following damage to the distal renal tubule, may be more common than reported (103,104). Careful monitoring of electrolytes is therefore recommended in all instances of amphotericin therapy.

- A 43-year-old HIV-infected patient presented with nephrogenic diabetes insipidus associated with amphotericin deoxycholate therapy for ocular candidiasis; rechallenge was positive (105).

Mechanism

The exact mechanisms involved in amphotericin-induced uremia are not yet fully understood. Changes in tubular ion permeability have been demonstrated both in vitro and in vivo (12,100,106). The uremia can be caused by tubuloglomerular feedback, a mechanism whereby increased delivery and re-absorption of chloride ions in the distal tubule initiates a reduction in the glomerular filtration rate. Tubuloglomerular feedback is amplified by sodium deprivation and suppressed by sodium loading. Other possible mechanisms are renal arteriolar spasm, calcium deposition during periods of ischemia, and direct cellular toxicity (12). Yet other lines of research have looked at the roles of prostaglandins and TNFα, with evidence that indometacin may abate prostaglandin-mediated toxicity (107), an approach that is not practical in most patients requiring antifungal drugs.

- Renal damage due to amphotericin has also been reportedly caused by a tumor lysis-like syndrome in a 41-year-old woman with visceral leishmaniasis, with hyperkalemia, hyperphosphatemia, hyperuricemia, and acute renal insufficiency (108).

Differences among formulations

The nephrotoxicity of lipid formulations of amphotericin varies from formulation to formulation.

Amphotericin B deoxycholate

The epidemiology of the nephrotoxicity of conventional amphotericin B has been investigated in a retrospective study in 494 adult inpatients who received two or more doses (109). Nephrotoxicity was defined as a 50–100% increase in the baseline creatinine concentration. The median cumulative dose was 240 mg and most of the patients received it for empirical therapy. Overall, 139 patients (28%) had renal toxicity, including 58 (12%) with moderate to severe nephrotoxicity. For each 10 mg increase in the mean daily dose, the adjusted rate of renal toxicity increased by a factor of 1.13. Five risk factors were defined: a mean daily dose of 35 mg or more, male sex, weight 90 kg or more, chronic renal disease, and concurrent use of amikacin or ciclosporin. The incidence of moderate to severe nephrotoxicity was 4% in patients with none of these risk factors, 8% in those with one, 18% in those with two, and 29% in those with three or more. Nephrotoxicity rarely led to hemodialysis ($n = 3$). However, at the time of discharge or death, 70% of the patients with moderate to severe nephrotoxicity had a serum creatinine concentration that was at least 44 μmol/l above baseline. This study shows dose-dependency of nephrotoxicity related to DAMB, accentuated by other nephrotoxic drugs and patient risk factors. The authors suggested that in patients with more than two risk factors alternative antifungal drugs should be considered.

The nephrotoxicity of amphotericin deoxycholate has been investigated in a retrospective multicenter study in 239 immunosuppressed patients with suspected or proven aspergillosis for a median duration of 15 days (110). The serum creatinine concentration doubled in 53% of the patients and exceeded 221 μmol/l in 29%; 15% underwent dialysis, and 60% died. Multivariate Cox proportional hazards analysis showed that patients whose creatinine concentration exceeded 221 μmol/l, and patients with allogeneic and autologous bone marrow transplants were at greatest risk of requiring hemodialysis. The use of hemodialysis, the duration of amphotericin therapy, and the use of nephrotoxic agents were associated with a greater risk of death, whereas patients who underwent solid organ transplantation were at lowest risk. The findings of this study suggest that raised creatinine concentrations during therapy with amphotericin are associated with a substantial risk of hemodialysis and a higher mortality rate, but these risks vary in different patients.

Amphotericin-associated nephrotoxicity has been studied in a retrospective analysis of 69 recipients of blood stem-cell transplants with multiple myeloma who received at least two doses of amphotericin deoxycholate during 1992–95 (111). Nephrotoxicity occurred in 30 patients (43%) and developed rapidly. Patients who developed nephrotoxicity were similar to those who did not in many aspects associated with their treatment. However, baseline-estimated creatinine clearance, ciclosporin therapy, nephrotoxic drug therapy within 30 days of starting amphotericin, and the number of concomitant nephrotoxic drugs were significant predictors of amphotericin-associated nephrotoxicity. The authors concluded that recipients of bone marrow or peripheral blood stem-cell transplants who have multiple myeloma and are receiving ciclosporin or multiple nephrotoxic drugs at the start of amphotericin therapy should be considered at high risk of amphotericin-associated nephrotoxicity.

In a retrospective study, renal function was investigated in patients receiving ciclosporin alone or in combination with amphotericin (24-hour infusion) after allogeneic stem-cell transplantation (112). Of 84 patients, 22 were treated with amphotericin. There was a statistically significant reduction in renal function compared with the 62 patients who received ciclosporin alone. However, renal insufficiency in all patients remained in a clinically acceptable range and was reversible in patients who survived to 1 year after transplantation.

Continuous infusion of amphotericin has been assessed in an open study in six lung transplant recipients with invasive or semi-invasive bronchopulmonary azole-resistant candidal infections who were treated for 40 (17–73) days by 24-hour continuous infusions of amphotericin 1 mg/kg (113). They received at least 1000 ml/day of 0.9% saline intravenously. Apart from ciclosporin, five patients received aminoglycosides for at least 2 weeks, and four received ganciclovir. Calculated creatinine clearance fell from 57 (43–73) ml/minute to a nadir of 35 (28–39) and recovered to 52 (33–60) after the end of therapy. One patient needed temporary hemofiltration for 7 days. Besides three episodes of mild hypokalemia there were no adverse effects attributable to amphotericin. Asymptomatic colonization with *Candida* persisted for 10 months in one case, but the other five patients were cured.

Amphotericin B colloidal dispersion

During ABCD therapy 8.5% of patients developed nephrotoxicity compared with 21% in those given amphotericin deoxycholate (5).

In a randomized, double-blind, multicenter trial, ABCD (Amphotec; 6 mg/kg/day) was compared with liposomal amphotericin (1.0–1.5 mg/kg/day) for the first-line treatment of invasive aspergillosis in 174 patients (114). The median duration of therapy was 13 (1–357) days in those given ABCD, and 15 (1–87) days in those given liposomal amphotericin. For evaluable patients ($n = 103$) given ABCD or liposomal amphotericin, the respective rates of therapeutic response (52 versus 51%), mortality (36 versus 45%), and death due to fungal infection (32 versus 26%) were similar. Renal toxicity was significantly lower (25 versus 49%) and the median time to onset of nephrotoxicity longer (301 versus 22 days;) in the patients who received ABCD. Rates of drug-related toxicity in the patients who received ABCD and liposomal amphotericin were respectively 53 versus 30% (chills), 27 versus 16% (fever), 1 versus 4% (hypoxia), and 22 versus 24% (toxicity requiring study drug withdrawal). Based on the results of this trial, ABCD appears to have equivalent efficacy to liposomal amphotericin, and superior renal safety in the treatment of invasive aspergillosis.

© 2006 Elsevier B.V. All rights reserved.

However, infusion-related chills and fever occurred more often with ABCD.

Amphotericin B lipid complex (ABLC)

A comparison of ABLC with amphotericin deoxycholate showed significant differences, with a doubling of baseline creatinine in 28% during ABLC compared with 47% during conventional therapy (5).

There has been a retrospective comparison of the renal effects of ABLC with amphotericin deoxycholate in the treatment of invasive candidiasis and cryptococcosis in dosages of 0.6–5 mg/kg/day; most patients received 5 mg/kg/day (115). Changes in serum creatinine were evaluated in three ways: doubling of the baseline value, an increase from below 132 μmol/l (1.5 mg/dl) at baseline to over 132 μmol/l, and an increase from below 132 μmol/l at baseline to at least 177 μmol/l (2.0 mg/dl). These endpoints were achieved significantly more often with amphotericin deoxycholate than with ABLC, and the time needed to reach each of the endpoints was significantly shorter with amphotericin deoxycholate. An increased serum creatinine concentration was reported as an adverse event more often in patients receiving amphotericin deoxycholate than in patients receiving ABLC (24 versus 43%).

The rates of ABLC-associated nephrotoxicity in various clinical settings at a university hospital have been estimated retrospectively and compared with previously reported rates of nephrotoxicity (116). Data from 33 adult patients (20 men, 13 women; mean age 49 years) with and without neutropenia receiving ABLC were collected, and the degree of nephrotoxicity was determined using two definitions: (1) doubling of baseline serum creatinine concentration using the peak value within the first 7 days and (2) end-of-therapy doubling of baseline serum concentration using the end-of-therapy value. Using the selected definitions of ABLC-associated nephrotoxicity, there were only two cases. This rate was significantly below the 42% rate reported in the only large published study (95% CI = 1.7, 19.6). The median change in serum creatinine concentration was 8.9 (–97 to 380) μmol/l. The concomitant use of nephrotoxic agents was not associated with significant changes in serum creatinine concentration. The authors concluded that ABLC infrequently causes clinically significant nephrotoxicity, and that earlier data derived from a single study in febrile patients with neutropenia should be interpreted cautiously.

Liposomal amphotericin B (L-Amb, AmBisome)

In a prospective double-blind study of more than 600 patients, 0.6 mg/kg of DAMB was compared with 3.0 mg/kg of L-Amb, a dose relation at the lower limit of equivalent doses determined in an animal model (117). At these dosages, in a large prospective double-blind study, there was a doubling of serum creatinine concentration in 19% of neutropenic patients receiving empirical therapy with L-AmB and 34% receiving conventional amphotericin (47).

Liposomal amphotericin has been given to an immunosuppressed renal transplant patient with cerebral aspergillosis for almost 10 months at a cumulative dose of 42 g with no apparent changes in the function of the renal allograft, as measured by serum creatinine, creatinine clearance, and potassium concentrations (118). Therapy was ultimately successful and was discontinued after surgical resection of a residual sclerotic lesion.

Liposomal amphotericin (3 mg/kg/day) has been compared with conventional amphotericin (0.7 mg/kg/day) for induction therapy of moderate to severe disseminated histoplasmosis in a randomized, double-blind, multicenter trial in 81 patients with AIDS (119). The duration of induction was 2 weeks, to be followed by 10 weeks of itraconazole in the case of a response. Clinical success was achieved in 14 of 22 patients treated with conventional amphotericin compared with 45 of 51 patients who received liposomal amphotericin (difference, 24%; 95% CI = 1%, 52%). Culture conversion rates were similar. Three patients treated with conventional amphotericin and one treated with liposomal amphotericin died during induction. Infusion-related adverse effects were more common with conventional amphotericin (63%) than with liposomal amphotericin (25%). Nephrotoxicity occurred in 37% of patients treated with conventional amphotericin and 9% of patients treated with liposomal amphotericin. The results of this study suggest that liposomal amphotericin is less toxic than conventional amphotericin and is associated with improved survival.

Prevention

Avoidance of salt depletion and a salt load (500–1000 ml of 0.9% saline) reduce the renal toxicity of DAMB (120–126). Also the maintenance of adequate serum potassium concentrations by replacement therapy may be important and may contribute to "kidney sparing" (127). Other preventive measures, including dopamine infusion, are of no value (128).

It has been suggested that amphotericin-induced nephrotoxicity may be mitigated by increasing renal blood flow and glomerular filtration rate with low-dose dopamine (1–3 μg/kg/minute). The efficacy of low-dose dopamine in preventing nephrotoxicity associated with amphotericin deoxycholate has been evaluated in a prospective randomized study in 71 patients after antineoplastic chemotherapy for autologous bone marrow transplantation or acute leukemia (128). The patients were randomly assigned to receive low-dose dopamine by continuous infusion (3 μg/kg/minute) or no dopamine. Amphotericin deoxycholate 0.5 or 1.0 mg/kg/day was given for respectively 8 and 13 days on average. Nephrotoxicity, defined as a 1.5-fold or greater increase in baseline serum creatinine concentration, was slightly less common, but not significantly so, in those given dopamine (67 versus 80%). The grade of nephrotoxicity was the same. Ten patients developed grade IV nephrotoxicity and were withdrawn from the study. The authors concluded that dopamine offers little benefit in preventing amphotericin deoxycholate-associated nephrotoxicity.

In a randomized, controlled, single-center study, continuous infusion of amphotericin reduced nephrotoxicity and infusion-associated reactions compared with the standard infusion over 2–4 hours in patients with neutropenia, refractory fever, and suspected or proven invasive fungal infections (129). However, the concentration-dependent

© 2006 Elsevier B.V. All rights reserved.

pharmacodynamics of antifungal polyenes raise concerns about the antifungal effectiveness of this mode of administration in particular, as its therapeutic efficacy has not been adequately studied in animals or in patients with documented infections.

Skin

An allergic skin reaction to amphotericin has been reported (130).

- A 3-year-old child had a severe allergic reaction during treatment with liposomal amphotericin for persistent neutropenic fever following unrelated allogeneic cord blood stem-cell transplantation. The patient developed an extensive maculopapular rash and severe itching that was unresponsive to antihistamine and glucocorticoid medication and resolved only after drug withdrawal. Continuation of therapy with conventional amphotericin for 20 days was well tolerated, suggesting that the lipid carrier was responsible for the adverse event.

Immunologic

A literature review found no support for the routine use of a test dose of amphotericin before the first therapeutic dose of amphotericin deoxycholate, as is still recommended by the manufacturers (131). The mechanism of common infusion-related adverse effects does not appear to be allergic in nature, and true allergic reactions are rare. Moreover, the absence of a reaction to a test dose does not necessarily indicate that patients will not have a severe infusion-related reaction later in the course of therapy, and the procedure of administering a test dose can lead to a detrimental delay in adequate antifungal therapy. The authors recommended starting therapy with amphotericin deoxycholate at the full therapeutic target dose, with careful bedside monitoring for infusion-related adverse events throughout therapy.

Anaphylaxis is rare with amphotericin (67). It is important to note that a patient may tolerate one formulation and respond with anaphylaxis to another.

- Anaphylaxis after ABCD occurred in a patient who had previously been treated with both amphotericin deoxycholate and ABLC without infusion-related adverse effects (65). During the first infusion of ABCD he developed spontaneously reversible severe back pain and then swelling of his lips, respiratory distress, and left-sided hemiparesis, which resolved after 24 hours. An MRI scan suggested an ischemic event in the right putamen, lending support to the hypothesis that he had had an anaphylactic reaction to ABCD, hypoperfusion, and a subsequent stroke.
- In another patient, serious adverse events (fever, severe rigors, a fall in blood pressure, worsening mental status, increasing creatinine concentration, and leukocytosis) occurred after unrecognized substitution of one amphotericin formulation (ABLC) by another (ABCD) (132). After discovery of the switch, ABLC therapy was reinstituted and tolerated without incident.

These cases underscore the need to monitor patients closely when infusing the first dose of a different formulation of amphotericin.

Second-Generation Effects

Pregnancy

Experience with amphotericin in pregnancy is limited. Amphotericin crosses the placenta and can increase creatinine concentrations in the neonate. High tissue concentrations of amphotericin persist weeks after treatment has been stopped (133).

Susceptibility Factors

Age

Neonates

The safety and efficacy of liposomal amphotericin in 40 preterm and 4 full-term neonates with invasive yeast infections have been studied retrospectively (134). The initial dosage was 1 mg/kg/day, and was increased stepwise by 1 mg/kg to a maximum of 5 mg/kg, depending on the clinical condition. There were no infusion-associated reactions. Blood pressure, hepatic, renal, and hematological indices were not altered. Hypokalemia was noted in 16 infants but was always transient and responsive to potassium supplementation. Treatment with liposomal amphotericin was successful in 72% of the children. However, 12 of the 40 preterm infants succumbed to the fungal infection; all had a birth weight of less than 1.5 kg.

Changes in serum creatinine and serum potassium have been measured in 21 neonates of very low birth weight who received amphotericin for presumed or documented yeast infections (135). The median dosage was 2.6 (range 1–5) mg/kg/day, and the median duration of therapy was 2 (11–79) days. Hypokalemia (below 3 mmol/l) was observed in 30% before treatment and in 15% during treatment. However, 21 days after the end of therapy, hypokalemia was not present in any patient. The maximum creatinine concentration fell from 121 (71–221) μmol/l to 68 (31–171) μmol/l during treatment and 46 (26–62) μmol/l at 21 days after the end of therapy. However, creatinine concentrations were available for only 10, 18, and 15 of the 21 patients respectively, and no information was provided on the number of patients who had an increase in serum creatinine during therapy. All patients responded to therapy with liposomal amphotericin, although the number of proven invasive fungal infections was small (7/21).

Infants

The safety and efficacy of ABLC in 11 neonates with systemic *Candida* infections have been reported (136). The infants were aged 3–14 (median 7) weeks and weighed 0.7–5 (median 1.4) kg. The median duration of ABLC treatment was 23 (range 4–41) days at an average dose of 4.9 (range 3.2–6.5) mg/kg/day. Nine of the eleven patients improved clinically, and eight of nine evaluable patients had a mycological cure. No infant discontinued treatment because of adverse drug reactions, and none had appreciable hepatic or hematological toxicity. Renal function improved or did not change in 8 of the 11. The median pretreatment serum creatinine concentration was 80 (range 35–522) μmol/l and the median creatinine

© 2006 Elsevier B.V. All rights reserved.

concentration at the end of treatment was 44 (range 18–628) μmol/l.

Children

The disposition of liposomal amphotericin in children and adolescents is similar to that in adults. Liposomal amphotericin and conventional amphotericin have been compared in a randomized, multicenter study in 204 children with cancers, pyrexia, and neutropenia (137). There was a 2.6 times lower incidence of adverse effects with the liposomal formulation. There were severe adverse effects in 1% of those who received liposomal amphotericin and 12% of those who received the conventional formulation.

Data on the safety of amphotericin deoxycholate have been reported for 50 therapeutic courses in 44 children and adolescents with cancer and a median age of 6.8 years (range 9 months to 18 years) (50). Amphotericin deoxycholate was given in a dose of 1 mg/kg over 2 hours for a mean duration of 7.8 days. Most of the patients received the drug as empirical antifungal therapy in the setting of persistent fever and neutropenia. Nephrotoxicity, defined as a 100% increase in the serum creatinine from baseline, was observed in only one patient. Infusion-related reactions (fevers and/or rigors) occurred in 24% of treatment courses. Thus, amphotericin deoxycholate was relatively well tolerated in this population, although the mean duration of therapy was comparatively short.

The safety and efficacy of ABLC have been studied in an open, emergency-use, multicenter study in 111 treatment episodes in children with invasive mycoses refractory to or intolerant of conventional antifungal drugs (138). The mean daily dosage was 4.85 (range 1.1–9.5) mg/kg, and the mean duration of therapy was 33 (range 1–191) days. While the proportion of patients with deteriorating renal function was not mentioned, the mean serum creatinine concentration in the entire study population did not change significantly between baseline (109 μmol/l) and withdrawal of ABLC (117 μmol/l) over 6 weeks. Similarly, there were no significant differences between initial and end-of-therapy concentrations of serum potassium, magnesium, transaminases, alkaline phosphatase, and hemoglobin. However, there was a significant increase in mean total bilirubin (from 63 to 91 μmol/l) at the end of therapy. ABLC was withdrawn because of toxicity in 7 of the 111 children; adverse events leading to withdrawal included intolerable infusion-related reactions and allergic reactions. Among the 54 evaluable patients, a complete or partial therapeutic response was obtained in 38.

Drug Administration

Drug dosage regimens

By lowering the infusion rate and using continuous infusion, fewer toxic reactions have been observed. In contrast, varying the infusion time of daily doses between 1 and 6 hours made no important change in regard to toxicity (139–144). Alternatively, smaller starting doses have been suggested to reduce toxicity, a strategy that is often not advisable in acute severe mycoses. The use of lipid formulations reduces the incidence and severity of general toxic reactions and of nephrotoxicity (22,47,49). It is currently unclear, however, whether lipid formulations of amphotericin have a broader therapeutic index than conventional DAMB. It has to be borne in mind that lipid formulations, while affecting the pharmacokinetics of amphotericin, have no targeting properties that discriminate between the cell membrane of the pathogen and that of host cells. It therefore appears possible that some, if not all, of their advantages are in the avoidance of high concentrations of reactive amphotericin, an effect that could also be obtained by continuous infusion of the conventional formula (62). Monitoring of blood concentrations of amphotericin B is not practical, and there are no validated recommendations for its use, neither for avoidance of toxicity nor for monitoring of efficacy.

Drug administration route

Amphotericin given intravenously does not lead to adequate CSF concentrations, and it can rarely be given intrathecally in cases of cerebral infection. Nevertheless, amphotericin is effective even in cryptococcal meningitis, in the absence of marked meningeal inflammation. Continuous infusion may be associated with less toxicity, but experience is limited.

Delirium (145) and parkinsonism (146) have been described after intrathecal or intraventricular therapy.

Drug–Drug Interactions

Aminoglycoside antibiotics

Amphotericin prolongs the half-life of aminoglycoside antibiotics (147).

Antifungal azoles

In evaluating possible antagonism between amphotericin and antifungal azoles, details of the experimental set-up are crucial. When filamentous fungi were exposed to subfungicidal concentrations of azoles, before exposure to an amphotericin + azole combination, antagonism could always be shown both in vitro and in vivo (148–150).

In vitro studies and experiments in animals have given conflicting results relating to potential antagonism between the effects of fluconazole and amphotericin on *Candida* species (149). However, large, randomized, double-blind comparisons of fluconazole with and without amphotericin for 5 days in non-neutropenic patients with candidemia showed no evidence of antagonism, but faster clearance of the organism from the blood and a trend toward an improved outcome in those who received the combination (151).

The combination of amphotericin with ketoconazole appears to lead to antagonism (148). A study of the effects of combinations of amphotericin with fluconazole, itraconazole, or ketoconazole against strains of *Aspergillus fumigatus* in vitro showed antagonistic effects in some strains, but different effects in other strains (152). In one group of mice infected with *Candida*, combinations of amphotericin with fluconazole were more effective

© 2006 Elsevier B.V. All rights reserved.

than fluconazole alone; in another group the combination showed no interaction, but was not better than either drug given alone (153).

Although there are no clinical data, it can be expected that similar antagonism occurs between amphotericin and squalene oxidase inhibitors, which also eliminate the primary target ergosterol from the fungal cell membrane.

Ciclosporin

Because ciclosporin causes a reduction in renal function, there is increased nephrotoxicity if amphotericin is also given (112,147).

Cisplatin

Amphotericin-induced hypomagnesemia may be more profound in patients who develop a divalent cation-losing nephropathy associated with cisplatin (12).

Cytotoxic drugs

Amphotericin can enhance the risk of adverse effects from cytotoxic drugs (154).

Digitalis

Hypokalemia due to amphotericin can enhance the toxicity of digitalis (12,127).

Diuretics

The concurrent use of diuretics is associated with a higher risk of nephrotoxicity from amphotericin (155).

Flucytosine

Amphotericin in combination with flucytosine results in an increased risk of hematological complications, because amphotericin often impairs renal function, causing retention of flucytosine (10).

Neuromuscular blocking drugs

Hypokalemia due to amphotericin can enhance the curariform effect of neuromuscular blocking agents (12,127,154).

Tacrolimus

Tacrolimus (FK 506), a macrolide immunosuppressant, has adverse effects similar to those of ciclosporin, including nephrotoxicity. Increased nephrotoxicity can be expected when it is given with amphotericin (156).

Ampiroxicam

See also Non-steroidal anti-inflammatory drugs

General Information

Ampiroxicam is a piroxicam prodrug, which is completely converted to piroxicam after oral administration. Its adverse effects profile is expected to be similar to that of piroxicam. A few cases of photosensitivity have been reported (1–5).

Amprenavir

See also Protease inhibitors

General Information

Amprenavir is an HIV protease inhibitor with an enzyme inhibitory constant of 0.6 nmol/l, similar to the inhibitory constants of other protease inhibitors. Its in vitro IC_{50} against wild-type clinical HIV isolates is 115 ng/ml. It has a long half-life (7–10 hours). It can be given twice-daily without food restrictions and had high potency when given as monotherapy in dose-finding studies (1). The recommended doses are 1200 mg bd for adults and 20 mg/kg bd or 15 mg/kg tds for children under 13 years of age or adolescents under 50 kg. Capsules and solution do not have equal systemic availability, and the recommended dose for amprenavir oral solution is 1.5 ml/kg bd or 1.1 ml/kg tds. The systemic availability increases with increasing doses. Amprenavir is about 90% bound to $alpha_1$ acid glycoprotein and 40% to albumin. It does not penetrate the brain well, because it is exported by P glycoprotein. It is mainly metabolized by CYP3A4 and its clearance is reduced in liver disease. The clinical pharmacology of amprenavir has been reviewed (2).

The use of amprenavir has been limited to patients who are highly motivated, because of the high capsule burden (16/day).

Fosamprenavir is a prodrug of amprenavir with better systemic availability. In large clinical trials the most common adverse events in patients taking fosamprenavir, with or without ritonavir, plus abacavir and lamivudine were diarrhea, nausea, vomiting, abdominal pain, drug hypersensitivity, and skin rashes (3).

Observational studies

In a monotherapy trial ($n = 37$), adverse effects were frequent but generally mild, and included rash, diarrhea or loose stools, and headache. In general, these adverse effects tend to disappear or weaken in severity within the first 2–4 weeks of treatment.

General adverse effects

The adverse effects of amprenavir in patients treated with combination therapy included nausea, vomiting, diarrhea, epigastric pain, flatulence, paresthesia, headache, rash, and fatigue (4). The contribution of a single drug to the observed adverse effects is difficult to establish. Amprenavir inhibits CYP3A4 to a greater extent than saquinavir, and to a much lesser extent than ritonavir (5). Co-administration with rifampicin and rifabutin should be avoided. Those who take

© 2006 Elsevier B.V. All rights reserved.

amprenavir have complained of diarrhea, nausea, headache, and fatigue (6). The frequency of diarrhea may be as high as 50%.

Organs and Systems

Nervous system

Neurotoxicity has been attributed to amprenavir (7).

- A 61-year-old man, who had taken various antiretroviral drugs, took amprenavir 750 mg bd and after the first dose had hallucinations, disorientation, tinnitus, and vertigo. The symptoms abated within 2 hours and recurred after the next dose.

Drug–Drug Interactions

Clarithromycin

A pharmacokinetic study has shown a minor interaction of amprenavir with clarithromycin in healthy men (8). The mean AUC, $C_{max.ss}$ and $C_{min.ss}$ of amprenavir increased by 18, 15, and 39% respectively. Amprenavir had no effect on the AUC of clarithromycin, but the median $t_{max.ss}$ increased by 2 hours, renal clearance increased by 34%, and the AUC for 14-(*R*)-hydroxyclarithromycin fell by 35%. These effects were felt not to be clinically important and dosage adjustment was not recommended.

Efavirenz

Four HIV-infected children undergoing intense antiretroviral combination therapy were switched to regimens including amprenavir and efavirenz after the failure of other drugs (9). Pharmacokinetic studies suggested that combinations of these drugs can result in suboptimal concentrations of amprenavir. This was evident in two of the children taking amprenavir and efavirenz, in combination with two NRTIs, who had undetectable concentrations of amprenavir within 4 hours of administration. The addition of ritonavir to the combination restored the blood concentrations of amprenavir to those normally recorded (median 3500 ng/ml). The most probable reason for this effect is enhanced metabolism of amprenavir due to induction by efavirenz.

Indinavir

In an open, randomized study of amprenavir combined with indinavir, nelfinavir, and saquinavir (10) the amprenavir AUC increased by 35% when it was combined with indinavir, and indinavir concentrations also fell, suggesting that this protease inhibitor combination should be avoided. There was no significant interaction of amprenavir with nelfinavir.

Methadone

Amprenavir is extensively metabolized by and induces CYP3A4. Plasma methadone concentrations fell by 35% when amprenavir was used (11).

Rifamycins

Co-administration of amprenavir with rifampicin and rifabutin should be avoided (12).

Ritonavir

In attempts to lower the amprenavir capsule burden, low-dose ritonavir has been used as a pharmacokinetic booster. When ritonavir was added to amprenavir, the amprenavir AUC increased 3–4 times (13), which should allow the total daily capsule burden to be reduced. Adverse effects included diarrhea, nausea, paresthesia, rash, increased cholesterol, and increased triglycerides. The frequency of adverse events correlated with the dose of ritonavir.

Saquinavir

In an open, randomized study of amprenavir combined with indinavir, nelfinavir, and saquinavir (10), saquinavir lowered the amprenavir AUC by 32%; amprenavir did not alter the pharmacokinetics of saquinavir.

Food–Drug Interactions

Grapefruit juice

In 12 healthy volunteers, co-administration of a single dose of amprenavir 1200 mg with grapefruit juice slightly reduced the C_{max} compared with water (7.11 versus 9.10 μg/ml) and slightly increased the t_{max} (1.13 versus 0.75 hours), but did not affect the AUC (14). Thus, grapefruit juice has no clinically important effect on amprenavir pharmacokinetics.

Amrinone

See also Phosphodiesterase type III, selective inhibitors of

General Information

Amrinone is an inhibitor of phosphodiesterase type III, and has a positive inotropic effect. Its adverse effects (1–5) include thrombocytopenia (10%), hypotension, tachydysrhythmias (sometimes resulting in syncope and death) (9%), worsening cardiac ischemia (7%), worsening heart failure (15%), gastrointestinal disturbances (39%), neurological complications (17%), liver damage (7%), fever (6%), nephrogenic diabetes insipidus, hyperuricemia, flaking of the skin, brown discoloration of the nails, and reduced tear secretions. The figures in parentheses are taken from a study of the use of amrinone in 173 patients with chronic ischemic heart disease or idiopathic cardiomyopathies (3).

Other reported adverse effects include acute pleuropericardial effusions, perforated duodenal ulcer, acute myositis and pulmonary infiltrates, vasculitis with pulmonary infiltrates and jaundice, influenza-like illnesses, chest pain, headache, dizziness, anxiety, maculopapular rash, and night sweats (6).

Organs and Systems

Cardiovascular

There has been one report of paroxysmal supraventricular tachycardia in one of 16 patients with cardiogenic shock given amrinone (7).

Hematologic

Thrombocytopenia due to amrinone has been briefly reviewed (8).

Amtolmetin guacil

See also Non-steroidal anti-inflammatory drugs

General Information

Amtolmetin guacil (2-[2[1-methyl-5-(4-methylbenzoyl)-2-yl] acetamido] acetic acid 2-methoxyphenyl ester) is a non-acid prodrug of tolmetin. It has been introduced in various countries, and its launch was characterized by claims of better gastrointestinal tolerability than older compounds (1,2). Clinical and endoscopic comparative studies have been carried out in patients with various osteoarticular diseases (3–5). In most of these studies amtolmetin showed similar anti-inflammatory activity to other NSAIDs (diclofenac, flurbiprofen, ibuprofen, indometacin, naproxen) but less gastrotoxicity at endoscopic evaluation, with no difference in the incidence of gastrointestinal symptoms. Unfortunately, the clinical studies were small and of short duration, and the prognostic value of endoscopic studies with respect to severe gastrointestinal complications (bleeding, perforation, and obstruction) is debatable. It has been suggested that the mechanism of the gastric sparing effect of amtolmetin might be related to the local production of nitric oxide, which can counteract the damaging effects of prostaglandin inhibition (6,7).

© 2006 Elsevier B.V. All rights reserved.

A renal sparing effect has also been reported, but clinical experience with this compound is limited (8).

Amylin analogues

General Information

Amylin is a hormone produced in the beta-cells of the islets of Langerhans and is co-secreted with insulin. It has glucoregulatory effects that may complement the actions of insulin.

Pramlintide (rINN) is a non-aggregating analogue of amylin. It reduces postprandial glucose excursions, probably by reducing stomach emptying, not by stimulating the release of glucagon-like peptide (GLP-1) (1). It can only be given by injection.

The most common adverse effect of pramlintide is nausea. Hypoglycemia can occur if the dose of insulin is not reduced when pramlintide is added. In no studies was there evidence of cardiac, hepatic, or renal toxicity or hypersensitivity reactions.

Pramlintide has been studied in a double-blind, placebo-controlled, multicenter study in 480 patients with type 1 diabetes for 1 year, followed by an 1-year open extension (2). Glucose control improved with pramlintide. Hypoglycemia was less frequent with pramlintide, but nausea and anorexia doubled in frequency and constituted the most common reason for withdrawal.

In a comparable study, 656 patients with type 2 diabetes took preprandial pramlintide 60 micrograms tds, 90 micrograms bd, or 120 micrograms bd (3). Only 120 micrograms bd gave a sustained reduction in HbA_{1c}. In the first 4 weeks there was an increase in the risk of hypoglycemia, but not thereafter. Mild to moderate nausea and headache were the most frequent adverse effects; nausea abated during treatment.

Insulin + pramlintide

Pramlintide 30 micrograms was given to 16 patients using insulin pumps as an injection at meal times (4). Mealtime insulin was reduced by 17%. Serum fructosamine improved. Nausea was the most common adverse effect. There was no hypoglycemia.

Adverse effects

Skin

Contact dermatitis has been attributed to *Rhus* species (1,2), including a case that followed exposure to a homeopathic remedy (3).

Oral or parenteral exposure to certain contact allergens can elicit an eczematous skin reaction in sensitized individuals. This phenomenon has been called systemic contact dermatitis (SCD) and is relatively rare compared with classical contact dermatitis.

In 42 patients with systemic contact dermatitis caused by ingestion of *Rhus* (24 men and 18 women, average age 44 years, range 24–72), 14 of whom had a history of allergy to lacquer, there were skin lesions such as generalized maculopapular eruptions (50%), erythroderma (29%), vesiculobullous lesions (14%), and erythema multiforme-like lesions (7%) (4). Many patients (57%) developed a leukocytosis with a neutrophilia (74%). In some patients (5%) there were abnormalities of liver function. The lymphocyte subsets of 12 patients studied were within the reference ranges with no differences between patients with or without a history of allergy to lacquer. The authors concluded that the skin eruptions were caused by toxic reactions to *Rhus* rather than by immunological mechanisms.

In 31 patients with *Rhus* allergy over a 10-year period the clinical manifestations included maculopapular eruptions (65%), erythema multiforme (32%), erythroderma (19%) pustules, purpura, wheals, and blisters (5). All the patients had generalized or localized pruritus, and other symptoms included gastrointestinal problems (32%), fever (26%), chills, and headache. Many developed a leukocytosis (70%) with neutrophilia (88%), and some had toxic effects on the liver or kidneys. All responded to glucocorticoids or antihistamines.

Erythema multiforme in a photodistribution has been attributed to *Rhus verniciflua*, the Japanese lacquer tree (6). The rash was reproduced by challenge with the drug and sunlight. On contact with *R. verniciflua* the patient had a flare of the eruption, which was limited to the areas previously exposed to sun. Immunohistochemical studies suggested that the keratinocytes in the skin that retain the photoactivated substances may facilitate epidermal invasion of lymphocytes by persistent expression of intercellular adhesion molecules.

Anakinra

General Information

Anakinra is an interleukin-1 receptor antagonist. It has been used to treat rheumatoid arthritis (1,2). It has been tried in graft-versus-host disease, but without success (3). According to published trial data, moderate injection site reactions were the primary adverse effect and required treatment withdrawal in under 5% of patients. An erythematous rash was seldom observed. Although a few patients have developed antibodies to anakinra, these have not so far been associated with lack of efficacy or allergic skin reactions.

Drug–Drug Interactions

Etanercept

Regulatory agencies have issued an important post-marketing warning of an increased risk of serious infections and neutropenia in patients who receive concomitant anakinra and etanercept (4). This warning was based on an analysis of a randomized clinical trial in 242 patients with rheumatoid arthritis, in which 7% of patients receiving concomitant treatment had serious infections, compared with none in those treated with etanercept alone. Concurrent administration of these two drugs was therefore not recommended.

Androgens and anabolic steroids

See also Hormonal contraceptives—male

General Information

The classic androgen is natural testosterone, which can be given orally in micronized form, but has much more often been used as the orally active 17-methyl derivative or an injectable ester. Androgens are used to some extent in male hypogonadism, when they can promote libido and potency and increase the frequency of erections and the volume of the ejaculate (1). The use of androgens by either sex as "sexual tonics" is a matter of dispute. Some centers have used androgens to treat postmenopausal women complaining of weak libido, poor energy, or a feeling of malaise (2); workers who use this contentious approach have suggested that they should be given in association with estrogens, because of the adverse effects of androgens on serum lipids.

While some anabolic steroids are still available in the legitimate trade, others are manufactured and distributed illegally, and the contents and potency of these are unknown; some adverse effects could be due to impurities or content variation.

From about 1955 onwards, a number of so-called anabolic steroids were developed for which it was claimed, on the basis of animal experiments, that the virilizing effects had been reduced compared with testosterone, whereas the effects on tissue build-up and nitrogen retention had been maintained. These compounds were therefore promoted for such purposes as the promotion of appetite and weight increase in children and the advancement of convalescence. In fact, it has never been at all clear that these compounds are anything other than weak and expensive androgens. Even in these "tonic" doses, they can cause virilization in women and precocious development of secondary characteristics in children. In the much higher doses later developed for use in such conditions as aplastic anemia, mammary carcinoma, terminal uremia, and even hereditary angioedema (3), their androgenic effects are very pronounced indeed, and other serious complications can occur, for example in the liver (SED-12, 1038) (4–10). One formerly well-known "anabolic" steroid, metandienone (Dianabol), was withdrawn as early as 1982, and other withdrawals have followed.

When androgen therapy is used in postmenopausal women who complain of poor libido, poor energy, or a feeling of malaise (2), it should be given in association with estrogens, because of its adverse effects on serum lipids.

Hormonal contraception in men

The use of intramuscular testosterone + oral desogestrel for hormonal contraception in men is discussed in a separate monograph (Hormonal contraceptives—male).

General adverse reactions

Adverse effects of pharmacological doses of androgens include, as one would expect from male hormones, hirsutism with acne and other signs of virilization, along with adverse lipoprotein profiles, endometrial hyperplasia in women, and an increased risk of cardiovascular disease. Some compounds are particularly likely to cause liver disorders.

Male hormone replacement therapy has been reviewed (11). Hypogonadism can be accompanied by hot flushes, similar to those seen in postmenopausal women, and gynecomastia. The potential risks of testosterone replacement in adult men are precipitation or worsening of sleep apnea, hastened onset of clinical significant prostate disease, benign prostatic hyperplasia, prostatic carcinoma, gynecomastia, fluid retention, polycythemia, exacerbation of hypertension, edema, and an increased risk of cardiovascular disease.

The adverse effects of long-term testosterone therapy in HIV-positive men are irritability, weight gain, fatigue, hair loss, reduced volume of ejaculate, testicular atrophy, truncal acne, breast tenderness, and increased aggression (12).

Supraphysiological concentrations of androgen hormones can cause acne, hirsutism, and deepening of the voice.

Adverse effects of androgens in women

There are clear differences of opinion about the use of androgens in women. An Australian reviewer has argued that women may have symptoms secondary to androgen deficiency and that "prudent" androgen replacement can be effective in relieving both the physical and psychological symptoms of such insufficiency (13). The reviewer suggested that testosterone replacement for women is safe, with the caveat that doses should be restricted to the "therapeutic" window for androgen replacement in women, such that the beneficial effects on well-being and quality of life are achieved without incurring undesirable virilizing effects. The predominant symptom of women with androgen deficiency is claimed to be loss of sexual desire after a premature or natural menopause, while other indications for androgens include premenopausal iatrogenic androgen deficiency states, glucocorticoid-induced bone loss, management of wasting syndromes, and possibly premenopausal bone loss, premenopausal loss of libido, and the treatment of the premenstrual syndrome.

© 2006 Elsevier B.V. All rights reserved.

Some reservations about this approach arise when one considers the possible adverse effects and the doubts that have been raised as to whether there is in fact a safe therapeutic window when treating women with androgens. This comes clearly to the fore in a thoughtful paper by another Australian author, a speech therapist (14). For women treated with androgens or related compounds for any reason, virilization of the voice, which soon becomes permanent, is a distressing complication that has not received a great deal of specific study. This review provides some pointers for clinical practice. She reports on four women aged 27–58 years who sought otolaryngological examination because of significant alterations to their voices, the primary concerns being hoarseness, lowering of habitual pitch, difficulty in projecting their speaking voices, and loss of control over their singing voices. Otolaryngological examination with a mirror or flexible laryngoscope showed no apparent abnormality of vocal fold structure or function, and the women were referred for speech pathology with diagnoses of functional dysphonia. Objective acoustic measures using the Kay Visipitch showed significant lowering of the mean fundamental frequency in each woman, and perceptual analysis of the patients' voices during quiet speaking, projected voice use, and comprehensive singing activities showed a constellation of features typically noted in pubescent men. The original diagnosis of functional dysphonia was queried, prompting further exploration of each woman's medical history. In each case the vocal symptoms had started shortly after the beginning of treatment with medications containing virilizing agents, notably danazol, nandrolone decanoate, and testosterone. Although some of the vocal symptoms abated in severity with 6 months of voice therapy and after withdrawal of the drugs, a number of symptoms remained permanent, suggesting that each subject had suffered significant alterations in vocal physiology, including muscle tissue changes, muscle coordination dysfunction, and proprioceptive dysfunction. The study showed that both the projected speaking voice and the singing voice proved highly sensitive to virilizing effects.

It has been known for more than 30 years that some 50% of women have voice changes with anabolic steroids. While it has sometimes been thought that safe doses can be identified, studies of individual patients, including one of the cases documented here, throw doubt on this. The effects can be disastrous for any woman and incapacitating to a singer; clearly the use in women of any product having any androgenic potency must be undertaken with great reticence.

Organs and Systems

Cardiovascular

Particularly when androgens/anabolics are misused to promote extreme muscular development, there is a risk of cardiomegaly and ultimate cardiac failure. Androgen-induced hypertension may be due to a hypertensive shift in the pressure-natriuresis relation, either by an increase in proximal tubular reabsorption or by activation of the renin–angiotensin system (15). This effect is not related to higher doses or longer treatment and can develop after a few months but can also be delayed for many years.

Respiratory

There has been a single published report, which could have been coincidental, of obstructive sleep apnea during use of testosterone (16).

Nervous system

Use of androgenic steroids is likely to produce a sensation of energy and euphoria, but also with a tendency to sleeplessness and irritability (1). More extreme changes in mental state can result in extreme swings in mood, ranging from depression to aggressive elation. An unusual complication in one case was a toxic confusional state and choreiform movements caused by an anabolic steroid (SED-12, 1038) (17), but it may have been due to the non-specific results of endocrine stress in a susceptible individual.

- A 40-year-old Korean woman who had taken oxymetholone for aplastic anemia (doses not stated) developed cerebral venous thrombosis accompanied by a tentorial subdural hematoma (18).

Hiccups have been classified as a neurological reaction that can be triggered by many factors. There have been a few published reports of persistent hiccups associated with oral and intravenous glucocorticoids and one of progesterone-induced hiccups, which were thought to be secondary to the glucocorticoid-like effects of progesterone on the brainstem.

- Anabolic steroid-induced hiccups have been reported in a champion power lifter (19). The hiccups occurred within 12 hours of an increase in the dose of oral methandrostenolone from 50 to 75 mg/day, and persisted for 12 consecutive hours until medical attention was sought. The hiccups abated rapidly after the dose of methandrostenolone was reduced, but he was unwilling to abandon it completely.

Psychological, psychiatric

Apart from the physical effects of exogenous anabolics and androgens, they can also have behavioral effects, including promotion of sexual behavior (which may or may not be regarded as an unwanted effect) and perhaps enhanced aggressiveness. Men who use androgenic anabolic steroids to enhance their sporting achievements seem to be more likely to have cyclic depression (20), but young men who have stopped using anabolic steroids can also develop depression and fatigue as withdrawal effects (21).

Androgens can rarely cause psychotic mania.

- A 28-year-old man with AIDS and a history of bipolar disorder was given a testosterone patch to counter progressive weight loss and developed worsening mania with an elevated mood, racing thoughts, grandiose delusions, and auditory hallucinations (22). His condition improved in hospital after removal of the patch and the administration of antipsychotic drugs. No cause for the psychosis, other than the use of testosterone, was found.

Suicide—or attempted suicide—in eight users of anabolic steroids has been described in Germany; the cases were

© 2006 Elsevier B.V. All rights reserved.

related variously to hypomanic states during use of anabolic steroids or depression after withdrawal (23). Some of the users had committed acts of violence while using the drugs. In all cases, there were risk factors for suicidality and the drugs may simply have triggered the suicidal decision.

Endocrine

While both androgens and anabolic steroids have male hormone effects, resulting in virilization, they suppress endogenous secretion of follicle-stimulating hormone (FSH) and luteinizing hormone (LH); the result is that on withdrawal the system is for a time deprived of sufficient amounts of male hormone (24); this can lead to hypogonadism until endogenous secretions recover. A transdermal product has a particularly marked effect on circulating concentrations of serum dehydrotestosterone, and this may prove to be the case with other forms of administration; the effects of dehydrotestosterone on the prostate and other systems do not appear to have been systematically studied.

Metabolism

Androgens alone have unfavorable effects on lipids and are atherogenic (2). However, the simultaneous administration of estrogens appears to have a protective effect on the lipid profile. Androgen implants combined with estrogens cause a fall in total cholesterol and LDL cholesterol, without significant effects on HDL cholesterol or triglycerides. There is a similar reduction in total cholesterol in postmenopausal women treated with estrogen plus methyltestosterone, with a reduction in HDL2 cholesterol and triglycerides but no change in LDL cholesterol. Testosterone replacement therapy should therefore be given to women only if they are concurrently using estrogen replacement therapy.

In sufficient doses, androgens can alter regional fat distribution, with a reduction in subcutaneous fat; despite their body-building effects they have therefore been used as part of slimming programs in men (25). In women, testosterone causes an increase in lean body mass with a reduction in total body fat (26).

One residual medical use for oxandrolone in some centers is as a growth-promoting treatment for girls with Turner's syndrome, in which it is regarded by certain workers as an acceptable supplement (in a dose of 0.06 mg/kg/day) to recombinant human growth hormone. A risk of this treatment is altered glucose metabolism, but this effect is usually transient. In a series of 18 patients, one girl developed non-ketotic hyperglycemia 50 months after the end of treatment; in the other 17 girls the effect of treatment on glucose metabolism was reversible (27). There was a moderate, but not significant, rise in fasting blood glucose throughout the course of the longitudinal study. Fasting insulin increased continuously during treatment but fell after the end of treatment; subsequent concentrations were slightly higher than before treatment, but this could have been an effect of age.

Fluid balance

Androgens, particularly oxymetholone, can lead to increased water retention (28), but it is not clear whether this occurs via a mineralocorticoid or an estrogenic effect.

Hematologic

Hemoglobin can increase with high doses of androgens (29). Severe aplastic anemia has been reported.

- A 26-year-old woman developed severe aplastic anemia, complicated by superior sagittal sinus thrombosis, while taking fluoxymesterone 30 mg/day (30).

Anabolic steroids have been reported to be thrombogenic (31–33). Stanozolol, fluomesterone, metandienone, methyltestosterone, oxymesterone, and oxymetholone all reduce the synthesis or increase the degradation of clotting factors; as a rule this effect is not clinically significant, but it can result in an interaction with anticoagulants.

Liver

Particularly because the bulk of oral treatment with androgens has been with a 17-substituted compound (methyltestosterone) there have been considerable problems with liver toxicity (5). Liver dysfunction, first indicated by a rise in alkaline phosphatase and then by increases in other enzymes, transaminases and lactate dehydrogenase, is the earliest and most common sign of dysfunction. Peliosis hepatis (characterized by blood-filled cysts in the liver), hepatomas, and hepatocellular carcinoma can follow with prolonged treatment. Large hepatocellular carcinomas have been described on various occasions (8). The anabolic steroids are as risky in this respect as more traditional androgens; a case of a liver cell adenoma in a child (9) and two cases of nodular hepatocellular carcinoma (10) have been reported in patients who took oxymetholone, metenolone acetate, or other anabolic steroids for 5–15 years. It must be stressed that the complication is not limited to the 17-substituted compounds; other anabolic steroids and androgens, if given in sufficient doses (which are likely to be in excess of physiological amounts), can also damage liver function. Early damage to liver function, for example by methyltestosterone, has been shown to be reversible (6), but longer-term effects are not. The reversibility however depends on the nature of the derangement. Patients with severe cholestasis occurring late with stanozolol recovered biochemically over 3–6 months after drug withdrawal (7).

- A Japanese girl aged 20 years, who had been legitimately treated with oxymetholone (30 mg/day) for 6 years for aplastic anemia, developed a hepatic adenoma (34). In this case, in contrast to some earlier reports, there was a predisposing factor in the form of familial adenomatous polyposis.
- Reversible hepatotoxicity, in the form of abnormal liver function tests, led to the withdrawal of stanozolol in a patient with lipodermatosclerosis (35). Since some dermatologists continue to have faith in anabolic steroids in this condition, the patient was then given oxandrolone, which is reputed to be less hepatotoxic. The

© 2006 Elsevier B.V. All rights reserved.

hepatic problems did not recur, although several months later the patient developed a cardiomyopathy, which may have been coincidental.

Skin

Acne is common in patients taking androgens (36). When the effect of testosterone and anabolic steroids on the size of sebaceous glands was studied in a series of male athletes, high doses of all the products tested were found to enlarge the glands (37).

It has been claimed that testosterone implants are much less likely to cause acne than are injections of testosterone enanthate in equivalent doses; it is not clear why this might be expected and the claim seems dubious.

Multiple halo nevi have been described in a patient who took oxymetholone (SED-12, 1038) (38).

Hair

Hirsutism is common in patients taking androgens, and is often irreversible (39,40). In contrast, in women, loss of scalp hair can occur (41). Of 81 female-to-male transsexual subjects, mean age 37 years (range 21–61), treated with testosterone esters ($n = 61$; 250 mg intramuscularly every 2 weeks) or testosterone undecanoate ($n = 20$; 160–240 mg/day orally), 31 developed male-pattern baldness; thinning of the hair was related to the duration of androgen administration and was present in about half of the transsexuals after 13 years (42).

Musculoskeletal

The ability of androgens to counter osteoporosis is the basis of their use as a supplement to estrogens in one version of hormone replacement therapy. Testosterone can increase markers of bone formation (43). However, the early closure of epiphyses, with an arrest of growth, is a risk if children are exposed to these substances; this latter effect may be produced by the estrogen to which testosterone is metabolized. In some patients with excessive growth (such as Klinefelter's syndrome or Marfan syndrome) the effect is exploited therapeutically (SEDA-21, 434). Follow-up in these subjects at the age of 21–30 years showed no abnormalities of testicular function as a consequence of treatment.

A potential adverse effect of oxandrolone is acceleration of puberty and skeletal maturation (44).

- A 9-year-old boy with early puberty took oxandrolone for 22 months because of constitutional delay of growth. His height velocity increased above the 97th percentile and his bone age developed twice as fast as his chronological age. The oxandrolone was withdrawn, but his growth velocity did not decrease and his bone age continued to accelerate.

The authors hypothesized that oxandrolone could have induced early puberty. They concluded that in young children oxandrolone should be used with caution for short periods only.

Sexual function

In men, the (often desired) effects can include an increase in libido. After some time, androgenic treatment in men will lead to a reduction in the volume of the testes and azoospermia or oligospermia because of suppression of gonadotropins. Severe priapism occasionally occurs.

- A 20-year-old man with idiopathic hypogonadotrophic hypogonadism receiving a testosterone ester in a dose of 250 mg intramuscularly every 2 weeks developed priapism (46).

Reproductive system

In women and children, the main effect will be one of virilization in its various forms, ranging from hirsutism and deepening of the voice to enlargement of the female clitoris and male pattern baldness; the effect on the voice rapidly becomes irreversible because of changes in the larynx; laryngeal polyps have also been observed (46). In women, menstrual abnormalities are likely. Short-term treatment can produce increases in estradiol, dihydrotestosterone, testosterone (total and unbound), and the ratio of dihydrotestosterone to testosterone.

When ill-advisedly used to promote growth in boys by administration for some years, oxandrolone caused gynecomastia in a high proportion of subjects treated; 23 of the 33 patients affected subsequently required mastectomy (47,48).

Long-Term Effects

Drug abuse

There is a persistent illegal market in androgenic anabolic steroids, to promote physical strength. A difficulty in determining the ultimate consequences of anabolic steroid abuse for body-building or to advance sporting achievement is that individuals who are susceptible to such abuse may well have taken several different types of substance at the same time or in succession. Indeed, an analysis of the hair of seven body-builders showed what the authors termed a "complete pharmacopeia" of drug residues, ranging from glucocorticoids, anabolic steroids, and androgens to beta-adrenoceptor agonists, antidepressants, diuretics, and human chorionic gonadotropin (49).

The claimed body-building effect of the so-called anabolic compounds reflects their ability to promote muscular development, even beyond physiological limits, and this can bring with it cardiovascular complications. Surreptitious misuse by athletes remains a recurrent problem in professional sport (50); apart from the cardiovascular risks, one observes numerous physiological changes, including effects on plasma levels of enzymes, minerals and vitamins and reduced concentrations of HDL cholesterol (51).

- Poststeroid balance disorder was diagnosed in a 20-year-old Polish athlete who had been given two courses of metandienone, oxymetholone, and nandrolone phenylpropionate (52). Vertigo occurred twice just after "doping" and persisted in spite of a 1.5-year break in taking anabolic steroids. There was positional nystagmus, the eye-tracking test was abnormal, and there were abnormal responses in caloric tests. In computed

© 2006 Elsevier B.V. All rights reserved.

dynamic posturography, the incidence and degree of body sway were increased and consequently the field of the outspread area was enlarged. These findings pointed to a permanent poststeroid disorder of the central part of the equilibrium organ.

- A German report of a 22-year-old male body-builder who had taken both testosterone propionate and nandrolone decanoate in rising doses over a period of 4 months detailed the emergence of fulminant acne, a sternoclavicular bone lesion, and loss of libido (53). Severe acne after excessive androgen use has been reported before, and the apparently osteoarthritic complication in this case was probably secondary to the acne.
- A Texas group observed erythrocytosis in a young body-builder taking androgens and followed up this observation by examining hematological measures in nine male competitive body-builders who admitted to using these steroids illicitly (54). Although erythropoietin concentrations were normal (and even tended to be low), six subjects had a raised hematocrit with erythrocytosis.
- Cholestasis and renal insufficiency occurred together in a German body-builder who had been taking two anabolic steroids together over a period of 80 days (55).
- A large hepatic hematoma led to intra-abdominal hemorrhage in a 24-year-old man who for 2 years had taken two anabolic steroids as well as clomiphene and human chorionic gonadotropin (56). The authors obtained information from health clubs that users commonly took some 300 mg of nandrolone weekly, whereas the recommended dose was only 50 mg monthly.

An Australian study of 41 past and present users of anabolic steroids, together with controls from a similar population (“potential users”) has vividly portrayed the risks that prolonged use of these products brings (57). Complications included alterations in libido (61%), changes in mood (48%), reduced testicular volume (46%), and acne (43%). The mean systolic and diastolic blood pressures were raised in 29% of current users, 37% of past users, and only 8% of controls, although these differences were not significant. Gynecomastia was found in 10 past users (37%), two current users (12%), and none of the controls, while mean testicular volume was significantly smaller in current users (18 ml). There were abnormal liver function tests in 20 past users (83%), eight present users (62%), and five potential users (71%).

- A partial empty sella syndrome occurred in an elite 39-year-old body-builder with a 17-year history of drug abuse involving growth hormone, anabolic steroids, testosterone, and thyroid hormone (58).

The pituitary is a hormone-responsive gland, but it has not previously been shown to suffer negative feedback in response to any of these substances. Any one of them could in principle have contributed to the effect, or it could have been an indirect consequence of drug abuse, by way of an increase in intracranial pressure, which is a known cause of empty sella syndrome.

Drug withdrawal

Withdrawal of high doses of androgens or anabolic steroids after the system has become accustomed to them can lead to menopause-like reactions, such as anxiety, chills, tachycardia, anorexia, piloerection, insomnia, sweats, hypertension, myalgia, nausea, vomiting, irritability, and hot flushes. Young men who have used these compounds can experience depression and fatigue for a time after withdrawal.

Tumorigenicity

Danazol is a weak androgen and also has a series of other hormonal and anti-hormonal properties. It inhibits pituitary gonadotropin and has been used in the treatment of endometriosis, fibrocystic disease of the breast, idiopathic thrombocytopenic purpura, and hereditary angioedema. Its hepatotoxic effects include reversible rises in serum transaminases and cholestatic hepatitis; a few cases of hepatocellular tumors have been reported.

- A 34-year-old woman who had taken danazol 400 mg/day for 13 years for hereditary angioedema developed a mass in the right hypochondrium. Her alcohol intake was under 20 g/day. She had a large heterogeneous hepatic tumor, a well-differentiated hepatocellullar carcinoma in a non-cirrhotic liver.

The hypothesis that hepatocellular carcinoma had been caused by danazol was accepted in the absence of other causes (59).

Susceptibility Factors

Age

In children, who may be exposed to androgens or anabolic steroids accidentally or in ill-advised therapy (for example to improve appetite), there will be a particular risk of virilization, premature sexual development, and early closure of the epiphyses. Virilization has even been reported after topical androgen administration (60).

Interest in the use of androgens in elderly men continues, with on the one hand the long-standing hope that potency and libido may be restored, and, on the other hand, the belief that cardiovascular prospects might be improved. The uncertainties that exist in this latter respect have been well reviewed in a paper that merits reading in full; it is best summarized in the author’s own conclusion that “· · · overall, the androgens are as likely to prevent arterial disease as they are to cause it · · ·” (61).

Other features of the patient

One possible use of anabolic agents is in the treatment of the physical wasting associated with HIV infection. Some experience has been gained, but it is still not clear whether such treatment is warranted, bearing in mind the limited benefits that can be expected and the well-documented risks of anabolic drug therapy (62). The effects and adverse effects of testosterone replacement with a non-genital transdermal system, Androderm, have been studied in 41 HIV-positive men with low testosterone concentrations (63). Nine men taking placebo and 11 taking testosterone reported adverse events. Five men taking testosterone had

© 2006 Elsevier B.V. All rights reserved.

reactions at the site of administration; other adverse events in this group included problems related to resistance mechanisms ($n = 2$), gastrointestinal system ($n = 2$), and skin and appendages ($n = 1$); there was one severe adverse event (a suicidal amitriptyline overdose). There were skin reactions at the site of application of the placebo or testosterone patch in 19% of the participants. One man had blisters on one occasion, related to rupture of the patch. The mean erythrocyte count increased with testosterone and fell with placebo. Hemoglobin concentration increased with testosterone and fell with placebo.

Older data pointed to some reduction in insulin requirements when patients with diabetes mellitus received androgens, and it is wise to avoid these drugs altogether in patients with diabetes.

Drug Administration

Drug formulations

Testosterone is available as oral testosterone undecanoate, buccal testosterone, intramuscular testosterone esters, testosterone implants, and testosterone transdermal patches and gel.

After oral administration there is large variability in systemic availability, which makes this route generally unsuitable.

Buccal testosterone tablets provide sustained release of testosterone and also bypass first-pass metabolism in the liver. Common adverse effects include gum irritation, pain, and tenderness, and edema (64) and headache (65).

Intramuscular testosterone is given as a deep intramuscular injection of single testosterone esters or a mixture of testosterone propionate, testosterone phenylpropionate, testosterone isocaproate, and testosterone decanoate (Sustanon), every 2–3 weeks. In one series of 551 injections, 162 were associated with pain and bleeding; injection in the gluteal site caused fewer complaints and was less susceptible to bleeding, but was painful more often than injection in the deltoid muscle or thigh (66). There were no serious adverse effects and the only systemic adverse effect was episodes of sudden non-productive cough associated with faintness after eight injections which the authors thought might have been due to pulmonary oil microembolism. Systemic availability of testosterone after intramuscular administration is variable and there can be fluctuations in mood and sexual function (67). High testosterone concentrations can cause raised lipid concentrations (68).

Topical application of testosterone, as a gel or from transdermal patches, can lead to absorption and systemic effects (SEDA-16, 158). Transdermal absorption of testosterone (usually from treatment of vulvar lichen sclerosus et atrophicus) can lead to increased libido, clitoral hypertrophy, pubic hirsutism, thinning of the scalp hair, facial acne, voice change, hirsutism, and even virilization (69).

The use of transdermal patches for administering testosterone to hypogonadal men ("Andropatch") seems logical and convenient, but a British study in 50 treated patients showed that patient acceptance was surprisingly poor (70). There were adverse effects in 84%, mostly skin problems; 72% requested a return to depot injections, and 5% returned to oral therapy. The reservoir patches, 6 cm in diameter, were, to quote the report literally, judged to be too large, uncomfortable, and visually obtrusive, while the noise they made on bodily movement distracted dogs, wives, and children; they fell off in showers and attracted ribald remarks from sports partners; they could only be removed with difficulty and left bald red marks on the body. The nature of the complaints suggests that they might be accommodated by further technical development of the product.

One unusual variant involves applying a transdermal preparation to the scrotum (71), a technique that has been claimed to mimic more closely the natural pattern of release of endogenous testosterone. It is not clear that applying it at this site has any special merit, although some work suggests that the scrotal skin is less likely than other skin areas to exhibit local reactions. Certainly topical preparations of testosterone can elicit such reactions, with pruritus and blistering being common, while induration, erythema, and allergic reactions can also occasionally occur.

Testosterone implants, like implants of other substances, can be subject to extrusion, probably in about a tenth of cases treated, and can also give rise to local irritation (72).

Drug–Drug Interactions

Anticoagulants

Many androgens and anabolic steroids reduce the dose of oral anticoagulant that a patient requires, sometimes by as much as 25% (73), and hemorrhage has sometimes resulted from their use. From the results of a study in which stanozolol reduced warfarin requirements, the investigators concluded that stanozolol increased fibrinolysis, reduced the production of vitamin K-dependent clotting factors, and increased the amount of the natural anticoagulant antithrombin III (74).

Anesthetic ether

See also General anesthetics

General Information

Diethyl ether (SED-9, 172) is obsolete as a general anesthetic (1). It is highly inflammable and therefore incompatible with modern surgical and anesthetic techniques. It has an unpleasant smell and irritates mucous membranes; this can cause coughing, straining, laryngeal spasm, and hypersalivation. Recovery is slow and accompanied by nausea and vomiting in up to 85% of patients. Liver damage is as frequent as with halothane. Ether raises intracranial pressure and can cause convulsions. It can cause impaired immune responsiveness and contact dermatitis has been reported, together with a systemic allergic reaction (SEDA-5, 120).

Angiotensin II receptor antagonists

See also Individual agents

General Information

Inhibition of the renin–angiotensin system by ACE inhibitors has proved efficacious in the treatment of hypertension, cardiac failure, myocardial infarction, in secondary prevention after myocardial infarction, and for kidney protection in diabetic and non-diabetic nephropathy. The development of specific antagonists to subtype 1 of the angiotensin II receptor (AT_1) has provided a new tool for inhibiting the renin–angiotensin system.

Experimental data and preliminary clinical experience have suggested that the efficacy of AT_1 receptor antagonists in the treatment of hypertension is similar to that of ACE inhibitors. However, the two drug categories also

© 2006 Elsevier B.V. All rights reserved.

have potential differences, because of their different mechanisms of action. Since they have an action that is exclusively targeted at angiotensin II, the AT_1 receptor antagonists should lack the effects of ACE inhibitors that are mediated through the accumulation of bradykinin and other peptides. Furthermore, since a significant amount of angiotensin II can be generated by enzymes other than ACE, particularly the chymases, AT_1 receptor antagonists achieve more complete blockade of the effects of angiotensin than ACE inhibitors do. Nevertheless, whether these differences are clinically important is still being investigated.

The first attempt at blocking the AT_1 receptor with the peptide analogues of angiotensin II resulted in the discovery of saralasin, an antagonist that lacked oral activity and had partial agonist properties. Losartan was the first agent in the new class of orally active AT_1 receptor antagonists. Other agents with different receptor affinities and binding kinetics, such as candesartan, eprosartan, irbesartan, losartan, tasosartan, telmisartan, and valsartan, have since become available (1). Variations in chemical structure may lead to marginal but potentially clinically significant differences in the time-effect profile. Non-competitive antagonists may have longer durations of action than competitive antagonists, because they bind irreversibly to angiotensin II receptors. There have been several reviews of this class of agents (2,3). All have emphasized their remarkable tolerance profile. In double-blind, placebo-controlled trials, the type and frequency of reported adverse effects were consistently no different from placebo (4).

The angiotensin II receptor antagonists are being considered for the treatment of diseases other than hypertension (heart failure with or without left ventricular systolic dysfunction, during and after acute myocardial infarction, diabetic nephropathy, other forms of glomerulopathy, restenosis after coronary angioplasty, and atherosclerosis).

Comparative studies

The RESOLVD (Randomized Evaluation of Strategies for Left Ventricular Dysfunction) trial was a pilot study investigating the effects of candesartan, enalapril, and their combination on exercise tolerance, ventricular function, quality of life, neurohormone concentrations, and tolerability in congestive heart failure (5). Candesartan alone was as effective, safe, and well tolerated as enalapril. The combination of candesartan with enalapril was more beneficial in preventing left ventricular remodelling than either alone. Although the trial was not powered to assess effects on cardiovascular events, it was terminated prematurely because of a trend toward a greater number of events in the candesartan alone and combination groups compared with enalapril alone.

In the ELITE study losartan produced greater survival benefit in elderly patients with heart failure than captopril (6). ELITE II was performed in order to confirm this. It included 3152 patients aged 60 years and over with NYHA class II–IV heart failure and was powered to detect a clinically significant effect on all-cause mortality. Median follow up was 555 days. Losartan was not superior to captopril in improving survival; however, it was better tolerated. Significantly fewer patients taking losartan withdrew because of adverse effects, including effects attributed to the study drug, or because of cough. Fewer patients discontinued treatment because of adverse effects (10 versus 15%), including effects attributed to the study drug (3 versus 8%) or because of cough (0.4 versus 2.8%) (6).

The results of SPICE (The Study of Patients Intolerant of Converting Enzyme Inhibitors) and of the previously published RESOLVD led to the design of the current CHARM trial, which is investigating the effect of candesartan in 6600 patients with heart failure in three different ways: versus an ACE inhibitor in patients with preserved left ventricular function; versus placebo in patients intolerant of ACE inhibitors; and in addition to ACE inhibitors in all other patients. While waiting for the results of this trial it is advisable to continue to use ACE inhibitors as the initial therapy for heart failure. In patients with documented intolerance of ACE inhibitors (which may represent 10–20% of patients with heart failure) angiotensin receptor antagonists may be useful as a substitute to block the renin–angiotensin–aldosterone system.

Placebo-controlled studies

The SPICE was a smaller trial (270 patients, 12 weeks follow-up) which evaluated the use of candesartan versus placebo in patients with heart failure and a history of intolerance of ACE inhibitors (most commonly because of cough, symptomatic hypotension, or renal insufficiency). Titration to the highest dose of candesartan 16 mg was possible in 69% of the patients (84% in the placebo group). Death and cardiovascular events tended to be lower with candesartan (7).

The results of another trial in heart failure with another angiotensin receptor antagonist (valsartan) are now available but are still to be published. In the VAL-HeFT (Valsartan in Heart Failure Trial) valsartan 160 mg bd was compared with placebo in 5010 patients with heart failure and left ventricular systolic dysfunction receiving optimal conventional therapy, including ACE inhibitors. The results showed a non-significant effect on mortality (19% on placebo, 20% on valsartan), but a highly significant effect on the primary endpoint of all-cause mortality and morbidity (32% on placebo, 29% on valsartan). A subgroup analysis suggested that the combination of valsartan, an ACE inhibitor, and a beta-blocker was not beneficial and might even be harmful, whereas the combination of valsartan and an ACE inhibitor caused a reduction of 45% (8).

General adverse effects

The safety profile of angiotensin II receptor antagonists is so far remarkably good. Except for hypotension, virtually no dose-related adverse effects have been reported. Headache, dizziness, weakness, and fatigue are the most common adverse effects. There have been reports of raised liver enzymes (9), cholestatic hepatitis (10), and pancreatitis (11) with losartan. Several cases of angioedema have been reported but no other obvious hypersensitivity reactions.

Organs and Systems

Cardiovascular

The action of angiotensin II receptor antagonists in interfering with the activity of the renin–angiotensin system is so similar to the action of the ACE inhibitor drugs that episodes of first-dose hypotension, renal impairment, and hyperkalemia would be anticipated. However, there have been only a few such reports to date, although this may reflect the careful screening of patients for clinical trials, from which, by inference, obviously high-risk patients may have been excluded.

Respiratory

Cough has been specifically studied, because the mechanism of action of losartan differs from the ACE inhibitors, in that there is no accumulation of kinins, which have been implicated in the non-productive cough associated with ACE inhibitors (12). In 135 patients known to have ACE inhibitor-induced cough, lisinopril, losartan, or hydrochlorothiazide were given. Of the patients rechallenged with lisinopril, 72% developed a cough compared with only 29 and 34% challenged with losartan and hydrochlorothiazide respectively (13). However, in a Prescription Event Monitoring (PEM) study in four cohorts of 9000 patients exposed to losartan, enalapril, lisinopril, or perindopril, the rate of cough was high even with losartan. The authors attributed this to a carry-over effect, since presumably patients taking losartan have previously had cough with an ACE inhibitor (14).

A compilation of three controlled trials in 1200 patients showed incidence rates of cough of 3.6% with valsartan versus 9.5% with ACE inhibitors and 0.4% with placebo (1).

In a PEM study in 9000 patients cough occurred in 3.1% of patients taking losartan, compared with 3.9, 14, and 16% in patients taking enalapril, lisinopril, and perindopril respectively (14). The unusual low rate of cough with enalapril was surprising and emphasizes the limitations of PEM studies. Worthy of remark is a possible confounding effect, discussed by the authors, related to the fact that a large number of patients were given losartan because they had had cough with an ACE inhibitor. Because of a carry-over effect, cough may still be reported, especially in the first week when patients change to losartan. This carry-over effect may have been the cause of cough reported with losartan in other cases (15).

In a multicenter controlled study in patients with hypertension and a history of ACE inhibitor-induced cough, eprosartan significantly reduced the risk of cough by 88% compared with enalapril (16).

Immunologic

Because ACE inhibitor-induced anaphylaxis is thought to be related to accumulation of bradykinin, it was assumed that angiotensin II receptor antagonists would not cause this reaction. However, angioedema has been described within 30 minutes of a first dose of losartan 50 mg in a 52-year-old man (17). The author also referred to a single case of losartan-induced angioedema mentioned in the manufacturers' package insert from among 4058 patients treated with losartan. In an international safety update report based on 200 000 patients there were 13 cases of angioedema (18). Two had also taken an ACE inhibitor and three others had previously developed angioedema when taking ACE inhibitors.

Angiotensin-converting enzyme inhibitors

See also Individual agents

General Information

Angiotensin-converting enzyme (ACE) inhibitors inhibit the conversion of angiotensin I to angiotensin II. The ACE is also a kininase, and so ACE inhibitors inhibit the breakdown of kinins. Some of the adverse effects of these drugs are related to these pharmacological effects. For example, cough is thought to be due to the action of kinins on axon fibers in the lungs and hypotension is due to vasodilatation secondary to reduced concentrations of the vasoconstrictor angiotensin II.

Our knowledge of the use of ACE inhibitors has expanded dramatically during recent years, thanks to the publication of the results of a number of large clinical trials (1).

The Heart Outcomes Prevention Evaluation (HOPE) study showed that virtually all patients with a history of cardiovascular disease, not only those who have had an acute myocardial infarction or who have heart failure, benefit from ACE inhibitor therapy (2). The authors selected 9297 patients at increased risk of cardiovascular disease, defined as a history of a cardiovascular event or evidence of disease, such as angina. People with diabetes but no indication of heart disease were included, but they had to have an additional risk factor. They were allocated to receive the ACE inhibitor ramipril 10 mg/day or placebo. The trial was stopped early, according to the predefined rules, because of an overwhelming effect of ramipril on the primary end-point, a 22% reduction in a composite measure of myocardial infarction, stroke, and death from cardiovascular causes. Significance was also achieved on outcomes as diverse as myocardial infarction, revascularization, heart failure, cardiac arrest, and worsening angina. Patients with diabetes had a similar 25% reduction for the composite cardiovascular end-point. Moreover, patients taking ramipril had 16% less overt nephropathy (defined as urine albumin over 300 mg/24 hours, or urine total protein excretion over 500 mg/24 hours, or a urine albumin/creatinine ratio over 36 mg/mmol). They also needed 22% less laser therapy for retinopathy. Since all the patients in the HOPE study were not hypertensive, and since the cardiovascular benefit was greater than that attributable to the fall in blood pressure, the authors suggested that ACE inhibitors are cardioprotective, vasculoprotective, and renal protective, independently of their blood pressure lowering effect.

Relative to the dosage issue, the dosage–plasma concentration relation for enalaprilat (the active metabolite of enalapril) in patients with heart failure and its relation to drug-related adverse effects has been investigated (3). In patients taking enalapril for more than 3 months, in dosages of 5–20 mg bd, there were highly variable trough concentrations of enalaprilat. They were affected by serum creatinine, the severity of heart failure, and body weight. Adverse effects, such as cough and rises in serum creatinine and potassium, were more common at high enalaprilat trough concentrations. The authors concluded that these results provide a rationale for individually adjusting ACE inhibitor doses in case of adverse effects.

Use in hypertension

In hypertension, the Captopril Prevention Project (CAPPP) trial evaluated an ACE inhibitor as an alternative first-line agent in mild to moderate hypertension. It was a prospective randomized open study with blinded end point evaluation (PROBE design), comparing an antihypertensive strategy based on either captopril or conventional therapy with a beta-blocker or a diuretic in patients with mild to moderate hypertension. At the end of follow-up the incidence of cardiovascular events was equal with the two strategies. However, imbalances in the assignment of treatment resulted in a 2 mmHg higher average diastolic blood pressure at entry in the group assigned to captopril. This difference in blood pressure alone would be sufficient to confer an excess of cardiovascular risk within this group, could mask real differences between the regimens in their effects on coronary events, and could explain the greater risk of stroke among patients who took captopril. The authors claimed that the overall results support the position that from now on one should consider ACE inhibitors as first-line agents, equal to diuretics and beta-blockers (4). The CAPPP study also reported a reduced risk of diabetes with captopril, which may be explained by the fact that thiazides and beta-blockers cause changes in glucose metabolism and by favorable effects of ACE inhibition on insulin responsiveness.

The second Swedish Trial in Old Patients with hypertension, STOP-2, was designed to compare the effects of conventional antihypertensive drugs on cardiovascular mortality and morbidity with those of newer antihypertensive drugs, including ACE inhibitors, in elderly patients (5). The study was prospective, randomized, and open, but with a blinded end-point evaluation. It included 6614 patients aged 70–84 years with hypertension (blood pressure over 180 mmHg systolic, or over 105 mmHg diastolic, or both). The patients were randomly assigned to conventional drugs (atenolol 50 mg/day, metoprolol 100 mg/day, pindolol 5 mg/day, or hydrochlorothiazide 25 mg/day plus amiloride 2.5 mg/day) or to newer drugs (enalapril 10 mg/day or lisinopril 10 mg/day, or felodipine 2.5 mg/day or isradipine 2.5 mg/day). Blood pressure fell similarly in all treatment groups. There were equal incidences of the primary end-points (fatal stroke, fatal myocardial infarction, and other fatal cardiovascular disease combined) in all groups (20 events per 1000 patient years). Subgroup analyses showed that conventional therapy,

© 2006 Elsevier B.V. All rights reserved.

ACE inhibitors, and calcium antagonists had similar efficacy in preventing cardiovascular mortality and major morbidity. This finding argues against the hypothesis that some classes of antihypertensive drugs have efficacy advantages over others, at least in this population of elderly hypertensive patients. Therefore, the choice of antihypertensive treatment will be related to other factors, such as cost, co-existing disorders, and adverse effects. With respect to the reported adverse effects, since the study was open, causality cannot be established. Nevertheless, the size of the study and its naturalistic design allowed accurate assessment of the incidence of adverse effects in this population of elderly hypertensive patients. With ACE inhibitors the most frequently reported adverse effects were cough 30%, dizziness 28%, ankle edema 8.7%, headache 7.7%, shortness of breath 7.3%, and palpitation 5.5%. Actually, little detail was given in the section devoted to safety in the main publication of the results of the trial.

Use in heart failure

In heart failure much debate has been generated by the observation of general "under-use" of ACE inhibitors and the use of smaller doses than have been beneficial in clinical trials. This was partly related to concern about safety with the highest doses, especially in high-risk groups, such as the elderly and patients with renal insufficiency (6). Actually, outcome trials effectively excluded elderly patients (75–80 years and over) and usually patients with renal insufficiency. As elderly patients have poorer renal function, they are more likely to have vascular disease in their renal and carotid arteries, and may be more prone to symptomatic hypotension, it cannot be assumed that the benefit to harm balance observed in younger patients will be the same, at the same doses, in elderly people. The NETWORK trial, a comparison of small and large doses of enalapril in heart failure, was poorly designed and is not conclusive. However, it suggested that apart from a trend to more fatigue with higher doses (10 mg bd), the incidence of adverse effects, including symptomatic hypotension, was similar across the three dosages (2.5, 5, and 10 mg bd) (7).

In heart failure the issue of whether it is justified to use doses of ACE inhibitors substantially smaller than the target doses used in the large-scale studies that established the usefulness of these drugs has been examined in the ATLAS (Assessment of Treatment with Lisinopril and Survival) trial (8). This trial randomized 3164 patients with New York Heart Association (NYHA) class II–IV heart failure and ejection fractions less than 30% to double-blind treatment with either low doses (2.5–5.0 mg/day) or high doses (32.5–35 mg/day) of the ACE inhibitor lisinopril for 39–58 months, while background therapy for heart failure was continued. When compared with the low-dose group, patients in the high-dose group had a non-significant 8% lower risk of death but a significant 12% lower risk of death plus hospitalization for any reason and 24% fewer hospitalizations for heart failure. Dizziness and renal insufficiency were more frequent in the high-dose group, but the two groups were similar in the number of patients who required withdrawal of the study medication. These findings suggest that patients with heart failure should not generally be maintained on very low doses of an ACE inhibitor, unless higher doses cannot be tolerated. However, the ATLAS trial did not address this issue properly. The doses in the small-dose arm were actually very small, and much smaller than those used in routine practice, as reported in several other studies (9). The doses in the large-dose arm may have been unnecessarily high. The recommendation of using target doses proven to be effective in large-scale trials remains unchallenged.

In the studies of left ventricular dysfunction (SOLVD), adverse effects related to the long-term use of enalapril have been thoroughly investigated (10).

Use in myocardial infarction

In the acute infarction ramipril efficacy (AIRE) study, oral ramipril in 2006 patients with heart failure after acute myocardial infarction resulted in a substantial reduction in deaths within 30 days (11).

More trials during and after myocardial infarction have been published and subjected to meta-analysis (12). This very large database provides valuable information on the rate of the most common adverse effects. Of all trials of the effects of ACE inhibitors on mortality in acute myocardial infarction, only the CONSENSUS II trial did not show a positive effect. In this trial, enalaprilat was infused within 24 hours after the onset of symptoms, followed by oral enalapril. The reasons for the negative result of CONSENSUS II remain unresolved, but hypotension and a proischemic effect linked to a poorer prognosis have been suggested.

Use in nephropathy

The results of two trials in patients with chronic nephropathy have reinforced the benefit of ACE inhibitors in slowing the progression of chronic renal insufficiency due to renal diseases other than diabetic nephropathy (13–15) and have provided sufficient information on the safety profile of these agents in chronic renal insufficiency. This was found to be essentially the same as in patients with normal renal function. The current practice of avoiding ACE inhibitors in severe renal insufficiency, to prevent further renal impairment and hyperkalemia, is no longer justified, although careful monitoring should still be observed.

Ramipril has a renal protective effect in non-diabetic nephropathies with nephrotic and non-nephrotic proteinuria (14). It also improves cardiovascular morbidity and all-cause mortality in patients with some cardiovascular risk (2).

The Ramipril Efficacy in Nephropathy (REIN) trial was designed to test whether glomerular protein traffic, and its modification by an ACE inhibitor, influenced disease progression in non-diabetic chronic nephropathies (13). Patients were stratified before randomization by 24-hour proteinuria. Treatment with ramipril or placebo plus conventional antihypertensive therapy was targeted at the same bloodpressure control. At the second interim analysis, ramipril had slowed the fall in glomerular filtration rate (GFR) more than expected from the degree of blood pressure reduction. In the follow-up study GFR almost stabilized in patients who had been originally randomized to ramipril and had continued to take it for more than 36 months. The combined risk of doubling of the serum creatinine or end-stage renal insufficiency was half that found in those taking placebo plus conventional

© 2006 Elsevier B.V. All rights reserved.

therapy. In patients with proteinuria of 1–3 g/day the fall in GFR per month was not significantly affected, but progression to end-stage renal insufficiency was significantly less common with ramipril (9/99 versus 18/87) for a relative risk of 2.72 (CI = 1.22, 6.08) (14); and so was progression to overt proteinuria (15/99 versus 27/87; RR = 2.40; CI = 1.27, 4.52).

The results of this trial show that ramipril was well tolerated and even protective in cases of advanced renal insufficiency. One major reason for the current practice of underprescription and of prescription of suboptimal doses of ACE inhibitors, especially in patients with heart failure, is the presence of renal insufficiency (16). In such patients, not only should ACE inhibitors no longer be avoided, they are indeed indicated for preservation of renal function.

General adverse effects

The commonest unwanted effects of ACE inhibitors are related to their pharmacological actions (that is inhibition of angiotensin-converting enzyme and kininase II): renal insufficiency, potassium retention, pronounced first-dose hypotension, cough, and the serious but less common angioedema. Skin rashes and taste disturbances are uncommon, but may be more likely with sulfhydryl-containing drugs, particularly captopril. Rare hypersensitivity reactions include rashes, bone-marrow suppression, hepatitis, and alveolitis. If administered in the second or third term of pregnancy, ACE inhibitors can cause a number of fetal anomalies, including growth retardation, renal impairment, oligohydramnios, hypocalvaria, fetal pulmonary hypoplasia, and fetal death. Neonatal anuria and neonatal death can also occur (17,18). Tumor-inducing effects have not been reported.

The frequencies and the profile of adverse effects of five major classes of antihypertensive agents have been assessed in an unselected group of 2586 chronically drug-treated hypertensive patients (19). This was accompanied by a questionnaire-based survey among patients visiting a general practitioner. The percentages of patients who reported adverse effects spontaneously, on general inquiry, and on specific questioning were 16, 24, and 62% respectively. With ACE inhibitors the figures were 15, 22, and 55%. The percentage of patients in whom discontinuation was due to adverse effects was 8.1% with ACE inhibitors (significantly higher than diuretics). Compared with beta-blockers, ACE inhibitors were associated with less fatigue (RR = 0.57; 95% CI = 0.38, 0.85), cold extremities (RR = 0.11; CI = 0.07, 0.18), sexual urge (RR = 0.52; CI = 0.33, 0.82), insomnia (RR = 0.10; CI = 0.04, 0.26), dyspnea (RR = 0.38; CI = 0.17, 0.85), and more coughing (RR = 13; CI = 5.6, 30). The authors did not find a significant effect of age on the pattern of adverse effects. Women reported more effects and effects that were less related to the pharmacological treatment.

Organs and Systems

Cardiovascular

Marked reductions in blood pressure, without any significant change in heart rate, can occur at the start of ACE inhibitor therapy. Such reductions, which are not orthostatic, are sometimes symptomatic but rarely fatal. The volume of evidence is greatest with the longer established agents, but continues to suggest that the problems of first-dose hypotension are most likely to occur in patients whose renin–angiotensin system is stimulated (renin-dependent states), such as in renovascular hypertension or other causes of renal hypoperfusion, dehydration, or previous treatment with other vasodilators (20). These conditions can co-exist, particularly in severe heart failure (21–23). Similar problems have occurred in the treatment of hypertensive neonates and infants (24), but again were particularly likely in the setting of high plasma renin activity associated with either renovascular disease or concurrent diuretic treatment.

The use of very low doses to avoid first-dose hypotension is common, although the rationale remains unclear (25). It is even less clear whether or not there are differences between different ACE inhibitors, that is whether first-dose hypotension is agent-specific or a class effect (26,27).

Respiratory

Cough

DoTS classification

Dose-relation: collateral effect
Time-course: time-independent
Susceptibility factors: genetic (polymorphisms of the bradykinin B_2 receptor gene and the ACE gene); sex (men); exogenous factors (non-smokers).

A non-productive irritant cough is associated with ACE inhibitors (28,29). The dose-relatedness of this adverse effect is not clear.

Frequency

In different studies there has been large variability in the absolute incidence of cough (0.7–48%), the discontinuation rate (1–10%), and the relative incidences with different ACE inhibitors (30). However, the placebo-controlled, randomized, HOPE study has provided a remarkable database, with the largest cohort and the longest follow-up ever reported with such therapy (over 9000 patients followed for 5 years on average). Compared with placebo, ACE inhibitor therapy with ramipril caused cough leading to drug withdrawal in 7.3% of patients (compared with 1.8% for placebo) (13).

Mechanism

The mechanism of this effect has been explored (31–33). It may be more complicated than just an increase in concentrations of bradykinin and substance P, increased microvasculature leakage, and stimulation of vagal C fibers (34). Sulindac and indometacin may abolish or reduce the intensity and frequency of cough, supposedly because of inhibition of prostaglandin synthesis (35,36). Common variant genetics of ACE, chymase, and the bradykinin B_2 receptor do not explain the occurrence of ACE inhibitor-related cough (37). In general, bronchial hyper-reactivity has been causally implicated and may also be associated with exaggerated dermal responses to

© 2006 Elsevier B.V. All rights reserved.

histamine (31,33). However, in one report, airways hyperresponsiveness was not a consistent finding (38).

Susceptibility factors

Cough is more common in non-smokers (39) and in women (39,40). It has been speculated that the risk of cough is genetically predetermined. The possibility that polymorphisms of the human bradykinin B_2 receptor gene may be involved in ACE inhibitor-related cough has been investigated in a case-control study (41). The DNA of 60 subjects with and without cough who were treated with ACE inhibitors was compared with that of 100 patients with untreated essential hypertensive and 100 normotensive subjects. The frequencies of the TT genotype and T allele were significantly higher in the subjects with cough than in subjects without. These tendencies were more pronounced in women. Subjects with the CC genotype were less susceptible to cough. According to the authors, high transcriptional activity of the bradykinin B_2 receptor promoter may be related to the risk of ACE inhibitor-related cough. This is the first demonstration that a genetic variant is involved in ACE inhibitor-related cough. It may therefore be possible to predict the occurrence of cough related to ACE inhibitor use.

The genetic basis of ACE inhibitor-induced cough and its relation to bradykinin have been further explored in a study of the effect of cilazapril in two groups of healthy volunteers genotyped for ACE insertion/deletion (I/D) polymorphism (42). The cough threshold to inhaled capsaicin was significantly lower in the genotype II group than in the DD group. Skin responses to intradermal bradykinin were significantly enhanced in the genotype II group. There was no difference in responsiveness to intradermal substance P. The authors suggested that these findings provide further evidence of the link between ACE inhibitor-induced cough and I/D polymorphism of the ACE gene, and that this supports the hypothesis that ACE inhibitors cause cough by modulating tissue concentrations of bradykinin.

Chinese patients experience more cough from ACE inhibitors than Caucasians. A review of the pharmacokinetics and blood pressure-lowering efficacy of ACE inhibitors as well as of ACE and angiotensinogen gene polymorphism did not find significant differences between Chinese and Caucasians to account for the difference in cough incidence (43).

Management

ACE inhibitor-associated cough seems to be a class effect: switching to another ACE inhibitor rarely solves the problem, although there are occasional anecdotal reports (40,44). However, most patients who develop a cough related to an ACE inhibitor are able and willing to continue therapy. In a small randomized study inhaled sodium cromoglicate relieved the symptom (45). In those in whom the symptom is intolerable, a switch to an angiotensin receptor antagonist is justified.

Obstructive airways disease

It has been suggested that ACE inhibitors are also associated with an increased incidence of symptomatic obstructive airways disease, leading to bronchospasm and asthma (46). However, a prescription event monitoring study of more than 29 000 patients taking ACE inhibitors, compared with 278 000 patients taking other drugs, failed to confirm this association (47).

Endocrine

Gynecomastia has been reported in a patient taking captopril 75 mg/day; it resolved when captopril was withdrawn but recurred when the patient was given enalapril (48). This suggests that gynecomastia may not be simply attributable to the sulfhydryl group of captopril.

Metabolism

ACE inhibition has been associated with increased insulin sensitivity in diabetic patients, and it has therefore been hypothesized that ACE inhibitors can precipitate hypoglycemia in such patients. A Dutch case-control study suggested that among users of insulin or oral hypoglycemic drugs, the use of ACE inhibitors was significantly associated with an increased risk of hospital admission for hypoglycemia (49). However, a French case/non-case study from the pharmacovigilance database did not confirm this finding (50).

In a matched case-control study of 404 cases of hospitalization for hypoglycemia in diabetic patients and 1375 controls, the risk of hypoglycemia was greater in those who used insulin versus a sulfonylurea and was not influenced by the use of ACE inhibitors (51). However, the use of enalapril was associated with an increased risk of hypoglycemia (OR = 2.4; CI = 1.1, 5.3) in sulfonylurea users. Although the authors emphasized the fact that previous reports of ACE inhibitor-related hypoglycemia were more frequent with enalapril, it is unclear why only enalapril, and not ACE inhibitors as a class, was associated with a significantly increased risk of hypoglycemia, and why this occurred only in sulfonylurea users.

Conversely, it has been suggested that the protective effect of ACE inhibitors against severe hypoglycemia should be tested in high-risk patients with high ACE activity. About 10–20% of patients with type 1 diabetes mellitus have a risk of severe hypoglycemia. In 307 unselected consecutive diabetic outpatients, those with the ACE DD genotype had a relative risk of severe hypoglycemia of 3.2 (95% CI = 1.4, 7.4) compared with those with the genotype II (52). There was a significant relation between serum ACE activity and the risk of severe hypoglycemia.

Electrolyte balance

ACE inhibitors can cause hyperkalemia because they inhibit the release of aldosterone. The effect is usually not significant in patients with normal renal function. However, in patients with impaired kidney function and/or in patients taking potassium supplements (including salt substitutes) or potassium-sparing diuretics, and especially aldosterone antagonists, hyperkalemia can occur. In two cases, hypoaldosteronism with diabetes was implicated (53,54).

Hyponatremia, defined as a plasma sodium concentration of 133 mmol/l or under, has been investigated in a prospective study of elderly patients with hip fractures. ACE inhibitors were the most frequently used drugs (five

© 2006 Elsevier B.V. All rights reserved.

of 14 cases) (55). Of course, this does not prove a cause and effect relation, since in elderly people ACE inhibitors are likely to be among the most frequently prescribed drugs. However, hypoaldosteronism would be a likely mechanism.

Hematologic

ACE inhibitors are used to treat erythrocytosis, for example after transplantation (56). Efficacy in treating erythrocytosis in chronic obstructive pulmonary disease has also been described with the angiotensin II receptor antagonist losartan (57). ACE inhibitors can also lower normal erythrocyte counts and cause anemia (58). This effect has been assessed in a retrospective study of 92 patients after transplantation with and without erythrocytosis, comparing patients taking the same anti-rejection therapy (steroids plus ciclosporin or steroids, ciclosporin, and azathioprine) taking ACE inhibitors with those not taking ACE inhibitors (59). There were significantly lower hemoglobin and erythropoietin concentrations in patients taking ACE inhibitors. When enalapril was given to those who had not previously taken an ACE inhibitor, the hemoglobin concentration fell by around 10% and erythropoietin by around 40%. These effects were not affected by the presence or absence of azathioprine. Although the hemoglobin-lowering effect of ACE inhibition is not a new finding, the lack of an influence of azathioprine adds some further understanding to the effect.

Liver

Hepatic injury is a rare adverse effect of the ACE inhibitors (60,61). Both acute and chronic hepatitis and cholestatic jaundice can occur (62,63), as can cross-reactivity, as identified in a report involving enalapril and captopril (64).

Pancreas

Acute pancreatitis has been reported with both enalapril and lisinopril (65,66).

Urinary tract

The ACE inhibitors can cause reversible impairment of renal function in the setting of reduced renal perfusion, whether due to bilateral renal artery stenosis, severe congestive heart failure, volume depletion, hyponatremia, high dosages of diuretics, combined treatment with NSAIDs, or diabetes mellitus (67). Beyond treatment of the cause, preventive measures include withholding diuretics for a few days, beginning therapy with very small doses of ACE inhibitors, and cautious dosage titration. Therapy involves increasing dietary sodium intake and reducing dosages of diuretics or temporarily withdrawing them. The ACE inhibitor may have to be given in reduced dosages or withdrawn for a time. Because they prolong survival in heart failure and after myocardial infarction, if withdrawal is deemed necessary ACE inhibitors should be reintroduced after a brief respite.

The agreed mechanism of renal function impairment with ACE inhibitors is as follows: when perfusion pressure or afferent arteriolar pressure is reduced in the glomerulus, glomerular filtration is maintained by efferent arteriolar vasoconstriction, an effect of angiotensin II. Blocking the formation of angiotensin II, and perhaps increasing the formation of bradykinin, causes selective efferent arteriolar vasodilatation and results in a reduction in glomerular filtration (68).

In a retrospective study of 64 patients, mean age 71 years, with acute renal insufficiency associated with an ACE inhibitor, over 85% presented with overt dehydration due to diuretics or gastrointestinal fluid loss (69). Bilateral renal artery stenosis or stenosis in a solitary kidney was documented in 20% of cases. In seven patients dialysis was required, but none became dialysis dependent. After resolution of acute renal insufficiency, the plasma creatinine concentration returned to baseline and renal function was not significantly worsened. Two-year mortality was the highest in a subgroup of patients with pre-existing chronic renal insufficiency.

Skin

There have been numerous reports of different rashes in association with ACE inhibitors. The most common skin reaction is a pruritic maculopapular eruption, which is reportedly more common with captopril (2–7%) than with enalapril (about 1.5%). This rash occurs in the usual dosage range and is more common in patients with renal insufficiency (70). Lichenoid reactions, bullous pemphigoid, exfoliative dermatitis, flushing and erythroderma, vasculitis/purpura, subcutaneous lupus erythematosus, and reversible alopecia have all been reported (70–72).

The ACE inhibitors can worsen psoriasis by a mechanism mediated by inhibition of the activity of leukotrienes, which are implicated in the pathogenesis of psoriasis (73).

The ACE inhibitor-related pemphigus has been reviewed in the light of two cases of pemphigus attributed to fosinopril and quinapril (74). Drug-related pemphigus can be classified into two major types, based on the clinical course: induced pemphigus and triggered pemphigus, in which endogenous factors are more important and the drug plays a secondary role. The first type is usually related to thiol drugs. It is impossible to distinguish drug-related pemphigus reliably from idiopathic pemphigus on the basis of clinical findings, histopathology, or immunofluorescence. Captopril tends to be associated with pemphigus foliaceus, whereas the non-thiol ACE inhibitors are more often associated with pemphigus vulgaris, although there are exceptions. A transition from pemphigus vulgaris to pemphigus foliaceus is more common than the reverse. Several mechanisms have been proposed to be involved in the induction of pemphigus: interaction of the thiol group with sulfur-containing groups on the keratinocyte membrane, leading to acantholysis by biochemical interference with adhesion mechanisms; antigen modification resulting in antibody formation; inhibition of suppressor T cells, resulting in pathogenic autoantibody formation by B cell clones; or enzyme activation or inhibition. The maximum latency to the development of pemphigus reported for ACE inhibitors is 2 years. It can take up to 17 months for lesions to resolve after drug withdrawal. A significant proportion of cases will not improve or resolve spontaneously on drug withdrawal alone. It is important to withdraw the offending drug, treat the bullous reaction

© 2006 Elsevier B.V. All rights reserved.

appropriately, and advise avoidance of ACE inhibitors, although substitution of enalapril for captopril or vice versa has been successful in some cases.

Immunologic

Angioedema

Angioedema is a potentially fatal complication that has been associated with several different ACE inhibitors, with a reported incidence of 0.1–0.5%.

Presentation

Angioedema due to ACE inhibitors can manifest as recurrent episodes of facial swelling, which resolves on withdrawal, or as acute oropharyngeal edema and airways obstruction, which requires emergency treatment with an antihistamine and corticosteroids. It may be life-threatening (75) and may need tracheostomy (76). It is occasionally fatal (77). An unusual presentation with subglottic stenosis has also been reported (78). A variant form is angioedema of the intestine, which tends to occur within the first 24–48 hours of treatment (79,80).

- Two patients presented with isolated visceral angioedema with episodes of recurrent abdominal symptoms (81). Each had undergone surgical procedures for symptoms that persisted after surgery and were ultimately relieved by withdrawal of their ACE inhibitors.
- Another similar case was diagnosed as angioedema of the small bowel after an abdominal CT scan (82). Angioedema occurred in a 58-year-old woman 3 hours after biopsy of a hypopharyngeal mass under general anesthesia and was accompanied by transient electrocardiographic features of anterior myocardial infarction with severe hypokinesis of the anterior wall regions on echocardiography but no significant change in creatinine kinase activity (83). Only T wave inversion persisted on follow-up. Repeat echocardiography showed significant spontaneous improvement and coronary angiography showed normal coronary arteries. Hypotension and hypoxemia did not seem to occur, and the authors could not therefore speculate on the mechanism of the concomitant cardiac changes.
- Recurrent episodes of tongue swelling have been reported with cilazapril (84) and perindopril (85).
- A 74-year-old man with a permanent latex condom catheter developed penile swelling that was non-pitting and involved the subcutaneous tissue of a normal scrotum, after taking lisinopril 5 mg/day for 6 days (86). Removal of the catheter had no effect. After other possible causes were ruled out, ACE inhibitor-induced angioedema was suspected and lisinopril was withdrawn. Within a few days, the swelling, which had not spread, resolved.

Time-course

Angioedema can occur within the day after the start of treatment (87) and the risk is highest within the first month of ACE inhibitor use. However, it can occur many months after the start of therapy (88,89) or even years after (90).

Susceptibility factors

Black Americans are at increased risk of angioedema (91), with an overall rate of 1.6 per 1000 person years of ACE inhibitor use.

Anaphylactoid reactions, with hypotension, and flushing, occasionally associated with abdominal cramping, diarrhea, nausea, and sweating, have been reported in patients taking ACE inhibitors undergoing hemodialysis. Angioedema can also occur in these patients; it is occasionally life-threatening and is usually associated with the concurrent use of ACE inhibitors and dialysers in which the membrane is made of polyacrylonitrile (also known as AN69) (92,93). This combination should be avoided, since well-established alternatives are available.

For unclear reasons, ACE inhibitor-induced angioedema was more prevalent among immunosuppressed patients after cardiac or renal transplantation than among other patients (94). In 156 cardiac patients and 341 patients with renal transplants, this adverse effect was observed in 4.8 and 1% respectively, that is 24 times and 5 times higher than in the general population (0.1–0.2%).

Mechanism

The exact mechanism of angioedema associated with ACE inhibitors has not been determined. Although the reaction may be immune mediated, IgE antibodies or other specific antibodies have not been detected. Some authors have speculated that it may be related to a deficiency of carboxypeptidase N and complement components, because of its parallel role with that of ACE in enzymatic inactivation of bradykinin. The involvement of high concentrations of bradykinin in the pathogenesis of angioedema related to the use of ACE inhibitors is still hypothetical, since no definitive increase in bradykinin plasma concentration during attacks of angioedema has been shown. However, kinin concentrations are difficult to measure. In a well-documented study, a newly developed reliable assay for specific measurement of plasma bradykinin, excluding other immunoreactive kinins, detected a very high concentration of bradykinin (47 pmol/l) during an acute attack of angioedema in a patient taking captopril (95).

There have been reports of a lupus-like syndrome with captopril (96) and lisinopril (97).

Second-Generation Effects

Fetotoxicity

Enalapril, captopril, and lisinopril (and presumably other ACE inhibitors) cross the placenta in pharmacologically significant amounts (17). There is clear evidence of fetotoxicity when ACE inhibitors are used beyond the first trimester of pregnancy. Since continuation of treatment beyond the first trimester carries an excess risk of low fetal birth weight and other more severe complications, it is important to withdraw the ACE inhibitor at this time. Intrauterine growth retardation, oligohydramnios, and neonatal renal impairment, often with a serious outcome, are characteristic (98); failure of ossification of the skull or hypocalvaria also appear to be part of the pattern (17). There is also evidence that persistence of a patent ductus arteriosus is also more likely to occur.

Susceptibility Factors

Renal disease

Enalapril has been specifically studied in patients who are resistant to other drugs and intolerant of captopril (99) and in patients with collagen vascular disease and renal disease known to be at high risk of adverse effects (100). In the first study (99), the major reasons for discontinuing captopril were a low white blood cell count, proteinuria, taste disturbance, and rash. In the vast majority of the 281 patients, these adverse effects did not recur during enalapril treatment. The main adverse events that warranted withdrawal of enalapril were impairment of renal function (5%), hypotension (2%), and rashes (2%). The authors noted that patients with angioedema should not be given alternative ACE inhibitors.

In the second study (100) of 738 high-risk patients the main reasons for the withdrawal of enalapril were increases in serum creatinine (4%), hypotension (1%), and nausea (1%).

The long-term safety of enalapril in patients with severe renal insufficiency and hypertension has been evaluated in a pooled analysis of three similar, randomized, placebo-controlled clinical trials in 317 patients with renal insufficiency (101). Only patients without diabetes were included. Follow-up was for 2 and 3 years. One protocol used a fixed dose (5 mg/day) and the other two allowed titration up to 40 mg/day. Cough occurred in 18% of the patients taking enalapril and in 6.1% of those taking placebo. Hypotension (5.9 versus 1.2%) and paresthesia (7.8 versus 2.4%) were more frequent with enalapril. Angioedema (1.3 versus 0.6%) and first-dose hypotension (1.3 versus 0%) tended to occur more often with enalapril. Hyperkalemia, defined as any increase from baseline and left to the judgement of the investigators, was excessive in the enalapril-treated patients (28 versus 8.8%). Finally, the hematocrit fell more often with enalapril (7.1 versus 2.0%).

It is important to stress that although it is a risk factor, renal insufficiency is a good indication for ACE inhibitors, which slow the progression of chronic renal insufficiency (102). In trials in patients with chronic renal insufficiency (13–15,17), the safety profile was essentially the same as in patients with normal renal function. The current practice of avoiding ACE inhibitors in severe renal insufficiency, to prevent further renal impairment and hyperkalemia, seems no longer justified. However, patients with bilateral renal artery stenosis carry an excess risk of renal insufficiency when treated with ACE inhibitors. These agents are therefore contraindicated in such patients.

Drug–Drug Interactions

Aspirin

Antagonistic effects of cyclo-oxygenase inhibitors (indometacin or aspirin) have been repeatedly reported both in hypertension and in heart failure, strongly suggesting that there may be prostaglandin participation in the clinical response to ACE inhibitors (103,104). In animals, although not in all experimental models, aspirin can attenuate the beneficial effects of ACE inhibitors on ventricular remodelling after myocardial infarction. However, there are conflicting reports on the clinical significance of this interaction (105).

Positive studies

From a post-hoc analysis of the SOLVD trial, it appears that in patients with left ventricular systolic dysfunction, the use of aspirin was associated with improved survival and reduced morbidity. In aspirin users, benefit from enalapril was retained but reduced (106).

The WASH pilot study (Warfarin/Aspirin Study in Heart Failure) compared the effects on cardiovascular events of warfarin and aspirin, and on antithrombotic therapy in patients with heart failure, most of whom were also taking an ACE inhibitor. Patients taking aspirin had more events and hospitalizations related to worsening heart failure than patients in the two other groups (unpublished data, reported at the 1999 annual meeting of the European Society of Cardiology, John Cleland, personal communication). The authors speculated that this may have been related to a negative interaction between ACE inhibitor therapy and aspirin, which would counteract the beneficial effects of ACE inhibitors. The Warfarin-Antiplatelet Trial in Chronic Heart Failure (WATCH) is indirectly addressing the issue. It is based on the hypothesis that warfarin or clopidogrel (an antiplatelet agent that acts by a pathway independent of cyclo-oxygenase) may be preferred to aspirin as antithrombotic therapy in patients with heart failure. It will randomize 4500 patients, most of whom will be taking ACE inhibitors. Meanwhile, it may be advisable to avoid aspirin in patients with heart failure and no clear indication for aspirin (no evidence of atherosclerosis), and to consider substituting warfarin or clopidogrel for aspirin in patients with refractory or rapidly progressive heart failure (107). In all other cases, because each drug is clearly associated with a substantial clinical benefit, it would be excessive to deny patients aspirin or ACE inhibitors.

In a series of studies of ACE inhibitor-induced improvement in pulmonary function, treatment with aspirin 325 mg/day for 8 weeks in patients with mild to moderate heart failure due to primitive dilated cardiomyopathy did not affect ventilation and peak oxygen consumption during exercise when the patients were not taking an ACE inhibitor but worsened pulmonary diffusion capacity and made the ventilatory response to exercise (tidal volume, ventilation to carbon dioxide production) less effective in those who were, regardless of the duration of ACE inhibition (108).

A systematic overview of major ACE inhibitor trials (CONSENSUS II, AIRE, TRACE, SMILE) found a trend toward less benefit from ACE inhibitors among aspirin users (109). Although the interaction was not statistically significant, the authors concluded that the data did not "refute the hypothesis of a major aspirin interaction with ACE inhibitors," especially because patients taking aspirin had only 60% of the benefit seen in patients not taking it.

GUSTO-1 and EPILOG, two different antithrombotic trials, GUSTO-1 and EPILOG, the first in acute myocardial infarction and the second during coronary stenting, compared the event rates in patients taking aspirin, an ACE inhibitor, or both (110). In each of these trials, events

© 2006 Elsevier B.V. All rights reserved.

were more frequent in patients taking the combination than in those taking aspirin alone. The authors interpreted these findings as suggesting that ACE inhibitors may reduce the benefit of aspirin in these patients, whereas the results of the ACE inhibitor trials suggested that aspirin may interfere with the effect of ACE inhibitors.

Negative studies

A post-hoc analysis of the CATS trial database in patients with acute myocardial infarction suggested that aspirin does not attenuate the acute and long-term effects of captopril (111). Because of the demonstrated benefit on morbidity and mortality with each agent, textbooks and official guidelines do not recommend withholding either aspirin or ACE inhibitors in patients with heart failure or myocardial infarction. With no sufficient proof of lack of interaction, the use of small doses of aspirin (100 mg/day or less) is recommended.

In a study of the effects of aspirin 325 mg/day, both acute (4 hours after the dose) and chronic (6 weeks), in 62 patients with mild to moderate heart failure taking enalapril (more than 10 mg/day for at least 3 months), there were no significant changes in mean arterial pressure or in forearm blood flow and vascular resistance measured by venous plethysmography (112). In another arm of the study the same results were observed with ifetroban 250 mg/day, a thromboxane A_2 receptor antagonist.

Conclusions

Two post-hoc analyses of clinical trials (110) have added to the confusion engendered by these conflicting results. GUSTO-1 and EPILOG, two different antithrombotic trials, the first in acute myocardial infarction and the second during coronary stenting, compared the event rates in patients taking aspirin, an ACE inhibitor, or both (110). In each of these trials, events were more frequent in patients taking the combination than in those taking aspirin alone. The authors interpreted these findings as suggesting that ACE inhibitors may reduce the benefit of aspirin in these patients, whereas the results of the ACE inhibitor trials suggested that aspirin may interfere with the effect of ACE inhibitors.

These conflicting results may be partly explained by the various mechanisms of the vasodilatory action of ACE inhibitors, which may differ according to the regional peripheral circulation. In none of the studies was central hemodynamics or cardiac output assessed.

However, none of the trials post-hoc analysis, which suggested that there is an interaction between aspirin and ACE inhibitors, was specifically designed to examine this question. Post-hoc and subgroup analyses may be heavily biased, and multivariate adjustment may not have been able to account fully for confounding factors. Aspirin in itself may be harmful in certain patients, such as those with heart failure, because of its antiprostaglandin activity, rather than because it interferes with the actions of ACE inhibitors, a phenomenon that would also manifest as an aspirin–ACE inhibitor interaction.

The interaction between aspirin and ACE inhibitors in patients with heart failure is probably clinically important (105). Both drugs are often prescribed for a large number of patients with a variety of cardiovascular diseases. These agents have mechanisms of action that interact at the physiological level, and there are consequently many theoretical reasons to expect important clinical consequences. In animals, although not in all experimental models, aspirin can attenuate the beneficial effects of ACE inhibitors on ventricular remodelling after myocardial infarction. Some clinical studies have suggested that there is minimal, if any, adverse peripheral hemodynamic effect. In the most recent such study, the acute (4 hours after the dose) and chronic (6 weeks) effects of aspirin 325 mg/day were investigated in 62 patients with mild to moderate heart failure treated with enalapril (more than 10 mg/day for at least 3 months) (112). This did not produce significant changes in mean arterial pressure or in forearm blood flow and vascular resistance measured by venous plethysmography. In another arm of the study the same results were observed with ifetroban 250 mg/day, a thromboxane A_2 receptor antagonist. These conflicting results may be explained by the various mechanisms of the vasodilatory action of ACE inhibitors, which may differ according to the regional peripheral circulation. In none of the studies was central hemodynamics or cardiac output assessed. There is evidence that co-administration of aspirin and ACE inhibitors can be detrimental to renal function in patients with heart failure.

Beta-lactams

Intestinal absorption of beta-lactams occurs at least in part by an active mechanism involving a dipeptide carrier, and this pathway can be inhibited by dipeptides and tripeptides (113,114), which reduce the rate of absorption of the beta-lactams. ACE inhibitors, which have an oligopeptide structure, are absorbed by the same carrier (115) and interact with beta-lactams in isolated rat intestine (116).

A second potential site of interaction between ACE inhibitors and beta-lactams is the renal anionic transport system, and concomitant administration sometimes results in pronounced inhibition of the elimination of beta-lactams (117).

Diuretics

Because of dehydration, patients taking diuretics can be particularly sensitive to the hypotensive effect of ACE inhibitors (20).

Potassium supplements, potassium-sparing diuretics, or salt substitutes

Concurrent administration of potassium supplements, potassium-sparing diuretics, or salt substitutes can precipitate hyperkalemia in ACE inhibitor-treated patients, in whom aldosterone is suppressed (SED-14, 674). Regular monitoring of serum potassium is essential in these patients, because of the risk of hyperkalemia in patients given potassium (or potassium-sparing diuretics) and ACE inhibitors or angiotensin receptor antagonists.

In a retrospective study, five patients developed extreme hyperkalemia (9.4–11 mmol/l) within 8–18 days of starting combination therapy with co-amilozide and an ACE inhibitor (118).

In eight healthy subjects, treatment with spironolactone and losartan increased mean plasma potassium

© 2006 Elsevier B.V. All rights reserved.

concentration by 0.8 mmol/l (up to 5.0 mmol/l) and reduced mean urinary potassium excretion from 108 to 87 mmol/l (119).

Until more data are available, it is prudent to consider angiotensin II receptor antagonists similar to ACE inhibitors as risk factors for hyperkalemia in patients taking potassium-sparing diuretics.

Selective cyclo-oxygenase-2 (COX-2) inhibitors

Non-selective non-steroidal inflammatory drugs can attenuate the antihypertensive effects of ACE inhibitors and increase the risk of renal insufficiency. In 2278 patients taking NSAIDs, 328 taking ACE inhibitors, and 162 taking both, no nephrotoxicity was found in patients taking monotherapy, but there were three cases of reversible renal insufficiency in patients taking the combination (120).

This effect is more prominent in patients with low renin concentrations. The interaction of COX-2 inhibitors with ACE inhibitors has been much less well investigated. In a review of Phase II/III studies of COX-2 inhibitors, it was reported that the co-administration of rofecoxib 25 mg/day and benazepril 10–40 mg/day for 4 weeks was associated with an average increase in mean arterial pressure of about 3 mmHg compared with ACE inhibitor monotherapy (121).

One report has described a case of increased blood pressure in a patient taking rofecoxib and lisinopril (122).

- The blood pressure of a 59-year-old man with hypertension and normal renal function rose when rofecoxib 25 mg/day was added to lisinopril 10 mg/day (from an average of 135/80–85 to 168/98 mmHg within 5 weeks). Four days after rofecoxib was withdrawn the blood pressure was 127/78 mmHg. Rechallenge with the same dose of rofecoxib produced the same effect and the blood pressure fell when the dosage of lisinopril was increased to 20 mg/day on continuous rofecoxib. The authors did not report on the course of renal function.

The increase in blood pressure with COX-2 inhibitors from interaction with ACE inhibitors may be greater in some patients than has previously been reported.

Animal products

General Information

Drug substances of animal origin can produce anaphylactic or anaphylactoid reactions, particularly after parenteral administration (1). Animal products can also transmit an infectious disease because of the presence of a pathogenic microbe.

The following products are covered in this monograph:

- bear bile
- bee products (bee pollen, propolis, and royal jelly)
- carp bile
- fish oils
- gangliosides (from bovine brain)
- ghee
- glycosaminoglycans (Arumalon, chitosan, chondroitin, and glucosamine)
- green-lipped mussel
- Imedeen
- Kombucha "mushroom"

© 2006 Elsevier B.V. All rights reserved.

- oyster extract
- rattlesnake meat
- shark products (shark cartilage and squalene)
- Spanish fly
- toad venom

Bear bile

Bear bile contains bile acids, cholesterol, and phospholipids (phosphatidylcholine, phosphatidylethanolamine, and phosphatidylinositol). It has been used for centuries in traditional Chinese medicine to treat liver and eye complaints and convulsions, and, in combination with curcuma and capillaris, gallstones and cholecystitis. More recently it has been touted as a treatment for stroke on the basis of animal experiments. It has few or no adverse effects, but by the same token probably has little or no efficacy, although it does contain ursodeoxycholic acid, which in purified form is effective in managing gallstones.

Bee products

Bee pollen

Bee pollen products are used as general tonics. Their use has been associated with allergic reactions, including anaphylaxis (2).

Propolis

Propolis (SEDA-12, 410) (SEDA-13, 459) (SEDA-18, 4) or bee-glue is a resinous material used by bees to seal hive walls and to strengthen the borders of the combs and the hive entrance. It has antiseptic, antimycotic, and bacteriostatic properties and is found in cosmetics and "natural products" for self-treatment.

Oral mucositis with ulceration caused by propolis has been reported in an HIV-negative man (3). Infectious stomatitis is common in HIV-positive patients. Therefore, the first approach is usually the administration of antiviral therapy, antimycotic therapy, or both. However, other causes, such as contact allergy, should be suspected if the patient is exposed to a potentially allergenic substance.

Propolis can cause allergic contact dermatitis (4), and have been reported in HIV-infected patients (5–7). It has been associated with allergy after its use in cosmetics and in the self-treatment of various diseases. Although most cases involve allergic contact dermatitis arising from topical application, a few reports have described an allergic reaction after oral ingestion. Adulteration of propolis capsules with excessive amounts of lead has been reported from New Zealand (8).

Royal jelly

Royal jelly (SEDA-21, 494) is a viscous secretion produced by the pharyngeal glands of the worker bee, *Apis mellifera*. It is widely used in alternative medicine as a health tonic. Its internal use by atopic individuals can cause severe, sometimes even fatal, asthma and anaphylaxis (9–11). Topical application can lead to contact dermatitis (12).

Two patients who were sensitized to a member of the Asteraceae (Compositae) family, mugwort, had severe systemic reactions (anaphylaxis and generalized urticaria/angioedema) due to honey and royal jelly (13). Both had positive skin tests and RAST to mugwort, and in one case the RAST inhibition assay showed strong cross-reactivity between the proteins of honey and mugwort. The authors suggested that there is a link between sensitization to Asteraceae and adverse reactions to honey and royal jelly.

Of 1472 hospital employees of a teaching hospital in Hong Kong, 461 had taken royal jelly in the past (14). Nine subjects reported 14 adverse reactions to royal jelly, including urticaria, eczema, rhinitis, and acute asthma. Of 176 subjects who responded to a questionnaire, 13 (7.4%) had positive skin tests to pure royal jelly, as did 23 of 300 consecutive asthma clinic attendees (7.3%). All but one of the 36 subjects with positive royal jelly skin tests was atopic to other common allergens. There were associations between positive royal jelly skin tests and atopy (OR = 33, 95% CI = 4.5, 252) and between adverse reactions to royal jelly and a history of clinical allergy (OR = 2.88, 95% CI = 0.72, 12), but not between royal jelly symptoms and previous royal jelly intake.

Carp bile

In Asia, the raw bile of the grass carp (*Ctenopharyngodom idellus*) is believed by some to be health promoting. However, eating it can result in hepatic dysfunction and nephrotoxicity (15). The former usually resolves within a few days, but the latter is more serious, culminating in acute renal insufficiency within 2–3 days after ingestion (16). Experiments in rats have shown that the bile of the grass carp loses its lethality when treated with colestyramine, which forms insoluble complexes with bile acids (17).

Fish oils

Fish oil supplements (SEDA-13, 460) (SEDA-18, 3), rich in long-chain polyunsaturated ω-3 fatty acids (eicosapentaenoic acid, docosahexaenoic acid), can reduce plasma concentrations of triglycerides and VLDL cholesterol, reduce platelet aggregation, prolong bleeding time, reduce blood pressure, increase the fluidity of the blood, and affect leukotriene production. Reported adverse effects include fullness and epigastric discomfort, diarrhea, and a fishy taste after belching. In addition to these mild symptoms, certain areas have been identified in which problems of a more serious nature could arise:

- a potential risk that the favorable changes in plasma lipids could be offset by a deleterious increase in LDL cholesterol or LDL apoprotein B;
- the possible adverse consequence of the capacity to increase bleeding time and to reduce platelet aggregation, especially in patients with pre-existing bleeding and platelet abnormalities and in those taking other antithrombotic agents;
- preliminary evidence that a detrimental effect on patients with aspirin-sensitive asthma is possible;
- an adverse effect on the metabolic control of patients with non-insulin-dependent diabetes mellitus, when these patients are not being treated with a sulfonylurea derivative (18);
- prothrombotic effects through changes on clotting factor concentration (19);
- possible contamination.

Gangliosides

Gangliosides extracted from bovine brain tissue (Cronassial, Sygen) have been widely used in Western Europe and South America for several neurological disorders.

Reported adverse effects of gangliosides, other than discomfort at the injection site, include a motor neuron disease-like illness, cutaneous erythema (with or without fever and nausea), and anaphylaxis. After evaluation of reported associations between the use of gangliosides and Guillain–Barré syndrome (20,21), the Committee for Proprietary Medicinal Products (CPMP) of the European Commission recommended in September 1994 that the marketing authorizations for Cronassial (a mixture of gangliosides for treating peripheral neuropathies) should be withdrawn. At the same time, the CPMP recommended that marketing authorizations for Sygen (a monosialoganglioside known as GM-1, used for the treatment of cerebral vascular insufficiency) should be suspended.

In 65 patients with ischemic stroke treated for 6 weeks with intramuscular Sygen (monosialoganglioside 40 mg/day) in a double-blind, placebo-controlled study, there were no significant differences between the groups (22). A subsequent double-blind, sequential, multicenter, randomized, placebo-controlled trial of two doses of Sygen did not provide convincing evidence of efficacy (23).

Ghee

Ghee is clarified butter from the milk of water buffaloes or cows. Although the butter is heated enough to eliminate non-sporulating organisms, the process is unlikely to kill the spores of *Clostridium tetani*. This may explain why a case-control study in rural areas of Pakistan identified its traditional use as an umbilical cord dressing as a risk factor for the development of neonatal tetanus (24).

Glycosaminoglycans

Glycosaminoglycans include chondroitin-4-sulfate, chondroitin-6-sulfate, and disaccharide polymers composed of equimolar quantities of D-glucuronic acid, *N*-acetylglucosamine, and sulfates.

Arumalon

Arumalon (Rumalon) (SEDA-14, 440) is a glycosaminoglycan-peptide complex, a "chondroprotective" agent containing a watery extract of cartilage and an extract of the red bone marrow of calves. Parenteral use has been associated with local reactions at the site of the injection and with allergic symptoms (such as fever, malaise, symptoms of pronounced inflammation, nephrotic syndrome). Polymyositis and fatal dermatomyositis are also alleged to be associated with it.

- After 18 intramuscular injections of Arumalon, a 62-year-old woman with degenerative hip-joint changes developed a severe illness, with fever up to 39°C, swellings of the finger, hand, and knee joints, a rash, leukopenia (1.9×10^9/l), thrombocytopenia (113×10^9/l), and increased transaminases and lactate dehydrogenase activity (25). There was a positive lymphocyte transformation test with Arumalon and its constituents, and Arumalon-specific antibodies in the cultured lymphocyte fluid but not the serum. She became completely free of symptoms only after 1 year while taking a maintenance dose of prednisone 15 mg/day.

Chitosan

Chitosan is a polymer of glucosamine and *N*-acetylglucosamine, obtained from crustacean shells. It has been used to lower blood lipid concentrations, for body weight reduction (26), and as an excipient in pharmaceutical formulations.

Chondroitin

Chondroitin (Arteparon) (SEDA-14, 441) is a glycosaminoglycan, a "chondroprotective" agent prepared from bovine lung and tracheal cartilage. Mucopolysaccharide polysulfuric acid ester (also known as glycosaminoglycan polysulfate), said to be its major principle, resembles heparin in its molecular structure and can have the same effect on platelet aggregation. Chondroitin has been associated with life-threatening thromboembolic complications (myocardial infarction, pulmonary embolism, hemiplegic apoplexia, cerebral hemorrhage, death). Other reported adverse effects include local reactions at the site of the injection, serious allergic symptoms, arthropathy, subcutaneous fat necrosis, and reversible alopecia.

Glucosamine

Glucosamine is 2-amino-2-deoxy-D-chitin glucopyranose, which is present in joint cartilage. It has been used to treat osteoarthritis and has a small beneficial effect (27).

Asthma has reportedly been exacerbated by the use of a glucosamine-chondroitin supplement for osteoarthritis (28).

Interactions of glucosamine with warfarin (29,30) and acenocoumarol (31) have been described.

Green-lipped mussel

An extract of the New Zealand green-lipped mussel (*Perna canaliculus*) (SED-11, 1021) has been advocated for the treatment of arthritic symptoms. Reported adverse effects include flare-up of the disease, epigastric discomfort, flatulence, and nausea. Jaundice some weeks after starting treatment has been reported.

Imedeen

Imedeen is the trade name of an oral health food product containing freeze-dried proteins from the cartilage of deep-sea fish, which is advocated as an anti-wrinkling agent. Its use has been associated with generalized skin reactions and extensive Quincke's edema (32).

Kombucha "mushroom"

Kombucha "mushroom" (SEDA-20, 430) is a symbiotic yeast/bacteria aggregate surrounded by a permeable membrane. It has no proven efficacy for any indication and has serious adverse effects (33).

Liver damage has been reported after the ingestion of Kombucha tea (34). No other cause of the liver problem could be found. The patient recovered after withdrawal of Kombucha tea.

Anti-Jo1 antibody-positive myositis, associated with pleural effusions, pericardial effusion with tamponade,

© 2006 Elsevier B.V. All rights reserved.

and "mechanic's hands," was attributed to the consumption of Kombucha "mushroom" (35).

Oyster extract

A food supplement consisting of oyster extract, ginseng, taurine, and zinc (Ostrin plus GTZ 611) has been associated with Quincke's facial edema. The reaction developed immediately after intake of the food supplement, and the oyster extract was considered to be its most likely cause (36).

Rattlesnake meat

Dried rattlesnake meat (SEDA-14, 442) (SEDA-18, 2) is a well-known folk remedy that can be purchased without prescription in Mexico, El Salvador, and the South-western part of the USA. It is available as such and in the form of powder, capsules, or pills, which may be labeled in Spanish as "víbora de cascabel," "pulvo de víbora," or "carne de víbora."

All of 16 different formulations of rattlesnake powder capsules, obtained in six different cities in Mexico, were significantly contaminated with Gram-negative coliform bacteria: *Escherichia coli*, *Klebsiella pneumoniae*, *Enterobacter agglomerans*, *Enterobacter cloacae*, *Salmonella arizona*, and *Salmonella* of groups B, E4, and G; 81% of the capsules were contaminated with *Salmonella* species, the most frequent being *S. arizona* (37). Contamination was probably derived from both the flesh of the snake and fecal contamination during domestic preparation of the powder to produce the capsules.

Rattlesnake products can therefore cause serious systemic infections, particularly with *S. arizona*. Typical victims are Hispanic patients with an immunocompromising illness, such as systemic lupus erythematosus (38,39), AIDS (40), or cancer (41).

Of 22 Latino patients with *S. arizona* infection in Los Angeles County in 1986 and 1987, 18 reported taking snake capsules compared with two of 24 matched Latino controls with non-subgroup three salmonellosis or shigellosis (OR = 18.0, CI = 4.2, 76) (42). An average of 18 cases per year of *S. arizona* infection were reported in the county between 1980 and 1987. In this investigation most of the patients with *S. arizona* infection after snake capsule ingestion had underlying illnesses, such as AIDS, diabetes, arthritis, or cancer. The capsules were obtained primarily from Tijuana, Mexico and from Los Angeles pharmacies in Latino neighborhoods.

Although most patients respond well to intravenous therapy with ampicillin or co-trimoxazole, deaths have occurred. *S. arizona* peritonitis has been reported.

Shark products

Shark cartilage

Shark cartilage powder, prepared from cartilage from the fins of hammerhead sharks (*Sphyrna lewini*) or spiny dogfish (*Squalus acanthias*), is promoted as a treatment for arthritis and cancer (43), based on antiangiogenic properties, but crude extracts are ineffective (44), presumably because the active constituents, such as sphyrnastatins are not absorbed.

- A 38-year-old white man worked in a factory that ground shark cartilage (45). After 10 months of exposure, he reported chest symptoms at work in association with exposure to shark cartilage dust, and a physician diagnosed asthma. Six months later, he complained of shortness of breath at work and died from autopsy-confirmed asthma.

Symptomatic hypercalcemia has been reported in patients taking shark cartilage supplements (46).

There has been one report of hepatitis associated with the use of a shark cartilage product (47).

Occupational asthma has been attributed to shark cartilage dust (48).

Squalene

Squalene is a popular over-the-counter Asian folk remedy derived from shark liver oil. Oral capsules are readily available in Asian health food stores and the substance is also widely used in cosmetics.

Ingestion of squalene capsules has been associated with severe lipoid pneumonia due to aspiration; the patient also had abnormal liver function, which raised the possibility of hepatotoxicity (49). In nine patients with squalene-induced extrinsic lipoid pneumonia the most common pattern of parenchymal abnormalities on chest X-ray was areas of ground-glass opacity ($n = 9$, bilateral 6), followed by consolidation ($n = 7$, bilateral 3), and poorly defined small nodules ($n = 4$, bilateral 2) (50). The abnormalities were distributed in the right lower zone ($n = 9$), left lower zone ($n = 6$), and right middle zone ($n = 6$). Initial CT scans ($n = 8$) showed bilateral areas of ground-glass attenuation ($n = 8$), poorly defined centrilobular nodules ($n = 8$), crazy paving ($n = 6$), and consolidation ($n = 3$). The abnormalities were distributed in the right middle lobe ($n = 8$) and in both lower lobes ($n = 5$). Follow-up chest X-rays ($n = 9$) showed complete disappearance ($n = 2$) or reduction ($n = 7$) in the extent of the parenchymal abnormalities, and follow-up CT scans ($n = 3$) showed improvement ($n = 2$) or no change ($n = 1$).

Spanish fly

Spanish fly (SED-11, 1023), also known as cantharides, is the dried blistering beetle (*Cantharis vesicatoria* and related species), which contains cantharidin as a major active constituent. A related insect, which serves as an alternative source of cantharidin in the East, is the Chinese blistering beetle (*Mylabris* species). Spanish fly has gained a considerable reputation as an aphrodisiac, following observations that nearly toxic doses could cause priapism in men and pelvic congestion, occasionally with uterine bleeding, in women. These effects are due to an irritant effect on the genitourinary tract, which could be misinterpreted as increased sensuality. Cantharidin was formerly used medicinally as a counter-irritant and vesicant, but this use has been abandoned because of toxicity.

The effects of cantharidin poisoning include local vesicobullous formation, burning of the mouth, dysphagia, nausea, hematemesis, hepatotoxicity, gross hematuria, and dysuria. Mucosal erosion and hemorrhage occur in the upper gastrointestinal tract. Renal dysfunction is common and related to acute tubular necrosis and glomerular destruction. Priapism, seizures, and cardiac abnormalities are less common. Deaths have occurred (51). However, the lethal dose is not well established; one patient died after taking only 10 mg, while another survived even after taking 50 mg. Four patients with cantharidin poisoning had dysuria and dark urine, three had abdominal pain, one had flank pain, three had hematuria, two had occult rectal bleeding, and one woman had vaginal

© 2006 Elsevier B.V. All rights reserved.

bleeding; there was low-grade disseminated intravascular coagulation in two patients (52).

A report from Hong Kong described a fatal case due to the ingestion of a decoction of more than 200 dried *Mylabris* beetles as an abortifacient (53).

Toad venom

The dried venom of the Chinese toad (*Bufo bufo gargarizans*) is one of the ingredients of the traditional Chinese medicine kyushin. It has been used as an aphrodisiac and contains the bufadienolides bufalin and cinobufaginal, which are structurally related to cardenolides, such as digoxin, and create the false impression of high plasma digoxin concentrations (54). Digoxin Fab fragments have therefore been used to treat toad venom poisoning (55).

Poisoning with toad venom presents like digitalis toxicity (56). A deliberate overdose of kyushin in an attempt to commit suicide resulted in nausea, vomiting, general malaise, and electrocardiographic changes (for example atrioventricular block) (57). Fatal poisoning with toad venom presented with gastrointestinal symptoms, severe bradycardia, hyperkalemia, acidosis, and cardiac dysrhythmias (58).

The Chinese medicine Ch'an su, which is derived from dried toad venom, also contains bufalin and cinobufaginal, and has repeatedly been linked with serious, even fatal, cardiotoxicity (59).

Anorectic drugs

See also Individual agents

General Information

Anorectic drugs, which are structurally related to the amphetamines, act mainly on the satiety centre in the hypothalamus and also increase general physical activity (1). All of them, except fenfluramine, stimulate the central nervous system and can cause restlessness, nervousness, irritability, and insomnia. Adverse effects also occur through sympathetic stimulation and gastrointestinal irritation. Drug interactions can occur with monoamine oxidase inhibitors. Dexamfetamine, phenmetrazine, and benzfetamine can cause dependence. Some of them have been associated with cardiac valvulopathy and primary pulmonary hypertension (2).

Anorectic drugs act mainly on the satiety centre in the hypothalamus (1). They also have metabolic effects involving fat and carbohydrate metabolism. Most of them are structurally related to amfetamine and increase physical activity. Their therapeutic effect tends to abate after some months, and part of this reduction in effect may be due to chemical alterations in the brain. Fenfluramine commonly produces drowsiness in normal doses, but has stimulant effects in overdosage. Dexamfetamine, phenmetrazine, and benzfetamine all tend to cause euphoria, with a risk of addiction. Euphoria occasionally occurs with amfepramone (diethylpropion), phentermine, and chlorphentermine, but to a much lesser extent. Some adverse effects are due to sympathetic stimulation and gastrointestinal irritation; these may necessitate withdrawal but are never serious. There are interactions with monoamine oxidase inhibitors and antihypertensive drugs.

Antacids

General Information

Antacids are alkalis, such as aluminium hydroxide, magnesium salts (magnesium hydroxide and magnesium trisilicate), sodium bicarbonate, and calcium hydroxide. They are generally formulated in combinations (for example magnesium hydroxide + aluminium hydroxide, known as co-magaldrox), often with other components, such as simeticone (activated dimeticone, an anti-foaming agent), alginates (anti-reflux agents), and hydrotalcite (another type of antacid, the addition of which does not improve efficacy (1).

Comparative studies

Effervescent ranitidine 150 mg bd has been compared with as-needed calcium carbonate antacids 750 mg in a randomized study in 115 subjects who frequently self-treated heartburn (2). Effervescent ranitidine was significantly more effective than antacids in reducing heartburn, healing erosive esophagitis, alleviating pain, and improving quality of life. The overall incidences of adverse events were not significantly different in the two groups; 12% in the antacid group and 3% in the ranitidine group had adverse events related to the gastrointestinal system: nausea, vomiting, diarrhea, constipation, gas, fecal incontinence; and 1% in the antacid group and 4% in the ranitidine group had adverse events related to the central nervous system: headache, dizziness, insomnia, malaise, fatigue, weakness, nervousness.

Placebo-controlled studies

In a randomized, placebo-controlled, four-way, crossover study of the effects of low-dose ranitidine and an antacid on meal-induced heartburn and acidity in 26 subjects, ranitidine 75 mg significantly reduced gastric but not esophageal acidity, calcium carbonate 420 mg significantly reduced esophageal but not gastric acidity, and ranitidine plus calcium carbonate reduced both esophageal and gastric acidity (3). Both drugs given alone reduced heartburn severity compared with placebo.

General adverse effects

When they are given in conventional doses for symptomatic relief, antacids are safe, and adverse effects seldom limit the choice of formulation, except when troublesome diarrhea occurs (4). Change of bowel habit, usually in the form of mild diarrhea, is common, especially with magnesium salts. Other adverse effects usually occur as a direct consequence of ion absorption. They include alkalosis (particularly with large doses of soluble antacids), milk alkali syndrome when calcium is included, and the consequences of absorbing individual ions, particularly sodium but also bismuth and aluminium. Heart failure can be precipitated in susceptible patients by antacids with a high sodium content (see the Cardiovascular section). Antacids can interfere with the absorption of other drugs to a clinically important extent. Allergic reactions and tumor-inducing effects have not been described.

© 2006 Elsevier B.V. All rights reserved.

Alginates

The use, efficacy, and adverse effects of non-prescription alginate-containing formulations and H_2 receptor antagonists obtained from community pharmacies have been evaluated in 767 customers with dyspepsia (5). Most obtained some or complete symptom relief (75%) and were completely satisfied with the product (78%). H_2 receptor antagonists were more likely to produce complete relief of symptoms than alginate-containing formulations. Only 3% reported adverse effects: diarrhea, constipation, bloating, and flatulence from alginate formulations, and dry mouth, altered bowel habit, diarrhea, and constipation from H_2 receptor antagonists.

Simeticone

No specific adverse effects have been attributed to dimeticone and its activated form simeticone, which are commonly compounded with antacids. Its use has been associated with reduced hydrogen concentrations in the breath (6), but this has not been confirmed (7).

Organs and Systems

Cardiovascular

The sodium content of antacids varies greatly; a daily dose of some products may contain sodium equivalent to more than 1 g of salt. This may not be clear from the labeling or the name of the formulation. However, the amount can be sufficient to precipitate heart failure in predisposed individuals (8).

Nervous system

Absence seizures have been described during treatment with sodium bicarbonate (9).

Metabolism

Some antacids contain enough sugar to affect diabetic control (10). Since the sugar is not an active component, it will not be declared on the packaging in many countries.

Gastrointestinal

Formulations that contain alginates can cause gastric bezoars, as can tube-feed thickening when antacids are added (11).

With sodium bicarbonate, gastric rupture due to massive carbon dioxide release has been described, though it is very rare (12).

Second-Generation Effects

Lactation

Antacids are generally regarded as safe to use during pregnancy (13) and lactation (14), particularly those that are poorly absorbed from the gastrointestinal tract.

Table 1 The effects of aluminium-containing antacids on the absorption of some other drugs

Drug	Effect
Of probable or known clinical significance	
Diflunisal	Reduced absorption
Digoxin	Reduced absorption
Ferrous ions	Reduced absorption
Ketoconazole	Reduced absorption
Tetracycline	Reduced absorption
^{99m}TcPYP	Altered distribution[a]
Quinolone antibiotics	Reduced circulating concentrations (15)
Of dubious or unlikely clinical significance	
Aminophylline	Absorption retarded
Oral antidiabetic agents	Partly adsorbed by antacids
Cimetidine	Reduced peak concentration
Diazepam	Absorption retarded but complete
Indometacin	Reduced absorption
Isoniazid	Reduced peak concentration
Levodopa	Reduced absorption
Phenothiazines	Adsorbed in vitro
Phenytoin	Absorption retarded

[a] Accumulation of the radiopharmaceutical in the liver and reticuloendothelial system (16)

Drug–Drug Interactions

General

Concurrent antacid intake can alter the absorption of many other drugs. Antacids can reduce the peak concentration (C_{max}) by reducing the speed of absorption, and/or reduce the amount of absorption (that is the systemic availability). However, the effects are not always of clinical importance (Table 1). Interactions can be minimized by giving antacids and other medications 2–3 hours apart.

Oral anticoagulants

Since dimeticone is a surfactant, one might expect it to enhance the absorption of drugs, and there are some reports that this happens with ethyl biscoumacetate (17).

Antazoline

See also Antihistamines

General Information

Antazoline is a first-generation antihistamine.

Organs and Systems

Hematologic

Antazoline has sometimes produced thrombocytopenic purpura when used in normal doses (1). Antibodies to antazoline were present, obviously as a result of previous, yet uneventful, use.

© 2006 Elsevier B.V. All rights reserved.

- Antazoline-induced thrombocytopenic purpura occurred on three occasions in a 21-year-old woman (2). After withdrawal of the drug she recovered promptly. In vitro investigations showed the presence of an antibody in her serum, which in association with antazoline caused complement fixation when added to test platelets. Platelet agglutinins were also detected in her serum when antazoline was added.

The reactions in this case were drug specific and could still be demonstrated 9 months after the last exposure to the drug.

Anthracyclines and related compounds

See also Cytostatic and immunosuppressant drugs

General Information

Anthracyclines form a broad group of antitumor drugs within the group of cytotoxic antibiotics. The lead compounds were doxorubicin and daunorubicin; analogues include epirubicin, idarubicin, and aclarubicin. Mitoxantrone and pixantrone are related compounds of the anthracenedione family. Amsacrine is a related compound of the aminoacridine family.

Liposomal forms of doxorubicin (Caelyx, Myocet) and daunorubicin (DaunoXome) are in use. These drugs are licensed for the treatment of a wide range of tumors (Table 1). Much information regarding the anthracyclines has been previously published in major reviews and textbooks (1,2). With this in mind, their major toxic effects are outlined here, but concentrating in more detail on new findings, such as the interaction with trastuzumab.

Table 1 Licensed indications for anthracyclines

Drug	Where licensed	Licensed for the treatment of
Doxorubicin	USA and EU	Acute leukemia, lymphomas, soft tissue and osteogenic sarcomas, pediatric malignancies, and adult solid tumors (particularly lung and breast cancers)
Epirubicin	EU	Breast, ovarian, gastric, and lung cancers; malignant lymphomas, leukemias, and multiple myeloma; superficial and in-situ bladder carcinomas
Daunorubicin	USA and EU	Acute leukemias
Idarubicin	USA and EU	Relapsed or first-line treatment refractory advanced breast cancer, acute leukemias
Liposomal doxorubicin (Caelyx, Doxil)	USA and EU	Kaposi's sarcoma in AIDS
Liposomal pegylated daunorubicin (DaunoXome)	USA and EU	Kaposi's sarcoma in AIDS
Liposomal doxorubicin (Myocet)	EU	Breast cancer

Organs and Systems

Cardiovascular

Cardiomyopathy

Anthracyclines can cause the late complication of a cardiomyopathy, which can be irreversible and can proceed to congestive cardiac failure, ventricular dysfunction, conduction disturbances, or dysrhythmias several months or years after the end of treatment (3,4). Doxorubicin can cause abnormalities of right ventricular wall motion (5). A significant number of patients receiving anthracyclines develop cardiac autonomic dysfunction (6).

Dose-relatedness

The development of anthracycline-induced cardiomyopathy is closely related to the cumulative lifetime dose of the anthracycline. The recommended maximum cumulative lifetime dose of doxorubicin is 450–550 mg/m^2 (7) and of daunorubicin 400–550 mg/m^2 intravenously in adults (1,2). About 5% of doxorubicin-treated patients develop congestive cardiac failure at this dose; however, the incidence approaches 50% at cumulative doses of 1000 mg/m^2 (7–9). These figures are derived from experience with doxorubicin administered as a bolus or by infusion of very short duration (under 30 minutes). The incidence of clinical cardiotoxicity falls dramatically with other schedules of administration (that is weekly doses or continuous infusion for more than 24 hours).

In a randomized study of adjuvant chemotherapy comparing bolus against continuous intravenous infusion of doxorubicin 60 mg/m^2, cardiotoxicity, defined as a 10% or greater reduction in left ventricular ejection fraction, occurred in 61% of patients on a bolus median dose equal to 420 mg/m^2 compared with 42% on the continuous infusion schedule with a median dose of 540 mg/m^2; the rate of cardiotoxicity as a function of the cumulative dose of doxorubicin was significantly higher in the bolus treatment arm (10).

In 11 patients with anthracycline cardiotoxicity studied by heart catheterization and endomyocardial biopsy, myocytic damage correlated linearly with cumulative dose (11). There was a non-linear relation between electron microscopic changes and the extent of hemodynamic impairment. There was pronounced fibrous thickening of

© 2006 Elsevier B.V. All rights reserved.

the endocardium in most patients, especially in the left ventricle. Endocardial fibrosis may be the first morphological sign of cardiotoxicity.

Susceptibility factors

The risk of cardiotoxicity is greater in children and patients with pre-existing cardiac disease or concomitant or prior mediastinal or chest wall irradiation (12,13).

Of 682 patients, 144 who were over 65 years of age all had doses up to but not exceeding the usual cumulative dose for doxorubicin (14). The authors concluded that older patients without cardiovascular co-morbidity are at no greater risk of congestive heart failure.

The use of doxorubicin in childhood impairs myocardial growth, resulting in a progressive increase in left ventricular afterload, sometimes associated with impaired myocardial contractility (15). Of 201 children who received doxorubicin and/or daunorubicin 200–1275 mg/m^2, 23% had abnormal cardiac function 4–20 years afterwards. Of those who were followed for more than 10 years, 38% had abnormal cardiac function compared with 18% in those who were followed for less than 10 years (16,17). In another study, more than half of the children studied by serial echocardiography after doxorubicin therapy for acute lymphoblastic leukemia developed increased left ventricular wall stress due to reduced wall thickness. This stress progressed with time (18).

Predisposing factors to mitoxantrone cardiotoxicity include increasing age, prior anthracycline therapy, previous cardiovascular disease, mediastinal radiotherapy, and a cumulative dose of the drug exceeding 120 mg/m^2. In 801 patients treated with mitoxantrone, prior treatment with doxorubicin and mitoxantrone was significantly associated with risk of cardiotoxicity; however, age, sex, and prior mediastinal radiotherapy were not useful predictors (19).

Anesthesia is difficult in patients with cumulative anthracycline-induced cardiotoxicity, and it has proved fatal on occasions (20).

Comparative studies of anthracyclines

All anthracyclines have cardiotoxic potential. However, because only a few cycles of treatment are administered in most regimens, few patients reach the cardiotoxic threshold of cumulative anthracycline dose. There is therefore limited information about the comparative cardiotoxic potential of these agents.

Epirubicin is considered to cause substantially less cardiotoxicity than doxorubicin on a molar basis (4,21). This has been attributed to its more rapid clearance rather than a different action (22). In a randomized, double-blind comparison of epirubicin and doxorubicin, there was a significant reduction in left ventricle ejection fraction with doxorubicin but not with epirubicin (23). However, data from large clinical series and from morphological examination of endomyocardial biopsies in smaller series of patients suggest that the incidence and severity of cumulative cardiac toxicity associated with epirubicin 900 mg/m^2 is similar to that associated with doxorubicin 450–550 mg/m^2 (24). In 29 patients treated with epirubicin in cumulative doses ranging from 147 to 888 mg/m^2 the ultrastructural myocardial lesions were similar to those produced by doxorubicin (partial and total myofibrillar loss in individual myocytes) (25). With both drugs, severe lesions were associated with replacement fibrosis. None of the patients who received epirubicin in the study developed congestive cardiac failure.

Both mitoxantrone and the oral formulation of idarubicin have been thought to be less cardiotoxic than doxorubicin (26,27). The South West Oncology Group reported on 801 patients treated with mitoxantrone; 1.5% developed congestive cardiac failure, an additional 1.5% had a reduced left ventricular ejection fraction (LVEF), and 0.25% developed acute myocardial infarction (19). Idarubicin has been reported to cause short-term cardiac toxicity when used in high doses in leukemia, and there is no doubt that it causes cumulative dose-related toxicity as well (28). Electrocardiographic changes occurred in 7% of adults with acute leukemia receiving aclarubicin (29).

Presentation

The main effects of anthracycline-induced cardiotoxicity are reduced left ventricular function and chronic congestive heart failure. Other cardiotoxic events occur only rarely. Occasionally, acute transient electrocardiographic changes (ST–T wave changes, prolongation of the QT interval) and dysrhythmias can occur. Acute conduction disturbances, acute myopericarditis, and acute cardiac failure are also rare. In a study of the effects of anthracyclines on myocardial function in 50 long-term survivors of childhood cancer, there was cardiac failure in one patient and electrocardiographic abnormalities (non-specific ST segment and T wave changes) in two (13). In one patient with a VVI pacemaker, who received the combination of vincristine, doxorubicin, and dexamethasone, the pacemaker had to be reset after each cycle of treatment, as the pacing threshold had increased, resulting in bradycardia (30).

Hypokinetic heart wall motion abnormalities and early signs of chronic cardiomyopathy have been identified as a significant toxic effect of mitoxantrone in patients who received cumulative doses of 32–174 mg (31). Electrocardiographic T wave inversion and cardiac complications have been described from intensive therapy with mitoxantrone 40 mg/m^2 over 5 days and cyclophosphamide 1550 mg/m^2 for 4 days, given before bone marrow transplantation for metastatic breast cancer. All the patients had had previous exposure to doxorubicin in cumulative doses that did not exceed 442 mg/m^2 (19).

The authors of a study of the use of MRI scans to assess the subclinical effects of the anthracyclines concluded that increased MRI enhancement equal to or greater than 5 on day 3 compared with the baseline predicted significant reduction in ejection fraction at day 28 (32). In 1000 patients given doxorubicin chemotherapy and irradiation there were six cases of congestive heart failure and three cases of myocardial infarction; there was a cumulative cardiac mortality of 0.4% in all anthracycline-exposed patients (33).

Diagnosis

The diagnosis of anthracycline cardiomyopathy is based on the clinical presentation and investigations such as

© 2006 Elsevier B.V. All rights reserved.

radionuclide cardiac angiography, which can show a reduced ejection fraction (34), and echocardiography, which can show reduced or abnormal ventricular function (35,36). Dysrhythmias can be detected by electrocardiography, and QT_c interval prolongation may offer an easy, non-invasive test to predict patients who are at special risk of late cardiac decompensation after anthracycline treatment for childhood cancer (37). Radioimmunoscintigraphy can be used to highlight damaged myocytes, and changes such as myocardial fibrosis are characteristic on endomyocardial biopsy (13,38,39).

The subtle chronic abnormalities in myocardial function that occur 10–20 years after anthracycline exposure in childhood are best detected by exercise echocardiography, since these patients may have normal resting cardiac function (40).

It has been suggested that monitoring B type natriuretic peptide concentrations after anthracycline administration can reflect cardiac tolerance, and through serial monitoring allow a picture of the degree of left ventricular dysfunction to be established (41).

Mechanisms

Several mechanisms contribute to anthracycline cardiotoxicity. The principal mechanism is thought to be oxidative stresses placed on cardiac myocytes by reactive oxygen species. Amelioration of this toxicity is possible using dexrazoxane, an intracellular metal-chelating agent of the dioxopiperazine class (3). Dexrazoxane acts by depleting intracellular iron, thus reducing the formation of cardiotoxic hydroxyl anions and radicals. In patients without heart failure, in-vivo measurements of myocardial oxidative metabolism and blood flow did not change in patients with cancer receiving doxorubicin (42).

Anthracyclines have the ability inherent in their quinone structure to form free-radical semiquinones which result in very reactive oxygen species, causing peroxidation of the lipid membranes of the heart. However, this reaction has not been demonstrated with mitoxantrone, and the mechanism of its cardiotoxicity is unknown.

Abnormalities of left ventricular ejection fraction have been described in 46% of patients ($n = 14$) treated with mitoxantrone (14 mg/m^2) and with vincristine and prednisolone (43). A history of cardiac disease or of previous anthracycline exposure was excluded. Only one patient developed clinically overt congestive cardiac failure. Other reports have described less cardiotoxicity compared with the parent compound, doxorubicin (4,44).

Management

Anthracycline cardiomyopathy, although reportedly difficult to treat, often responds to current methods used to manage congestive cardiac failure.

Severe anthracycline-induced cardiotoxicity is generally considered irreversible, and it is associated with a poor prognosis and high mortality. However, in four cases the advanced cardiac dysfunction associated with doxorubicin recovered completely after withdrawal (45). Of 19 patients with anthracycline-induced congestive cardiac failure, 12 recovered after withdrawal, although reversal was modest (46).

The prolongation of the QT interval that occurs in patients who have recently finished doxorubicin therapy is slowly reversible over at least 3 years and the degree of prolongation is related to the cumulative dose (47).

Heart transplantation has been successful in patients with late, progressive cardiomyopathy without recurrence of the underlying malignant disease (48).

Cardiac dysrhythmias

Cardiac dysrhythmias have been reported after amsacrine therapy in association with hypokalemia. Pre-existing supraventricular dysrhythmias or ventricular extra beats are not absolute contraindications to its use (49). Of 5430 patients treated with amsacrine, 65 developed cardiotoxicity, including prolongation of the QT interval, non-specific ST–T wave changes, ventricular tachycardia, and ventricular fibrillation (50). There were serious ventricular dysrhythmias resulting in cardiopulmonary arrest in 31 patients; 14 died as a result. The dysrhythmias occurred within minutes to several hours after drug administration. The cardiotoxicity was not related to total cumulative dose, and hypokalemia was possibly a risk factor for dysrhythmias.

Sensory systems

Doxorubicin can cause conjunctivitis, periorbital edema, lacrimation, blepharospasm, keratitis, and reduced visual acuity (51). There have been two reports of persistent photophobia and chronic inflammation of the eye following accidental topical exposure to doxorubicin (52).

Hematologic

Myelosuppression, principally neutropenia, occurs in 60–80% of patients who receive conventional doses of anthracyclines (single-agent standard doses: doxorubicin 60–75 mg/m^2, epirubicin 60–90 mg/m^2 given 3-weekly) (53). On an equimolar basis, in both the single-agent and combination regimens, epirubicin causes less hematological toxicity than doxorubicin (24). The incidence and severity of myelosuppression is related to dose; it has been suggested that severe neutropenia occurs in all patients who are given high-dose anthracyclines (doxorubicin 100 mg/m^2 or more and epirubicin 120 mg/m^2 or more) (54). Neutrophil nadirs occur at 7–10 days after treatment, and full neutrophil recovery usually occurs by day 21 (24). Platelets are less affected; about 35% of patients receiving epirubicin 120 mg/m^2 have grade-3 thrombocytopenia (55). Anemia occurs rarely (24).

Although the extent of leukopenia is not related to cumulative anthracycline dose, patients who have received extensive prior chemotherapy develop more severe leukopenia, possibly because of diminished bone marrow reserve (24). There was a strong correlation between dose and both leukocyte nadirs and platelet nadirs in 287 patients who received single-agent epirubicin 40, 60, 90, or 135 mg/m^2 every 3 weeks (56). Myelosuppression correlates with exposure to epirubicin, as reflected by the plasma AUC (57).

Myelosuppression is not prevented by prolonged doxorubicin infusion (53), although this can mitigate other adverse effects. Hematological toxicity associated with

© 2006 Elsevier B.V. All rights reserved.

high-dose regimens can be partially ameliorated by giving hemopoietic growth factors, with or without autologous bone marrow or peripheral blood progenitor cell rescue (58–60). However, other adverse effects, mainly mucositis, then become dose-limiting. It has been suggested that mitoxantrone 14 mg/m^2 is more myelosuppressive than doxorubicin 70 mg/m^2, which in turn is more myelosuppressive than epirubicin 70 mg/m^2, each given at 3-week intervals (61).

Secondary acute myeloid leukemia, with or without a preleukemic phase, has been rarely reported in patients being concurrently treated with epirubicin or doxorubicin in association with DNA-damaging antineoplastic agents; such cases have a short latency period (1–3 years) (62,63). In one study, three of 77 patients who received epirubicin plus cisplatin and two who received other epirubicin-containing combinations developed acute myelogenous leukemia 15–33 months after the start of epirubicin treatment for advanced breast cancer (62). However, all had received prior treatment with alkylating agents and/or radiotherapy, which are recognized independent leukemogenic risk factors. Despite high mean lifetime epirubicin doses in this study (mean 800 mg/m^2), there was no relation between cumulative dose and the risk of acute myelogenous leukemia. In a second study, four of 351 patients with metastatic breast cancer who received fluorouracil + epirubicin + cyclophosphamide, but none of 359 who received cyclophosphamide + methotrexate + 5-fluorouracil, developed leukemia (three acute myelogenous leukemia, one acute lymphoblastic leukemia) (63). No secondary leukemias were documented in other large comparative studies of epirubicin-containing regimens (64,65). Nevertheless, a retrospective analysis of case reports, published in abstract form without references or methods, concluded that when epirubicin was combined with alkylating agents it was associated with an increased risk of secondary acute myelogenous leukemia in women with breast cancer (66).

Prolongation of the prothrombin time after the use of amsacrine 1200 mg/m^2 for acute myeloid leukemia was related to transient deficiency of factor X (67).

Mouth and teeth

Mucositis is a well-documented toxic effect of anthracyclines; it has been reported in 8% of combination chemotherapeutic courses including epirubicin in a dose of 180 mg/m^2 (68).

Gastrointestinal

The anthracyclines are classed as moderately to strongly emetogenic. Nausea and vomiting occurs in 21–55% of patients, but is substantially reduced by pretreatment with antiemetic drugs (53,55). In one randomized study, epirubicin 70 mg/m^2, doxorubicin 70 mg/m^2, and mitoxantrone 14 mg/m^2 were compared (61). The first cycles of epirubicin and mitoxantrone were given without antiemetic drugs, unless specifically requested, but thereafter antiemetic drugs were given as required; doxorubicin was given with antiemetic drugs from cycle one. Doxorubicin and epirubicin were significantly more emetogenic than mitoxantrone; there was grade 3 nausea and vomiting in 22% of those who received doxorubicin, 18% of those who received epirubicin, and none of those who received mitoxantrone. Oral idarubicin may cause more emesis, which is quoted as occurring in 25–86% of patients; however, these effects are said to be usually mild to moderate (27).

With the advent of the 5-hydroxytryptamine (5-HT$_3$) receptor antagonists (ondansetron, granisetron, tropisetron), used in conjunction with dexamethasone, nausea and vomiting can be ameliorated in most patients.

Mucositis and stomatitis are potentially severe and dose-limiting adverse effects of the anthracyclines. Both the frequency and the severity are dose-dependent (56,69). Their onset and recovery generally parallel the hematological toxicity, but they can occur earlier (5–10 days after treatment starts). Areas of painful erosions, mainly along the side of the tongue and on the sublingual mucosa, are common. Mucositis occurs in about 9% of patients who receive oral idarubicin in standard doses (27).

Diarrhea has also been reported with the anthracyclines. In a typical study, in which epirubicin 100 mg/m^2 was given for 1–8 cycles, one of 39 patients had grade 1/2 diarrhea and two of 39 had grade 3/4 diarrhea (70). Of patients who take oral idarubicin 10–38% are said to develop diarrhea, again generally mild to moderate (27).

Urinary tract

All anthracyclines can cause discoloration of the urine and other body fluids (that is tears) (1,2).

Skin

Anthracyclines can cause local irritant reactions. These range from erythema and phlebitis at the injection site to potentially severe vesicant reactions requiring skin grafting (24). Care appropriate to the administration of a vesicant must be observed during infusion. Various treatments have been used immediately after extravasation in an attempt to lessen the injury, including ice, steroids, vitamin E, and bicarbonate. The current recommended treatment is by intermittent cooling of the affected area, together with intermittent use of topical dimethylsulfoxide 99% (71). There is also evidence of the efficacy of intravenous dexrazoxane, and the first dose should preferably be given within 6 hours (72). In three patients who had extravasation of epirubicin or doxorubicin, healing occurred without sequelae (73,74); all three received three doses of intravenous dexrazoxane over 3 days (1000 mg/m^2 on the first two days and 500 mg/m^2 on day 3), the first dose being administered at 2–5 hours after extravasation. A fourth patient received dexrazoxane 1500 mg 1 hour after extravasation of doxorubicin and repeated 5 hours later, and 750 mg on day 2; the wound healed slowly and required surgery after 3 months (75). A fifth patient received dexrazoxane more than 6 hours after extravasation of epirubicin; the wound healed slowly and with a crusted center (76).

Reactivation of skin damage can also occur at sites of prior radiation therapy ("radiation recall") (77).

- Widespread allergic contact dermatitis occurred in a 73-year-old man after intravesical administration of epirubicin; a patch test with an aqueous solution of the drug (0.1%) was positive (78).

© 2006 Elsevier B.V. All rights reserved.

A syndrome of palmar–plantar erythema (progressing in some patients to blistering and desquamation) has been reported in seven of eight patients with advanced breast or ovarian cancer who received high-dose doxorubicin (125–150 mg/m^2) (79). By contrast, in a similar dose intensification study in which patients received epirubicin 200 mg/m^2 with cyclophosphamide and growth factor support, the palmar–plantar syndrome did not occur (80).

In 60 patients receiving polyethylene glycol-coated liposomal doxorubicin (Doxil) 35–70 mg/m^2 by infusion over 1–2 hours there were four patterns of skin eruption: hand–foot syndrome (40%), a diffuse follicular rash (10%), an intertrigo-like eruption (8%), and new melanotic macules (0.5%) (81).

Hair

Complete or partial alopecia occurs in the majority (60–90%) of patients who receive anthracyclines, and although it is reversible it can be distressing (24). Scalp cooling during chemotherapy to minimize hair loss is now little used, because of limited efficacy, the discomfort of scalp cooling techniques, and concern about the potential creation of a "sanctuary" for circulating tumor cells. Alopecia is less frequent (about 35% of patients) in patients who take oral idarubicin 40–45 mg/m^2 every 3 weeks (27).

Nails

Painful onycholysis, blue discoloration of the nails (82), and reversible loss of fingernails (83) have been attributed to mitoxantrone.

Sweat glands

There has been a single report of hidradenitis associated with mitoxantrone (84).

Long-Term Effects

Mutagenicity

There was an increased number of chromosomally aberrant lymphocytes in nurses who handled cytostatic agents (doxorubicin, cyclophosphamide, vincristine, fluorouracil, and methotrexate) many years ago, before modern facilities for the preparation of chemotherapeutic drugs were in use (85). No long-term fertility problems were identified in 205 men who were treated with doxorubicin during childhood (86).

Tumorigenicity

In 604 women who were given six cycles of epirubicin after 4 years of tamoxifen, there were 12 non-breast second malignancies (87). Although the authors did not analyse these in respect to population expectation, they thought that the frequency was relatively high.

Second-Generation Effects

Teratogenicity

There is no conclusive evidence about whether anthracyclines adversely affect human fertility or are teratogenic. In 26 of 28 pregnancies, three or more chemotherapeutic agents were used to treat acute leukemia ($n = 20$), non-Hodgkin's lymphoma ($n = 3$), Ewing's sarcoma ($n = 2$), breast cancer ($n = 2$), and myoblastoma ($n = 1$) (88). The anthracyclines were introduced at various gestational ages, ranging from time of conception to 38 weeks, but in most cases chemotherapy was started in the second trimester. The outcomes were 24 normal infants, including a set of twins. Four of the five cases of infant death occurred in those with hematological malignancies (acute leukemia and non-Hodgkin's lymphoma), one each due to maternal death and therapeutic abortion and two resulting from spontaneous abortion. Neonatal pathological examination showed no congenital anomalies or organ defects, one case of marrow hypoplasia, and one case of neonatal sepsis. These findings suggest that anthracyclines have no detectable effect on the offspring up to the age of 54 months. However, bias inherent in reporting pregnancies with a successful outcome is obvious, so extreme caution must be exercised in the use of anthracyclines in pregnancy, and they should be avoided if at all possible.

Fetotoxicity

Cardiac failure occurred in a 3-day-old neonate whose mother had been given idarubicin 9 mg/m^2 as part of induction therapy for acute lymphoblastic leukemia at 22 weeks; the baby was delivered at 28 weeks (89). In the absence of another known cause, the cardiotoxicity was attributed to idarubicin exposure 6 weeks before.

Susceptibility Factors

Hepatic disease

Since the main route of metabolism and elimination of anthracyclines is via the bile, dosage reduction is recommended if there is hepatic impairment. This was first suggested after a report of increased toxicity in patients with liver metastases who received full-dose anthracycline treatment, followed by a second report that suggested that the clearance of anthracyclines is reduced in patients with hepatic metastases (90,91). These reports led to the current recommendations for anthracycline doses, based on serum bilirubin concentration or sulfobromophthalein clearance. However, the question of whether liver dysfunction significantly affects anthracycline clearance is unclear, and the dosage modifications suggested (see Table 2) have never been validated. Indeed, there is evidence that anthracycline kinetics are altered in patients with raised serum transaminases alone,

Table 2 Effects of liver function on doses of doxorubicin and epirubicin

Drug	Serum bilirubin concentration	BSP retention	Recommended dose
Doxorubicin	20–50 μmol/l	9–15%	50% of normal
	>50 μmol/l	>15%	25% of normal
Epirubicin	20–50 μmol/l		50% of normal
	>50 μmol/l		25% of normal

© 2006 Elsevier B.V. All rights reserved.

which may be a better basis for dosage modification (92). In practice, many clinicians make empirical dosage modifications in patients with abnormal liver biochemistry tests (57).

Drug Administration

Drug formulations

The anthracyclines have been formulated in liposomal formulations in order to alter their pharmacokinetics and improve their therapeutic index. Examples include:

- pegylated liposomal doxorubicin (Caelyx/Doxil);
- liposomal doxorubicin (Myocet);
- liposomal daunorubicin (DaunoXome).

These formulations are dealt with in a separate monograph.

Drug administration route

The anthracyclines are most commonly given intravenously, either as bolus doses or, less often, as infusions over varying lengths of time. Alternative routes have been tried, such as the intraperitoneal, intrapleural, and intravesical routes (93,94).

Intraperitoneal

Intraperitoneal instillation of doxorubicin has been used in the early postoperative period in patients with retroperitoneal or visceral sarcoma, in an attempt to eradicate microscopic residual disease after complete macroscopic surgical excision (95). Three of 17 patients had pyrexia, one peritoneal sclerosis, one a pancreatic fistula, and two abdominal pain. There were no anastomotic disruptions or intra-abdominal hemorrhages.

Intrapleural

Adverse effects associated with the intrapleural instillation of doxorubicin in doses of 10–40 mg consist of fever (11–15%), anorexia (24–29%), nausea (20–29%), and chest pain (28–29%) (94,96). Cardiomyopathy and myelosuppression were not reported (96).

Intravesical

Intravesical epirubicin has been used to treat superficial bladder cancers. At a dose of 50 mg, the overall incidence of adverse events was 16–25% (93). The frequency of adverse events tended to increase with dose but not the number of instillations. Most adverse events were mild and transient; the commonest were localized to the bladder and included chemical cystitis (10–38%), urinary tract infection (2–13%), and hematuria (2–33%). Contracted bladder or hemorrhagic cystitis have been reported in 1–6% of patients (93).

Adverse events occurred in 31 of 194 patients who received epirubicin 80 mg intravesically compared with 12 of 205 who received placebo after transurethral resection (97). Systemic adverse events (usually cardiac or hematological adverse events or hypersensitivity) generally occurred in under 5% of patients. In two studies of intravesical epirubicin, there were reports of myocardial infarction (9%), stroke (3%), angina pectoris (3%), or atrioventricular block (2%) (98,99). There were no reports of myelosuppression in clinical trials of intravesical epirubicin, apart from thrombocytopenia in one of 37 patients in one cancer trial (98) and hemoglobinemia in two of 40 patients in another (100).

Biochemical abnormalities have been reported in trials of intravesical epirubicin. In one trial, liver function tests were impaired in seven of 40 patients who received epirubicin and in 10 of 35 patients who received epirubicin and verapamil concomitantly (101). In another study, liver function tests were impaired in one of 69 patients who received combination prophylaxis with epirubicin 50 mg and BCG 150 mg after transurethral resection (102).

Hypersensitivity has been reported in 0–8% of patients in trials of intravesical epirubicin; the symptoms included generalized skin rash, vulval irritation, or urinary frequency and dysuria, or were not stated (100,103,104). One of 34 patients developed symptoms characterized as allergic (dizziness, nausea, hypotension) 1 hour after instillation of epirubicin (105). Two patients who received epirubicin developed severe allergic reactions and one died (106,107).

Non-specific systemic adverse events (flu-like symptoms, malaise, fever, nausea, vomiting, anorexia, rash) occurred in under 5% of patients who received intravesical epirubicin (98,103,108). Alopecia was reported in one of 37 patients (98).

Intravesical epirubicin and doxorubicin appear to have similar tolerability profiles (104,109–112).

Valrubicin (a novel *N*-trifluoroacetyl, 14-valerate derivative of doxorubicin) is currently licensed in the USA for intravesical use in prophylaxis in patients with BCG-refractory carcinoma in situ after transurethral resection. It has a similar toxicity profile to that of epirubicin and doxorubicin (113).

Drug overdose

Very high single doses of anthracyclines can cause acute myocardial degeneration within 24 hours and severe myelosuppression within 10–14 days. Treatment should aim to support the patient during this period and should include such measures as blood transfusion and reverse barrier nursing. Delayed cardiac failure can occur up to 6 months after overdosage.

Drug–Drug Interactions

Etoposide

The combination of idarubicin plus etoposide (total doses 180 mg and 5760 mg respectively) was associated with a case of acute promyelocytic leukemia (114).

Taxanes

The combination of doxorubicin plus paclitaxel is cardiotoxic.

Of 57 patients who had received at least three courses of chemotherapy with a combination of doxorubicin 50 mg/m^2 plus paclitaxel 175–225 mg/m^2, left ventricular ejection fraction did not fall overall but was significantly reduced in eight patients; it fell by more than 14% in

© 2006 Elsevier B.V. All rights reserved.

three cases and by 33–48% in the other five; none of the patients developed clinical heart failure (115).

Two studies of the combination of epirubicin plus paclitaxel have shown less reduction in left ventricular ejection fraction and no clinical evidence of cardiac failure (116,117).

Clinically significant cardiac insufficiency has been reported in a patient who was given epirubicin (316 mg/m^2) followed by six cycles of docetaxel (100 mg/m^2/cycle) (118).

Trastuzumab

An interaction of doxorubicin with the anti-HER_2 receptor humanized monoclonal antibody, trastuzumab (Herceptin), has been reported. Most patients who received trastuzumab in early trials had been pretreated with anthracyclines. Despite this, preliminary information suggested that reduced systolic cardiac function was an adverse effect of trastuzumab (119). More recently, this problem has been further highlighted in a study of women with metastatic breast cancer (120). Patients who had not received prior anthracycline-containing adjuvant chemotherapy were at greater risk of cardiotoxicity when they received trastuzumab in combination with doxorubicin or cyclophosphamide (27 and 75% respectively), compared with only 11% of patients who received trastuzumab in combination with paclitaxel (120,121). The risk of cardiac events in patients treated with doxorubicin, cyclophosphamide, and trastuzumab increased markedly after a cumulative doxorubicin dose of 360 mg/m^2. This suggests synergistic cardiotoxicity with trastuzumab and doxorubicin. Trastuzumab is therefore currently licensed only for use in conjunction with paclitaxel or docetaxel and not with conventional doxorubicin.

The mechanism of trastuzumab-induced cardiotoxicity and its synergy with doxorubicin is as yet unknown. However, the cardiac failure responds to standard medical management (122).

Since trastuzumab is active as a single agent and in combination with chemotherapy in patients whose tumors overexpress HER_2, the interaction with doxorubicin is clearly of concern. Although it is possible to avoid this problem by not combining trastuzumab with doxorubicin, there are compelling reasons for further exploring its use with anthracyclines. For example, follow-up results from the CALGB 8541 study have shown that patients who received high and moderate (standard) doses of cyclophosphamide plus doxorubicin plus fluorouracil survived longer than those who received low doses (123). Moreover, examination of patients' HER_2 status in this trial showed that those whose tumors expressed large amounts of the HER_2 protein had a significantly worse survival if treated with moderate or low doses of cyclophosphamide plus doxorubicin plus fluorouracil, compared with high doses (124). These results suggest that patients whose tumors express large amounts of the HER_2 receptor protein may require high-dose anthracyclines, presenting the problem of how then to treat them with trastuzumab without causing cardiotoxicity.

In an attempt to avoid cardiotoxicity after the administration of trastuzumab with doxorubicin, alternative adjuvant regimens have been suggested. Trastuzumab could be combined with other anthracyclines (epirubicin or liposomal formulations), which are inherently less cardiotoxic, or given sequentially rather than concomitantly with the anthracycline. Alternatively, non-anthracycline combinations, such as cyclophosphamide plus doxorubicin plus fluorouracil or based around taxanes, cisplatin, and vinorelbine are being investigated (125).

Caution should of course be exercised when giving other cytotoxic drugs, especially myelotoxic agents or agents that cause significant mucositis/stomatitis, in combination with anthracyclines.

Anthracyclines—liposomal formulations

See also Anthracyclines and cytostatic and immunosuppressant drugs

General Information

Liposomes are microscopic particles composed of a lipid bilayer membrane enclosing active drug in a central aqueous compartment (1). The aim of liposomal encapsulation of a drug is to alter its pharmacokinetics, thus improving efficacy and/or reducing toxicity (2). Current formulations of liposomal formulations of anthracyclines are as follows:

- pegylated liposomal doxorubicin (Caelyx/Doxil)
- liposomal doxorubicin (Myocet)
- liposomal daunorubicin (DaunoXome).

Sterically stabilized liposomal doxorubicin (pegylated liposomal doxorubicin; Caelyx/Doxil) is coated with polyethylene glycol (3), which results in so-called "stealth liposomes." In liposomal daunorubicin the liposome consists of a lipid bilayer of distearoylphosphatidylcholine and cholesterol in a 2:1 molar ratio (4). Both formulations have a hydrophilic outer layer, which attracts a coating of water around the liposomal shell. This increases the circulation time by making the formulation virtually invisible to the reticuloendothelial system.

The second liposome system (Myocet) was designed to preserve the antitumor effects of doxorubicin but with reduced cardiotoxicity. This type of liposome is readily recognized and phagocytosed by the mononuclear phagocyte system. In animals most of the injected cytotoxic agent is rapidly taken up by phagocytes, minimizing exposure of normal tissues, and thus diminishing some acute and chronic adverse effects (5,6). The doxorubicin is then released by the phagocytes in a controlled fashion, similar to a slow infusion.

Pharmacokinetics

The differences between liposomal doxorubicin and liposomal daunorubicin are due to the differences in their liposomal packaging.

Pegylated liposomal doxorubicin (Caelyx/Doxil) and liposomal daunorubicin (DaunoXome) produce lower peak plasma concentrations and longer circulation times than free drug (7).

Liposomal doxorubicin in Myocet has systemic availability, metabolism, and excretion similar to that of conventional doxorubicin, but at a slower rate (8). In dogs, the plasma concentrations of doxorubicin from Myocet were 1000-fold greater than conventional doxorubicin at 6 hours, but the difference diminished at 24 hours (9). This distinguishes Myocet from Doxil, which persists in the circulation for significantly longer.

Caelyx has linear pharmacokinetics and its disposition occurs in two phases, the first relatively short (5 hours) and the second prolonged (55 hours). Unlike free doxorubicin, most of the pegylated liposomal doxorubicin is

© 2006 Elsevier B.V. All rights reserved.

confined to the vascular fluid volume, and its blood clearance depends on the liposomal carrier. Liposomal daunorubicin acts similarly to Caelyx, but produces a lower AUC and has a higher clearance and a shorter terminal half-life (10).

Pegylated liposomes (diameter about 70–100 nm) and liposomal daunorubicin (diameter 45 nm) are small enough to pass intact through defective blood vessels that supply tumors. This, rather than any particular affinity for tumor cells, is the reason for their accumulation in tumor tissue (2). Caelyx provides a greater concentration of doxorubicin in Kaposi's sarcoma tumors than in normal skin.

Organs and Systems

Cardiovascular

The incidence of cardiotoxicity in anthracycline-treated patients has been related to the peak plasma drug concentration (11,12). One of the aims in developing pegylated liposomal doxorubicin was to reduce plasma concentrations of free doxorubicin and restrict myocardial penetration, to minimize cardiotoxicity. Preclinical data suggested that the liposomal formulation was indeed less cardiotoxic than the free drug: about 50% more pegylated liposomal doxorubicin than free doxorubicin can be given to rabbits without producing the same frequency of cardiotoxicity (13).

Cardiac adverse events that have been considered probably or possibly related to pegylated liposomal doxorubicin have been reported in 3–9% of patients (14–16). These include hypotension, pericardial effusion, thrombophlebitis, heart failure, and tachycardia (14,15).

Left ventricular failure has been reported in a few patients, particularly those who received high cumulative lifetime doses of pegylated liposomal doxorubicin (over 550 mg/m^2) (14,15). However, cumulative doses of 450 mg/m^2 or more and 550 mg/m^2 have been administered without significant reduction in ejection fraction or the development of cardiac failure (17,18). To date, no or minimal cardiotoxicity has been observed in patients with AIDS-related Kaposi's sarcoma who received pegylated liposomal doxorubicin in high cumulative doses (19).

Both peak and overall concentrations of doxorubicin in myocardial tissue are reduced by 30–40% after Myocet relative to conventional doxorubicin (9). This reduced myocardial exposure resulted in a significant reduction in cardiotoxicity, assessed both functionally and histologically (5,6). Compared with free doxorubicin 75 mg/m^2 given 3-weekly, Myocet 75 mg/m^2 caused significantly less congestive cardiac failure (1 versus 6%) (20). However, a high dose of Myocet (135 mg/m^2, median cumulative dose 405 mg/m^2) caused a significant increase in cardiac toxicity: 38% of patients had a protocol-defined cardiac event, including 13% who developed congestive heart failure (21).

In one study there was a significant (over 20%) reduction in the shortening fraction with liposomal daunorubicin measured by echocardiography (22). In contrast, in another study there was no significant fall in cardiac function, even after cumulative doses of liposomal daunorubicin over 1000 mg/m^2 (23).

Women with metastatic breast cancer were randomized to receive either liposomal doxorubicin (Myocet) 75 mg/m^2 ($n = 108$) or conventional doxorubicin 75 mg/m^2 ($n = 116$) (24). The liposomal formulation was less cardiotoxic than the conventional one, and the cumulative doses before the onset of cardiotoxicity were 780 versus 570 mg/m^2 respectively; the liposomal formulation provided comparable antitumor activity. In another study the authors tried to define the cumulative toxic intravenous dose of daunorubicin (DaunoXome) and concluded that it may be 750–900 mg/m^2 or even higher (exceeding 1000 mg/m^2) (25).

Respiratory

Acute dyspnea, low back pain, and/or pain at the site of tumor have been described, beginning within 1–5 minutes of the start of infusion of pegylated liposomal doxorubicin (26). Three of 35 patients were described as suffering acute dyspnea, two with back pain and two with abdominal pain. In each case the symptoms resolved within 5–15 minutes of stopping the infusion, which was restarted without adverse effects. The mechanism of these symptoms was unclear. However, because the dyspnea was reminiscent of that seen in hemodialysis neutropenia, complete blood counts were obtained from four patients about 2 minutes after the onset of symptoms. All four had relative neutropenia (neutrophil counts of 3–46% of pretreatment), which resolved by the end of the infusion. In vitro, pegylated liposomal doxorubicin, in concentrations predicted to be present in the plasma during the start of treatment, stimulates neutrophil adhesion to human umbilical vein endothelial cells (26). Thus, pegylated liposomal doxorubicin may cause transient sequestration of neutrophils in the pulmonary circulation, resulting in reduced lung compliance and associated dyspnea.

Hematologic

In a phase I dose-finding study of pegylated liposomal doxorubicin, myelosuppression was not a major problem with the doses tested (20–80 mg/m^2, re-dosing every 3–4 weeks). Median nadir white cell and platelet counts were well above 2×10^9/l and 100×10^9/l respectively. In the occasional patient in whom profound granulocytopenia developed there was quick recovery of the cell counts within less than 7 days. Neutropenic fever was documented in only one patient at the top dose of 80 mg/m^2 (17). There was no significant indication of cumulative myelosuppression. Treatment-related anemia was generally mild and blood transfusions were not required. However, two patients with head and neck malignancies and extensive pretreatment were given erythropoietin to maintain hemoglobin concentrations above 9.0 g/dl (17).

Pooled data from 12 phase I or II studies, in 308 patients with solid tumors who received pegylated liposomal doxorubicin in doses of 10–80 mg/m^2, showed that there was neutropenia (neutrophil count below 1×10^9/l) in 50%, anemia in 19%, and thrombocytopenia in 9.2% (27).

Of 71 patients with metastatic breast cancer treated with pegylated liposomal doxorubicin in doses of 45–60 mg/m^2 given 3- or 4-weekly, grade 3/4 neutropenia occurred in 10% and thrombocytopenia in 1% (27).

If pegylated liposomal doxorubicin and liposomal daunorubicin are used to treat AIDS-related Kaposi's sarcoma, one has to consider additional factors that affect

© 2006 Elsevier B.V. All rights reserved.

the white cell count. In patients with HIV/AIDS, myelosuppression was the most frequent dose-limiting adverse effect of liposomal anthracyclines (22,23). In one study of 30 patients with Kaposi's sarcoma given liposomal daunorubicin 40 mg/m^2, 53% developed granulocytopenia (white cell count below 1×10^9/l); 17% had a hemoglobin concentration below 8.0 g/dl, but none had thrombocytopenia (22).

In another study in 53 patients with AIDS-related Kaposi's sarcoma given pegylated liposomal doxorubicin 20 mg/m^2 every 3 weeks, 21 had leukopenia and three had thrombocytopenia (28).

At doses of 20 mg/m^2 liposomal doxorubicin, combined tolerability data from 705 patients with AIDS-related Kaposi's sarcoma showed that neutropenia (below 1×10^9/l) and anemia were the most common adverse events, affecting 50 and 19% of patients respectively (14).

In summary, myelosuppression after treatment with pegylated liposomal doxorubicin does not appear to be a major problem in patients with solid tumors and relatively intact immunological systems, but is the dose-limiting adverse effect in immunocompromised patients with HIV/AIDS.

High-dose Myocet (135 mg/m^2) caused significant hematological toxicity, namely grade 4 neutropenia in 98% and thrombocytopenia in 46 of 52 patients (21). However, Myocet 75 mg/m^2 3-weekly caused less hematological toxicity than conventional doxorubicin (20).

Gastrointestinal

Stomatitis and pharyngitis have been confirmed, along with hand–foot syndrome, as dose-limiting adverse effects of pegylated liposomal anthracyclines (17). Stomatitis was dose-limiting at high single doses over 70 mg/m^2. Similarly, 12 of 35 patients who received pegylated liposomal doxorubicin 50 mg/m^2 every 3 weeks for advanced ovarian carcinoma required dose reduction (to 40 mg/m^2) or treatment delay (to 4 weeks) because of mucositis (18). Stomatitis and mucositis are dose-dependent (29). In the treatment of Kaposi's sarcoma in patients with HIV/AIDS, mucositis and stomatitis are rarely problematic and are not dose-limiting. Presumably this is because significantly lower doses of pegylated liposomal doxorubicin are used in these patients.

Nausea and vomiting have been reported but appear to be mild and infrequent adverse effects of pegylated liposomal anthracyclines and liposomal daunorubicin (23,30). In most patients pegylated liposomal doxorubicin can be given without prophylactic antiemetics. In one study there was only mild nausea and vomiting in eight of 53 patients who had not received prophylactic antiemetics (28). Further reviews in patients with AIDS-related Kaposi's sarcoma have reported nausea and vomiting in 17 and 8% of patients respectively (29). Pooled data from 12 phase I and II studies in patients with solid tumors showed that 3.6% of patients had had grade 3/4 nausea or vomiting (27). Diarrhea has similarly been recognized as a mild and infrequent adverse effect of pegylated liposomal doxorubicin (three of 53 patients) (28).

Myocet (75 mg/m^2) causes significantly less vomiting (11 versus 23%) than conventional free doxorubicin (75 mg/m^2) (20). It also leads to lower peak-free doxorubicin concentrations in the gastrointestinal mucosa compared with conventional doxorubicin, and less gastrointestinal toxicity (5). However, high-dose Myocet (135 mg/m^2) caused grade 4 mucositis in 10 of 52 patients (21).

Liver

The authors of a case report suggested that pegylated liposomal doxorubicin was the probable cause of hepatic failure in a patient who, 2 weeks after treatment with pegylated liposomal doxorubicin 10 mg/m^2 (cumulative dose 20 mg/m^2) (15), developed jaundice and ascites (31). Despite withdrawal of other potentially hepatotoxic drugs, the patient died of hepatorenal failure 12 weeks later. This may have been an idiosyncratic effect augmented by hepatitis B viral infection (15,32), as there have been no other reports of hepatorenal failure (14,33).

Skin

Skin toxicity, manifesting primarily as palmar–plantar erythrodysesthesia or hand–foot syndrome, is one of the principal dose-limiting adverse effects of pegylated liposomal anthracyclines (for example Caelyx 50 mg/m^2 given every 4 weeks) and may warrant dosage modification, depending on the severity of the symptoms (17,18). In pooled tolerability data, grade 3/4 hand–foot syndrome was reported in 54 (17.5%) of 308 patients (27). The median time to the development of grade 3/4 hand–foot syndrome was 51 days, corresponding to the second or third cycle of treatment (27). Myocet, even when given in a high dose (135 mg/m^2), was not associated with the hand–foot syndrome characteristic of pegylated liposomal doxorubicin (20,21). This was presumed to be due to differences in the liposomal formulation. Pegylated liposomes circulate for prolonged periods and may undergo some eccrine excretion, particularly in cases of hyperhidrosis, whereas with Myocet the liposome is phagocytosed by the reticuloendothelial system and the active drug is then slowly released into the circulation, similar to a slow infusion. Severe forms of hand–foot syndrome may need acute intervention with oral dexamethasone and topical dimethylsulfoxide; oral vitamin B_6 has not been proven to be useful.

Conjunctivitis and skin pigmentation have been reported but are mild (23,27,28).

Unlike extravasation of conventional doxorubicin, which can cause severe local inflammation and tissue damage, extravasation of liposomal doxorubicin was associated with only mild transient irritation at the infusion site in the eight documented cases (34,35).

Four cases of extravasation of liposomal daunorubicin have been reported and were associated with only mild irritation and transient erythema and swelling, similar to pegylated liposomal doxorubicin (36).

In 60 patients receiving polyethylene glycol-coated liposomal doxorubicin (Doxil) 35–70 mg/m^2 by infusion over 1–2 hours there were four patterns of skin eruption: hand–foot syndrome (40%), a diffuse follicular rash (10%), an intertrigo-like eruption (8%), and new melanotic macules (0.5%) (37).

Hair

Alopecia can occur during treatment with doxorubicin (38). It is generally mild during treatment with Caelyx and occurs in 6–9% of patients. The incidence of alopecia with single-agent Myocet is higher.

Immunologic

Acute hypersensitivity reactions have been reported with the first infusion of pegylated liposomal doxorubicin (14,15). The symptoms included flushing, shortness of breath, facial swelling, headache, chills, back pain, tightness in the chest and throat, and hypotension. Similar reactions have been reported after the intravenous administration of colloid imaging agents and unloaded liposomes.

Acute reactions to infusion have been observed on first exposure to the drug in six of 56 patients treated with pegylated doxorubicin 20–60 mg/m^2 (17). The reactions developed at 3–25 minutes after the start of the infusion and were characterized by flushing, sensation of choking, back pain, and in one instance hypotension. All the symptoms disappeared shortly after discontinuation of the infusion. Three patients were re-treated successfully using premedication (hydrocortisone, cimetidine, and diphenhydramine) and a slower infusion rate (initial rate 1 mg/minute). Similarly, acute onset symptoms of dyspnea, back pain, and tumor site pain have been reported in other studies (26). Since this reaction generally improves on rechallenge with or without premedication, it has been termed pseudoallergic.

Long-Term Effects

Tumorigenicity

Two patients with acute promyelocytic leukemia developed therapy-related myelodysplasia 2.0–2.5 years after complete remission and then acute myeloid leukemia; both had received anthracyclines (39). In both cases the cytogenetic changes that usually occur after the use of alkylating agents were observed. There has only been one previous similar report after successful therapy with anthracyclines, but these observations suggest that anthracyclines can cause acute myeloid leukemia similar to that caused by alkylating agents.

A flare phenomenon is a well-documented effect of hormonal therapies and/or hormone-responsive tumors. A prostate-specific antigen flare occurred in four of 28 patients who received liposomal doxorubicin (Caelyx) for symptomatic androgen-independent prostate cancer (40).

Second-Generation Effects

Teratogenicity

Pegylated liposomal doxorubicin is embryotoxic in rats and embryotoxic and abortifacient in rabbits. Teratogenicity cannot therefore be ruled out, but there is no reported experience in pregnant women. Equally, it is not known if the drug is excreted into human breast milk, so breastfeeding should be discontinued before the administration of pegylated liposomal doxorubicin.

Susceptibility Factors

Since Caelyx has activity in Kaposi's sarcoma, many studies have been performed in patients with HIV/AIDS. Thus, assessment of the tolerability of Caelyx and Doxil has been complicated by underlying immune suppression, neutropenia, and co-morbidity commonly present in patients with HIV/AIDS. This has led to a difference in the dose-limiting adverse effects in patients with solid tumors compared to those with Kaposi's sarcoma. Tolerance differs in patients with HIV/AIDS (standard dose 20 mg/m^2 Caelyx every 3 weeks) and those with solid tumors (standard dose 50 mg/m^2 every 4 weeks).

Drug Administration

Drug administration route

Pegylated liposomal doxorubicin has been given to three patients via a catheter located in the hepatic artery (41). No severe adverse effects, such as nausea, vomiting, stomatitis, alopecia, or cardiotoxicity, were observed. There was mild leukopenia (2.8×10^9/l) in one patient; neither anemia nor thrombocytopenia were reported.

Drug overdose

Acute overdose with pegylated liposomal doxorubicin worsens the toxic effects of mucositis, leukopenia, and thrombocytopenia. There have been no reports of overdose of liposomal daunorubicin, but the primary anticipated toxic effect would be myelosuppression.

Drug–Drug Interactions

General

No formal drug interaction studies have been conducted with pegylated liposomal doxorubicin, liposomal daunorubicin, or Myocet. Caution should be exercised when using drugs known to interact with doxorubicin or daunorubicin. Equally, caution should be exercised when giving any other cytotoxic drugs, especially myelotoxic agents, at the same time.

Anthrax vaccine

See also Vaccines

General Information

Inactivated anthrax vaccine is mainly used for protection against occupational anthrax exposure. A complete vaccine series consists of three 0.5-ml subcutaneous doses at 2-week intervals, followed by three additional doses 6, 12, and 18 months after the first dose. Mild local reactions occur in 30% of vaccinees, including local erythema and tenderness, which occurs within 24 hours and begins to subside within 48 hours. The reactions tend to increase in severity by the fifth injection. Systemic reactions are rare and usually characterized by malaise and lassitude, chills, and fever (1).

Until recently, there has been little research into anthrax vaccines, other than that carried out for anti-bacteriological warfare purposes by the military. Currently, three human vaccines against *Bacillus anthracis* (produced in Russia, the UK, and the USA) are commercially available. The results of two field trials of two vaccines produced in Russia and the USA have been analysed (2). The US killed vaccine was 93% effective in preventing cases of anthrax, and the Russian live attenuated vaccine afforded 75% protection when given by scarification and 84% when a jet-gun was used. The rates of local reactions (erythema, induration, and edema) and systemic reactions (fever, malaise, arthralgia, rash, headache) after the US vaccine were 5.75 and 0.4% respectively, compared with 0.54% local reactions and no systemic reactions after placebo. Adverse effects data on the Russian vaccine were not presented.

In the search for new vaccines against anthrax, manufacturers have aimed for better quality purified protective antigen vaccines with better adjuvants, vaccines made through recombinant gene technology, and mutant vaccines with altered protective antigens.

In a study by the Advisory Group of Medical Countermeasures of the UK Ministry of Defence only mild discomfort at the injection site was reported after the administration of a total of 55 000 doses of anthrax vaccine (3).

Antianginal drugs

See also Individual agents

General Information

Drugs that are used in the treatment of angina pectoris include agents from the following groups:

- Nitric oxide donors
- Beta-blockers
- Calcium channel blockers
- Potassium channel activators.

New agents, such as L-carnitine and trimetazidine, are also being studied (1).

Safety factors that govern the choice of antianginal drug

Insights into the epidemiology, physiology, cellular biology, molecular biology, and treatment of ischemic heart disease have shown that there are three major modifiable risk factors (hypertension, hypercholesterolemia, smoking) that are the main targets of our preventive strategies. However, evidence that intervention is beneficial has been considerably strengthened.

Hypertension

In high-risk elderly people, treatment of hypertension prevents coronary events (2,3). In the Hypertension Optimal Treatment (HOT) study, which included middle-aged and elderly subjects, good blood pressure control resulted in improved outcome, the optimal blood pressure in non-diabetic subjects being about 138/82 mmHg (4). The target blood pressure was achievable but most patients required more than one drug. A further finding was that low-dose aspirin was beneficial in high-risk subjects. The HOT study found particular benefits of rigorous blood pressure lowering in diabetic subjects, findings that were confirmed by the UK Prospective Diabetes Study (UKPDS) (5), which did not find an advantage in macrovascular complications with angiotensin converting enzyme

© 2006 Elsevier B.V. All rights reserved.

inhibitors compared with beta-blockers (6). The CAPPP study similarly showed no benefit of captopril over other drugs (7). This originally led to the advice that drugs other than diuretics and beta-blockers should be used infrequently (8); however, subsequent recommendations for the choice of initial therapy have been increasingly based on indications for other conditions that often co-exist with hypertension (9). The Syst-Eur study of systolic hypertension gave further prominence to isolated systolic hypertension as a treatable risk factor and provided some reassuring data on the efficacy of calcium antagonists (10). Despite rather depressing news about inadequate blood pressure control in the UK (11) and USA (12), the increased use of antihypertensive drugs appears to have resulted in less left ventricular hypertrophy (13). This may account in part for the considerable fall in mortality from cardiovascular disease observed since the late 1960s.

Hypercholesterolemia

The landmark 4S study of cholesterol-lowering therapy has convincingly shown the effectiveness of treating patients with high serum cholesterol concentrations and ischemic heart disease (14). This has largely been confirmed by subsequent studies (15–17), and the beneficial effects of lowering serum cholesterol have been extended to primary prevention (18,19). Currently, statins are recommended in all those over the age of 55 years and/or in those with pre-existing cardiovascular disease (20). Statins reduce cardiac events if begun early after acute coronary syndromes (21) and may also be indicated in any patient with aortic stenosis, regardless of severity (22).

Smoking

The risks of smoking have been highlighted (23). Evidence has emerged that changing from high-tar to low-tar cigarettes is ineffective in reducing myocardial infarction (24), and the antismoking lobby has become more vocal (25,26). The role of cigarette smoking as a major factor in myocardial infarction has been further emphasized by a study of the survivors of the ISIS studies (27). Smoking increased the risk of a non-fatal myocardial infarction five-, three-, and two-fold in the age ranges 30–49, 50–59, and 70–79 respectively. In addition, the results of this study suggested that enforcement of a European Union upper limit of cigarette tar of 12 mg will result in only a modest reduction in myocardial infarction. Preventing adolescents from smoking seems to be the only strategy, as few adults start smoking after the age of 18 (28). Passive smoking (29) and cigar smoking (30) may be associated with coronary disease, making this initiative even more important. The US ruling in July 1995 that nicotine is an addictive substance (31) was a monumental advance in fighting smoking, since cigarettes are considered to be nicotine delivery systems. If the FDA gains legal jurisdiction in regulating tobacco, active steps will be taken to reduce smoking among children.

The roles of these modifiable risks have thus become more important, and other risks interventions, such as dietary antioxidants (32) and physical activity (33), have also been highlighted. In addition, observational studies have implicated hyperhomocysteinemia as a powerful risk for premature atherosclerotic coronary artery disease (34). Whether or not treating this risk factor is beneficial in reducing cardiac events is currently being tested (35). In the USA, grain is already enriched with folic acid (140 μg/100 g) (36), and this has resulted in reduced homocysteine concentrations in the middle-aged and older population from the Framingham Offspring Study cohort (37).

In recent years, potassium channel activators have been added to the antianginal armamentarium. In addition, the line between antianginal drugs and drugs used to prevent angina has become somewhat blurred. Aspirin has now become a mainstay drug in the treatment and prevention of ischemic heart disease (38), and another antiplatelet drug, clopidogrel, has also been licensed for this indication. Lipid-lowering drugs have also been advocated for both primary and secondary prevention, and the role of beta-blockers in the secondary prevention of myocardial infarction has been extended into the treatment of systolic heart failure. The angiotensin-converting-enzyme (ACE) inhibitor enalapril has gained a licence for the prevention of coronary ischemic events in patients with left ventricular dysfunction, following the Studies of Left Ventricular Dysfunction Trials (39). More recently, evidence on lisinopril and trandolapril has suggested that these drugs prolong the lives of subjects who have a myocardial infarction, either uncomplicated or complicated by impaired ventricular function (40). The benefits of ACE inhibitors in secondary prevention are now beyond doubt, and are especially marked in diabetic patients (41).

Our view of drug therapy has subtly changed with these findings. The physician's role was to use drugs to relieve the symptoms of angina. Nowadays, drugs must not only relieve symptoms but also, when possible, improve life expectancy (20). We are also more concerned with the quality of symptomatic relief. The notion of "well-being" has become important and has been assessed in "quality-of-life" comparisons of different agents (42). Subtle effects that individually might not be detected have been highlighted in such studies and can modify our view of a drug's adverse effects profile. As the subtle adverse effects of drugs become more important, serious drug toxicity becomes even more unacceptable.

Other susceptibility factors

The roles of other modifiable susceptibility factors have become more important, and other interventions, such as dietary antioxidants (32) and physical activity (33), have also been highlighted in the past. However, a meta-analysis of the effect of vitamin E supplements has suggested that doses over 400 IU/day can increase the risk of death from any cause (43).

Pharmacoeconomics

A further consideration, the economic evaluation of drugs, has become an issue, although not without criticism (44). In its most rigorous form the cost of drug therapy is measured against the aggregate number of years of improved health that such therapy might be expected to bring (45). These so-called "quality-adjusted life years" (QUALYs) are reduced if a drug has an adverse effect, so that the net benefit of a drug that prolongs life but makes

© 2006 Elsevier B.V. All rights reserved.

that life miserable may well be a negative number of QUALYs. Such studies have put a price-tag on mild adverse events as well as on beneficial effects. In time we may pay increasing attention to the price of adverse effects when choosing a drug.

The drug treatment of angina is time-consuming, empirical, and often relatively unrewarding. Drug treatment simply palliates the underlying disease, and no symptomatic treatment improves survival or prevents myocardial infarction. This is in contrast to surgical intervention, which, in good hands, prolongs survival (46) and improves its quality. The three main comparisons of coronary surgery with medical therapy (47–49) are now out of date, since both medical therapy and surgical techniques have improved considerably since they were completed. However, long-term medical therapy is now more often being reserved for patients who for one reason or another are unsuitable for surgery or percutaneous coronary angioplasty, which, at least for single-vessel disease, is superior to antianginal drug treatment (50) but may be equivalent to lipid-lowering therapy (51). Preventive therapy must now be the dominant strategy.

Anti-CD4 monoclonal antibodies

See also Monoclonal antibodies

General Information

Anti-CD4 monoclonal antibodies are used to treat various autoimmune diseases, such as rheumatoid arthritis, asthma, and psoriasis (1–3). Keliximab (rINN) (IDEC CE9.1) is a human-cynomolgus monkey chimeric (primatized) antibody with specificity for human and chimpanzee CD4. Clenoliximab (rINN) is an immunoglobulin G4 derivative of keliximab. These antibodies induce a more than 80% down-regulation of CD4 molecules on the surface of T lymphocytes.

Observational studies

In an open, dose-escalating study, 24 patients were allocated to five consecutive daily doses of a humanized IgG1 anti-CD4 monoclonal antibody (4162W94) (4). There was at least one predefined infusion-related adverse effect (for example fever, chills/rigors, headache, nausea, vomiting, diarrhea, dyspnea, or hypotension) in 17 patients. Most of these events were mild or moderate in intensity, occurred on the first day of dosing, and resolved within 8 hours. In some patients the adverse events were associated with the

© 2006 Elsevier B.V. All rights reserved.

appearance of TNF alfa in the plasma during the 3 hours after the start of antibody infusion, suggesting that they resulted from cytokine release. There was systolic hypotension, defined as a systolic pressure below 90 mmHg and a fall of at least 20 mmHg, in one patient who was given 10 mg. There were non-specific skin rashes in one patient in each of the groups who were given 10, 30, and 100 mg and in three of those given 300 mg. There were three serious adverse events: fatal rupture of an aortic aneurysm, thought to be unrelated to the drug, an episode of severe reversible airways obstruction in a patient with asthma, and an episode of unexplained collapse, presumed to be vasovagal, followed by full recovery several hours after the end of the first infusion. No opportunistic or other infections were reported.

Placebo-controlled studies

In a placebo-controlled study in 48 patients with active rheumatoid arthritis, CD4 blockade produced clinical benefit (5). Adverse events were reported in 97% of the patients, compared with 73% of those given placebo. In both groups most of the events were mild to moderate. Serious adverse events were reported in five patients who received anti-CD4; syncope/vasovagal attacks ($n = 3$), back pain ($n = 1$), abdominal pain/rectal bleeding ($n = 1$). Skin rashes occurred in 62% of the patients who received the antibody. In five cases a skin biopsy was performed, and showed a cellular infiltration centered on the blood vessels, suggesting a drug-induced vasculitis.

In a randomized, dose-ranging, placebo-controlled study of keliximab in chronic severe asthma, there were no serious adverse effects related to treatment (1).

Anticholinergic drugs

See also Individual agents

General Information

There are many anticholinergic drugs, some structurally related to atropine, others quaternary ammonium compounds or tertiary amines. Although many of these products are claimed to have superior efficacy, specificity, or tolerance, few have ever been critically compared with others. The so-called freedom from adverse effects claimed for many of these compounds can often be traced to uncritical clinical work, the use of ineffective doses, or mere lack of activity of the compound.

General adverse effects

An indication of what may be expected in the way of adverse reactions can be obtained by fitting a drug into its structural class (see Table 1), since the pattern of effects of drugs in each class is generally very similar. The drugs closely related to atropine have the full range

Table 1 General classification of anticholinergic drugs (rINNs except where stated)

Atropine and closely related agents
Atropine
Hyoscine (BAN)
Ipratropium
Oxitropium
Tiotropium
Synthetic quaternary ammonium compounds
Clidinium
Emepronium bromide
Isopropamide
Mepenzolate
Methanthelinium (pINN)
Oxyphenonium
Poldine (pINN)
Propantheline
Tertiary amines used in visceral disorders
Adiphenine
Dicycloverine
Oxyphencyclimine
Piperidolate
Drugs with primarily anticholinergic effects used mainly in Parkinson's disease
Tertiary amines related to diphenhydramine
Chlorphenoxamine
Orphenadrine
Trihexyphenidyl-related compounds
Biperiden
Procyclidine
Trihexyphenidyl (benzhexol)
Compounds related to both atropine and diphenhydramine
Benzatropine
Etybenzatropine
Compounds used topically for pupillary mydriasis
Cyclopentolate
Eucatropine
Homatropine
Tropicamide

of antinicotinic and antimuscarinic activity of atropine itself. Of the synthetic compounds used in visceral disorders, the quaternary compounds are fully ionized in the pH range found in body fluids and are therefore less lipid-soluble than the corresponding tertiary amines. This means that they penetrate physiological barriers less readily; less drug is absorbed in the intestine, less enters the cerebrospinal fluid and aqueous humor, and less enters cells. Consequently, these drugs tend to be relatively less active by mouth and to have fewer effects on the brain and the eye than the tertiary amines. Of the latter, some have little antimuscarinic activity and indeed probably very little useful activity at all; they may have some specific relaxant effect on smooth muscle, but it seems to be of little clinical significance.

Of the drugs in this class used largely in parkinsonism, the tertiary amines related to diphenhydramine have some antihistaminic activity, as one would expect; some of these drugs are also related to atropine. The derivatives of trihexyphenidyl (benzhexol) are also pharmacologically closely similar: for example, they have some excitatory effects if given in sufficient doses.

The unwanted peripheral effects of all atropine-like drugs include flushing of the skin, dryness of the mucous membranes with fever, tachycardia, reduced salivary secretion and dryness of the mouth, drying up of the gastrointestinal secretions and decreased gastric acidity, and reduced muscle tone in the gut and constipation. Bladder tone and frequency of micturition are reduced and acute urinary retention is a risk, especially in older men with prostatic hyperplasia. Nasal, bronchial, and lacrimal secretions are reduced.

Herbal sources of anticholinergic drugs

Tropane alkaloids, such as hyoscyamine and/or scopolamine, occur in the solanaceous plants *Atropa belladonna*, *Datura stramonium*, *Hyoscyamus niger*, and *Mandragora officinarum*. These alkaloids are powerful anticholinergic agents and can elicit peripheral symptoms (for example blurred vision, dry mouth) as well as central effects (for example drowsiness, delirium). They can potentiate the effects of anticholinergic medicaments.

Organs and Systems

Cardiovascular

The potential dysrhythmogenic effect of anticholinergic drugs has been examined retrospectively in nearly 4000 patients taking flavoxate, oxybutynin, and hyoscyamine between 1991 and 1995, compared with over 10 000 patients who had no exposure to these drugs (1). All the patients were over 65 years old and they were reasonably matched for co-morbidities, although not surprisingly more women than men were taking the antispasmodic drugs (75% women in the treated group versus 67% in the control population). The encouraging conclusion was that there was no evidence that these drugs promote ventricular dysrhythmias or sudden death. However, the authors noted that more detailed analysis of these data is needed and that it may also be advisable to consider data from newer drugs.

Nervous system

Orofacial dyskinesia, though familiar with dopaminergic drugs, can apparently also occur with some anticholinergic drugs; for example, it has been described with trihexyphenidyl in a patient who did not have this reaction with levodopa (SEDA-18, 160).

Sensory systems

Anticholinergic drugs cause passive pupillary dilatation by paralysing the iridal sphincter, suppress accommodation by paralysing the ciliary muscle, and increase the vascular permeability of the iris and ciliary bodies. They are used topically for diagnostic and refractive purposes, and in combination with other drugs as part of the treatment of several serious ocular conditions, including inflammatory states. Topically applied drugs can cause local adverse effects in the eye (SEDA-23, 504) and systemic effects if sufficient drug is absorbed.

All anticholinergic drugs can cause acute closed-angle glaucoma in patients with an anatomical predisposition. They also cause photophobia and disturbances of accommodation leading to difficulties in reading and driving.

Psychological, psychiatric

Anticholinergic drugs can cause vivid and sometimes exotic hallucinations and this has led to their misuse. Plants containing atropine and related substances were used in witches' brews in the Middle Ages to conjure up the devil, but even synthetic tertiary amines given in eye-drops and depot plasters containing atropine (SEDA-13, 114) have caused hallucinations. Postoperative confusion in elderly patients has been clearly correlated with drugs that have anticholinergic properties (SEDA-13, 114), and the use of anticholinergic drugs for the treatment of Parkinson's disease has long been associated with neuropsychiatric adverse effects. Cyclopentolate is a short-acting cycloplegic with a rapid onset (and considerable intensity) of action, which particularly in children has been reported to cause hallucinations and psychotic episodes (2). It has been suggested that a partial structural affinity of the side-chain to some hallucinogens aggravates the problems associated with cyclopentolate.

Anticholinergic drugs can impair short-term memory. The effects in non-demented patients are reversible, receding within a few weeks of withdrawing treatment (3). Comparisons of dopaminergic drugs with anticholinergic drugs in healthy volunteers have shown that anticholinergic drugs caused significant impairment of memory function, more confusion, and dysphoria (SEDA-13, 115).

Immunologic

Allergic reactions to local application in the eye can occur, usually in the form of contact dermatitis and conjunctival redness and are more common with hyoscine

© 2006 Elsevier B.V. All rights reserved.

than with atropine, although contact dermatitis is less likely (4).

Long-Term Effects

Drug dependence

Patients taking long-term anticholinergic drugs can develop dependence (SEDA-15, 136).

Susceptibility Factors

Anticholinergic drugs clearly may cause problems in patients with closed-angle glaucoma (or a narrow angle between the iris and cornea), paralytic ileus, pyloric stenosis, or urinary retention. Because of their effects on temperature control they may be undesirable in patients with pyrexia (especially children) and during very hot weather.

Drug Administration

Drug overdose

The clinical effects of overdosage with atropine-like drugs, as recorded in a series of 119 patients, are presented in Table 2 (5). Infrequent manifestations (less than 10% of cases) included seizures, convulsions, vomiting, rash, urinary retention, abdominal distress, paralytic ileus, and constipation. Death, when it occurs, is due primarily to the effects on the central nervous system; a stage of excitement is followed by drowsiness, stupor, and coma, with generalized central depression.

Table 2 Clinical manifestations of anticholinergic drug intoxication in 71 adults and 48 children

Adverse effect	Adults (%)	Children (%)
Pupils widely dilated and poorly reactive	79	88
Flushed face, dry mucous membranes	55	90
Tachycardia (>100)	44	65
Incoherence, confusion, or disorientation	66	56
Restlessness, hyperactivity, or agitation	39	58
Auditory or visual hallucinations	52	27
Ataxia or motor incoordination	35	48
Carphology	37	44
Hyper-reflexia, twitching, or increased muscle tone	25	35
Apprehension, fear, or paranoia	23	14
Somnolence or coma	34	16
"Toxic delirium"	14	40
Giddiness; labile or inappropriate affect	18	13
Dysarthria or slurred speech	14	14
Fever (>100°F)	18	25
Thirst or dry mouth	18	14
Blindness or blurred vision	20	13
Retrograde amnesia	18	13

Drug–Drug Interactions

Other anticholinergic drugs

Some antidepressants, neuroleptic drugs, antihistamines, antispasmodics, and antidysrhythmic drugs have anticholinergic activity, as do some herbal remedies (see the section on Herbal sources of anticholinergic drugs in this monograph). The combined use of such drugs can lead to inadvertent anticholinergic overdosage.

Anticoagulant proteins

General Information

There are several endogenous anticoagulants proteins, antithrombin III, protein C, and protein S. Severe sepsis and septic shock are associated with activation of the coagulation system and depletion of these endogenous anticoagulants. Anticoagulant proteins prevent microthrombus formation, thereby reducing the risk of multiorgan failure.

Antithrombin III

Antithrombin III is a plasma alpha$_2$-glycoprotein that accounts for most of the antithrombin activity in plasma and also inhibits other proteolytic enzymes. Hereditary or acquired antithrombin III deficiency results in thromboembolism. The effectiveness of treatment with antithrombin III, prepared as a concentrate from human plasma, is still a matter of dispute (1,2). Apart from vasodilatation, leading to a reduction in blood pressure, remarkably few adverse effects have been noted (2,3). The fall in blood pressure seems to be related to the rate of the infusion.

High doses of antithrombin III, given to patients with severe sepsis, increased the risk of hemorrhage, particularly when it was given concomitantly with heparin, while there was no treatment benefit (4).

Protein C

The protein C pathway serves as a natural defence mechanism against thrombosis. Patients with severe sepsis have a very low concentration of activated protein C

© 2006 Elsevier B.V. All rights reserved.

compared with healthy individuals. Protein C is available as either a concentrate prepared from human plasma or as recombinant human activated protein C (drotrecogin alfa). The latter increased the risk of bleeding in patients with severe sepsis (5).

Organs and Systems

Cardiovascular

In a phase III trial of drotrecogin alfa, hypertension (2.6 versus 0.6% with placebo) was one of the most frequent adverse effects (6).

Psychological, psychiatric

In a phase III trial, hallucinations occurred in 1.1% of patients treated with drotrecogin alfa versus 0.1% in the placebo group (6).

Hematologic

The predominant adverse effect of activated protein C is bleeding. In a phase III trial, in which 1690 patients with severe sepsis were treated with drotrecogin alfa or placebo, serious bleeding episodes occurred in 3.5% of patients treated with drotrecogin alfa, compared with 2.0% of those treated with placebo (7–9). It has been suggested that the risk of bleeding can be minimized by withholding drotrecogin alfa immediately after major surgery; when surgery must be performed during the treatment period, drotrecogin alfa should be temporarily withdrawn (10,11).

Drotrecogin alfa should be used with care in patients receiving heparin, thrombolytic drugs, oral anticoagulants, glycoprotein IIb-IIIa inhibitors, and aspirin or other antiplatelet drugs (6).

Immunologic

In two of 370 patients treated with drotrecogin alfa during a phase III trial, antibodies to activated protein C were found, but these were not inhibitory; no cases of neutralizing antibodies have been found (7).

Because activated drotrecogin alfa reduces inflammation, it is theoretically possible that there is an increased risk of infection. However, a phase III trial did not show an increased rate of infection in the drotrecogin alfa-treated patients compared with placebo (6).

Antidepressants, second-generation

See also Individual agents

General Information

The newer antidepressants that have followed the monoamine oxidase inhibitors and tricyclic antidepressants are listed in Table 1. Most of them are covered in separate monographs. They have a wide variety of chemical structures and pharmacological profiles, and are categorized as "second generation" antidepressants purely for convenience. Although these drugs are widely considered to be as effective as each other and as any of the older compounds, they have different adverse effects profiles. No new antidepressant has proven to be sufficiently free of adverse effects to establish itself as a routine first line compound; some share similar adverse effects profiles with the tricyclic compounds, while others have novel or unexpected adverse effects. Complete categorization of each compound will rest on wide-scale general use beyond the artificial confines of clinical trials. This also includes the experience that accumulates from cases of overdosage, which cannot be anticipated before a new drug is released. The selective serotonin reuptake inhibitors are dealt with as a separate group, since they have many class-specific adverse effects.

© 2006 Elsevier B.V. All rights reserved.

Table 1 Second-generation antidepressants (rINNs except where stated)

Compound	Structure	Comments
Amfebutamone (bupropion)	Aminoketone	Modulates dopaminergic function Increased risk of seizures in high doses
Maprotiline	Tetracyclic	Strong inhibitory effect on noradrenaline uptake Skin rashes (3%) Increased incidence of seizures in overdose Similar adverse effects profile to tricyclic compounds
Mianserin (pINN)	Tetracyclic	Sedative profile Increased incidence of agranulocytosis Possibly safer in overdose Fewer cardiac effects
Milnacipran	Tetracyclic	Inhibitor of serotonin and noradrenaline reuptake
Mirtazapine	Piperazinoazepine	Noradrenergic and specific serotonergic antidepressant (NaSSA); similar to mianserin
Nefazodone	Phenylpiperazine	Weak serotonin reuptake inhibitor Blocks 5-HT_2 receptors Chemically related to trazodone
Reboxetine	Morpholine	Selective noradrenaline reuptake inhibitor (NRI or NARI)
Trazodone	Triazolopyridine	Weak effect on serotonin uptake Blocks 5-HT_2 receptors Fewer peripheral anticholinergic properties Sedative profile
Tryptophan	Amino acid	Precursor of serotonin Eosinophilia-myalgia syndrome
Venlafaxine	Bicyclic; cyclohexanol	Serotonin and noradrenaline uptake inhibitor Nausea, sexual dysfunction, and cardiovascular adverse effects
Viloxazine	Bicyclic	Fewer anticholinergic or sedative effects and weight gain Causes nausea, vomiting, and weight loss Can precipitate migraine

Antidysrhythmic drugs

General Information

Classification

Drugs used in dysrhythmias can be classified in different ways, the usual classification being according to their effects on the cardiac action potential (1), as shown in Table 1.

Antidysrhythmic drugs with Class I activity reduce the rate of the fast inward sodium current during Phase I of the action potential and increase the duration of the effective refractory period expressed as a proportion of the total action potential duration. The action potential duration is itself affected in different ways by subgroups of the Class I drugs:

- class Ia drugs, of which quinidine is the prototype, prolong the action potential;
- class Ib drugs, of which lidocaine is the prototype, shorten the action potential;
- class Ic drugs, of which flecainide is the prototype, do not alter action potential duration.

The beta-adrenoceptor antagonists (class II) and bretylium inhibit the effect of catecholamines on the action potential.

Antidysrhythmic drugs with class III activity prolong the total action potential duration. These drugs act by effects on potassium channels, altering the rate of repolarization.

Antidysrhythmic drugs with class IV activity prolong total action potential duration by prolonging the plateau phase (phase III) of the action potential via calcium channel blockade.

Other classifications of antidysrhythmic drugs have been proposed, but the most useful clinical classification

Table 1 Electrophysiological classification of antidysrhythmic drugs

Class I	Ia Quinidine Procainamide Disopyramide	Ib Lidocaine Aprindine Mexiletine Phenytoin Tocainide	Ic Flecainide Encainide Lorcainide Propafenone (also has class II activity)
Class II	Beta-adrenoceptor antagonists Bretylium		
Class III	Amiodarone Sotalol (d-sotalol; l-sotalol has class II activity)		
Class IV	Verapamil

relates to the sites of action of the antidysrhythmic drugs on the various cardiac tissues, as shown in Table 2.

General adverse effects

There have been many reviews of the pharmacology, clinical pharmacology, pharmacokinetics, and adverse effects and interactions of antidysrhythmic drugs (2–13).

The patterns of adverse effects of the antidysrhythmic drugs depend on three features:

1. All antidysrhythmic drugs have effects on the cardiac conducting tissues and can all therefore cause cardiac dysrhythmias.
2. All antidysrhythmic drugs have a negative inotropic effect on the heart, and can result in heart failure. However, the degree of negative inotropy varies from drug to drug; for example, it is less marked with drugs such as lidocaine and phenytoin and very marked with the beta-adrenoceptor antagonists, verapamil, and class 1a drugs.
3. Each antidysrhythmic drug has its own non-cardiac effects, which can result in adverse effects. These are summarized in Table 3.

Table 2 Classification of antidysrhythmic drugs by their actions in different parts of the heart

Sinus node	Anomalous pathways	Atria	Ventricles	Atrioventricular node
Class Ic	Class Ia	Class Ia	Class Ia	Class Ic
Class II	Class Ic	Class Ic	Class Ib	Class II
Class IV	Class III	Class III	Class Ic	Class III
				Class IV

Table 3 Non-cardiac adverse effects of some antidysrhythmic drugs

Drug	Common non-cardiac adverse effects
Acecainide	Gastrointestinal and nervous system effects
Adenosine	Flushing, dyspnea
Ajmaline derivatives	Liver damage; agranulocytosis; nervous system effects
Amiodarone	Corneal microdeposits; altered thyroid function; lipofuscin deposition in skin, lungs, liver, nerves, muscles
Aprindine	Agranulocytosis; nervous system effects; liver damage
Cibenzoline	Gastrointestinal and nervous system effects; hypoglycemia
Disopyramide	Anticholinergic effects
Dofetilide	Nervous system effects
Encainide	Nervous system effects
Flecainide	Nervous system effects
Lidocaine	Nervous system effects
Lorcainide	Nervous system effects
Mexiletine	Nervous system effects
Moracizine	Nervous system effects
Procainamide	Lupus-like syndrome; neutropenia
Propafenone	Nervous system effects
Quinidine	Anticholinergic effects; hypersusceptibility reactions
Tocainide	Nervous system effects

Clinical studies

The efficacy of a large range of antidysrhythmic drugs in converting atrial fibrillation to sinus rhythm acutely and in maintaining it during long-term treatment has been the subject of a systematic review (14). Adverse effects were too sporadically reported to be suitable for proper review. The efficacy results are summarized in Table 4.

There is some doubt about whether conversion to sinus rhythm produces a better long-term outcome than rate control. Five randomized controlled comparisons of rhythm control versus rate control, mostly in patients with persistent atrial fibrillation ($n = 5175$ in all), have all suggested that there are no major differences in beneficial outcomes between the two strategies (15,16), although there were fewer adverse drug reactions in patients randomized to rate control in three of the studies and in all the studies rate control was associated with fewer hospital admissions. Furthermore, in an analysis of cost-effectiveness, rate control plus warfarin was much cheaper than rhythm control in preventing thromboembolism, largely because of the use of expensive modern antidysrhythmic drugs for the latter (17). Although these results suggest that rate control might be preferable to rhythm control, they do not give any information about patients in whom sinus rhythm is established permanently after pharmacological or physical conversion, since many of the patients in whom rhythm control is used as a strategy will actually have paroxysmal atrial fibrillation.

Organs and Systems

Cardiovascular

Cardiac dysrhythmias

Antidysrhythmic drugs can themselves cause cardiac dysrhythmias, their major adverse effect. The risk of antidysrhythmic-induced cardiac dysrhythmias (prodysrhythmic effects) has been estimated at about 11–13% in non-invasive studies (18,19) and at up to 20% in invasive electrophysiological studies. However, the risk varies from drug to drug and is particularly low with class III drugs. In one study the quoted risks of dysrhythmias were: flecainide 30%, quinidine 18%, propafenone 7%, sotalol 6%, and amiodarone 0% (20). However, amiodarone does cause dysrhythmias, especially when the QT_c interval is over 600 ms.

The prodysrhythmic effects of antidysrhythmic drugs have been extensively reviewed (21–36).

Dysrhythmias secondary to antidysrhythmic drugs are arbitrarily defined as either early (within 30 days of starting treatment) or late (22,23). A lack of early dysrhythmias in response to antidysrhythmic drugs does not predict the risk of late dysrhythmias (24).

Ventricular dysrhythmias due to drugs may be either monomorphic or polymorphic. The class Ia drugs are particularly likely to cause polymorphic dysrhythmias, as is amiodarone (although to a lesser extent). In contrast, the class Ic drugs are more likely to cause monomorphic dysrhythmias (25).

Class Ic antidysrhythmic drugs have been reported to cause the characteristic electrocardiographic changes of Brugada syndrome, which consists of right bundle branch block, persistent ST segment elevation, and sudden

[2] Ventricular fibrillation, polymorphic ventricular tachycardia, torsade de pointes
[3] Symptomatic bradycardia, junctional rhythm, non-sustained and/or monomorphic ventricular tachycardia

cardiac death, in two patients (37). Class Ia drugs did not cause the same effect.

The prodysrhythmic effects of antidysrhythmic drugs have been reviewed in discussions of the pharmacological conversion of atrial fibrillation (38) and the relative benefits of rate control in atrial fibrillation or maintaining sinus rhythm after cardioversion (39).

Mechanisms

There are four major mechanisms whereby antidysrhythmic drugs cause dysrhythmias (21):

1. Worsening of a pre-existing dysrhythmia. For example, ventricular extra beats can be converted to ventricular tachycardia or the ventricular rate in atrial flutter can be accelerated when slowing of the atrial rate results in the conduction of an increased number of atrial impulses through the AV node.
2. The induction of heart block or suppression of an escape mechanism. For example, slowing of conduction through the AV node can impair a mechanism that allows the conducting system to escape a re-entry mechanism.
3. The uncovering of a hidden mechanism of dysrhythmia. For example, antidysrhythmic drugs can cause early or delayed afterdepolarizations, which can result in dysrhythmias.
4. The induction of a new mechanism of dysrhythmia. For example, a patient in whom myocardial ischemia has predisposed to dysrhythmias may be more at risk when an antidysrhythmic drug alters conduction.

Combinations of these different mechanisms are also possible.

The prodysrhythmic effects of antidysrhythmic drugs have been reviewed, with regard to mechanisms at the cellular level (40) and molecular level (41). As far as the cellular mechanisms are concerned, the antidysrhythmic drugs have been divided into three classes (which do not overlap with the classes specified in the electrophysiological classification).

1. Group 1 drugs have fast-onset kinetics and the block saturates at rapid rates (about 300 beats/minute).
2. Group 2 drugs have slow-onset kinetics and the block saturates at rapid rates.
3. Group 3 drugs have slow-onset kinetics and there is saturation of frequency-dependent block at slow heart rates (about 100 beats/minute).

The fast-onset kinetics of the Group 1 drugs makes them the least likely to cause dysrhythmias. Group 2 drugs, which include encainide, flecainide, procainamide, and quinidine, are the most likely to cause dysrhythmias, because of their slow-onset kinetics. Although this also applies to the Group 3 drugs, which include propafenone and disopyramide, block is less likely to occur during faster heart rates and serious dysrhythmias are therefore less likely during exercise.

The most common mechanism of dysrhythmias at the molecular level is by inhibition of the potassium channels known as IK_r, which are encoded by the human ether-a-go-go-related gene (HERG). The antidysrhythmic drugs that affect these channels include almokalant, amiodarone, azimilide, bretylium, dofetilide, ibutilide, sematilide, D-sotalol, and tedisamil (all drugs with Class III actions) and bepridil, disopyramide, prenylamine, procainamide, propafenone, quinidine, and terodiline (all drugs with Class I actions). Other drugs that affect these channels but are not used to treat cardiac dysrhythmias include astemizole and terfenadine (antihistamines), cisapride, erythromycin, haloperidol, sertindole, and thioridazine.

Susceptibility factors

There are no good predictors of the occurrence of dysrhythmias, but there are several susceptibility factors (26,27), including a history of sustained tachydysrhythmias, poor left ventricular function, and myocardial ischemia. Potassium depletion and prolongation of the QT interval are particularly important, and these particularly predispose to polymorphous ventricular dysrhythmias (for example torsade de pointes). Altered metabolism of antidysrhythmic drugs (for example liver disease, polymorphic acetylation or hydroxylation, and drug interactions) can also contribute.

The prodysrhythmic effects of antidysrhythmic drugs have been reviewed in the context of whether patients who are to be given class I or class III antidysrhythmic drugs should first be admitted to hospital for observation in the hope of identifying those who are most likely to develop dysrhythmias (20). The risk of sudden death in patients taking amiodarone was significantly increased in those who had had a prior bout of torsade de pointes. The risk of sotalol-induced torsade de pointes was higher in patients with pre-existing heart failure. Women are at a greater risk of prodysrhythmic drug effects (SEDA-18, 199). The highest risk was in women with heart failure

© 2006 Elsevier B.V. All rights reserved.

who took more than 320 mg/day (22%); the corresponding figure in men was 8%. The authors delineated certain subgroups that they considered to be at specific risk of dysrhythmias, listing drugs that should be avoided in those subjects. They recommended avoiding drugs of classes Ia and III in women without coronary artery disease, drugs of class Ic in men with coronary artery disease, and drugs of classes Ia, Ic, and III in men with congestive heart failure and women with coronary artery disease.

Factors that predict atrial flutter with 1:1 conduction as a prodysrhythmic effect of class I antidysrhythmic drugs (cibenzoline, disopyramide, flecainide, propafenone, and quinidine) have been studied in 24 patients (aged 46–78 years) with 1:1 atrial flutter and in 100 controls (42). Underlying heart disease was present in nine patients. There was a short PR interval (PR < 0.13 ms) with normal P wave duration in leads V5 and V6 in nine of the 26 patients and only seven of the 100 controls. Signal-averaged electrocardiography showed pseudofusion between the P wave and QRS complex in 19 of the 26 patients and only 11 of the 100 controls. There was rapid atrioventricular nodal conduction (a short AH interval or second-degree atrioventricular block during atrial pacing at over 200 minute) in 19 of the 23 patients. Pseudofusion of the P wave and QRS complex had a sensitivity of 100% and a specificity of 89% for the prediction of an atrial prodysrhythmic effect of class I antidysrhythmic drugs.

Reducing the risk

The methods for minimizing the risks of prodysrhythmic effects of antidysrhythmic drugs (43) are as follows:

- Care in choosing those who are likely to benefit from antidysrhythmic drug therapy.
- Identification and correction, if possible, of impaired pump function and ischemic damage.
- Correction of electrolyte abnormalities.
- Exercise testing before and during the early stages of drug therapy: widening of the QRS complex during exercise predicts a high risk of ventricular tachycardia as does prolongation of the QT interval.
- Instruction of patients about the signs and symptoms that can occur with dysrhythmias.
- Monitoring renal and hepatic function in order to predict reduced drug elimination.
- Avoiding drug interactions or changing the dosage of the antidysrhythmic drug in anticipation of a change in its disposition secondary to an interaction.

Measurement of the concentrations of antidysrhythmic drugs and their metabolites in the plasma can be useful in recognizing the need for changing dosage requirements when cardiac, hepatic, or renal dysfunction occurs, in maintaining serum drug or metabolite concentrations within optimal ranges, and for predicting dosage changes required when interacting drugs are added (28). However, in most hospitals plasma drug concentration measurement is not routinely available for these drugs.

Another strategy for reducing the risk of prodysrhythmias is to use combinations of different classes of antidysrhythmic drugs in lower dosages than those used in monotherapy.

Torsade de pointes can be prevented by withholding antidysrhythmic drug therapy from patients who have pre-existing prolongation of the QT interval, and by correction of low serum potassium and magnesium concentrations before therapy. During therapy patients at risk should have frequent monitoring of the electrocardiogram and serum electrolytes.

The prodysrhythmic risks of using antidysrhythmic drugs have been mentioned in the context of a set of guidelines on the management of patients with atrial fibrillation (44,45). The recommended drugs for maintaining sinus rhythm after cardioversion vary depending on the presence of different risk factors for dysrhythmias:

- heart failure: amiodarone and dofetilide;
- coronary artery disease: sotalol and amiodarone;
- hypertensive heart disease: propafenone and flecainide.

Management

The management of drug-induced cardiac dysrhythmias includes withdrawal of the drug and the administration of potassium if necessary to maintain the serum potassium concentration at over 4.5 mmol/l and magnesium sulfate (SEDA-23, 196). Magnesium sulfate is given intravenously on a dose of 2 g over 2–3 minutes, followed by continuous intravenous infusion at a rate of 2–4 mg/minute; if the dysrhythmia recurs, another bolus of 2 g should be given and the infusion rate increased to 6–8 mg/minute; rarely, a third bolus of 2 g may be required (46). If magnesium is ineffective, cardiac pacing should be tried.

There is some anecdotal evidence that atrioventricular nodal blockade with verapamil or a beta-blocker can also be effective. However, in two cases the addition of a beta-blocker (either atenolol or metoprolol) to treatment with class I antidysrhythmic drugs (cibenzoline in one case and flecainide in the other) did not prevent the occurrence of atrial flutter with a 1:1 response (47). However, the author suggested that in these cases, although the beta-blockers had not suppressed the dysrhythmia, they had at least improved the patient's tolerance of it. In both cases the uses of class I antidysrhythmic drugs was contraindicated by virtue of structural damage, in the first case due to mitral valvular disease and in the second due to an ischemic cardiomyopathy.

Adverse hemodynamic effects of antidysrhythmic drugs

Many antidysrhythmic drugs have negative inotropic effects (48–50). This means that such drugs should be avoided in patients with a history of heart failure, a low left ventricular ejection fraction, or a cardiomyopathy. The general risk of induction or a worsening of heart failure is up to about 5%, but those who have risk factors have a risk of up to 10%. The negative inotropic effects are most marked with drugs of classes Ia, Ic, II, and IV. For drugs with class I activity there is a strong relation between their negative inotropic effect and the extent to which they block the inward sodium current (50). Thus, class Ib drugs that are associated with a short recovery time of sodium channels have a smaller negative inotropic effect than class Ia drugs, which in turn have less of an effect than class Ic drugs. However, the overall hemodynamic effects of antidysrhythmic drugs depend not only on their negative inotropic effects on the heart, but also on their effects on the peripheral circulation (51). Thus, although all drugs with class I activity have similar negative inotropic effects on the heart, disopyramide has large hemodynamic effects (because it increases

Table 5 Some important drug–drug interactions with antidysrhythmic drugs

Object drug(s)	Precipitant drug(s)	Result of interaction
Adenosine	Dipyridamole	Increased effect
Adenosine	Theophylline	Reduced effect
Anticholinergic drugs	Disopyramide, quinidine	Potentiation
Antihypertensive drugs	Bretylium	Severe hypotension
Beta-adrenoceptor antagonists	Propafenone	Potentiation
Class I drugs	Beta-adrenoceptor antagonists	Negative inotropy
Class I drugs	Class I drugs	Potentiation
Class I drugs	Drugs that cause potassium depletion	Prodysrhythmic effects
Digoxin	Amiodarone, quinidine, verapamil	Digoxin toxicity
Disopyramide	Enzyme-inducing drugs	Increased metabolism
Neuromuscular blockers	Quinidine	Potentiation
Procainamide	Cimetidine, trimethoprim	Reduced metabolism
Quinidine	Enzyme-inducing drugs	Increased metabolism
Theophylline	Mexiletine	Cardiac dysrhythmias
Verapamil	Beta-adrenoceptor antagonists	Negative inotropy/bradycardia/asystole
Warfarin	Amiodarone, quinidine	Warfarin toxicity

peripheral resistance) and its hemodynamic effect is therefore greater than that of mexiletine, for example. Similarly the adverse hemodynamic effects of encainide and tocainide are greater than those of procainamide (52).

Death

Sudden death due to antidysrhythmic drugs has been reported in several trials in patients who have had ventricular dysrhythmias after myocardial infarction. The drugs that have been incriminated include disopyramide, encainide, flecainide, mexiletine, moracizine, procainamide, and quinidine (53–59). The class III drug d-sotalol has also been associated with an increased risk of mortality in such patients (60). This increase in mortality is thought to be due to an increased risk of cardiac dysrhythmias, perhaps as a consequence of rate-dependent conduction block and preferential slowing of conduction in the ischemic areas. Cardiac dysrhythmias of this sort may also occur through slowing of the rate of conduction around non-conducting ischemic or infracted areas in the heart.

Susceptibility Factors

Age

The safety of antidysrhythmic drugs in children has not been thoroughly studied. However, the risk of prolongation of the QT interval seems to be considerably less than that in adults (61), although it has been reported with quinidine, disopyramide, amiodarone, sotalol, and diphemanil.

Drug Administration

Drug overdose

The use of techniques of circulatory support (extracorporeal oxygenation and intra-aortic balloon pump) in seven cases of overdose with antidysrhythmic drugs (disopyramide, flecainide, prajmaline, and quinidine) has been reviewed (62).

Drug–Drug Interactions

General

Some important drug–drug interactions with antidysrhythmic drugs are summarized in Table 5.

Antiepileptic drugs

See also Individual agents

General Information

Over 15 drugs are licensed worldwide for the treatment of epilepsy and are the subject of separate monographs. Some of them can be grouped into classes (carbamazepine and its analogue oxcarbazepine, barbiturates, hydantoins, benzodiazepines, and succinimides), while others (for example valproate, felbamate, gabapentin, levetiracetam, lamotrigine, tiagabine, topiramate, vigabatrin, and zonisamide) stand on their own. Individual drugs differ in their spectra of activity and in adverse effects profiles. For adverse effects that occur with all drugs, frequency and severity vary from one agent to another: for example, sedation is more common with barbiturates and benzodiazepines, ataxia and diplopia are more common with phenytoin and carbamazepine, and aplastic anemia is more common with felbamate. Certain adverse effects are related to specific properties shared only by certain drugs: for example, renal stones can occur with drugs causing carbonic anhydrase inhibition (acetazolamide, topiramate, zonisamide), whereas reduced efficacy of oral contraceptives can occur with inducers of isozymes that metabolize these steroids (carbamazepine, oxcarbazepine, phenytoin, barbiturates, felbamate, and topiramate).

The clinical pharmacology and adverse effects of some new antiepileptic drugs (ganaxolone, levetiracetam, losigamone, pregabalin, remacemide, rufinamide, stiripentol, and zonisamide) have been reviewed (1).

The uses and adverse effects of antiepileptic drugs in the treatment of painful peripheral neuropathy have been reviewed (2).

Clinical studies

Efficacy and tolerability data from double-blind, placebo-controlled add-on trials of new antiepileptic drugs in patients with refractory partial epilepsy have been reviewed (3). Although there were differences in adverse events profiles among the various drugs, the review identified major methodological problems, which hamper comparisons across studies and drugs. These included variability in the use of COSTART terminology, marked differences in the occurrence of specific adverse events in the placebo groups (an indication of heterogeneous evaluation procedures), and the use of non-optimal dosages or non-optimal titration schedules in many trials (3).

In a multicenter, randomized, double-blind comparison of diazepam (0.15 mg/kg followed by phenytoin 18 mg/kg), lorazepam (0.1 mg/kg), phenobarbital (15 mg/kg), and phenytoin (18 mg/kg) in 518 patients with generalized convulsive status epilepticus, lorazepam was more effective than phenytoin and at least as effective as phenobarbital

© 2006 Elsevier B.V. All rights reserved.

or diazepam plus phenytoin (4). Drug-related adverse effects did not differ significantly among treatments and included hypoventilation (up to 17%), hypotension (up to 59%), and cardiac rhythm disturbances (up to 9%).

Comparisons of different antiepileptic drugs

Quality of life

The effects of carbamazepine and lamotrigine on health-related quality of life have been compared for 1 year in 260 patients with newly diagnosed epilepsy randomized to 48 weeks of treatment (5). Patients taking carbamazepine had significantly worse quality of life at week 4 but not later. They also had more cognitive adverse effects in general and more changes in energy and affect during the first 4 weeks of treatment.

Cost-effectiveness

The cost-effectiveness of four antiepileptic drugs used to treat newly diagnosed adult epilepsy has been studied by cost minimization analysis in 12 European countries (6). The analysis took account of each drug's adverse effects and tolerability profiles. Lamotrigine incurred higher costs than carbamazepine, phenytoin, and valproate, whose costs were similar.

Withdrawal of therapy

Gabapentin, lamotrigine, topiramate, and vigabatrin have been compared using Kaplan–Meier survival analysis in 61 patients to see how long they chose to keep taking each drug and, if they stopped, why they stopped (7). The results are shown in Table 1. Lamotrigine seemed to be the best tolerated of the four drugs and topiramate the least. These results have been mirrored by those of two larger retrospective studies (8,9).

Gabapentin and vigabatrin as first-line add-on treatments have been compared in 102 patients with partial epilepsy (10). The improvement rate was 48% with gabapentin and 56% with vigabatrin. There were seven withdrawals in each group because of adverse events. Of the serious adverse events only one was thought to be drug-related—depression and weight gain in a patient taking vigabatrin.

General adverse reactions

The use of antiepileptic drugs (gabapentin, lamotrigine, and topiramate) as mood stabilizers has been reviewed (11). The authors concluded that the benefit : harm ratios of these drugs have not been well enough established for their routine use in bipolar disorder.

Carbamazepine and valproic acid have been compared in a randomized study in 30 patients (12). Significantly more patients taking carbamazepine reported adverse events, including nausea and vomiting, dizziness, lethargy, and ataxia and tremors.

In a comparison of carbamazepine and lamotrigine for trigeminal neuralgia in 18 patients with multiple sclerosis, lamotrigine was more effective (13). After withdrawal of carbamazepine, drowsiness resolved in 16 patients; cerebellar signs improved partially in five patients and completely in two; brainstem signs improved partially in four patients and completely in 3; ambulation improved in 11. In one patient taking lamotrigine a skin rash forced withdrawal.

General adverse reactions

The most important adverse effects of antiepileptic drugs affect the central nervous system and include sedation, fatigue, dizziness, cognitive dysfunction, ataxia, dysarthria, nystagmus, and headache. These effects are often dose-related; they are more prominent with multiple drug therapy and they are usually reversible after dosage adjustment. Behavioral disturbances are relatively common, especially in children and in patients with pre-existing mental handicap. Exacerbation of seizures and psychiatric reactions are not uncommon. Hepatotoxic reactions have especially been reported with felbamate, valproate, carbamazepine, and phenytoin. Endocrine and metabolic changes occur with most drugs, but their clinical relevance is usually limited. Carbamazepine, phenytoin, barbiturates, and to a lesser extent felbamate, topiramate, and oxcarbazepine, are enzyme inducers, whereas felbamate and valproate are enzyme inhibitors. These effects cause significant drug interactions. Most anticonvulsants precipitate attacks in patients with acute intermittent porphyria.

Hypersusceptibility reactions

Hypersusceptibility reactions can involve any system, but they most often affect the skin, leading to drug withdrawal in up to 20% of patients. Aplastic anemia and hepatotoxicity have drastically curtailed the use of felbamate.

Tumorigenesis
Pseudolymphoma and a condition resembling malignant lymphoma occur very rarely with phenytoin. There is no evidence of a significant increase in the incidence of other tumors.

Second-generation effects
The use of older antiepileptic drugs in pregnancy is associated with a two- to three-fold increase in the risk of fetal malformations, including facial clefts and cardiac defects. Neural tube defects, including spina bifida, are seen in 2–3% of offspring exposed to valproate and in 1% of those exposed to carbamazepine. There is some evidence that fetal exposure to barbiturates and possibly phenytoin can cause impaired postnatal mental development, but in most studies it has been difficult to discriminate the effects of drugs from those of genetic and environmental factors. There are insufficient data to assess fetal risks after exposure to the newer drugs.

Organs and Systems

Cardiovascular

Cardiac dysrhythmias induced by anticonvulsants are rare and occur mainly in patients other than those known to be at high risk of sudden death (14). Phenytoin has been rarely associated with bradydysrhythmias, almost exclusively after intravenous dosing, and some of these have been fatal. Hypotension can also complicate intravenous phenytoin. Carbamazepine can depress cardiac conduction, mostly in elderly or otherwise predisposed patients. Third-degree atrioventricular block occurred in one patient with pre-existing right bundle branch block treated with topiramate, but a cause-and-effect relation was uncertain (SEDA-21, 76).

Respiratory

Respiratory adverse effects are extremely rare, apart from respiratory depression associated with high-dose benzodiazepines or drug overdose.

Nervous system

Most major anticonvulsants can cause cerebellovestibular and oculomotor symptoms (ataxia, dysarthria, dizziness, fatigue, tremor, diplopia, blurred vision, and nystagmus), alterations in cognitive function, and disorders of mood and behavior. Less common effects include parkinsonism (almost exclusively with valproate), exacerbation of seizures, headache, dyskinesias, and dystonias. Neurophysiological evidence of peripheral neuropathy may be common, but neuropathic symptoms are relatively rare. Monoplegia, Babinski reflexes, restless legs syndrome, and retinal/optic nerve disorders are very rare (except for vigabatrin-induced asymptomatic visual field defects, which are relatively common). Neurological adverse effects are usually dose-dependent and more prominent in patients on multiple drug therapy, although it has been suggested that neurotoxicity relates more to total drug load (in terms of sum of defined daily doses for each drug) than to the actual number of drugs taken (SEDA-22, 81).

In some cases, seizure exacerbation occurs as a manifestation of drug intoxication, and is reversible on dosage reduction or elimination of unnecessary polypharmacy (15). In other cases, seizure exacerbation reflects an adverse reaction to a given drug in specific seizure types or syndromes. Carbamazepine in particular can precipitate or exacerbate a variety of seizures, most notably absence, atonic, or myoclonic seizures, especially in children with generalized epilepsies characterized by bursts of diffuse and bilaterally synchronous spike-and-wave EEG activity. Aggravation of seizures has also been reported with phenytoin and vigabatrin, particularly in children with generalized epilepsies. Gabapentin has been implicated in precipitating myoclonic jerks, while benzodiazepines occasionally trigger tonic seizures, particularly when they are given intravenously to patients with Lennox–Gastaut syndrome. Evidence that ethosuximide predisposes to tonic-clonic seizures remains inconclusive.

Experimental or clinical evidence of polyneuropathy, sometimes with paresthesia, has been found in up to 50% of patients treated chronically with carbamazepine, phenytoin, phenobarbital, and/or valproate (SEDA-18, 61), but it is usually not associated with troublesome symptoms.

The risk of aggravating juvenile myoclonic epilepsy with carbamazepine and phenytoin has been assessed in a retrospective study of 170 patients, of whom 40 had taken carbamazepine or phenytoin (16). There was aggravation of seizures in 23 patients, 6 benefited, and there was no effect in the other 11. Of the 28 patients who used carbamazepine, 19 had aggravated symptoms, including myoclonic status in 2. Of the 16 patients who used phenytoin, 6 had aggravated symptoms, including one in association with phenobarbital. Vigabatrin was given in only one case, in association with carbamazepine, and provoked mixed absence and myoclonic status.

Antiepileptic drugs have sometimes been associated with a paradoxical increase in seizures. The evidence for this comes from isolated reports and clinical impressions. Somerville asked five pharmaceutical companies responsible for the development of new antiepileptic drugs to provide data concerning increases in seizure frequency during randomized, placebo-controlled, add-on trials in patients with uncontrolled partial seizures (17). Seizure frequency in individual patients taking the active drug or placebo was compared with the baseline pretreatment seizure frequency. More than 40% of the patients in trials of tiagabine, topiramate, and levetiracetam had an increase in seizures while taking a placebo. Increased seizure frequency was no more likely to occur when they were taking any of the three drugs than when they were taking placebo. A doubling or more of seizure frequency was significantly less likely to occur with topiramate or levetiracetam than with placebo, but more likely with tiagabine. There was some evidence of a dose–response effect with tiagabine, but a negative effect with topiramate (aggravation less likely with increasing dose). Unfortunately, the author did not obtain data on gabapentin and lamotrigine. Thus, aggravation of seizures in patients using some of the new antiepileptic drugs occurs no more often than

© 2006 Elsevier B.V. All rights reserved.

with placebo and probably represents spontaneous fluctuation of seizure frequency.

Retrospective studies have suggested that antiepileptic drugs can be associated with peripheral nerve dysfunction. This has been studied prospectively in 81 patients (aged 13–67 years) without polyneuropathy who took sodium valproate ($n = 44$) or carbamazepine ($n = 37$) as monotherapy in standard daily doses (18). After 2 years one patient had clinical signs of polyneuropathy and six patients had symptoms of polyneuropathy, but electrophysiology did not show significant changes or trends. Only one patient had abnormal electrophysiological findings, which were only subclinical, and eight patients had abnormal values at two subsequent visits. There were no consistent patterns, and the data were unaffected when the drugs were examined separately or when patients were grouped according to whether or not they had symptoms of polyneuropathy. The authors concluded that previously untreated young to middle-aged patients who take valproic acid or carbamazepine for 2 years are not at risk of polyneuropathy.

Sensory systems

Visual field defects associated with various antiepileptic drugs (carbamazepine, diazepam, gabapentin, phenytoin, tiagabine, and vigabatrin) have been reviewed (19). The true frequency is unknown, but in a retrospective study in 158 patients with partial epilepsy visual field defects were detected in 21 (13%); 13 patients had concentric visual field constriction without subjective spontaneous manifestations. Of these 13 patients, 9 were taking vigabatrin.

Visual-evoked potentials and brainstem auditory-evoked potentials have been measured in 58 children and adolescents taking carbamazepine, phenobarbital, or sodium valproate monotherapy and 50 sex- and age-matched controls (20). After 1 year the patients taking carbamazepine had significantly prolonged visual-evoked P100 latencies compared with both baseline and control values; they also had significantly prolonged peak latencies of auditory waves I-III-V and interpeak interval I-V. Those taking sodium valproate had significantly prolonged visual-evoked P100 latencies. In contrast, children taking phenobarbital had no changes.

In 100 epileptic patients aged 8–18 years taking carbamazepine or valproate in modified-release formulations either alone or with added vigabatrin interpeak latencies of I-III and III-V of brainstem-evoked potentials were significantly delayed and N75/P100 and P100/N145 amplitudes in the visual-evoked potentials were reduced (21). However, the addition of vigabatrin did not worsen the effects caused by the other two drugs alone.

Psychological, psychiatric

Behavioral and psychiatric disturbances are not uncommon (22). Although epilepsy is itself associated with an increased risk of such disturbances, drugs play an important role. Phenobarbital-induced behavioral disturbances, especially hyperkinesia, are especially common in children, with an incidence of 20–50% and need for drug withdrawal in 20–30% of cases, whereas it is unclear whether and to what extent adults are affected.

Psychiatric effects

Among older drugs, valproic acid and carbamazepine are least likely to cause adverse psychiatric effects, though valproate rarely causes encephalopathy and reversible pseudodementia. Phenytoin has been implicated in psychiatric adverse effects with or without other signs of toxicity, and at serum concentrations above or below the upper limit of the target range, but the actual incidence of these reactions is unknown. Benzodiazepines can cause paradoxical excitation, particularly in children and in anxious patients, and several other psychiatric symptoms can complicate the benzodiazepine withdrawal syndrome. Psychiatric or behavioral disorders have been reported with ethosuximide, but the lack of systematic studies prevents assessment of incidence and cause-and-effect relation. Among newer drugs, vigabatrin has been implicated most commonly in psychiatric adverse effects. With gabapentin, lamotrigine, and levetiracetam aggressiveness or hyperactivity can occur, especially in patients with previous behavioral problems or learning disability. Adverse psychiatric reactions to lamotrigine are uncommon, whereas with topiramate, felbamate, and other new drugs information is still insufficient.

Overall, the problem of drug-induced psychiatric disorders can be minimized by avoiding unnecessarily large dosages and drug combinations and by careful monitoring of the clinical response. In patients with a previous history of psychiatric disorders, carbamazepine and valproate are the first-line drugs, and are least likely to cause behavioral disturbances. The ideal management of such disturbances is withdrawal of the offending agent. When continuation of treatment is necessary for seizure control, psychosocial intervention and psychotropic medication can be useful.

In a retrospective study of 89 patients who developed psychiatric symptoms during treatment with tiagabine, topiramate, or vigabatrin, the psychiatric problem was either an affective or a psychotic disorder (not including affective psychoses) (23). All but one of the patients had complex partial seizures with or without secondary generalization. More than half were taking polytherapy. Nearly two-thirds had a previous psychiatric history, and there was a strong association between the type of previous psychiatric illness and the type of emerging psychiatric problem. Patients taking vigabatrin had an earlier onset of epilepsy and more neurological abnormalities than those taking topiramate.

Patients with chronic epilepsy have a higher likelihood of psychosis than the healthy population (24,25). Psychosis is especially frequent in patients with temporal lobe epilepsy (26). Antiepileptic drugs have been reported to precipitate psychosis, although the literature is confounded by the inclusion of affective and confusional psychoses in this category. Moreover, the purported association has mostly been made through isolated case reports or small non-controlled case series. In fact, most antiepileptic drugs have been associated with psychosis: phenytoin and phenobarbital (27),

© 2006 Elsevier B.V. All rights reserved.

carbamazepine and valproate (28), felbamate (29), gabapentin (30), levetiracetam (31), topiramate (32), vigabatrin (33), and zonisamide (34). There have been no reports of psychosis associated with lamotrigine.

A retrospective chart review of 44 consecutive patients with epilepsy who had psychotic symptoms with clear consciousness has shown the difficulties in associating psychosis with drug effects (35). These patients were divided into two groups based on the presence or absence of changes in their drug regimen before the onset of the first episode of psychosis. In 27 patients the first episode of psychosis was unrelated to changes in their antiepileptic drug regimen, and in 23 of them the psychosis was temporally related to changes in seizure frequency. In 17 patients the first episode of psychosis developed in association with changes in their antiepileptic drug treatment, and in 12 of them the psychosis was temporally related to seizure attenuation or aggravation. This study therefore highlights the fact that psychosis can occur in relation to changes in seizure frequency, sometimes due to lack of effect of the new medication or to concomitant withdrawal of an efficacious medication.

Withdrawal of anticonvulsants with favorable mood stabilization properties, such as carbamazepine, has often been associated with acute psychosis (36,37). Moreover, the phenomenon of "forced normalization," by which complete seizure freedom in a patient with previous refractory epilepsy can lead to a psychotic state, may also contribute to the apparent association between drugs and psychosis (38).

Information from double-blind studies of psychosis as an adverse event is relatively scarce. A double-blind, randomized, add-on, placebo-controlled trial with carbamazepine showed that there was no increase in chronic psychotic symptoms in patients with suspected temporal lobe seizures (39).

The relation between psychosis and tiagabine has been assessed in an analysis of data from two multicenter, double-blind, randomized, placebo-controlled trials of add-on tiagabine therapy (32 or 56 mg/day) in 554 adolescents and adults with complex partial seizures during 8–12 weeks (40). There were psychotic symptoms (hallucinations) in 3 (0.8%) of 356 patients taking tiagabine and none of the 198 taking placebo, a non-significant difference. Thus, it appears that tiagabine does not increase the risk of psychosis, but the result is inconclusive.

An analysis of double-blind, placebo-controlled trials of vigabatrin as add-on therapy for treatment-refractory partial epilepsy showed that compared with placebo patients taking vigabatrin had a significantly higher incidence of events coded as psychosis (2.5% versus 0.3%) (17). There were no significant differences between treatment groups for aggressive reaction, manic symptoms, agitation, emotional lability, anxiety, or suicide attempts. In an open trial of topiramate, psychosis was seen in 30/1001 (3%) of the patients, and was severe enough to require withdrawal in eight (41).

Should certain antiepileptic drugs be contraindicated in patients with active psychosis? Unfortunately there is not enough solid information to answer this question. Undoubtedly, anticonvulsants that are less likely to cause psychosis (lamotrigine, carbamazepine, oxcarbazepine, valproate) should be preferred (42,43). However, patients with psychoses have been successfully treated even with drugs that are believed to be associated with psychosis, such as vigabatrin. For example, in a prospective study in 10 patients with psychosis and epilepsy to whom vigabatrin was added, there was no aggravation of the psychiatric disorder (44).

Cognitive effects

The appropriate methods and timing in assessing cognitive and behavioral adverse events during drug development programs have been thoroughly reviewed (45).

The authors of a critical review focusing on pediatric data concluded that adverse effects on learning and behavior may have been over-rated (46). Because of methodological flaws, many early studies could not discriminate between effects of drugs and the influence of heredity, brain damage, seizures, and psychosocial factors. In fact, the majority of children taking antiepileptic drugs do not experience major cognitive or behavioral effects from these medications. In some patients, however, drugs do produce detrimental effects, barbiturates and benzodiazepines being among those most commonly implicated (47). At least with some agents, such as gabapentin, behavioral adverse effects occur mainly in children with pre-existing learning disability. As to phenytoin, carbamazepine, and valproate which are the drugs most commonly recommended for first-line use, recent investigations have failed to show major differences in cognitive effects between these agents, although in some studies, patients taking phenytoin tended to have lower motor and information processing speeds (SED-13, 140) (48,49) (SEDA-19, 72) (SEDA-20, 64).

Endocrine

Although most anticonvulsants interfere with endocrine function, epilepsy may do so itself, and it is difficult to differentiate the effects of drugs from those of the disease. In any case, symptoms of endocrine dysfunction are less common than biochemical abnormalities.

Growth hormone

Normal growth hormone concentrations are found in carbamazepine-treated patients (50). Growth hormone secretion in response to levodopa stimulation was not affected by carbamazepine or phenobarbital, whereas phenytoin and anticonvulsant polytherapy caused an increase in growth hormone concentration, and valproate a fall at varying times after the administration of levodopa (51). Pubertal growth arrest has been described in a 12-year-old girl who had taken valproate for 18 months (SED-13, 152).

Adrenal–pituitary axis

Neither phenytoin, valproate, carbamazepine, nor phenobarbital altered the circadian ACTH/cortisol rhythm in epileptic patients (51). In some studies, phenytoin and carbamazepine were associated with increased serum concentrations of unbound cortisol (52), but cortisol

© 2006 Elsevier B.V. All rights reserved.

concentrations were unaffected in other studies (50) and Cushing's syndrome has not been described with these drugs. Valproate can depress ACTH concentrations by inhibiting corticotrophin-releasing factor, and it has been used to treat Nelson's syndrome (53). Serum concentrations of progesterone and cortisol and the excretion of 17-hydroxycorticosteroids have been reported to be lower in untreated patients with epilepsy and to be further reduced by phenytoin (54).

Sex hormones

Carbamazepine, phenobarbital, phenytoin, and anticonvulsant polytherapy increased both basal and stimulated concentrations of prolactin, whereas valproate did not (51). However, in other studies, prolactin was unchanged (50). In boys, phenobarbital lowered baseline LH and FSH concentrations and their response to releasing hormone; baseline prolactin concentration was raised in comparison with healthy children, and the response of prolactin concentrations to stimulation was impaired (55).

Serum concentrations of bound testosterone are increased by phenytoin, carbamazepine, phenobarbital, and primidone owing to increased synthesis of the specific transport protein, sex hormone-binding globulin (SHBG), but concentrations of unbound testosterone, dehydroepiandrosterone sulfate, and 17-α-hydroxyprogesterone and the free androgen index may be reduced (50,56–58). Increased FSH in 31% of carbamazepine-treated men may reflect impairment of spermatogenesis, whereas lower concentrations of inhibin B (in 12% of men) and testosterone/LH ratio (in 50%) indicate impaired function of Sertoli cells and Leydig cells respectively (50). Sexual activity was reduced, while mean plasma concentrations of LH, FSH, PRL, and SHBG were raised in 27 epileptic patients taking phenytoin, primidone, phenobarbital, or combinations of these (59). The often-reported reduction in sexual activity and occasional reports of impotence may be related to the reduction in unbound testosterone caused by enzyme induction. Valproate has been recommended for patients with dysfunctional libido or impotence, because it apparently does not reduce unbound hormone concentrations (60).

In an assessment of the effects of antiepileptic drugs on male sexual function, men taking carbamazepine had higher plasma concentrations of SHBG and lower concentrations of dehydroepiandrosterone compared with controls (61). Patients taking phenytoin had higher total testosterone concentrations and lower dehydroepiandrosterone concentrations. Patients taking carbamazepine and phenytoin also had a lower free androgen index, but free (unbound) testosterone, a more reliable index of active androgen concentrations, did not differ from that of controls. Patients taking valproate showed no differences in hormone concentrations compared with controls. Sexual experience scales showed that treated men embraced a stricter sexual morality than untreated controls, and expressed greater satisfaction with their marriages. Most of the hormonal changes could be explained by enzyme induction, and there was no evidence of hyposexuality in this population.

Reproductive endocrine disorders and sexual dysfunction have often been attributed to epilepsy itself, but antiepileptic drugs can cause various alterations in endocrine functions. Reproductive endocrine function was prospectively evaluated in 90 men taking valproate ($n = 21$), carbamazepine ($n = 40$), or oxcarbazepine ($n = 29$) as monotherapy for epilepsy, and in 25 healthy controls (62). There were increased serum androgen concentrations in 60% of those who took valproate. Carbamazepine had an opposite effect: men had mean low serum concentrations of dehydroepiandrosterone and a high SHBG concentration. Moreover, 18% of men taking carbamazepine for epilepsy reported reduced libido, impaired potency, or both. Low daily doses of oxcarbazepine (under 900 mg/day) did not have any effects on serum concentrations of reproductive hormones, but men taking high doses of oxcarbazepine (over 900 mg/day) had increased serum testosterone, gonadotropin, and SHBG concentrations. Serum insulin concentrations were high in all patients. Thus, the three antiepileptic drugs affected the serum concentrations of reproductive endocrine hormones in men with epilepsy, but in different ways. Valproate directly affects steroid synthesis or metabolism. Oxcarbazepine and carbamazepine differ in their effects, despite their close structural homology: oxcarbazepine does not reduce the activity of androgens, whereas carbamazepine does. The relevance of these hormonal changes to reproductive or sexual function remains to be demonstrated.

In another study changes in reproductive hormones associated with valproate or carbamazepine were prospectively analysed in 17 women and 22 men with recently diagnosed epilepsy (63). There were no clinical signs of hormonal disorders or weight gain during follow-up at 1 and 3 months. Valproate and carbamazepine caused alterations in reproductive hormonal function during the first month of treatment, and these changes were stable or progressive during the next 2 months. Serum testosterone concentrations increased in half of the women taking valproate; mean serum concentrations of gonadotropins and SHBG also increased, but the concentrations of serum dehydroepiandrosterone sulfate fell. On the other hand, in men after 3 months of valproate treatment, serum FSH concentrations were low and serum progesterone and dehydroepiandrosterone sulfate concentrations were high. Carbamazepine increased serum concentrations of SHBG and dehydroepiandrosterone sulfate, while the free androgen index fell. Thus, valproate was associated with increased serum androgen concentrations, but the profiles of hormonal changes were different in men and women. On the other hand, carbamazepine was associated with reduced sex steroid function in both sexes. Although these results are of interest, the study was not randomized and a large number of statistical comparisons were performed, so that no firm conclusions can be drawn.

Thyroid hormones

Total and free (unbound) thyroxine can be reduced by phenytoin and carbamazepine, but free triiodothyronine is normal or only slightly reduced. Thyroid-stimulating hormone is normal or only slightly altered and patients remain clinically euthyroid (50,64). Reductions in the concentrations of some thyroid hormones are probably related to enzyme induction; the concentrations return to

© 2006 Elsevier B.V. All rights reserved.

normal after substituting carbamazepine with oxcarbazepine, a less potent enzyme inducer (65). Hypothyroidism has been rarely described in patients taking phenytoin or carbamazepine (66). In contrast to earlier reports, there were no changes in thyroid hormones during treatment with valproate in a later study (67).

Serum thyroid hormones have been compared in 148 healthy children and 141 children with epilepsy who had been taking carbamazepine ($n = 61$), valproate ($n = 51$), or phenobarbital ($n = 29$) for at least 1 year (68). In all the groups mean thyroxine and free thyroxine concentrations were lower than in controls, and those taking carbamazepine and valproate also had lower concentrations of triiodothyronine and thyroid-binding globulin and increased mean TSH concentrations. There was subclinical hypothyroidism, defined as a TSH concentration greater than two standard deviations above the control mean, in 26% of the children taking valproate, 8.2% of those taking carbamazepine, 7.1% of those taking phenobarbital, and 3.6% of controls. However, the magnitude of the TSH increase was usually small and the children were clinically euthyroid.

The effects of antiepileptic drugs on thyroid function have also been studied in an open prospective study in 90 men with epilepsy (40 taking carbamazepine, 29 taking oxcarbazepine, and 21 taking valproate monotherapy) and 25 control subjects (69). Serum thyroxine and/or free thyroxine concentrations were below the reference ranges in 45% of men taking carbamazepine and 24% of men taking oxcarbazepine. Thyroid peroxidase and/or thyroglobulin concentrations were increased in 13% of those taking carbamazepine, 17% of those taking oxcarbazepine, and 6% of controls, but these changes were not associated with altered serum thyroid hormone concentrations. Serum triiodothyronine and thyrotropin (TRH) concentrations in those taking carbamazepine or oxcarbazepine were normal. In men taking valproate, the concentrations of thyroid hormones, thyrotropin, and antithyroid antibodies were normal. Thus, low serum thyroid hormone concentrations appear to be frequent in men taking carbamazepine or oxcarbazepine and are probably not due to liver enzyme induction or activation of immunological mechanisms. The clinical significance of these changes is uncertain: serum TSH was not affected and all the patients were clinically euthyroid. Similar results have been obtained in a retrospective study in 37 children taking valproate or carbamazepine (70).

Metabolism

Phenytoin rarely causes hyperglycemia, and the blood glucose concentration can increase in phenytoin intoxication (SED-13, 139) (71). A reduction in the insulin response to glucose has been noted with therapeutic doses of phenytoin, but glucose intolerance does not arise, probably owing to increased sensitivity to insulin.

Changes in body weight associated with anticonvulsants have been reviewed (72), including the effects of the antiepileptic drugs that have been most commonly associated with this adverse effect (valproic acid, carbamazepine, vigabatrin, and gabapentin) (73). Unlike most anticonvulsants, topiramate, felbamate, and zonisamide can cause weight loss.

Preliminary evidence suggests that certain idiosyncratic reactions to anticonvulsants are mediated by reduced free radical scavenging activity, as indicated by lower selenium concentrations and a higher lipid peroxide index in affected patients (SEDA-19, 62).

Serum lipids

Phenytoin increases high-density lipoprotein (HDL) cholesterol (74), and may also increase total cholesterol and serum triglyceride concentrations (SED-13, 143) (75). In a 5-year prospective study with carbamazepine, there was a persistent rise in total cholesterol and HDL cholesterol, whereas triglycerides and low-density lipoprotein (LDL) cholesterol increased only transiently (76). In a more recent study, total cholesterol fell when 12 patients were switched from carbamazepine to oxcarbazepine, but HDL cholesterol and triglycerides were unchanged (77). In a comparison of 101 epileptic patients with matched controls, valproate was associated with lower total and LDL cholesterol, whereas carbamazepine was associated with higher HDL cholesterol and apolipoprotein A concentrations and phenobarbital with higher concentrations of total and HDL cholesterol and apolipoproteins A and B. The ratio of total to HDL cholesterol was reduced with valproate and carbamazepine but not with phenobarbital (78).

The clinical relevance of these findings is uncertain. The increased HDL cholesterol seen with some drugs might confer some protection against atherosclerosis and coronary heart disease (SEDA-18, 63).

Porphyrin metabolism

Enzyme inducers, such as phenytoin, carbamazepine, and barbiturates, can precipitate attacks in patients with acute intermittent porphyria.

- A patient with uncontrolled posttraumatic epilepsy and acute intermittent porphyria was given phenytoin, carbamazepine, and clonazepam on successive occasions (79). Phenytoin and carbamazepine caused significant increases in porphobilinogen excretion and acute attacks of porphyria. In contrast, clonazepam caused no increase in porphobilinogen excretion.

Valproate (SED-12, 134) (80,81), ethosuximide (82), and some benzodiazepines (83) have also been implicated in the precipitation of acute attacks of porphyria, although valproate is considered safe for patients with porphyria cutanea tarda (SED-13, 150) (84).

Neither vigabatrin nor gabapentin caused porphyrin accumulation in chicken embryo cultured liver cells, whereas felbamate, lamotrigine, and tiagabine were porphyrinogenic in this model (85). For gabapentin, safety in porphyrias has been confirmed in preliminary clinical observations (SEDA-19, 70) (SEDA-20, 62).

Amino acids

Compared with healthy controls, 51 patients with epilepsy taking a variety of antiepileptic drugs (mostly carbamazepine) had higher mean plasma concentrations of homocysteine (86). This effect, which could be related to reductions in the concentrations of folate and vitamin B6, was likely to be drug-induced, but a causative role

© 2006 Elsevier B.V. All rights reserved.

of the underlying disease could not be excluded. Although homocysteine is an experimental convulsant and a risk factor for atherosclerosis, the clinical relevance of these findings is uncertain.

Phenytoin can reduce blood and CSF thiamine concentrations (87).

Hyperammonemia and carnitine deficiency are adverse effects of valproate, although carnitine deficiency can also be caused by other anticonvulsants (88).

Concentrations of lipoprotein(a) were measured in 51 patients taking long-term carbamazepine, phenobarbital, phenytoin, or valproate and 51 age- and sex-matched controls (89). Lipoprotein(a) concentrations were above 450 μg/ml in 11 patients compared with only 4 controls, and the mean serum lipoprotein(a) concentrations were 330 and 169 μg/ml respectively. The epileptic patients also had a thicker intima media of the common carotid artery. These results suggest that patients taking antiepileptic drugs may be at a higher risk of atherosclerosis.

Electrolyte balance

Phenytoin inhibits the release of antidiuretic hormone (ADH), but this effect is generally clinically unimportant (SED-13, 138) (90). In contrast, both carbamazepine and, to a greater extent, its analogue oxcarbazepine produce significant dose-dependent antidiuretic effects. This is mediated by an action on hypothalamic osmoreceptors or by increased renal sensitivity to ADH, and it can cause hyponatremia and hypo-osmolality. The incidence of hyponatremia ranges from 0% to 42% in patients taking carbamazepine, and from 23% to 73% in those taking oxcarbazepine (22,91). Factors that increase the risk are high dosage (and high serum drug concentrations), old age, a history of severe head trauma or polydipsia, and possibly concomitant intake of diuretics and various psychotropic drugs. Hyponatremia is usually mild and asymptomatic, but occasionally it can cause fatigue, lethargy, drowsiness, confusion, vomiting, and neurological abnormalities, including an increased susceptibility to seizures (91,92). Demeclocycline has been used in the management of carbamazepine-induced hyponatremia (93), but a reduction in drug dosage (or no action in asymptomatic cases) is usually sufficient.

Mineral balance

Alterations in mineral balance occur in a significant proportion of patients taking antiepileptic drugs. Reductions in serum calcium and phosphate and an increase in serum alkaline phosphatase occur in up to 50% of patients treated with enzyme-inducing anticonvulsants, and there can be clinical or biochemical evidence of rickets and osteomalacia. Phenytoin is most often implicated, but similar disturbances have been reported with carbamazepine and barbiturates. The pathogenesis of these changes may involve enhanced conversion of vitamin D to inactive metabolites, but there may be other mechanisms, such as antagonism of the action of 1,25-dihydroxycholecalciferol on bone (SED-13, 139) (94). Serum calcium, phosphate, and alkaline phosphatase should be checked periodically in patients at increased risk of osteomalacia, such as those with a low intake of vitamin D, inactivity, or lack of exposure to sunlight (95). Treatment with colecalciferol may be useful in patients with evidence of vitamin D deficiency (SEDA-16, 70).

Immunoreactive parathyroid hormone concentrations may be increased by anticonvulsants, while bone mineral content is reduced. Hypocalcemia and osteopenia can occur, despite normal serum concentrations of active vitamin D metabolites, suggesting that they may be independent of drug effects on vitamin D metabolism. Bone biopsies have shown increased osteoid but normal calcification front formation, accelerated rate of mineralization, and reduced mineralization lag time, suggesting increased skeletal turnover rather than osteomalacia (96). The risk of age-related fractures in drug-treated epileptic patients is not greatly increased (97).

Valproate has not been commonly implicated in the disturbances described above. In one study, after correction for age and sex, children taking valproate had 14 and 10% reductions in bone mineral density at the axial and appendicular sites respectively; however, the significance of these findings is uncertain (SEDA-20, 69).

Transient osteosclerosis of the long bones was reported in a 15-year-old boy taking valproate with severe pain in the extremities; it disappeared after drug withdrawal (SED-13, 150) (98).

Acid–base balance

Acetazolamide, sultiame, and topiramate inhibit carbonic anhydrase and occasionally produce biochemical or clinical manifestations of acidosis.

Hematologic

Chronic treatment with phenobarbital, phenytoin, and carbamazepine is associated with reduced serum folate concentrations. Although megaloblastic anemia is rare, macrocytic changes in red cells are common in these patients. The fact that serum folate is not reduced by valproate and zonisamide, which do not induce liver enzymes, is consistent with the hypothesis that enzyme induction plays a role in the pathogenesis of folate deficiency (99).

Blood dyscrasias, ranging from mild leukopenia to fatal aplastic anemia, can occur with most anticonvulsants, but severe hematological reactions are extremely rare, except for felbamate. Thrombocytopenia, platelet dysfunction, and altered coagulation are not uncommon in patients taking valproate, but severe hemorrhagic complications are rare. Newborns of mothers treated with enzyme-inducing anticonvulsants are at risk of serious hemorrhage during the first few days of life and should receive vitamin K prophylactically.

The combination of lamotrigine with valproate has been reported to have caused the production of lupus anticoagulant (100).

- A 5-year-old boy with generalized absence seizures, who had had a moderate reduction in fibrinogen and prolonged partial thromboplastin time while taking valproate was given add-on lamotrigine (2 mg/kg). His seizures disappeared, but the partial thromboplastin time increased and tests for lupus anticoagulant and IgG anticardiolipin antibodies became positive. Serum autoantibody screen and rheumatoid factor were

© 2006 Elsevier B.V. All rights reserved.

negative. The lupus anticoagulant disappeared after valproate was withdrawn.

The authors suggested that lamotrigine may have exacerbated a mild immune response initially induced by valproate, without clinical evidence of systemic disease.

In a large cohort study of the occurrence of bleeding complications in neonates exposed to maternal enzyme-inducing antiepileptic drugs in utero in 662 pregnancies in women with epilepsy, 463 had been exposed to carbamazepine, 212 to phenytoin, 44 to phenobarbital, 11 to primidone, and 7 to oxcarbazepine (101). Another 1324 "non-epileptic" pregnancies (1334 neonates) were matched for maternal age, parity, number of fetuses, and delivery date. None of the mothers had received vitamin K1 during pregnancy, but all the infants received vitamin K1 1 mg intramuscularly at birth. There were bleeding complications in five (0.7%) of the neonates exposed to maternal enzyme-inducing antiepileptic drugs and in five (0.4%) of the control subjects. Logistic regression analysis showed that bleeding was associated with premature birth and alcohol abuse, but not with exposure to enzyme-inducing antiepileptic drugs. These results contradict the widely held view, based on anecdotal evidence, that maternal enzyme-inducing antiepileptic drugs increase the risk of bleeding in the offspring. Thus, antenatal administration of vitamin K to mothers treated with enzyme-induced drugs may not be needed in most cases. However, prophylaxis may be worth considering when premature delivery is imminent in a woman who uses anticonvulsants. It is worth noting that the findings described in this article are only relevant to patients taking carbamazepine or phenytoin monotherapy. Therefore, extrapolation to individuals on polytherapy or to those taking other enzyme-inducing drugs is not possible.

Gastrointestinal

Nausea, vomiting, diarrhea, and changes in appetite can occur with all anticonvulsants, although they are usually transient and rarely require withdrawal. Felbamate and to a lesser extent valproate are the anticonvulsants that most often cause gastrointestinal adverse effects.

Liver

Virtually all of the major antiepileptic drugs can cause hepatotoxicity, although a fatal outcome is rare. Liver enzymes are increased up to three times the normal limit in up to 40% of patients treated with major antiepileptic drugs, without any additional evidence of overt hepatic disease. Repeated indiscriminate monitoring of liver function tests is not indicated in patients taking most antiepileptic drugs, and greater attention should be focused on the recognition of high-risk groups and supply of information about symptoms of incipient hepatic failure (102,103).

With phenytoin, carbamazepine, phenobarbital, primidone, and lamotrigine, hepatotoxicity usually occurs as part of a hypersensitivity reaction, with skin rashes and fever in the early weeks of treatment. More rarely, hepatic disease can develop after many years without signs of hypersensitivity. Once hepatotoxicity develops, mortality rates are 10–38% with phenytoin and about 25% with carbamazepine (104). Elderly patients may be at higher risk (105).

Fatal valproate hepatotoxicity may occur with greater frequency in children under the age of 2 years who are receiving multiple drug therapy and have additional handicaps (106).

Atrium, a proprietary mixture of phenobarbital, febarbamate, and difebarbamate, has caused several cases of hepatotoxicity, at least one of which was ascribed to the carbamates, because the patient had earlier tolerated phenobarbital (SEDA-18, 74). Atrium-induced hepatitis might be facilitated by defective CYP2C19 activity (SEDA-19, 77).

Pancreas

Pancreatitis is a rare adverse effect of valproate and can occur in isolation or in association with liver toxicity. In a review of the patients of 366 physicians, 23% of patients taking valproic acid had asymptomatic increases in serum amylase activity but there were only 39 cases of valproate-associated pancreatitis (107). Pancreatitis usually presented with epigastric pain, nausea, and vomiting, and was more common in patients aged under 20 years and with mental retardation. In most cases the pancreatitis started within the first 3 months of treatment, but in 18% the onset was after 2 years.

Pancreatitis with other antiepileptic drugs is extremely rare.

Urinary tract

Drugs that inhibit carbonic anhydrase (acetazolamide, topiramate, and zonisamide) are associated with a small risk (up to 1.5%) of nephrolithiasis. Increased excretion of *N*-acetyl-beta-glucosaminidase, a marker of renal tubular integrity, has been reported with valproate and carbamazepine, but it is probably not clinically significant (SEDA-18, 60).

Skin

All major anticonvulsants have adverse effects on the skin, ranging from a mild maculopapular rash to life-threatening Stevens–Johnson syndrome or Lyell's syndrome (toxic epidermal necrolysis), severe forms of erythema multiforme.

Mild adverse skin reactions to antiepileptic drugs include morbilliform rashes, fixed drug eruptions, bullous reactions, lichenoid-type reactions, urticaria (excluding angioedema), alopecia, pigmentation changes, and photosensitivity (108). There have been reports of positive rechallenge in some patients with exanthems, bullous eruptions, lichenoid-type reactions, and mild urticaria. Mild skin rashes during the first few weeks of treatment are among the most common causes of early withdrawal of carbamazepine, phenytoin, oxcarbazepine, barbiturates, and lamotrigine. Corticosteroids may suppress mild carbamazepine-induced eruptions, allowing continuation of treatment in a few patients.

Anticonvulsants are among the most important causative agents of serious and potentially fatal skin reactions. The management of severe reactions of any type is

© 2006 Elsevier B.V. All rights reserved.

controversial, but referral to a burns center is recommended. Essential supportive care includes fluids and nutrition management. Prophylactic antibacterial drugs are not recommended. Plasmapheresis has been recommended for emergency treatment of anticonvulsant-induced toxic epidermal necrolysis (SED-13, 141) (109). Most authors advise against the use of corticosteroids, as they increase the risk of infection and sepsis.

Several reports have suggested that patients with brain tumors who undergo radiation therapy while taking phenytoin may be at increased risk of developing Stevens–Johnson syndrome. A 47-year-old black man (110) and four other patients, including one who died (111), were seen in a 24-month period in one department. A review of 20 similar reported cases showed no relation to the dosage of phenytoin or radiation, or to the histological type of the tumor (110). Isolated reports have also implicated carbamazepine and phenobarbital in causing Stevens–Johnson syndrome in patients undergoing radiation therapy. In a 53-year-old man taking phenobarbital, eruptions were limited to the sites of radiation, which were multiple (112). Conversely, a retrospective review of 289 brain tumor patients treated with cranial radiation and anticonvulsant drugs did not identify an increased incidence of severe skin rashes (113). Only one patient with Stevens–Johnson syndrome was found in this series, although the incidence of milder skin rashes was higher than expected (18 versus 5–10%). In three patients who had toxic epidermal necrolysis after taking phenytoin or carbamazepine there was an increase in CD3+CLA+ cells, paralleling the severity of the disease in both peripheral blood and skin, tending to normalize as the condition improved (114). E selectin was detected in endothelial vessels in parallel with CLA expression on lymphocytes. There was overexpression of TNF-alpha, interferon gamma, and interleukin-2 in peripheral monocytes. These results suggest an important role for T cells in the production of drug-induced toxic epidermal necrolysis.

A psoriasiform eruption has been reported in a 28-year-old woman taking carbamazepine and valproate (115). Rechallenge was not attempted, and the association with either of these drugs was not clear.

Cross-reactivity in skin reactions is relatively common, especially with anticonvulsants with an aromatic ring (116). Valproate, clonazepam, or clobazam may be safer alternatives in patients who have had a rash from aromatic anticonvulsants. However, in a 41-year-old man a fixed drug eruption that occurred after phenytoin and carbamazepine also occurred after valproate (SEDA-22, 83).

Acne can complicate treatment with phenytoin and other enzyme-inducing anticonvulsants.

Hirsutism and gingival hyperplasia are important adverse effects of phenytoin and represent a relative contraindication to first-line use of this drug in young women.

Alopecia is not uncommon with valproate, and it can also occasionally occur with phenytoin, carbamazepine, vigabatrin, and gabapentin.

Musculoskeletal

Barbiturates can cause various connective tissue disorders, including Dupuytren's contracture and frozen shoulder.

Phenytoin in young children can cause acromegalic facial features.

Osteoporosis

Epilepsy and osteoporosis are very common and frequently overlap. Nevertheless, the prevalence of low bone density appears to be disproportionately higher in patients with epilepsy, and patients with epilepsy have an excessive risk of fractures. A meta-analysis of 94 cohort studies and 72 case-control studies has shown that anticonvulsant treatment is highly associated with fractures (relative risk over 2) (117). Other risk factors were low body weight, weight loss, physical inactivity, consumption of corticosteroids, primary hyperparathyroidism, type 1 diabetes mellitus, anorexia nervosa, gastrectomy, pernicious anemia, and age over 70 years.

Bone mineral density has been measured in 59 patients and 55 age- and sex-matched controls (118). Bone mineral density in the lumbar spine (L2-4) and femurs was lower in the patients, significantly so in the former case. This reduction depended on the duration of therapy. Excretion of pyridinoline cross-links was markedly increased and 25-hydroxycholecalciferol and 1,25-dihydroxycholecalciferol were significantly reduced. The proliferation rate of human osteoblast-like cells was increased by phenytoin in low doses.

Bone metabolism has been assessed in 27 children aged 3–17 years taking long-term valproate and lamotrigine (119). Valproate and lamotrigine were associated with short stature, low bone mineral density, and reduced bone formation. The effect was larger when the two drugs were used together.

The effects on bone metabolism of carbamazepine, valproate, or phenobarbital as monotherapy have been analysed in a case-control study in 118 ambulatory children with epilepsy and corresponding controls (120). Patients taking carbamazepine or phenobarbital had significantly raised alkaline phosphatase and bone and liver isoenzyme activities compared with controls. Although the authors concluded that children who take anticonvulsants may have their bone metabolism affected, this conclusion was based on abnormal values of a surrogate marker for bone disease.

There has been a prospective study of bone mineral density in patients with epilepsy (121). Femoral neck bone mineral density was analysed by dual-energy X-ray absorptiometry in 81 men with epilepsy. Bone mineral density was more than one standard deviation below normal in 47%, indicating an increased risk of fractures (122). Age and duration of therapy were the most significant risk factors associated with a low bone mineral density. Vitamin D deficiency was not a significant risk factor. Longitudinal analysis showed that only those in the youngest age group (25–44 years) had significant reductions in bone mineral density (1.8% annualized loss) while taking anticonvulsants. There was no evidence that a specific type of antiepileptic drug was more causally related to bone loss, although most patients were taking phenytoin or carbamazepine.

Markers of collagen and bone turnover in 60 children and adolescents with epilepsy taking carbamazepine monotherapy were measured at different pubertal stages after 2 years of treatment (123). Compared with

© 2006 Elsevier B.V. All rights reserved.

age-matched healthy children, there was an increase in several markers of bone turnover. In particular, there was a nearly 10-fold increase in postpubertal patients of *N*-telopeptides of type I collagen excretion, indicating increased bone resorption due to excessive osteoclastic activity. These data suggest that carbamazepine can cause increased bone turnover independent of pubertal age.

Predisposing factors for bone disease

In patients with epilepsy, several factors can influence bone health, including poor mobility and anticonvulsant drug treatment. Limitations to physical activity that result from neurological deficits or cerebral palsy underlying symptomatic epilepsies clearly constitute a risk factor for osteoporosis (124). Of 117 children with moderate to severe cerebral palsy, 77% had osteopenia, but the rate was 97% among those who were unable to stand and were over 9 years old; fractures occurred in 26% of the children who were over 10 years old (125). Similarly, adults with neurodevelopmental disorders residing in long-term care facilities have a high rate of both low bone mass and skeletal fractures, especially with concomitant use of anticonvulsant drugs (126). Reduced activity and participation in sports, because of frequent seizures, might also have an impact on bone mineralization.

Certain antiepileptic drugs (carbamazepine, phenytoin, phenobarbital, primidone) are inducers of cytochrome P450 isozymes and increase the breakdown of vitamin D (118,127). Although low vitamin D has been thought to be the cause of low bone density and osteomalacia, a reduction in bone density in the absence of vitamin D deficiency has been also found in children taking either enzyme-inducing agents (123,127) or valproate (128). Moreover, there is recent evidence that although subjects taking enzyme-inducing drugs tend to have lower bone mineral density than those taking non-inducers (clonazepam, ethosuximide, gabapentin, lamotrigine, topiramate, and valproic acid), this is not necessarily due to low vitamin D concentrations. In fact, even though 50% of patients with epilepsy have low vitamin D concentrations, there is no good correlation with bone mineral density (127).

Pathophysiology

The drug-related mechanisms that cause bone loss in patients with epilepsy are not completely understood. Although low vitamin D concentrations may play a part, a direct increase in the proliferation rate of human osteoblast-like cells (observed with phenytoin) might lead to impairment of bone formation (118).

Consequences

Low bone density leads to an increased risk of fractures. There was a 30% increased risk of non-seizure-related fractures in 348 non-institutionalized patients with epilepsy compared with a large control population (129). For non-seizure-related fractures the crude fracture rate was 1.6 fractures per 100 patient-years of observation; a similar rate (1.4) has been found in men with epilepsy (122). In addition, in children with epilepsy, treatment with valproic acid and/or lamotrigine for more than 2 years is associated with short stature, possibly in relation to a low bone mass and reduced bone formation (119).

Assessment

The results of multiple investigations suggest that patients with epilepsy and certain risk factors should be assessed for mineral loss: these include those taking enzyme-inducing agents or long-term treatment (especially polytherapy), those with low or lack of physical activity, postmenopausal women, and elderly people (118,127). Assessment should be done with dual-energy X-ray absorptiometry scanning of the hip (121) and measurement of several biochemical markers (serum total calcium, phosphate, alkaline phosphatase, gamma-glutamyltranspeptidase, aspartate transaminase, 25-hydroxycolecalciferol, and 1,25-dihydroxycolecalciferol). Patients with abnormal findings should have parathyroid hormone and sex hormone concentrations assayed or be referred to an endocrinologist for further assessment.

Despite increasing evidence of bone disease in patients with epilepsy, few pediatric (41%) and adult (28%) neurologists routinely evaluate it (130). A recent survey among neurologists showed that of those who detect bone disease through diagnostic testing, only 40% of pediatric and 37% of adult neurologists prescribed calcium or vitamin D, and about half referred patients to specialists (130). Under 10% of neurologists prescribed prophylactic calcium or vitamin D for patients taking anticonvulsants. This also reflects the fact that evidence about the indications for evaluating and treating bone disorders in patients with epilepsy is currently scarce.

Treatment

Calcium and vitamin D supplementation alone, although necessary to meet normal nutritional guidelines, may be inadequate in preventing bone loss in epilepsy. Bone loss associated with other chronic diseases and other bone-depleting medications has prompted a search for more aggressive therapy. Osteoporosis can be effectively treated with bisphosphonates, which disrupt osteoclastic bone resorption by causing apoptosis of osteoclasts. Oral bisphosphonates are typically administered daily. Third-generation intravenous agents, such as zoledronic acid, can be just as effective when administered once a year. However, there is not currently enough information to support the use of bisphosphonates in patients at risk who are taking antiepileptic drugs.

However, potential therapeutic interventions require randomized prospective studies. Variables that might be addressed in such trials include: the impact of monotherapy and polytherapy on the attainment of peak bone mass in adolescence and adulthood; bone health in women; characterization of the impact of limitations in physical activity on bone density in patients with epilepsy who have cerebral palsy or those with developmental disabilities or mental retardation; the effects of newer antiepileptic drugs on bone metabolism; standardization of the workup for bone disease in patients with epilepsy; and the effectiveness of the current recommendations for supplementation with calcium and vitamin D.

Sexual function

See the section on Endocrine in this monograph.

Reproductive system

The risk of anovulatory cycles and its association with epilepsy syndrome and anticonvulsants has been assessed in a cross-sectional cohort study in women with epilepsy and non-epileptic controls (131). There were 59 patients with localization-related epilepsy and 35 with idiopathic generalized epilepsy. They were treated with monotherapy and followed for 6 months or more. Anovulatory cycles occurred in 11% of cycles in controls, 14% of cycles in women with focal epilepsy, and 27% of cycles in women with idiopathic generalized epilepsy. Anovulatory cycles were more frequent in women taking valproate: 38% had at least one anovulatory cycle in contrast to 11% of women not taking valproate. Predictors of ovulatory failure included generalized idiopathic epilepsy syndrome, use of valproate currently or within 3 years, high concentrations of unbound testosterone, and fewer numbers of luteinizing hormone pulses, but not polycystic-like ovaries. However, the cross-sectional design of the study did not allow firm conclusions to be drawn, especially since previous antiepileptic drug exposure was not controlled.

The incidence of polycystic ovary syndrome in women taking antiepileptic drugs has been studied in a prospective cohort analysis of premenopausal women (aged 20–53 years) with focal epilepsy (132). Of 93 women, 38 were taking one antiepileptic drug (18 valproate, 20 carbamazepine), 36 were taking more than one drug, and 19 were taking no medications. Polycystic ovary syndrome was identified in two of the 19 patients taking no medication, four of the 38 patients taking monotherapy, and one of the patients taking more than one antiepileptic drug. The incidence of polycystic ovary syndrome in patients taking valproate monotherapy (11%) was similar to that in those taking carbamazepine (10%) and those not taking antiepileptic drugs (11%). These results suggest that polycystic ovary syndrome in women with focal epilepsy is not related to valproate or carbamazepine.

Women with valproate-associated obesity have high insulin concentrations and low concentrations of insulin-like growth factor-binding protein 1. These abnormalities might play a role in the pathogenesis of hyperandrogenism and polycystic ovaries in these women (133).

Immunologic

The anticonvulsant hypersensitivity syndrome is a potentially fatal reaction to arene oxide-producing anticonvulsants, such as phenytoin, carbamazepine, and phenobarbital (14,134). It occurs in 1 : 1000 to 1 : 10 000 exposures and its main manifestations include fever, rash, and lymphadenopathy, accompanied by multisystem abnormalities. Cross-reactivity among drugs is as high as 70–80%. The reaction may be genetically determined, and siblings of affected patients may be at increased risk. Management includes rapid withdrawal of the offending agent and care of conjunctival and skin lesions; the use of steroids is controversial, as is the value of cyclophosphamide and intravenous immunoglobulin (135). Early identification is essential for proper management, and it has been suggested that Bayesian analysis, especially when coupled with a lymphocyte toxicity assay, can improve the differential diagnosis (SEDA-19, 62).

- Within 5 days of being switched to valproate after developing a rash ascribed to carbamazepine, a 55-year-old man developed anticonvulsant hypersensitivity syndrome (maculopapular rash, fever, hepatitis, and eosinophilia) and ocular manifestations consistent with bilateral anterior uveitis (136).

Although mild conjunctivitis is common in the anticonvulsant hypersensitivity syndrome, uveitis has not been reported before in this context.

Death

A nested case-control study showed that the risk of sudden unexpected death in epilepsy (SUDEP) increases with increasing number of seizures, increasing numbers of drugs taken (with a relative risk of 9.89 for polytherapy with three drugs compared with monotherapy), and a high frequency of dosage changes (137). However, these data do not necessarily implicate a role of antiepileptic drugs in the pathogenesis of SUDEP: it is possible that polytherapy and frequent dosage changes are surrogate markers for the severity of the disease. On the other hand, a possible implication of carbamazepine in SUDEP was suggested in a separate survey by the observation that 11 of 14 patients who died suddenly (79%) were taking carbamazepine, while only 38% of patients in the same clinic were taking it (138). The effects of carbamazepine on heart function were discussed as a possible mechanism, but no comment was made on the possibility that the characteristics of patients taking carbamazepine may differ from those of patients taking other drugs.

Another study implicated nitrazepam as a possible cause of increased mortality (139). Among 294 assessable children who took nitrazepam, 62 continued treatment at the last time of follow-up. There were 1.98 deaths/100 patient-years during nitrazepam treatment compared with 0.58 deaths/100 patient-years after nitrazepam withdrawal (RR=3.4). The increase in risk occurred virtually entirely in younger children: among those aged under 3.4 years, the death rate per 100 patient-years was 3.98 on nitrazepam compared with 0.26 off nitrazepam (RR=15). Causes of death differed on and off nitrazepam. Of fourteen deaths during nitrazepam treatment, seven were sudden, six were due to pneumonia, and one was due to cystinosis: nine patients had at least one contributing factor, such as dysphagia, gastroesophageal reflux, or recurrent aspiration. In the off-nitrazepam period, there were two sudden deaths and one death each caused by status epilepticus, head trauma, and shunt complication; only one patient had a contributing factor (gastroesophageal reflux). These findings were interpreted as evidence that nitrazepam increases the risk of death in young children, possibly owing to its ability to increase secretions and to cause drooling, eating difficulties, and aspiration pneumonia (140,141). Although the data suggest a role of nitrazepam in these deaths, only incomplete information was given about the distribution of other risk factors (seizure disorder, associated

© 2006 Elsevier B.V. All rights reserved.

morbidity) in children who continued nitrazepam therapy. Nitrazepam should be used with caution in young children, especially those with difficulties in swallowing, aspiration pneumonia, or gastroesophageal reflux.

The risk of sudden death associated with antiepileptic drugs has been assessed in a retrospective case-control study in 6880 patients with epilepsy, from whom 57 cases of sudden death and 171 controls (living with the patients with epilepsy) were selected (142). Polytherapy, frequent dosage changes, and high carbamazepine concentrations were identified as risk factors for sudden death, all pointing to risks associated with unstable severe epilepsy. Because the study was retrospective it is difficult to know whether antiepileptic drugs in themselves are associated with sudden death, of if the higher risk is a result of uncontrolled seizures.

Long-Term Effects

Drug withdrawal

Although it has been suggested that worsening of seizures after withdrawal of non-benzodiazepine anticonvulsants may reflect loss of efficacy rather than an abstinence phenomenon (143), rapid drug withdrawal can still result in dangerous loss of seizure control and status epilepticus.

Psychiatric pathology can also occur after rapid drug withdrawal. Of 32 patients withdrawn from all anticonvulsants before a drug trial, 12 developed moderate to severe psychopathology (especially anxiety and depression) and 9 dropped out because of psychiatric symptoms (144). These findings reinforce ethical concerns about some trial designs involving withdrawal of pre-existing therapy.

Epileptic negative myoclonus status (almost continuous lapses in muscle tone associated with epileptiform discharges and interfering with postural control and motor coordination) rarely occurs after rapid withdrawal of clobazam or valproate (145).

Nausea and vomiting have been listed as withdrawal effects of anticonvulsants (146).

Tumorigenicity

Pseudolymphoma and a condition resembling malignant lymphoma occur very rarely with phenytoin (SED-13, 142). There is no evidence of a significant increase in the incidence of other tumors. There have also been reports of pseudolymphoma with other antiepileptic drugs, including carbamazepine (147–149), lamotrigine (150), phenobarbital (151), and valproic acid (151).

Second-Generation Effects

Teratogenicity

The incidence of major congenital anomalies among babies born to epileptic women is about 6–8%, compared with 2–4% in the general population. Although the disease itself and social and environmental factors may play a role, these abnormalities are related to a large extent to the effects of antiepileptic drugs (152–154).

None of the major anticonvulsants (phenytoin, carbamazepine, valproate, and phenobarbital) is free from teratogenic potential, and there is no pattern of malformations that is specific for a given drug. However, facial clefts and congenital heart defects are somewhat more common with phenytoin and barbiturates, whereas neural tube defects are more common with valproic acid (23% risk) and carbamazepine (0.5–1% risk) (SEDA-16, 72). The risk of congenital anomalies increases with increasing dosages and the number of drugs taken by the mother (SED-12, 123); with valproate, neural tube defects have also been linked to high peak serum drug concentrations. There is preliminary evidence that certain drug combinations, particularly those that include valproic acid, may be more harmful than others. In one study, the combination of phenytoin, phenobarbital, carbamazepine, and valproate was associated with the highest risk (155). In a much smaller study, the risk and severity of meningomyelocele and dysmorphic features associated with valproate seemed to be greater where a benzodiazepine had also been taken (SEDA-18, 61).

In addition to major malformations, a number of mostly craniofacial dysmorphic features, notably growth retardation, microcephaly, and mental retardation have been described as comprising a fetal antiepileptic drug syndrome. This syndrome, originally ascribed only to hydantoins and at one time known as the fetal hydantoin syndrome, has been observed in children exposed to phenytoin, barbiturates, carbamazepine, and valproate. A broad range of signs is observed in at most 5–10% of children exposed to these drugs in utero, but individual signs (for example hypertelorism) are seen in as many as 52% and digital hypoplasia in 23%. Few results from controlled studies are available, and selection criteria and methods of ascertainment are very variable. In one study the association between prenatal phenytoin exposure and digital hypoplasia or hypertelorism was confirmed, but at the age of 5.5 years none of the exposed children had all of the main characteristics of the hydantoin syndrome. The risk of developmental disturbances seemed to be lower than the 7–11% risk of the fetal hydantoin syndrome reported earlier (SED-13, 136) (156).

The rate of congenital malformations in the offspring of 517 mothers exposed to antiepileptic drugs during pregnancy has been examined in a prospective single-center study (157). The overall malformation rate was 9.7%. Malformations were classified as structurally severe (5.3%), structurally mild (2.2%), chromosomal genetic (0.4%), and deformities (1.8%). The malformation rate after exposure to polytherapy (9.6%, $n = 114$) was not higher than after exposure to monotherapy (10.5%, $n = 313$). Among monotherapy exposures, the rates for structural abnormalities were 16% with valproate ($n = 44$), 8.6% with primidone ($n = 35$), 7.1% with carbamazepine ($n = 113$), 4.8% with phenobarbital ($n = 83$), and only 3.2% with phenytoin ($n = 31$). There were no malformations in the offspring of 25 untreated patients. Among women exposed to valproate, the mothers of malformed babies took significantly higher dosages in the first trimester than mothers of non-

© 2006 Elsevier B.V. All rights reserved.

malformed babies (1712 versus 1008 mg/day). These data confirm that exposure to antiepileptic drugs is associated with an increased risk of fetal malformations, and that the risk may be especially high with high-dose valproate. However, these subgroup analyses should be interpreted cautiously, especially because the numbers were small and the confidence intervals were not calculated.

In a retrospective Dutch study, the rate of major congenital anomalies among 1411 children born of mothers who had taken antiepileptic drugs during the first trimester of pregnancy was 3.7% compared with 1.5% among 2000 children born of matched controls not exposed to anticonvulsants (158). Among monotherapies with a denominator higher than 50, the relative risk (RR) was increased significantly only for carbamazepine (RR = 2.6) and valproate (RR = 4.1); for valproate there was a relation with dose. Although the risk was not increased in offspring exposed to phenobarbital monotherapy, it increased significantly (RR = 2.6) when those exposed to phenobarbital plus caffeine were combined with those who were exposed to phenobarbital alone. Caffeine intake was also associated with an increased risk among exposures to phenobarbital in combination with other anticonvulsants. Among other polytherapies, there was an increased risk for combinations that included clonazepam and for the combination of carbamazepine with valproate. Cautious interpretation of these data is required, because of the retrospective design and the small sample sizes in the subgroup analyses.

The teratogenic effects of antiepileptic drugs have been assessed through the use of a surveillance system (MADRE) in infants with malformations (159). Exposure was defined by the use of antiepileptic drugs during the first trimester of pregnancy. Of 8005 cases of malformations, 299 infants had been exposed in utero to antiepileptic drugs. Of those exposed to monotherapy, 46 were exposed to carbamazepine, 10 to methylphenobarbital, 65 to phenobarbital, 24 to phenytoin, 80 to valproic acid, and 16 to other antiepileptic drugs. The following associations were found:

(a) carbamazepine: cardiac malformations;
(b) methylphenobarbital: oral clefts and cardiac malformations;
(c) phenobarbital: oral clefts and cardiac malformations;
(d) valproate: spina bifida, cardiac malformations, hypospadias, porencephaly, and other specified anomalies of the brain, anomalies of the face, coarctation of the aorta, and limb reduction defects.

Three groups of infants born to 128 049 women were identified at time of delivery: those exposed to anticonvulsant drugs, those unexposed to anticonvulsant drugs but with a maternal history of seizures, and those unexposed to anticonvulsant drugs with no maternal history of seizures (controls) (160). The aim was to determine whether the major malformations associated with antiepileptic drugs are related to maternal epilepsy or exposure to anticonvulsant drugs. The infants were examined systematically for major malformations, signs of hypoplasia of the midface and fingers, microcephaly, and small body size. The combined frequency of anticonvulsant embryopathy was higher in 223 infants exposed to one anticonvulsant drug than in 508 controls (21 versus 8.5%; OR=2.8; 95% CI=1.1, 9.7). The frequency of anticonvulsant embryopathy was also higher in 93 infants exposed to two or more anticonvulsant drugs than in controls (28 versus 8.5%; OR=4.2; 95% CI=1.1, 5.1). The 98 infants whose mothers had a history of epilepsy but took no anticonvulsant drugs during the pregnancy did not have a higher frequency of malformations than the control infants. Thus, fetal malformations in women with epilepsy are associated with the drugs rather than the epilepsy.

The developmental outcome in children of women exposed to antiepileptic drugs has been assessed in a retrospective survey that included 150 women on monotherapy, 74 on polytherapy, and 176 not exposed to any antiepileptic drugs (161). The odds ratio of additional educational needs in children exposed to antiepileptic drugs in utero compared with those not exposed was 1.49 (95% CI=0.83, 2.67). Those exposed to valproate monotherapy had an odds ratio of 3.4 (95% CI=1.63, 7.10), significantly higher than in those exposed to carbamazepine (OR=0.26; 95% CI=0.06, 1.15). Although the authors concluded that valproate during pregnancy impairs development in children exposed in utero, the fact that this was a retrospective study means that firm conclusions are not possible.

In a prospective study of electroencephalograms, intelligence tests (Wechsler), and neurological findings (Touwen) in 67 school-age and adolescent children born to mothers with epilepsy (risk group) and in 49 controls, focal electroencephalographic changes were more common in the offspring of mothers with primary generalized epilepsy, and pathological electroencephalograms were overall more common after maternal exposure to phenobarbital or primidone (162). The prevalence of minor neurological dysfunction was also increased in the risk group, especially in the offspring of mothers who had been exposed to polytherapy. Intelligence scores were lower after maternal exposure to polytherapies in which one of the drugs was phenytoin or primidone, but socioeconomic influences also affected the scores. Higher maternal dosages of primidone were associated with lower IQ scores in the children. This study has reinforced the evidence that antenatal exposure to anticonvulsants can adversely affect postnatal intellectual development. However, it is always difficult to control for confounders, such as hereditary and social and family factors. It is also possible that prenatal drug exposure affects neural vulnerability to external influences.

A case-control study in 116 children born to epileptic women has suggested that for subjects without inherited factors the risk of developmental disorders is related to antenatal exposure to polypharmacy (OR=4.8, 95% CI=1.3, 18) and valproate monotherapy (OR = 9.4, 95% CI = 1.7, 50) (163). The findings were presented in abstract form, precluding close scrutiny of methodological aspects.

The possibility has been raised that a child who is seemingly normal at birth might later show impaired physical and/or mental development as a result of prenatal exposure to the effects of seizures or drugs. In one study, there was a correlation between seizures during pregnancy and impaired cognitive ability and psychomotor function in the child (SEDA-16, 70). In another study there were delays in height and weight gain in the

© 2006 Elsevier B.V. All rights reserved.

offspring of epileptic mothers after the first month, but weight at 5.5 years of age was not affected (SED-13, 137). There was a reduction in mean head circumference without obvious intellectual impairment in children exposed to monotherapy with carbamazepine and barbiturates, but a low parental mean head circumference was a major confounding factor. In another study (164), children exposed to phenytoin in utero had lower language development scores and mean global IQ scores 10 points lower than matched controls exposed to non-teratogens; in contrast, children exposed prenatally to carbamazepine did not differ from controls. However, the validity of the statistical analysis and the comparability of groups in this study have been questioned.

Barbiturates have been most often implicated in detrimental effects on postnatal mental development. In two double-blind studies in 114 adult men exposed prenatally to phenobarbital, verbal intelligence scores were about 0.5 standard deviations lower than predicted from data in 153 matched controls (165). An exposure period that included the last trimester of pregnancy was most detrimental. Lower socioeconomic status and being the offspring of an unwanted pregnancy increased the magnitude of impairment, suggesting that adverse drug effects are magnified by interactions with environmental conditions.

Overall, the available evidence suggests that the incidence of mental deficiency in children of epileptic mothers is similar to that in the general population, although general intelligence may be lower and specific forms of cognitive dysfunction somewhat more frequent, owing to a combination of factors such as prenatal exposure to certain drugs, genetic influences, and postnatal environment.

Mechanisms

The mechanisms responsible for abnormal embryonic and fetal development in women taking antiepileptic drugs are unclear. There may be an interaction between the drugs and the underlying disease, and research has also focused on drug-induced folate or pantothenic acid deficiency, altered retinoid metabolism (SEDA-20, 59), and tissue damage caused by reactive metabolites or by embryonic hypoxia/reoxygenation. There is evidence that a genetic defect in arene oxide detoxification can increase the risk of birth defects, and epoxide hydrolase might prove useful in identifying probands at greater risk (SED-13, 137) (166).

Of the newer anticonvulsants, lamotrigine, gabapentin, tiagabine, and vigabatrin have little or no teratogenic potential in animals, whereas oxcarbazepine and topiramate are teratogenic in rodents. However, animal studies are not necessarily applicable to humans and clinical data are still insufficient to assess the effects of newer drugs on the development of the human fetus (153).

Management

Current guidelines stress the need for expert counseling, preferably before conception. Comprehensive management should include review of genetic risks, advice about contraception and interactions with oral contraceptives, information on teratogenic risks and methods for prenatal diagnosis, and integrated care by the family doctor, epileptologist, gynecologist, geneticist, and pediatrician (52,167).

Whenever possible, therapy should be optimized before pregnancy. Withdrawal of anticonvulsants can be considered after 2–5 years of seizure freedom, when other prognostic factors indicate little risk for recurrence; in that event, withdrawal should be completed at least 6 months before planning conception. In all other patients, the goal is the minimal drug load associated with acceptable seizure control. This involves selecting the most effective medication, preferably as monotherapy, at the lowest effective dosage. Control of tonic-clonic seizures before pregnancy is especially important. If possible, valproate should be avoided, especially in women with a family history of neural tube defects and in those who may object to early termination of pregnancy if a severe fetal defect should be diagnosed prenatally. If valproate is used, it should be given in two or three divided daily doses, preferably as a modified-release formulation, to minimize fluctuations in serum drug concentrations. Tobacco and alcohol should be avoided (52,167). Folate supplementation has been recommended in all women with epilepsy who plan to become pregnant and should be continued until the twelfth week of gestation. Although there is no consensus about optimal dosage, 0.4 mg/day of folic acid is a reasonable option; a larger dose (4 mg/day) is preferable if the woman has previously given birth to a child with a neural tube defect. Some authors also recommend 4 mg/day in women taking valproate or carbamazepine (168).

Because seizures themselves can adversely affect fetal outcome, and because in most patients any serious teratogenic effect will have occurred by the time pregnancy is diagnosed, changes in drug therapy during pregnancy are not recommended unless they are required by a change in the clinical response. If seizure frequency increases during pregnancy, possible non-compliance and changes in plasma drug concentration need to be considered.

Prenatal diagnosis with ultrasound at weeks 18–20 can assist in the early diagnosis of anomalies such as cleft palate, heart defects, and neural tube defects. In many patients, prenatal assessment of fetal development can be based on a combination of maternal serum alpha-fetoprotein (as screening for neural tube defect) and malformation-directed ultrasonography. Although amniocentesis at week 15–16 for alpha-fetoprotein determination can be considered for patients at high risk of neural tube defect, it carries a small risk of abortion and its use has fallen with advances in ultrasonography (including transvaginal ultrasonography).

Fetotoxicity

Contrary to early reports, which were affected by selection bias, later studies suggested that neither epilepsy nor prenatal exposure to antiepileptic drugs is associated with an increased risk of spontaneous abortion or other obstetric complications (169).

Prenatal exposure to enzyme-inducing anticonvulsants entails a risk of serious neonatal hemorrhage in the first few days after birth. To reduce the risk, some authorities recommend that pregnant women taking enzyme-inducing

© 2006 Elsevier B.V. All rights reserved.

drugs be given vitamin K (20 mg/day) during the last month of pregnancy. Intramuscular vitamin K (1 mg) should be given to the neonate immediately after birth. The value of additional vitamin K orally for the first 3 months of life is controversial (168).

After delivery, the maternal response to drug treatment and, if appropriate, serum drug concentrations should be monitored, because the disposition of anticonvulsants can change. The neonate should be monitored for potential residual effects of transplacentally acquired anticonvulsants and, in the case of barbiturates and benzodiazepines, withdrawal symptoms such as irritability and feeding difficulties.

Lactation

Most anticonvulsants are excreted in the breast milk in limited amounts, and their use is not generally a contraindication to breastfeeding. Barbiturates, ethosuximide, lamotrigine, and to a lesser extent carbamazepine and benzodiazepines can reach appreciable serum concentrations in breast-fed infants, who should be carefully observed.

Susceptibility Factors

Age

Children

Febrile seizures are the most common seizure disorder in childhood, occurring in 2–5% of children, but there is no unanimity regarding the need for long-term antiepileptic drug therapy. A subcommittee of the American Academy of Pediatrics has recently concluded that there are no long-term adverse effects of simple febrile seizures, and that although there is evidence that continuous antiepileptic therapy with phenobarbital or valproate and intermittent therapy with diazepam are effective in reducing the risk of recurrence, the potential adverse effects associated with antiepileptic drugs outweigh the relatively minor risks associated with simple febrile seizures (170). They recommended that long-term treatment is not indicated.

Renal disease

Renally eliminated drugs should be used in reduced dosages in patients with renal insufficiency.

Hepatic disease

Anticonvulsants that are metabolized should be used cautiously in patients with severe hepatic disease.

Other features of the patient

Most antiepileptic drugs are contraindicated in acute intermittent porphyrias.

Case reports have suggested that the risk of serious skin reactions to phenytoin is increased in patients with brain tumors undergoing cranial irradiation, but the incidence of these reactions is unknown (113). In a retrospective study of 289 patients with brain tumors, rash occurred in 18% of exposures to antiepileptic drugs, including 22% of exposures to phenytoin, compared with an expected rate of 5–10%. Most of the rashes occurred before the start of irradiation therapy. Only one patient developed erythema multiforme. These data suggest that the risk of serious skin reactions in patients with brain tumors is actually low, even though there was an increased frequency of milder rashes. Irradiation did not appear to contribute to the risk. However, it is possible that earlier publications about the risk of serious reactions resulted in the use of lower initial dosages or earlier withdrawal of medication, before the onset of more severe manifestations. The fact that skin rashes were more common in patients with glioma than metastatic disease could be related to the effects of underlying treatments (or disease) on immune function.

Of 65 consecutive patients with malignant glioma started on anticonvulsants (mostly phenytoin), a skin rash developed in 26%; other toxic effects occurred in 14% of patients, including three who developed an encephalopathy sufficient to require hospitalization (SEDA-20, 58).

Drug Administration

Drug formulations

The rationale and use of modified-release formulations of antiepileptic drugs (carbamazepine, valproic acid, and tiagabine) have been reviewed (171). The authors concluded that modified-release formulations afford the advantages of better patient compliance, fewer adverse effects, and less fluctuation in plasma concentrations, making monitoring of drug concentrations easier. They concluded that these advantages should lead to better seizure control and improved quality of life.

Drug overdose

Accidental or deliberate overdose with anticonvulsants is common and can cause serious morbidity, even though deaths are relatively rare (172–174). Clinical manifestations vary from drug to drug, and they tend to affect mainly the central nervous system, with signs ranging from impaired consciousness to motor and coordination disturbances and seizures (for a review, see SEDA-22, 84). Metabolic, cardiac, and respiratory disturbances are seen with individual drugs. Except for flumazenil in benzodiazepine overdose, there are no specific antidotes, and management is primarily supportive. Gastric lavage is indicated within 1 hour of a major overdose with most anticonvulsants. Oral activated charcoal and hemoperfusion can be useful in individual cases of overdose with phenytoin, carbamazepine, valproate, barbiturates, and some other drugs (SEDA-22, 84). In cases of valproate overdose, naloxone has been sometimes beneficial, and carnitine supplementation has been recommended (88).

Drug–Drug Interactions

General

The interactions of anticonvulsants are summarized in Table 2, Table 3, and Table 4. Phenytoin, carbamazepine, and barbiturates are enzyme inducers and can reduce the

Table 2 Interactions of antiepileptic drugs

Interfering drug(s) (precipitant drug(s))	Affected drug(s) (object drug(s))	Implications/comments	Mechanism
Carbamazepine	Phenytoin	Interaction inconsistent and usually of limited clinical significance	Induction and inhibition of phenytoin metabolism
Carbamazepine Phenobarbital Phenytoin Primidone	Ethosuximide Felbamate Lamotrigine Tiagabide Topiramate Valproate Zonisamide Clobazam Clonazepam Diazepam	Reduced effect of the object drug, usually compensated by the effect of the added drug; risk of toxicity when interfering drug is discontinued	Induction of metabolism of the object drug
Carbamazepine Phenytoin	Primidone	Signs of toxicity possible after addition of phenytoin owing to concomitant increase in plasma phenobarbital concentrations in some patients	Induction of primidone metabolism; phenytoin may inhibit the clearance of metabolically derived phenobarbital
Clobazam	Carbamazepine Primidone Valproate Phenytoin	Interaction inconsistent, usually of little clinical significance	Inhibition of metabolism of the object drug
Clobazam	Phenytoin Primidone	Interaction inconsistent, usually of no clinical significance	Unknown
Diazepam	Phenytoin	Interaction inconsistent, usually of no clinical significance	Inhibition of phenytoin metabolism
Ethosuximide	Valproate	Fall in valproate concentrations inconsistent; therapeutic synergism common	Therapeutic synergism due to pharmacodynamic interaction
Felbamate	Clonazepam Diazepam Phenobarbital Phenytoin Valproate	High risk of toxicity with phenytoin, phenobarbital, and valproate	Inhibition of metabolism of the affected drug
Felbamate	Carbamazepine	Risk of toxicity due to concomitant rise in carbamazepine epoxide concentration and pharmacodynamic interaction	Induction of carbamazepine metabolism, possible inhibition of epoxide hydrolase and pharmacodynamic interaction
Gabapentin	Felbamate	Interaction poorly documented; relevance doubtful	Perhaps reduced renal clearance of felbamate
Gamma-vinyl GABA	Phenytoin Phenobarbital Felbamate	Interaction inconsistent and usually of little clinical relevance	Unknown
Oxcarbazepine	Lamotrigine	Interaction less marked than that caused by carbamazepine	Induction of lamotrigine metabolism
Phenobarbital	Phenytoin	Interaction inconsistent and usually of little clinical significance	Induction and inhibition of phenytoin metabolism
Phenobarbital Phenytoin Primidone	Carbamazepine	Reduced effect of carbamazepine usually compensated by the action of the added drug; risk of carbamazepine toxicity when interfering drug is withdrawn	Induction of carbamazepine metabolism
Phenytoin	Phenobarbital	Interaction inconsistent and usually of limited clinical significance	Inhibition of phenobarbital metabolism
Tiagabide	Valproate	Effect of low magnitude, probably clinically irrelevant	Unknown
Topiramate	Phenytoin	Interaction inconsistent, usually of little clinical significance	Inhibition of phenytoin metabolism

Table 3 *Continued*

Interfering drug (precipitant drug(s))	Affected drug(s) (object drug(s))	Implications/comments	Mechanism
Vinblastine	Phenytoin	Reduced effect of phenytoin; interaction poorly documented	Unknown
Vincristine	Phenytoin	Reduced effect of phenytoin; interaction poorly documented	Unknown
Tegafur uracil	Phenytoin	Risk of phenytoin toxicity	Unknown
Antimicrobial drugs			
Aciclovir	Phenytoin Valproate	Reduced effect of the object drug; poorly documented	Unknown
Ceftriaxone	Phenytoin	Risk of toxicity; altered relation between total phenytoin concentration and effect	Displacement of phenytoin from binding sites and possible inhibition phenytoin metabolism
Chloramphenicol	Phenobarbital Phenytoin Primidone	Risk of toxicity of the object drugs	Inhibition of metabolism of the object drugs
Ciprofloxacin	Phenytoin	Reduced effect of phenytoin	Unknown
Fluconazole	Phenytoin	Risk of phenytoin toxicity	Inhibition of phenytoin metabolism
Isoniazid	Carbamazepine Diazepam Ethosuximide Phenobarbital Phenytoin Primidone Valproate	High risk of toxicity, especially with carbamazepine and phenytoin	Inhibition of metabolism of the object drugs
Ketoconazole	Carbamazepine Zonisamide	Risk of toxicity of the affected drugs	Inhibition of metabolism of the affected drugs
Erythromycin	Carbamazepine Phenytoin Valproate	Risk of toxicity; particularly with carbamazepine	Inhibition of metabolism of the affected drugs
Other macrolides (clarithromycin, flurithromycin, josamycin, ponsinomycin, triacetyloleandomycin)	Carbamazepine	High risk of carbamazepine toxicity	Inhibition of carbamazepine metabolism
Mefloquine	Valproate	Reduced effect of valproate; interaction poorly documented	Unknown
Metronidazole	Carbamazepine Phenytoin	Risk of toxicity; effect on phenytoin inconsistent	Inhibition of metabolism of the object drugs
Miconazole	Phenytoin Zonisamide	Risk of toxicity of the object drugs	Inhibition of metabolism of the object drugs
Nafcillin	Phenytoin	Altered relation between total phenytoin concentration and effect	Displacement of phenytoin from binding sites
Nitrofurantoin	Phenytoin	Reduced effect of phenytoin; interaction poorly documented	Unknown
Oxacillin	Phenytoin	Reduced effect of phenytoin; interaction poorly documented	Unknown
Panipenem-betamipron	Valproate	Reduced effect of valproate; interaction poorly documented	Unknown
Quinine	Carbamazepine Phenobarbital	Enhanced effect of the object drugs	Inhibition of metabolism of the object drugs
Rifampicin	Diazepam Ethosuximide Phenobarbital Phenytoin Valproate	Reduced effect of the object drugs	Induction of metabolism of the object drugs
Sulfadiazine	Phenytoin	Risk of phenytoin toxicity	Inhibition of phenytoin metabolism
Sulfafurazole	Phenytoin	Risk of phenytoin toxicity	Inhibition of phenytoin metabolism
Sulfamethoxazole	Phenytoin	Risk of phenytoin toxicity	Inhibition of phenytoin metabolism
Sulfamethoxazole + trimethoprim (co-trimoxazole)	Phenytoin	Risk of phenytoin toxicity	Inhibition of phenytoin metabolism

Table 3 *Continued*

Interfering drug (precipitant drug(s))	Affected drug(s) (object drug(s))	Implications/comments	Mechanism
Sulfamethoxypyridazine	Phenytoin	Risk of phenytoin toxicity	Inhibition of phenytoin metabolism
Sulfametizole	Phenytoin	Risk of phenytoin toxicity	Inhibition of phenytoin metabolism
Sulfaphenazole	Phenytoin	Risk of phenytoin toxicity	Inhibition of phenytoin metabolism
Trimethoprim	Phenytoin	Enhanced effect of phenytoin	Inhibition of phenytoin metabolism
Antiulcer agents			
Antacids	Gabapentin Phenobarbital Phenytoin	Reduced effect of the object drugs	Reduced absorption of the object drugs
Cimetidine	Carbamazepine Clobazam Clonazepam Diazepam Phenytoin Valproate	Risk of toxicity, particularly with phenytoin	Inhibition of metabolism of the object drugs
Omeprazole	Diazepam Phenytoin	Risk of toxicity of the object drugs	Inhibition of metabolism of the object drugs
Ranitidine	Phenytoin	Inconsistent, probably of little clinical significance	Unknown
Sucralfate	Phenytoin	Reduced effect of phenytoin	Reduced absorption of phenytoin
Cardiovascular			
Amiodarone	Clonazepam Phenytoin	Risk of toxicity of the object drugs	Inhibition of metabolism of the object drugs
Bishydroxycoumarin	Phenytoin	Risk of phenytoin toxicity	Inhibition of phenytoin metabolism
Dicoumarol	Phenobarbital Phenytoin	Risk of toxicity, particularly with phenytoin	Inhibition of metabolism of the object drugs
Diltiazem	Carbamazepine Phenytoin	Risk of toxicity, especially with carbamazepine	Inhibition of metabolism of the object drugs
Guanfacine	Valproate	Enhanced effect of valproate; interaction poorly documented	Unknown
Phenprocoumon	Phenytoin	Risk of phenytoin toxicity	Inhibition of phenytoin metabolism
Sulfinpyrazone	Phenytoin	Risk of phenytoin toxicity	Inhibition of phenytoin metabolism
Ticlopidine	Phenytoin	Risk of phenytoin toxicity	Inhibition of phenytoin metabolism
Verapamil	Carbamazepine Phenytoin	High risk of carbamazepine toxicity; interaction with phenytoin inconsistent	Inhibition of metabolism of the object drugs
Verapamil	10-monohydroxy–carbazepine	Interaction probably of limited clinical significance	Unknown
Psychotropic drugs			
Amitriptyline	Phenytoin	Risk of phenytoin toxicity; interaction poorly documented	Inhibition of phenytoin metabolism
Chlorpromazine	Phenobarbital Phenytoin Valproate	Probably of little clinical relevance; for phenytoin, a fall in concentration has also been reported	Inhibition of metabolism of the object drugs
Ethanol	Clobazam Diazepam Phenytoin	Risk of toxicity of the object drugs; chronic ethanol can reduce serum phenytoin concentrations	Inhibition of metabolism; induction of phenytoin metabolism by chronic ethanol
Fluoxetine	Carbamazepine Diazepam Phenytoin Valproate	Risk of toxicity of the object drugs; with carbamazepine and valproate, interaction inconsistent	Inhibition of metabolism of the object drugs
Fluvoxamine	Carbamazepine Diazepam Phenytoin	Risk of toxicity of the affected drugs; with carbamazepine, interaction inconsistent	Inhibition of metabolism of the object drugs
Haloperidol	Carbamazepine	Risk of carbamazepine toxicity	Inhibition of metabolism of the object drugs
Imipramine	Phenytoin	Risk of phenytoin toxicity; interaction inconsistent	Inhibition of phenytoin metabolism
Loxapine	Carbamazepine	Risk of carbamazepine toxicity; interaction poorly documented	Unknown
Mesoridazine	Phenytoin	Reduced effect of phenytoin; interaction poorly documented	Unknown
Methylphenidate	Phenytoin Primidone	Risk of toxicity of the affected drugs; interaction inconsistent	Inhibition of metabolism of the object drugs

Table 3 *Continued*

Interfering drug (precipitant drug(s))	Affected drug(s) (object drug(s))	Implications/comments	Mechanism
Nefazodone	Carbamazepine	Risk of carbamazepine toxicity; interaction poorly documented	Inhibition of Carbamazepine metabolism
Sertraline	Carbamazepine Diazepam Lamotrigine Phenytoin	Risk of toxicity of the object drugs	Inhibition of metabolism of the object drugs
Thioridazine	Phenobarbital Phenytoin	Probably of little clinical relevance; an increase in serum phenytoin has also been described	Unknown
Trazodone	Phenytoin	Risk of phenytoin toxicity	Inhibition of phenytoin metabolism
Valnoctamide	Carbamazepine	Risk of carbamazepine toxicity	Inhibition of epoxide hydrolase
Viloxazine	Carbamazepine Phenytoin Oxcarbazepine	Risk of phenytoin and carbamazepine toxicity; interaction with oxcarbazepine probably of little clinical significance	Inhibition of metabolism of the object drugs
Miscellaneous			
Acetazolamide	Phenobarbital	Interaction probably of little clinical significance	Unknown
Acetazolamide	Primidone	Interaction probably of little clinical significance	Possibly reduced absorption of primidone
Activated charcoal	Carbamazepine Lamotrigine Phenobarbital Phenytoin Valproate	With some drugs can be exploited to reduce drug concentrations in overdose	Sequestration in the gastrointestinal tract
Allopurinol	Phenytoin	Risk of phenytoin toxicity	Inhibition of phenytoin metabolism
Aminophylline	Carbamazepine	Reduced effect of carbamazepine; interaction poorly documented	Unknown
Caffeine	Carbamazepine	Reduced effect of carbamazepine; interaction poorly documented	Unknown
Calcium carbide	Phenytoin	Risk of phenytoin toxicity	Inhibition of phenytoin metabolism
Chlorphenamine	Phenytoin	Risk of phenytoin toxicity	Inhibition of phenytoin metabolism
Colestyramine	Valproate	Interaction probably of little clinical significance	Reduced absorption of valproate
Danazol	Carbamazepine	Risk of carbamazepine toxicity	Inhibition of carbamazepine metabolism
Dexamethasone	Phenytoin	Interaction inconsistent	Unknown
Diazoxide	Phenytoin	Altered relation between total phenytoin concentration and effect	Displacement from plasma protein binding sites
Disulfiram	Diazepam Phenytoin	Risk of toxicity, particularly with phenytoin	Inhibition of metabolism of the object drugs
Enteral feeding formulas (some)	Phenytoin	Reduced effect of phenytoin	Reduced absorption of Phenytoin
Folic acid	Phenobarbital Phenytoin	Reduced effect of the object drug	Accelerated metabolism of the object drugs
Grapefruit juice	Carbamazepine Phenytoin unbound fraction	Risk of carbamazepine toxicity	Inhibition of carbamazepine metabolism
Halofenate	Phenytoin unbound fraction	Altered relation between total phenytoin concentration and effect	Displacement from plasma protein binding sites
Influenza vaccine	Carbamazepine Phenobarbital Phenytoin	Risk of toxicity of the affected drugs; effect on phenytoin inconsistent	Inhibition of metabolism of the object drugs
Nicotinamide	Carbamazepine Primidone	Risk of toxicity of the object drugs	Inhibition of metabolism of the object drugs
Fenyramidol	Phenytoin	Risk of phenytoin toxicity; interaction poorly documented	Unknown
Tacrolimus	Phenytoin	Risk of phenytoin toxicity	Unknown
Tamoxifen	Phenytoin	Risk of phenytoin toxicity	Unknown
Theophylline	Phenytoin	Reduced effect of phenytoin; interaction poorly documented	Unknown

Table 3 *Continued*

Interfering drug (precipitant drug(s))	Affected drug(s) (object drug(s))	Implications/comments	Mechanism
Tolbutamide	Phenytoin	Risk of toxicity; altered relation between total phenytoin concentration and effect	Displacement from plasma protein binding sites and possibly inhibition of phenytoin metabolism

*Inconclusive evidence suggests that salicylic acid can potentiate valproate toxicity (mechanism unclear). Sulfafurazole, sulfamethoxypyridazine, possibly other sulfonamides, and sulfinpyrazone displace phenytoin from plasma protein binding sites with different affinities; total phenytoin concentrations may underestimate the concentration of unbound (pharmacologically active) drug.

Table 4 Drugs that inhibit the metabolism of antiepileptic drugs and cause intoxication

Analgesics
Bromfenac
Codeine
Dextropropoxyphene
Methadone
Paracetamol
Pethidine
Phenazone
Phenylbutazone

Anticoagulants
Dicoumarol[1]
Warfarin

Antineoplastic drugs
Aminocamptothecin
Busulfan
Cyclophosphamide
Etoposide
Ifosfamide
Methotrexate[2]
Teniposide
Topotecan
Vincristine

Antimicrobial drugs
Chloramphenicol
Delavirdine
Doxycycline
Griseofulvin[3]
Indinavir
Itraconazole
Ketoconazole
Mebendazole
Metronidazole
Misonidazole
Nelfinavir
Praziquantel
Ritonavir
Saquinavir

Cardiovascular drugs
Alprenolol
Amiodarone
Digitoxin[4]
Digoxin[5]
Disopyramide
Felodipine
Flunarizine
Lidocaine
Metoprolol
Mexiletine
Nifedipine
Nimodipine
Nisoldipine
Propranolol
Quinidine
Timolol

Glucocorticoids
Dexamethasone
Fludrocortisone
Methylprednisolone
Prednisolone
Prednisone

Immunosuppressants
Ciclosporin[6]
Tacrolimus

Neuromuscular blockers[7]
Atracurium
Metocurine
Oxacurium
Pancuronium
Pipecuronium
Rocuronium
Vecuronium

Oral contraceptives[8]

Psychotropic drugs
Alprazolam
Amfebutamone
Amitriptyline
Amoxapine
Bromperidol
Chlorpromazine
Citalopram
Clozapine
Desipramine
Doxepin
Haloperidol
Imipramine
Mesoridazine
Mianserin
Midazolam
Nefazodone
Nortriptyline
Olanzapine
Paroxetine
Protriptyline
Thioridazine[9]
Trazodone
Valnoctamide
Zotepine

Miscellaneous
Chenodeoxycholic acid
Cimetidine
Ethanol
Etretinate
Fentanyl
Folic acid
Furosemide[10]
Metyrapone
Omeprazole
Psoralens
Theophylline
Thyroxine
Tirilazad
Vitamin D analogues

[1] In addition to enzyme induction, phenobarbital can reduce dicoumarol absorption.
[2] Interaction seen only with phenytoin and mediated by displacement from plasma protein binding sites; no reduction in methotrexate activity is expected; the relation between total methotrexate concentration and effect can be altered.
[3] Some anticonvulsants can reduce griseofulvin absorption.
[4] The evidence is conflicting.
[5] In addition to enzyme induction, phenytoin can reduce digoxin absorption.
[6] With phenytoin, reduced absorption can contribute to the fall in ciclosporin concentrations.
[7] A pharmacodynamic interaction may contribute to the reduced effect of neuromuscular blocking drugs.
[8] Carbamazepine, phenytoin, phenobarbital and primidone, felbamate, oxcarbazepine, and topiramate stimulate the metabolism of oral contraceptive steroids.
[9] The concentration of the active metabolite mesoridazine falls more markedly.
[10] Phenytoin and phenobarbital reduce furosemide absorption.

serum concentrations and clinical effects of other anticonvulsants (valproate, carbamazepine itself, including autoinduction, ethosuximide, felbamate, lamotrigine, topiramate, tiagabine, zonisamide, benzodiazepines) and a large number of other drugs that are metabolized by inducible enzymes. Examples of affected agents include oral anticoagulants, glucocorticoids, dihydropyridine calcium channel blockers and other cardioactive drugs, neuroleptic drugs, antimicrobial drugs including antiretroviral drugs, and steroid oral contraceptives. The efficacy of the contraceptive pill can also be reduced by the weaker inducers of CYP3A4, oxcarbazepine, felbamate, and topiramate.

On the other hand, felbamate and to a lesser extent valproate inhibit a range of liver enzymes and can increase the concentration of several drugs, leading to potentiation of their effects.

Similarly, drugs given for the treatment of associated disorders may inhibit the metabolism of anticonvulsants and precipitate signs of intoxication (Table 3). Examples include the increase in serum phenytoin concentrations by isoniazid and the increase in serum carbamazepine concentrations by verapamil, diltiazem, and most macrolide antibiotics (175–179).

Plasma protein binding interactions are usually clinically unimportant, but they should be recognized, because they alter the relation between serum drug concentration and the clinical response: if displacement occurs, therapeutic and toxic effects are reached at a total drug concentration lower than usual. For example, valproic acid and salicylate displace phenytoin from plasma proteins; this usually results in a fall in total phenytoin concentration without any change in the concentration of unbound (pharmacologically active) phenytoin.

Pharmacodynamic interactions also occur. In particular, the adverse effects of any drug can be increased by other drugs with similar properties. One example is the reciprocal potentiation of the neurotoxic effects of carbamazepine and lamotrigine in patients taking a combination of these drugs (180). Some drugs (for example ciclosporin, clozapine) have a proconvulsant effect and can reduce the efficacy of antiepileptic drugs.

Cisatracurium

The effect of cisatracurium on the onset, duration, and speed of recovery from neuromuscular blockade has been studied in 24 patients taking antiepileptic drugs and 14 controls (181). The onset and duration of neuromuscular blockade were not different among the groups, but the speed of recovery was significantly faster in those taking antiepileptic drugs.

Steroid neuromuscular blockers

Patients taking carbamazepine or phenytoin are resistant to steroid neuromuscular blocking drugs (181).

Diagnosis of Adverse Drug Reactions

The routine drug management of epilepsy by community health nurses without prior training in epilepsy management has been evaluated by neurologists in Zimbabwe (182). Of 114 patients (aged 8–56 years, 84% with generalized seizures), 40% had been seizure-free for at least 6 months; 72% took phenobarbital, 36% took carbamazepine, and 20% took phenytoin; 68% took monotherapy. Specialist interventions were required in 60% of consultations. Serum drug concentrations were measured in 38 patients; 58% were below the target range and 16% were above. Increased dosage was required in 29% of patients and dosage reduction or withdrawal in 18%. In several cases drug withdrawal was undertaken to convert polytherapy to monotherapy.

The use of serum antiepileptic drug concentrations has been reviewed (183). The authors suggested that there is still no evidence that specific target drug concentrations are valid in determining appropriate therapy.

Antifungal azoles

See also Individual agents

General Information

The antifungal azoles are a class of synthetic compounds that have one or more azole rings and a more or less complex side chain attached to one of the nitrogen atoms. They are either imidazole or triazole derivatives. The imidazoles miconazole and ketoconazole were the first azoles developed for systemic treatment of human mycoses. However, severe adverse effects associated with the drug carrier (in the case of miconazole) and erratic absorption and significant interference with cytochrome P450 isozymes (in the case of ketoconazole) have limited their usefulness (1). However, the subsequently developed triazoles fluconazole, itraconazole, and voriconazole have become useful additions to the antifungal armamentarium. They have a wider spectrum of activity and greater target specificity and are generally well tolerated (1,2). Other azoles for topical use are reviewed in the monograph on Antifungal azoles and other drugs for topical use.

The azoles act by inhibiting the fungal enzyme lanosterol 14-α-demethylase, which is involved in the synthesis of ergosterol from lanosterol or 24-methylenedihydrolanosterol in the fungal cell membrane. The consequent inhibition of ergosterol synthesis originates from binding of the unsubstituted nitrogen (N-3 or N-4) of the imidazole or triazole moiety to the heme iron and from binding of their N-1 substituent to the apoprotein of a cytochrome P-450 (P-450(14)DM) of the endoplasmic reticulum (3). This inhibition interrupts the conversion of lanosterol to ergosterol, which alters cell membrane function. Itraconazole has the highest affinity for the cytochrome and is about three and ten times more active in vitro than miconazole and fluconazole, respectively (4). They also inhibit the uptake of triglycerides and phospholipids through the cell membrane.

Drug–Drug Interactions

General

Drug interactions with the antifungal azoles are common for several reasons:

- they are substrates of CYP3A4, but also interact with the heme moiety of CYP3A, resulting in non-competitive inhibition of oxidative metabolism of many CYP3A substrates; to a lesser extent they also inhibit other CYP450 isoforms;
- although fluconazole undergoes minimal CYP-mediated metabolism, it nevertheless inhibits CYP3A4 in vitro, albeit much more weakly than other azoles (5,6); however, fluconazole also inhibits several other CYP isoforms in vitro and interacts with enzymes involved in glucuronidation (7);
- interaction of antifungal azoles and other CYP3A substrates can also result from inhibition of P-glycoprotein-mediated efflux; P-glycoprotein is extensively co-localized and exhibits overlapping substrate specificity with CYP3A (7); in a cell line in which human P-glycoprotein was overexpressed, itraconazole and ketoconazole inhibited P-glycoprotein function, with 50% inhibitory concentrations of about 2 and 6 μmol/l respectively; however, fluconazole had no effect (8).
- the systemic availability of the antifungal azoles depends in part on an acidic gastric environment and the activity of intestinal CYP3A4 and P-glycoprotein.

For details of interactions with individual antifungal azoles, see individual monographs (fluconazole, itraconazole, ketoconazole, miconazole, and voriconazole).

Antifungal azoles and other drugs for topical use

See also Antifungal azoles

General Information

All the topically used azoles can cause local irritation, burning, and, if used intravaginally, burning, swelling, and discomfort during micturition. There is cross-sensitivity between econazole, enilconazole, miconazole, and probably all other phenethylimidazoles.

Contact allergy to topical imidazoles is rare, considering how commonly they are used. The imidazole derivatives most often reported to be allergens are miconazole, econazole, tioconazole, and isoconazole. As far as cross-reactivity is concerned, in one review, there were statistically significant associations between miconazole, econazole, and isoconazole; between sulconazole, miconazole, and econazole; and between isoconazole and tioconazole (1).

Of 3049 outpatients who were patch-tested for contact dermatitis at the Department of Dermatology, Nippon Medical School Hospital from January 1984 to August 1994, 218 were patch-tested with topical antimycotic agents (2). There were 66 positive tests with imidazole derivatives, of whom 35 were allergic to the active ingredients: 16 were allergic to sulconazole, 11 to croconazole, 3 to tioconazole, 3 to miconazole, 1 to bifonazole, and 1 to clotrimazole. Exposure to croconazole occurred after a significantly shorter time with less drug than with sulconazole. Of the 35 patients who were allergic to an imidazole, 21 cross-reacted to other imidazoles.

Azoles

Bifonazole

Bifonazole has a broad spectrum of activity in vitro against dermatophytes, moulds, yeasts, dimorphic fungi, and some Gram-positive bacteria. It has been used in a strength of 1% in creams, gels, solutions, and powders, applied once a day to treat superficial fungal infections of the skin, such as dermatophytoses, cutaneous candidiasis, and pityriasis versicolor (3). In a multicenter, double-blind, randomized, parallel-group comparison with flutrimazole cream 1% in the treatment of dermatomycoses in 449 patients the overall incidence of adverse effects (mainly mild local effects such as irritation or a burning sensation) was 5% (4).

Clotrimazole

Clotrimazole was the first oral azole. While it was effective in deep mycoses, its limited absorption and induction of liver microsomal enzymes after a few days, leading to accelerated metabolism of the compound, as well as its toxicity, preclude its use for systemic therapy. Clotrimazole is therefore currently only used for topical therapy of mucocutaneous candidiasis.

Comparisons of fluconazole 200 mg/day with clotrimazole 10 mg 5 times/day in the prevention of thrush in patients with AIDS showed little difference in the occurrence of undesirable effects and abnormalities in laboratory measurements but less efficacy of clotrimazole (5,6).

Local problems can occur, including hypersensitivity reactions (1). In one case of contact allergy, patch-testing was positive with clotrimazole (5% in petroleum), itraconazole (1% in ether), and croconazole (1% in ether) (7). The authors reviewed the possible cross-reactions between the subgroups of imidazoles.

- A 71-year-old woman had a severe exacerbation of vulval dermatitis for which she had been using Canesten (clotrimazole) cream (8). There was a positive patch-test reaction with clotrimazole (1% in petrolatum) and patch tests with the other constituents of Canesten were negative.

Topical vaginal administration of even relatively high doses of clotrimazole did not result in systemic toxicity (9).

Croconazole

In one case of contact allergy, patch-testing was positive with clotrimazole (5% in petroleum), itraconazole (1% in ether), and croconazole (1% in ether) (7). The authors reviewed the possible cross-reactions between the subgroups of imidazoles.

Econazole

Econazole is used topically on the skin and also intravaginally, after which about 3–7% is absorbed. It can cause pruritus (10) and vaginal burning (11).

Enilconazole

Enilconazole is used in 10% solution/cream. Contact dermatitis has been reported (12,13).

Isoconazole

Isoconazole is mainly used for vaginal infections with *Candida albicans*. Contact dermatitis has been reported (14), including an unusual case with a papulo-pustular reaction (15).

Itraconazole

In one case of contact allergy, patch-testing was positive with clotrimazole (5% in petroleum), itraconazole (1% in ether), and croconazole (1% in ether) (7). The authors reviewed the possible cross-reactions between the subgroups of imidazoles.

Lanoconazole (latoconazole)

Used in a 1% cream, lanoconazole is effective against *Tinea*, and is more active than clotrimazole or bifonazole. Several cases of contact dermatitis have been reported (16–20).

Miconazole

See the monograph on Miconazole.

Nimorazole

Nimorazole is believed to be active against *Trichomonas vaginalis*. No specific adverse effects have been described after local use.

© 2006 Elsevier B.V. All rights reserved.

Ornidazole
Complaints of dizziness (21), mild gastrointestinal symptoms (22), and headache (23) during treatment with intravaginal ornidazole have been reported, since ornidazole is relatively well absorbed after rectal and vaginal administration (23).

Terconazole
Terconazole is prepared in creams and ovules for intravaginal use. Besides local irritation it causes systemic reactions. Headache was reported in over a quarter of patients. Other effects include hypotension, fever, and chills. Terconazole is absorbed to a greater extent than other topical azoles (SED-12, 684).

Tioconazole
Tioconazole is mainly used for vaginal or inguinal *Candida* infections. It has fewer local adverse effects than some of the older imidazoles. Local irritation, burning, rash, erythema, and pruritus have been reported. In a few women there was marked burning on micturition; these women all had signs of vaginal epithelial atrophy (SED-12, 684) (24).

Other topical antifungal drugs

5-Bromo-4-chlorosalicylamide (multifungin)
5-Bromo-4-chlorosalicylamide is one of a group of local antiseptics and fungistatics that can cause photosensitization (25). There is cross-sensitization with bithionol, fenticlor, and tribromosalicylanide.

Buclosamide (N-butyl-4-chlorosalicylamide)
Photocontact dermatitis has been described with buclosamide (25). There is cross-reactivity with a number of other drugs, notably oral hypoglycemic drugs, diuretics, and sulfonamides. Because of these reactions, buclosamide is not recommended for topical use.

Captan (Orthocide-406)
Captan is one of the older fungicides. It is used for pityriasis versicolor and is included in some soaps and cosmetics to provide bactericidal and fungicidal effects. It is allergenic. It is carcinogenic in mice, and in several countries control agencies have taken steps to prohibit its use in cosmetics and non-drug products (SEDA-13, 236).

Ciclopirox
Ciclopirox, a substituted pyridone unrelated to the imidazoles, is effective against a wide variety of dermatophytes, yeasts, actinomycetes, molds, and other fungi. Ciclopirox olamine is generally well tolerated locally, and reactions occur in only 1–4% of cases (SEDA-12, 684).

Clodantoin
Contact dermatitis has been rarely reported with clodantoin.

Fluonilide (4-fluoro-3′,5′-thiocarbanilide)
Contact dermatitis has been reported with fluonilide (26).

Gentian violet
Gentian violet (27) was at one time the treatment of choice for vaginal and oral candidiasis but is now obsolete. The main problem is staining and the messiness of the application, since the purple-colored fluid has to be brushed on to the skin.

Hachimycin (trichomycin)
Contact dermatitis has been reported with hachimycin.

KP-363
KP-363, a benzylamine derivative, is used in creams and solutions in concentrations of 0.1 and 0.6%. It is reported to cause less irritation than bifonazole and tolciclate (SEDA-14, 235).

Naftitine
Naftitine is one of a series of allylamine antifungal agents, derived from heterocyclic spironaphthalenes. It is usually sold in the form of a 1% cream for topical treatment of dermatomycoses, dermatophytes, and yeasts. It is claimed to be more effective than the imidazoles. Local irritation and a burning sensation, if they occur, are only mild (SED-12, 684) (28), (SEDA-16, 297).

Natamycin (pimaricin)
No cases of contact dermatitis were described in industrial workers in frequent contact with natamycin (29).

In the Hungarian Case–Control Surveillance of Congenital Abnormalities between 1980 and 1996, of 38 151 pregnant women who delivered infants without any defects (controls) and 22 843 who had fetuses or neonates with congenital abnormalities, 62 (0.27%) and 98 (0.26%) were treated with vaginal natamycin in the two groups respectively (crude OR = 1.1; 95% CI = 0.8, 1.5). There was thus no evidence of a teratogenic effect of natamycin.

Nifuratel
Contact dermatitis, with facial edema and a generalized erythema, has been described in the partner of a woman treated with nifuratel vaginal suppositories (SED-11, 578) (30).

Niphimycin
Niphimycin, an antimycotic antibiotic derived from *Actinomyces hygroscopicus*, is effective against both dermatomycosis and onychomycosis, with a 16–26% success rate in the latter. Tolerance is reportedly good, but there is a notable lack of recent data (SEDA-12, 236).

Nystatin
See the monograph on Nystatin.

Pecilocin (Variotin)
Skin irritation has been reported in 2–6.5% of patients treated with pecilocin. Contact dermatitis has been described in a few cases (31,32). Of 44 patients treated with pecilocin who were patch-tested with pecilocin, 7 were allergic to it; in three of them the skin disease had been caused or exacerbated by pecilocin (33).

© 2006 Elsevier B.V. All rights reserved.

Pyrrolnitrin (Miutrin, 3-chloro-4-(3-chloro-2-nitrophenyl) pyrrole)
Contact dermatitis with pyrrolnitrin and cross-reactivity with dinitrochlorobenzene has been reported in one case (34).

Salicylic acid 3% with benzoic acid 6% (Whitfield's ointment)
Whitfield's ointment, used for *Trichophyton rubrum*, has a keratolytic effect, and local irritation can occur (SED-12, 685) (35).

Sulbentine (dibenzthion)
Photoallergic contact dermatitis has been described with sulbentine, probably through a breakdown product, benzylisothiocyanate (36).

Tolciclate
Tolciclate, a thiocarbamate, is active against most common dermatophytes. Contact dermatitis has been reported (37).

Tolnaftate
Tolerance of tolnaftate is good. Local erythema has been described, as has allergic dermatitis (38).

Antihistamines

See also Individual agents

General Information

Histamine is both a local hormone and a neurotransmitter in the central nervous system. It is synthesized in neurons and mast cells. There are H_1, H_2, and H_3 receptors in the central nervous system, but they differ in their localization, biochemical machinery, functions, and affinities for histamine; they are particularly important in maintaining a state of arousal or awareness (1).

The early antihistamines, H_1 histamine receptor antagonists, bore some structural resemblance to histamine and, like histamine, contained an ethylamine group. However, the structures of the many antihistamines that are available are disparate, and the traditional classification according to chemical structure (ethanolamine, ethylenediamine, alkylamine, piperazine, and phenothiazine) is outdated, since the second-generation antihistamines, such as terfenadine and astemizole, do not readily fit into the old classification system (2).

Antihistamines act as competitive antagonists of histamine at H_1 histamine receptors, thus inhibiting H_1 receptor-mediated reactions, such as vasodilatation, sneezing, and itching. Histamine release from mast cells and basophils makes a major contribution to the allergic response, and antihistamines are widely used in the treatment of certain symptoms of allergic disease.

The new second-generation antihistamines are more selective H_1 histamine receptor antagonists, and many of them have additional anti-allergic properties in vivo, for example they reduce the release of inflammatory mediators or inhibit the recruitment of inflammatory cells (3–7). They also enter the brain less well and are therefore less likely to cause central adverse effects.

The H_1 histamine receptor antagonists were discovered by Bovet and Staub at the Institut Pasteur in 1937 (8). Although the first antihistamine was too weak and toxic for clinical use, its discovery resulted in an enormous amount of research and led in 1942 to the development of the first antihistamine to be used in the treatment of allergic diseases phenbenzamine (Antegan) (9). Within a few years, three other antihistamines became available and are still in use today: mepyramine (pyrilamine) maleate (10), diphenhydramine (11), and tripelennamine (12). Despite their pronounced adverse effects, these were the first really useful drugs for the symptomatic relief of allergic disorders. During the last 25 years several compounds with greater potency, longer durations of action, and minimal sedative effects have emerged, the so-called second-generation H_1 antihistamines, as opposed to the older, or classic, first-generation antihistamines. Two papers have confirmed the safety of the second-generation antihistamines; in particular, loratadine, fexofenadine, norastemizole, and descarboxyloratadine (desloratadine) were shown not to have sedative effects (13,14).

Spontaneous reports of suspected adverse effects of antihistamines have been analysed (15). The drugs were divided into two groups, sedative and non-sedative. Adverse reactions profiles were broadly similar in the two groups.

First-generation antihistamines

Besides interacting with H_1 histamine receptors, the first-generation antihistamines also have affinity for 5-HT receptors, alpha-adrenoceptors, and muscarinic receptors. They also reduce cyclic GMP concentrations, increase atrioventricular nodal conduction, and inhibit activation of airway vagal afferent nerves. First-generation H_1 receptor antagonists easily cross the blood–brain barrier, and their consequent well-documented sedative and anticholinergic effects, together with short half-lives, greatly limit their use in the treatment of allergic symptoms. However, despite these deficiencies, first-generation drugs are still widely used, mainly as over-the-counter products, often in combination with other drugs. The incidence of adverse effects, especially sedation and antimuscarinic effects, with the first-generation antihistamines is very high, perhaps up to 50%. Although these adverse effects are rarely serious, and often disappear with continued therapy, they are often so troublesome that medication must be withdrawn.

Second-generation antihistamines

The second-generation antihistamines include acrivastine, astemizole, azelastine, carebastine, cetirizine, ebastine, loratadine, mizolastine, and terfenadine. They are used orally and some of them can be given by local application to the nose and eyes (2,16). They are relatively free from anticholinergic, antiserotonergic, and alpha-adrenergic activity. They cause markedly less sedation, perhaps because they penetrate the central nervous system less well than the first-generation antihistamines, being relatively hydrophilic (17–19).

Second-generation antihistamines have proved to be important therapeutic tools in the treatment of atopic disease, including both seasonal and perennial allergic rhinitis, urticaria, and atopic dermatitis (20). Several studies have shown that the use of second-generation antihistamines as adjunctive therapy can benefit patients whose allergic asthma co-exists with allergic rhinitis (21).

There are several novel antihistamines that are either metabolites or enantiomers of existing drugs. The aim has been to develop antihistamines with improved potency, onset and duration of action, and greater predictability and safety. Drugs of this kind that have received regulatory approval and are effective in several allergic conditions include desloratadine, fexofenadine, levocabastine, and levocetirizine. These have been developed in response to widespread concerns about the potential for cardiotoxicity and the impact of drug–drug interactions associated with some earlier second-generation H_1 receptor antagonists. Furthermore, the potential for sedation by some of the newer antihistamines still remains an issue for many. This

© 2006 Elsevier B.V. All rights reserved.

is important, as many patients using antihistamines want to remain alert and active and may also use other medications.

Organs and Systems

Cardiovascular

Tachycardia and hypertension have long been known as problems arising incidentally reported with various classic antihistamines (SEDA-22, 176).

Prolonged QT interval and ventricular dysrhythmias

DoTS classification

Dose-relation: toxic effect
Time-course: time-independent
Susceptibility factors: genetic (long QT syndrome); altered physiology (hypokalemia); drug interactions (metabolism inhibitors; drugs that prolong the QT interval); diseases (liver disease; cardiac disease with prolongation of QT interval)

Several antihistamines can cause ventricular dysrhythmias of the torsade de pointes type (22), first reported with astemizole (23) and later with terfenadine (24). Astemizole and terfenadine both have a dose-dependent effect on cardiac repolarization and cause prolongation of the QT interval, which can lead to ventricular dysrhythmias (such as torsade de pointes), syncope, and cardiac arrest. Reported cases relate preponderantly to overdosage, especially in children (SEDA-12, 142) (SEDA-14, 135) (SEDA-14, 137) (SEDA-17, 196) (23–25). Terfenadine and astemizole have been described as having dysrhythmogenic actions, and deaths have been described (26,27). The effects of some antihistamines on the QT interval are listed in Table 1.

With a few exceptions, antihistamines are rapidly and completely absorbed after oral administration; peak plasma concentrations are reached after 1–4 hours and are highly variable, owing to differences in tissue distribution and metabolism (20). Many of the second-generation antihistamines (for example astemizole, ebastine, loratadine, and terfenadine) undergo extensive first-pass metabolism to pharmacologically active metabolites; as a common feature, the reaction is primarily supported by CYP3A4. Under normal circumstances this extensive metabolism leads to low or undetectable plasma concentrations of the parent drug. However, sometimes metabolism of the parent compound can be compromised. Accumulation of unmetabolized astemizole or terfenadine can result in blockade of cardiac potassium channels in the ventricular myocytes that regulate the duration of the action potential; consequent prolongation of the QT interval can result in potentially life-threatening ventricular tachycardia (28).

Dysrhythmias can also occur with therapeutic doses of these and other antihistamines, if certain other susceptibility factors are present:

- impaired hepatic metabolism due to liver disease;
- simultaneous treatment with drugs that are inhibitors of the cytochrome P450 enzyme CYP3A4 (for example macrolide antibiotics, antifungal azoles, or grapefruit juice), leading to increased plasma concentrations thereby raising the risk of cardiotoxic effects (29) (SEDA-17, 196);
- pre-existing QT prolongation caused by congenital long QT syndrome, other heart disease, or treatment with antidysrhythmic drugs, such as class I antidysrhythmic drugs, amiodarone, or sotalol;
- electrolyte imbalance; in particular, hypokalemia predisposes to Dysrhythmias.

Terfenadine is especially likely to cause torsade de pointes in patients in whom these risk factors are present (SEDA-19, 176) (SEDA-21, 176). Ventricular dysrhythmias can also occur after overdosage of antihistamines that prolong the QT interval.

The mechanism responsible for dysrhythmias has been identified as blockade of HERG potassium channels (30). The dysrhythmogenic potential of antihistamines has been evaluated in vitro using cloned human potassium channels or guinea-pig heart muscle cells, and using an in vivo guinea-pig model. Studies in humans, including the assessment of drug interactions, are considered more reliable. Investigations in human volunteers have shown that there are no significant electrocardiographic changes with azelastine, cetirizine, fexofenadine, and loratadine even at several times the therapeutic doses, which shows that cardiotoxicity is not a class effect (31) (SEDA-19, 172). Mizolastine also appears to cause no cardiac problems in humans (32). Large doses of ebastine have shown cardiac effects in guinea pigs, but QT prolongation has not occurred in human studies with up to three times therapeutic doses (33). Slight QT prolongation was seen on further increased doses to 100 mg/day and when subjects were given erythromycin or ketoconazole, but the effect was less than the effect of terfenadine and was not considered clinically relevant (33). The active metabolite of ebastine, carebastine, had no effect on the QT interval, even in large doses.

The absolute risk of antihistamine-induced dysrhythmias is low in the general population. In an epidemiological study using a general practice database, the crude incidence of ventricular dysrhythmias was 1.9 per 10 000 person-years, corresponding to a relative risk of 4.2 for all antihistamines compared with non-use. Astemizole presented the highest relative risk, whereas terfenadine was in the range of other non-sedating antihistamines. Older age was associated with greater risk. The absolute risk in this study was one case per 5300 person-years of use (34).

In the USA, terfenadine was withdrawn from the market in 1998, and in other countries terfenadine has been moved from over-the-counter to prescription-only, with only 60 mg tablets available. The active metabolite of terfenadine, fexofenadine, is marketed as an alternative. For astemizole this option was not available, since the main metabolite (desmethylastemizole) is also cardiotoxic and has a half-life of 10 days; astemizole was therefore withdrawn from the market worldwide in June 1999.

Although it is widely believed that cardiotoxicity of antihistamines is limited to second-generation compounds, both hydroxyzine and diphenhydramine can block potassium channels. Caution should therefore be exercised in prescribing first-generation antihistamines for patients with a predisposition to cardiac dysrhythmias. For example, therapeutic doses of diphenhydramine caused prolongation of the QT interval in healthy volunteers and in patients undergoing angioplasty (35), and one cannot exclude the possibility that first-generation drugs that modulate

potassium channels may in some circumstances cause dysrhythmias (36). All antihistamines should be screened for cardiotoxicity, as some patients may be poor metabolizers or may be susceptible to plasma concentrations near to the usual therapeutic range. Useful information may be obtained from pharmacokinetic studies using potential inhibitors (see under Drug–Drug Interactions).

The single- and multiple-dose pharmacokinetics of ebastine (10 mg) have been determined in elderly and young healthy subjects using 24-hour Holter monitoring (37). There were no clinically relevant effects.

The incidence of ventricular dysrhythmias associated with non-sedating antihistamines (including cetirizine) has also been assessed using the UK-based General Practice Research Database (34). There were 18 cases over the period 1992–96. Astemizole was associated with the highest relative risk. The risk associated with terfenadine was no different from that with other non-sedating antihistamines, and there was no single case of ventricular dysrhythmia with the concomitant use of P450 inhibitors and terfenadine.

In a comparison of the dysrhythmogenic potential of a series of second-generation antihistamines, the antihistamines were given intravenously and electrocardiographic and cardiovascular parameters (blood pressure and heart rate) were measured. The lowest dose that produced significant prolongation of the QT_c interval

© 2006 Elsevier B.V. All rights reserved.

was compared with the dose required to inhibit by 50% the peripheral bronchospasm elicited by histamine 10 micrograms/kg intravenously. Astemizole, ebastine, and terfenadine produced pronounced dose-dependent QT_c interval prolongation. In contrast, terfenadine carboxylate, norastemizole, and carebastine, the major metabolites of terfenadine, astemizole, and ebastine, and cetirizine had no effects (38).

Respiratory

Phenothiazine derivatives can aggravate asthma. The use of the first-generation antihistamines in asthma was hampered by induction of coughing when inhaled and by their sedative properties when given orally. Furthermore, the desiccating and thickening effect on the airway mucus is undesirable. However, the American Academy of Allergy and Immunology (39) has stated that antihistamines are not contraindicated in patients with asthma, unless there have been previous adverse reactions (SEDA-14, 135).

The effect of the second-generation antihistamines in treating asthma has been investigated. They have a moderate, bronchodilatory effect and an effect on exercise-induced asthma, hyperventilation, and cold-air breathing, and to a varying degree give some protection against the early and late responses to allergen (2) (SEDA-14, 135).

Antihistamines are not first-choice drugs in asthma, however, and although they can contribute to the relief of seasonal asthma symptoms and accompanying allergic rhinitis, the results of a meta-analysis do not support the general use of antihistamines in adult asthmatics (40).

Ear, nose, throat

When used for the treatment of colds and allergic upper airways disorders, antihistamines (alone or in combination with decongestants) can reduce mucociliary motility in the middle ear, thus contributing to the development of otitis media (41).

Nervous system

The sedative and anticholinergic effects of antihistamines, when known, are summarized in Table 1.

Antihistamines and drowsiness

Central nervous depression causing sedation is the most common adverse effect of the first-generation antihistamines (SEDA-21, 171) (42). The sedative effect of antihistamines is evaluated using psychometric tests, tests of driving performance, and subjective scoring or visual analogue scales, but results from studies using healthy volunteers cannot necessarily be extrapolated to patients, one difficulty being that the treated disease can itself cause sedation (43). The drowsiness has been attributed to inhibition of histamine *N*-methyltransferase and to blockade of central histamine receptors, together with actions on other receptors, in particular 5-HT receptors (2,17,19,44). Daytime drowsiness can be a problem, above all when driving or operating machinery. As with many other nervous system depressants, this effect may abate or disappear after several days of use, but co-medication with certain other agents or a short period of withdrawal of therapy may reactivate the sedative effect.

The signal characteristic of the second-generation antihistamines is their freedom from sedation (2,16). The relative lack of sedative properties in the second-generation antihistamines has been ascribed to their relative hydrophilicity. Little is known about intracerebral concentrations of antihistamines and their metabolites, but positron emission tomography has shown that the first-generation antihistamine chlorphenamine occupied a larger fraction of brain histamine H_1 receptors than terfenadine (SEDA-20, 164). Differential affinity for, or different actions on, central and peripheral H_1 receptors (SEDA-21, 171) could also explain variations in sedative effect, but differences in receptor binding have only been shown for loratadine in vitro (45).

The nervous system depressant effects of fexofenadine (46,47), loratadine (48), and mizolastine (49) appear to be no greater than those seen with placebo. However, the generality of the claim that second-generation antihistamines are free of sedative effects has been challenged (50). The issue is complicated by evidence that sedation in allergic disease (and subsequent impairment in performance and learning) can be a consequence of the condition itself, as opposed to being wholly due to antihistamines (20). This raises concerns about the purported risk-free sedation profiles of certain antihistamines, given that they are often based on objective studies in healthy volunteers (42). Another issue is the tendency of patients with allergies to self-medicate, titrating their antihistamine dosage upwards to achieve relief of symptoms; neurological impairment does in fact occur if the doses of cetirizine, loratadine, or mizolastine are increased sufficiently (20). Thus, it is more correct to describe the second-generation antihistamines as having minimal sedative effects when taken in recommended doses. A grouping of the antihistamines into those with marked, moderate, and very low sedative effect is possible. However, the dividing lines are not sharp and classification often depends on how many studies are taken into account, since results are not consistent.

The designs of protocols used in comparisons between sedative and non-sedative compounds have been questioned. They may not accurately reflect the clinical use of each drug, and the data may be misused in advice to prescribers, even though the reason a comparator was included was merely to provide an active control. Extrapolation of the results of cognitive studies in healthy volunteers to patients may be inappropriate, as a drug that is sedative in a healthy volunteer may well not be perceived to be sedative by a patient with allergic symptoms, although caution must be taken in relying on subjective assessments of performance and drowsiness. Patients with mild to moderate allergic rhinitis complain of sleep difficulties, and many who take a sedative can function reasonably well during the next day without further medication. Duration of treatment can also play a part, and certain investigations may have been too brief; in some patients, sedation is induced by the drug only after some weeks of treatment (SEDA-12, 142). Such discrepancies could explain why, despite all the investigations with positive results, some studies report sedation in 30% of the patients (SED-11, 317) (SEDA-9, 149) (SEDA-10, 135).

It is likely that the controversy will be settled by accepting the relative merits of each drug, and that sedative drugs will continue to be prescribed, at least for overnight ingestion and for some skin conditions.

© 2006 Elsevier B.V. All rights reserved.

There is the special case of the use of antihistamines by individuals whose work may compromise their own safety or the safety of others, for example transport workers. Indeed, much of the support for second-generation drugs arises from safety considerations. Nevertheless, it is sometimes suggested that recommendations for the use of antihistamines by those involved in skilled activities should be based on studies of the patients themselves carrying out their day-to-day work, for example airline pilots with allergic rhinitis operating aircraft. This is an argument that lacks careful thought. In occupational medicine it is essential that controlled studies in healthy volunteers are used to establish whether an antihistamine has sedative properties, and then to choose the drug that is least likely to impair performance or cause drowsiness.

Observational studies

Antihistamines are effective and safe in preventing the symptoms of a mosquito bite; ebastine and loratadine did not cause sedation in such cases (51,52).

Comparative studies

The frequency of sedation due to acrivastine, cetirizine, fexofenadine, and loratadine has been investigated in four prescription-event monitoring studies in 43 363 patients in general practice in the UK (53). Prescriptions were obtained for each cohort in the immediate postmarketing period. Sedation and drowsiness were the main outcome measures. The odds ratios (adjusted for age and sex) for the incidences of sedation compared with loratadine were: 0.63 (95% CI = 0.36, 1.11) for fexofenadine, 2.79 (1.69, 4.58) for acrivastine, and 3.53 (2.07, 5.42) for cetirizine. There was no increased risk of accident or injury with any of the four drugs.

The effects of diphenhydramine, fexofenadine, and alcohol on driving performance have been studied in a randomized, placebo-controlled trial in the Iowa driving simulator (54). Participants had significantly better coherence after alcohol or fexofenadine than after diphenhydramine. Lane holding (steering instability and crossing the center line) was impaired after alcohol and diphenhydramine compared with fexofenadine. Mean response time to the blocking vehicle was slowest after alcohol (2.21 seconds) compared with fexofenadine (1.95 seconds). Self-reported drowsiness did not predict lack of coherence and was weakly associated with minimum following distance, steering instability, and left-lane excursion. In conclusion, the participants performed similarly when they took fexofenadine or placebo. After alcohol they performed the primary task well but not the secondary tasks, resulting in poorer driving performance. After diphenhydramine, driving performance was poorest, suggesting that diphenhydramine had a greater impact on driving than alcohol did. Drowsiness ratings were not a good predictor of impairment, suggesting that drivers cannot use drowsiness to indicate when they should not drive. Non-sedating antihistamines should therefore be preferred over sedating antihistamines in patients who drive (55).

Mequitazine has a low propensity to cause drowsiness, comparable to that of cetirizine and loratadine; it therefore differs from truly sedative antihistamines, such as dexchlorpheniramine, which cause drowsiness and fatigue in patients with atopy to a degree that is measurably different from placebo (56).

Although allergic rhinitis is not usually severe, it affects school learning performance and work productivity (57). The effects of loratadine and cetirizine on somnolence and motivation during the working day have been compared in 60 patients with allergic rhinitis in a parallel-group, double-blind study (58). Somnolence scores were similar in the two groups at baseline and at the time of dosing (0800 hours). However, cetirizine caused significantly more somnolence at 1000 hours, 1200 hours, and 1500 hours. The scores of motivation to perform activities were similar in the two groups at baseline and 0800 hours. The patients taking loratadine were relatively more motivated at 1000 hours, 1200 hours, and 1500 hours.

In a comparison of the effects over 7 days of a modified-release formulation of brompheniramine (12 mg bd) and loratadine (10 mg od), physicians' and patients' assessments were better for brompheniramine than for loratadine, but somnolence and dizziness were reported less often by those who took loratadine, although occurrences were claimed to be less frequent with brompheniramine as treatment continued (59).

The authors of a report of a comparison of the effectiveness of ebastine (10 and 20 mg) and loratadine (10 mg) for perennial allergic rhinitis claimed that ebastine provided greater symptomatic relief than loratadine, but with a similar low incidence of central effects and headache (60).

In a comparison of the incidence of drowsiness between cinnarizine (25 mg tds for 7 days, 25 mg bd for 15 days, and 25 mg daily for 15 days) and prochlorperazine (5 mg tds for 7 days, 5 mg bd for 15 days, and 5 mg od for 15 days), drowsiness was observed less often in those taking prochlorperazine (61).

In a comparison of diphenhydramine, chlorphenamine, cetirizine, loratadine, and placebo in 15 healthy elderly subjects, there were no significant differences between the first- and second-generation antihistamines (62). In another study, even the first-generation sedative drug chlorphenamine failed to cause significant sedation in a group of children (63).

In a comparison of astemizole, terfenadine, and triprolidine (positive control), only triprolidine caused reduced performance and motor incoordination (64).

In a comparison of the effects of acrivastine, terfenadine, and diphenhydramine on driving performance, there was a dose-dependent effect of acrivastine, with severely affected driving in doses of 16 and 24 mg (SEDA-19, 170). Terfenadine in doses of 60–180 mg did not affect driving performance.

In a comparison of cetirizine and loratadine, cetirizine 10 mg had acute sedative effects and impaired driving performance (65), whereas loratadine had no sedating potential; furthermore, there was an additive effect of alcohol and cetirizine but not alcohol and loratadine. However, in a study using a driving simulator cetirizine 10 mg did not affect driving ability (66). In other studies cetirizine 20 mg caused significant sedation, while in one study there was a dose-dependent sedative effect with 10 mg and 20 mg but not 5 mg (67). Pooling the available data (SEDA-16, 163) shows that cetirizine is little more sedative than loratadine and terfenadine.

© 2006 Elsevier B.V. All rights reserved.

In a comparison of ebastine and triprolidine, only those taking triprolidine had impairment of several parameters of car driving performance (SEDA-18, 182).

The effects of loratadine 10, 20, and 40 mg on tests of visuomotor coordination, dynamic visual acuity, short-term memory, digit symbol substitution, and subjective assessments of mood have been studied (68). Triprolidine was used as an active control and impaired performance on all the tasks presented. Loratadine 40 mg caused a significant impairment of the Digit Symbol Substitution Test and the Dynamic Visual Acuity Test, but the 10 and 20 mg doses were without effect. Loratadine did not affect objective sleepiness, as measured by Multiple Sleep Latency Test (69). In other studies of loratadine in the normal 10 mg dose the sedation rate was no different from placebo (SEDA-12, 143) (SEDA-14, 136).

In a comparison of the initial and 5-day steady-state effects of loratadine, diphenhydramine, and placebo, using a number of psychometric tests, there was no detectable effect of loratadine compared with placebo, whereas diphenhydramine clearly reduced performance (70).

Anticholinergic effects

The marked anticholinergic properties of the first-generation antihistamines can cause dryness of the oral and respiratory mucosae. Other antimuscarinic effects are less common, but nasal stuffiness, blurring of vision, urinary retention, and constipation can all occur.

Nervous system stimulation is less frequent than nervous system depression, but when it occurs it causes insomnia, irritability, and tremor; nightmares, and hallucinations. In overt intoxication, these effects may be related to anticholinergic effects. In an analysis of 113 200 admissions to a pediatric hospital there were only two patients with excitation, insomnia, visual hallucinations, and seizures, followed by coma (71).

Antidopaminergic effects

Antidopaminergic effects of antihistamine drugs can cause extrapyramidal symptoms, including neuroleptic malignant syndrome (SEDA-19, 173) (SEDA-22, 178) (72). Prolonged use of antihistamine-containing decongestants can cause facial dyskinesias, including blepharospasm, swallowing difficulties, and dysarthria. As patients with these effects have often been taking combination products containing antihistamines, proper evaluation of interactions is needed before final assessment is possible. As a dyskinesia can be unilateral, a neurological disorder should be excluded before thinking about an adverse effect (SEDA-1, 144).

The prognosis of drug-induced parkinsonism has been discussed (73,74). Negrotri and Calzetti (73) considered that the results of Martí-Massó and Poza (74) were over-optimistic. This they ascribed to uncertainty in the collection of their data, which may not have provided adequate evidence of the course of clinical recovery, although differences in cumulative dosages and concurrent use of other drugs could also have been involved. The differences in prognosis may be attributable to the fact that the patients studied by Martí-Massó and Poza (34) were diagnosed earlier, were less severely affected, and had a good prognosis. Cinnarizine-induced extrapyramidal signs have tended to be associated with old age and prolonged treatment. However, cinnarizine-induced akathisia, parkinsonism, and depression have been reported in a 25-year-old patient after only 11 days of treatment (75).

Sensory systems

A questionnaire showed that women taking antihistamines and/or cold formulations had a tone average 9 dB higher than those not taking such medication (76). Audiography showed differences in threshold of 6.4 and 12.8 dB at 500 and 1000 Hz respectively. The medications involved were primarily meclozine for dizziness and terfenadine for allergy.

Psychological, psychiatric

In healthy volunteers promethazine caused impaired cognitive function and psychomotor performance (77). The test battery consisted of critical flicker fusion, choice reaction time, compensatory tracking task, and assessment of subjective sedation. Cetirizine and loratadine at all doses tested were not significantly different from placebo in any of the tests used.

School performance in 63 children aged 8–10 years was not impaired by short-term diphenhydramine or loratadine (78).

Comparative studies

The effects of ebastine 10 mg on cognitive impairment have been assessed in 20 healthy volunteers who performed six types of attention-demanding cognitive tasks, together with objective measurements of reaction times and accuracy (79). Ebastine was compared with placebo and a positive control, chlorphenamine (chlorphenamine, 2 mg and 6 mg). Compared with placebo, ebastine had no effect on any objective cognitive test nor any effect on subjective sleepiness. In contrast, chlorphenamine significantly increased reaction times, decreased accuracy in cognitive tasks, and increased subjective sleepiness. The effect of chlorphenamine increased with plasma concentration.

In a double-blind, placebo-controlled, randomized trial of the effects of levocetirizine 5 mg and diphenhydramine 50 mg on objective measurements (a word-learning test, the Sternberg Memory Scanning Test, a tracking test, and a divided attention test that measured both tracking and memory scanning simultaneously) in 48 healthy volunteers (24 men and 24 women). Levocetirizine had no effect, while diphenhydramine significantly affected divided attention and tracking after acute administration (80). However, on day 4 the effects of diphenhydramine did not reach significance, suggesting a degree of tolerance to this first-generation drug.

The effects of levocetirizine on cognitive function have been assessed in two comprehensive and well-controlled studies. The first analysed the effects of single and multiple doses of levocetirizine on measures of nervous system activity, using integrated measures of cognitive and psychometric performance. In a three-way crossover design, 19 healthy men took either levocetirizine 5 mg, diphenhydramine 50 mg (positive control), or placebo once-daily on five consecutive days. Critical flicker fusion tests were

© 2006 Elsevier B.V. All rights reserved.

performed on days 1 and 5 at baseline and up to 24 hours after drug administration. The primary outcome was that, in contrast to diphenhydramine, levocetirizine did not have any deleterious effect on any cognitive or psychometric function compared with placebo (81). In a double-blind, crossover study levocetirizine 5 mg once-daily for 4 days was compared with cetirizine 10 mg, loratadine 10 mg, promethazine 30 mg, and placebo in terms of CNS inhibitory effects in 20 healthy volunteers (82). With the exception of promethazine none of the drugs had disruptive or sedative effects on objective measurements in a comprehensive battery of psychomotor and cognitive tests.

Metabolism

Appetite stimulation and resulting weight gain is a well-known feature of cyproheptadine, but astemizole also causes weight gain in approximately 3% of patients within weeks of treatment (16,83). Cetirizine also has been reported to cause weight gain (about 2.8%) when it is used for a prolonged time (SEDA-17, 200). Increased body weight occurred in three participants in a trial of azelastine (SEDA-21, 172).

In a double-blind, randomized, placebo-controlled study of the effect of cetirizine, clemastine, and loratadine for 7 days on blood glucose concentration in patients with allergic rhinitis, cetirizine produced a significant increase in postprandial blood glucose and a small rise in fasting blood glucose; clemastine caused a small fall in fasting and a small rise in postprandial blood glucose (84). The mechanisms of these effects are not known.

Hematologic

Blood dyscrasias are infrequent with antihistamines, but agranulocytosis, hemolytic anemia, and thrombocytopenia have been described. Thrombocytopenia has been attributed to antazoline (85), agranulocytosis to chlorphenamine (SEDA-16, 162) and mebhydrolin (86), and aplastic anemia to chlorphenamine (87).

Gastrointestinal

Antihistamines do not commonly cause gastrointestinal effects, but nausea, vomiting, gastric pain, diarrhea, or constipation can occur (88).

Liver

Repeated reports of changes in liver function may reflect coincidence, in view of the widespread use of these drugs. Occasionally, however, hepatitis (89) or cholestatic jaundice seems to have occurred.

Skin

Although antihistamines are often used in the treatment of allergic conditions, topical use often produces skin sensitization and subsequent contact dermatitis (90,91). This effect occurs more often with the use of ethylenediamines and phenothiazines; the latter also produce photoallergic cutaneous reactions (92). A photoallergic contact dermatitis followed by a persistent light reaction was attributed to topical dioxopromethazine hydrochloride incorporated into a gel in a woman with periocular pruritus (93). Photosensitivity in sun-exposed areas where she had not applied the formulation persisted for up to 500 days, with a reduced minimal erythema dose (MED) for UVA together with abnormal delayed infiltrated reactions to UVB in repeated phototests.

Cross-reactions between phenothiazine tranquillizers and first-generation antihistamines are possible, as well as reactions between antihistamines and ethylenediamine present in some creams and ointments. As local sensitization is quite common, topical use of antihistamines is not recommended. Despite these disadvantages they are still available in many countries as over-the-counter products. Topical antihistamines in sufficient doses can also cause systemic adverse effects.

Subacute cutaneous lupus-like dermatitis has been associated with cinnarizine and brompheniramine (94,95).

Long-Term Effects

Drug abuse

Some antihistamines, for example tripellenamine (often used in combination with pentazocine), have a particular abuse potential and are used by drug addicts. Psychiatric disturbances, dysphoria, depression, confusion, and hallucinations can occur while under the influence of an antihistamine or during drug withdrawal. Chronic parenteral abuse can cause skin lesions, muscular fibrosis, and vasculitis.

Drug withdrawal

Since dyskinesia can occur after withdrawal of phenothiazine neuroleptic drugs, it is not unlikely that the same problem may follow termination of prolonged antihistamine therapy.

Tumorigenicity

Tumor-inducing effects have been reported in animal studies on methapyrilene; the significance of this finding is not clear (SEDA-4, 171). An association between antihistamine exposure and accelerated tumor growth seen in experimental animal models has found no support in an epidemiological study (96).

Second-Generation Effects

Teratogenicity

Teratogenic effects have not been proven in humans, although some piperazine derivatives have teratogenic effects in laboratory animals. Some studies have suggested an association between palate malformation and antihistamines (97–99).

Teratogenic activity has been attributed to doxylamine, a constituent of many combinations with vitamin B6 and antispasmodic agents, and used in the treatment of hyperemesis gravidarum. However, extensive studies and reviews have suggested that the incidence of malformations is not higher in children whose mothers have taken formulations containing antihistamines as a group, and in particular the combination of doxylamine/pyridoxine with or without dicycloverine (100–102).

© 2006 Elsevier B.V. All rights reserved.

A meta-analysis of 24 controlled studies of the association between antihistamines and major congenital malformations (more than 200 000 participating women) did not show an increased risk of malformations (103). Experience with the first-generation antihistamines is more comprehensive than with the second-generation compounds, and in a recent review it was concluded that some of the first-generation drugs can be used for allergic rhinitis in pregnancy (104). Some authors advise avoiding brompheniramine because of a supposed association with birth defects (SEDA-21, 172).

Studies with various antihistamines (105,106) have failed to provide evidence of teratogenicity. However, the samples may not have been large enough to provide adequate statistical power or to establish the true incidence of individual malformations. In study of the effect of treatment with diazepam and promethazine during pregnancy carried out in the late 1980s (minimal doses for the whole pregnancy 50 mg and 250 mg respectively), children of both sexes in the diazepam group had lower birth weights, but normal body weights at 8 months of age; there were no changes in body weight in the promethazine group (107). The incidence of major malformations with terfenadine (mean dose 30–120 mg/day) has been estimated prospectively. Rates of major malformations did not differ from matched controls amongst those exposed during the first trimester. However, birth weight was lower in babies exposed to terfenadine, but not when babies below 2500 g were compared. These findings emphasize the general value of continued studies on antihistamines during pregnancy; the findings with terfenadine may be equally applicable to its metabolite fexofenadine (108).

Cleft palate is seen more often in infants whose mothers have used antihistamines for the treatment of hyperemesis gravidarum (4.44 per 1000 births) than in infants of mothers without hyperemesis gravidarum and not treated with antihistamines (0.78 per 1000) (98). However, children of mothers suffering from hyperemesis gravidarum but not treated also showed a high incidence of cleft palate (3.14 per 1000). It is likely that cleft palate could be a consequence of the maternal condition rather than of drug teratogenicity.

Lactation

There have been no specific reports of harm resulting from the use of antihistamines during lactation, although there have been few studies. Triprolidine and loratadine would reach a breastfed infant in low concentrations (109).

Susceptibility Factors

Hepatic disease

Because sedation can lead to hepatic encephalopathy in patients with hepatic failure, sedative antihistamines should be avoided in such patients. In addition, some antihistamines are themselves hepatotoxic.

Other features of the patient

In view of their anticholinergic effects antihistamines should be avoided in cases of glaucoma and prostatism.

Antihistamines can be dangerous to drivers and people operating machinery, primarily because of their sedative effects but also because of blurring of vision.

Drug Administration

Drug overdose

- A 48-year-old woman was found dead after taking guaifenesin, diphenhydramine, and chlorphenamine, with heart blood concentrations of 27, 8.5, and 0.2 mg/l respectively (110).

Drug–Drug Interactions

Anticholinergic drugs

Drugs with anticholinergic effects (including phenothiazines, tricyclic antidepressants, quinidine, and disopyramide) will have their effects increased by antihistamines.

Cytochrome P450 isozymes

Several of the non-sedating antihistamines (astemizole, ebastine, loratadine, and terfenadine, but not cetirizine, desloratadine, fexofenadine, levocetirizine, or norastemizole) are metabolized by the cytochrome P450 isozyme CYP3A4 (SEDA-21, 177) (111). Concomitant treatment with drugs that inhibit this metabolic pathway (such as ketoconazole, itraconazole, erythromycin, clarithromycin) lead to increased plasma concentrations of the unmetabolized drug. Currently, only astemizole and terfenadine have been associated with cardiac adverse effects caused by such interactions. Terfenadine given with grapefruit juice, which also inhibits CYP3A4, resulted in higher plasma concentrations, but not QT interval prolongation (112).

Pooled human liver microsomes have been used to determine whether loratadine, desloratadine, and 3-hydroxydesloratadine are inhibitors of CYP1A2, CYP2C9, CYP2C19, CYP2D6, and CYP3A4 (113). Loratadine did not inhibit CYP1A2 or CYP3A4 at concentrations up to 3829 ng/ml, about 815 times greater than the expected maximal human plasma concentration (mean 4.7 ng/ml) after the recommended dose of 10 mg/day. Loratadine inhibited CYP2C19 and CYP2D6 with IC_{50} values of about 0.76 μmol/l (291 ng/ml) and 8.1 μmol/l (3100 ng/ml) respectively, about 60 and 660 times the expected loratadine therapeutic concentrations. Neither desloratadine nor 3-hydroxydesloratadine inhibited CYP1A2, CYP2C9, CYP2C19, CYP2D6, or CYP3A4 by more than 25% at concentrations of about 3000 ng/ml. These results suggest that loratadine and its active metabolites desloratadine and 3-hydroxydesloratadine are unlikely to affect the pharmacokinetics of co-administered drugs that are metabolized by these five cytochrome P450 enzymes.

Drugs acting on the brain

Drugs that have effects on the brain (hypnotics, sedatives, narcotic analgesics, neuroleptic drugs, alcohol, lithium,

© 2006 Elsevier B.V. All rights reserved.

anticonvulsants) will interact with antihistamines, especially the first-generation drugs. The second-generation antihistamines have not yet been proven to interact with drugs such as alcohol or diazepam (114–117).

Histamine

The unwanted effects of histamine injections can be partially blocked by H_1 histamine receptor antagonists, which were once used to prevent systemic adverse effects of histamine when it was used to stimulate gastric acid secretion, which is mediated by H_2 receptors.

Meglumine

When diphenhydramine was mixed with meglumine iodipamide to prevent an allergic reaction to the latter, a precipitate was formed. These two drugs should be regarded as incompatible for in vitro mixing.

Pseudoephedrine

Combinations with decongestants such as pseudoephedrine have been advocated for upper respiratory conditions, but pseudoephedrine can cause additional adverse effects, such as nervousness and raised blood pressure (118,119).

Stimulants

To counteract the sedative effects of the classic antihistamines, combinations with stimulants, such as pemoline and prolintane, have been tried. The efficacy of such combinations has not been proven, but additional adverse effects such as irritability (120) and hallucinations (121) have been observed.

D-Tubocurarine chloride

Tubocurarine can cause release of histamine by direct mast cell degranulation which can result in systemic effects, such as cutaneous flushing, local wheal and flare formation, hypotension, and occasionally bronchospasm. Preoperative oral terfenadine 60 mg + ranitidine 150 mg attenuated the reduction in blood pressure but not cutaneous flushing after the administration of tubocurarine and morphine in 60 women undergoing elective gynaecological surgery in a placebo-controlled study (122).

Interference with Diagnostic Tests

Skin testing

Since antihistamines inhibit the cutaneous response to histamine and allergens, they should be withdrawn (usually for a week, astemizole for up to 8 weeks) before skin testing for allergy is undertaken.

Antimony and antimonials

General Information

Antimony is a brittle, bluish-white, metallic element (symbol Sb; atomic no 51). The symbol Sb comes from the Latin word stibium.

Antimony is found in such minerals as dyscrasite, jamesonite, kermesite, pyrargyrite, stephanite, tetrahedrite, and zinkenite.

The Arabic word for antimony stibnite or antimony trisulfate was kohl, from which the word alcohol ultimately derives (1). Antimonious ores were sometimes confused with lead ores, and alquifou was the name of a Cornish lead ore that looked like antimony and was used by potters to give a green glaze to earthenware. The word that the Quechua Indians of Peru use for antimony is surúcht, which gives soroche, a synonym for mountain sickness, which antimony was thought to cause.

Antimony salts have in the past found many uses in medicine, and antimony compounds, especially pentavalent ones, are still used to treat *Schistosoma japonicum* infestation and leishmaniasis (2). Antimony is also used as an emetic. Attention is being paid to the anticancer potential of antimony compounds (3,4). As with many other metals, occupational and environmental exposure is possible and can act additively with medical exposure.

Common adverse effects of antimony treatment include anorexia, nausea, vomiting, muscle ache, headache, lethargy, and bone and joint pain.

Antimony has been suggested to be a causal factor in sudden infant death syndrome, since fungal transformation of fire retardants containing antimony in cot mattresses will lead to the formation of stibine (SbH_3). However, the involvement of stibine in cot death is most unlikely (5,6).

Salts of antimony

Meglumine antimoniate

Meglumine antimoniate is a pentavalent antimonial chemically similar to sodium stibogluconate and is considered to have similar efficacy and toxicity. Meglutamine antimoniate solution contains pentavalent antimony 8.5% and stibogluconate 10%.

Sodium stibogluconate

Sodium stibogluconate is a pentavalent antimonial that contains pentavalent antimony 10%.

© 2006 Elsevier B.V. All rights reserved.

Stibocaptate

Stibocaptate is a trivalent antimony compound, whose toxic effects, especially its acute adverse effects, are similar to those of the pentavalent compounds.

Uses

Antimony salts have in the past found many uses in medicine, and antimony compounds, especially pentavalent ones, are still used to treat *Schistosoma japonicum* infestation and leishmaniasis (2). The standard treatment of most South American cutaneous leishmaniasis is systemic, because of the propensity of the parasites to spread to mucous membranes. The drugs in common use remain parenteral, and are fairly toxic. Sodium stibogluconate, in a dose of 20 mg/kg for 30 days, remains the gold standard, with liposomal amphotericin a possible alternative. Both drugs are also the preferred choice for all strains of visceral leishmaniasis. Stibogluconate achieves a cure in certain cases (7,8) and is reasonably safe, although transient pancreatitis, musculoskeletal pains, and loss of appetite have been reported. Primary unresponsiveness (cure not obtained by the first course of treatment) is being increasingly reported (9) and is a particular problem in the Bihar region of North-East India, where a report documented primary unresponsiveness in 33% of cases (10). The new treatment options for visceral leishmaniasis have been reviewed (11).

Antimony is also used as an emetic. Attention is being paid to the anticancer potential of antimony compounds (3,4). As with many other metals, occupational and environmental exposure is possible and can act additively with medical exposure.

Pharmacokinetics

Antimony is excreted in the urine. Peak concentrations are seen at about 1–2 hours after an intramuscular injection of meglumine antimonate. Serum concentrations fall to about 10% of peak concentrations after about 8 hours. There is some accumulation of antimony during continued treatment. On a weight for weight basis children require a higher dose and tolerate antimony better. Toxicity is more likely in patients with impaired renal function, as would be expected for a drug that is mainly excreted in the urine.

Observational studies

The characteristics of 111 consecutive patients with visceral leishmaniasis in Sicily have been described (12). They were given intramuscular meglumine antimoniate (560 mg/m^2 of pentavalent antimony), generally for 21 days. There were adverse effects in 16 patients, including rash ($n = 3$) and dry cough ($n = 13$). All the adverse effects bar one (a severe urticarial rash) were transient and self-limiting and did not require drug withdrawal.

Comparative studies

In a prospective, open trial, conventional treatment with sodium stibogluconate ($n = 69$) was compared with meglumine antimoniate ($n = 58$) for cutaneous *Leishmania braziliensis* (13). The trial was too small and of too short a duration to compare efficacy reliably, but significantly fewer patients on meglumine antimoniate developed the myalgia/arthralgia, headache, and abdominal pain that are the most common adverse effects of the drug, and that tend to increase as treatment continues. About 30% developed significant adverse effects early in treatment and 70% late when stibogluconate was used, whereas 12% had early and 45% late adverse effects for antimoniate. Unfortunately, QT intervals were not monitored; a fatal dysrhythmia, usually preceded by increased QT dispersion, is the complication of sodium stibogluconate therapy most likely to lead to death.

There has been a further comparison of meglumine antimoniate ($n = 47$) and sodium stibogluconate ($n = 64$) (14). The trial was too small to examine the efficacy of the two drugs, but there were more adverse events with sodium stibogluconate, with a greater proportion with raised transaminase and amylase activities. There were no differences in electrocardiographic abnormalities between the two groups.

Allopurinol

Allopurinol and meglumine antimoniate (Glucantime™) have been evaluated in a randomized, controlled trial in 150 patients with cutaneous leishmaniasis (15). They received oral allopurinol (15 mg/kg/day) for 3 weeks, or intramuscular meglumine antimoniate (30 mg/kg/day, corresponding to 8 mg/kg/day of pentavalent antimony, for 2 weeks), or combined therapy. There were a few adverse effects in those who used allopurinol: nausea, heartburn ($n = 3$), and mild increases in transaminases ($n = 2$). These symptoms subsided on drug withdrawal.

In an open study, 72 patients each received meglumine antimoniate (60 mg/kg/day) or allopurinol (20 mg/kg/day) plus low-dose meglumine antimoniate (30 mg/kg/day) for 20 days, and each was followed for 30 days after the end of treatment (16). Only six patients in the combined treatment group complained of mild abdominal pain and nausea; however, one patient who received meglumine antimoniate developed a skin eruption. Generalized muscle pain and weakness occurred in four patients.

Paromomycin

In patients with visceral leishmaniasis, paromomycin (12 or 18 mg/kg/d) plus a standard dose of sodium stibogluconate for 21 days was statistically more effective than sodium stibogluconate alone in producing a final cure (17). In an open, randomized comparison of sodium stibogluconate either alone ($n = 50$) or in combination with two regimens of paromomycin ($n = 52$ and $n = 48$), there was improved parasitological cure in both groups given combination therapy (18). There were no differences in adverse events or biochemical and hematological measurements between any of the treatment arms. There was one serious adverse event (myocarditis) in the sodium stibogluconate monotherapy group. It should be noted that there were insufficient auditory examinations performed to assess any ototoxic effects of paromomycin.

Placebo-controlled studies

A randomized, double-blind, placebo-controlled study of sodium stibogluconate for 10 and 20 days has been conducted in 38 US military personnel with cutaneous leishmaniasis; 19 received sodium stibogluconate for 10

© 2006 Elsevier B.V. All rights reserved.

days (and placebo for 10 days), and 19 received sodium stibogluconate for 20 days (19). Treatment withdrawal was necessary as a result of pancreatitis in seven patients (four in the 10-day treatment group and three in the 20-day group), and this occurred during the first 10 days of therapy in all seven patients. Myalgia occurred in 8 patients in the 10-day group and in 13 patients in the 20-day group. Patients in the 20-day group had myalgia on significantly more days than those in the 10-day group. Increases in amylase, lipase, and transaminases and falls in white blood cell count, hematocrit, and platelet count also differed significantly between the two groups.

General adverse effects

Common adverse effects of antimony treatment include anorexia, nausea, vomiting, muscle ache, headache, lethargy, and bone and joint pain.

Common adverse effects of meglumine antimonate are anorexia, nausea, vomiting, malaise, myalgia, headache, and lethargy. Muscle, bone, and joint pains have been described (SEDA-12, 710) (SEDA-13, 838) (20). Cardiac toxicity and electrocardiographic changes are dose-related. The general condition of the patient with visceral leishmaniasis probably plays a crucial role in these and other adverse effects. Malnutrition is common, the immune status often severely impaired, and patients are susceptible to intercurrent infections (SEDA-12, 710).

In 96 patients with visceral, mucosal, or viscerotropic leishmaniasis, who were given sodium stibogluconate 20 mg/kg/day for 20–28 days, adverse effects were common and necessitated withdrawal of treatment in 28% of cases. They included arthralgias and myalgias (58%), pancreatitis (97%), increased transaminases (67%), headache (22%), bone marrow suppression (44%), and rash (9%) (8). Arthralgias are more likely to represent reactions to the tissue of the dead or dying parasite than true allergies to the drug.

In 53 patients with dermal leishmaniasis after kala-azar, who were given sodium stibogluconate 20 mg/kg/day intramuscularly, adverse effects were changes in electrocardiographic ST segments and T waves (7%), arthralgias (11%), allergic rashes (7%), swelling at the site of injection (5%), neuralgia (4%), and a metallic taste (6%) (21).

Organs and Systems

Cardiovascular

Electrocardiographic changes are common in patients taking antimony salts; in one group there was an incidence of 7%. The most common changes are ST segment changes, T wave inversion, and a prolonged QT interval. The role of conduction disturbances in cases of cardiac failure and sudden death is not known. Cases of sudden death have been seen early in treatment after a second injection (SEDA-13, 838) (SEDA-16, 311).

Changes in the electrocardiogram depend on the cumulative dose of antimony, and sudden death can occur rarely (22).

- A 4-year-old boy with visceral leishmaniasis was given intravenous sodium stibogluconate 20 mg/kg/day (1200 mg/day) and oral allopurinol 16 mg/kg/day (100 mg tds). On day 3 he reported chest pain and a persistent cough. Electrocardiography was unremarkable. The drugs were withdrawn and 3 days later he developed a petechial rash on the legs. Sepsis and other causes of petechial rashes were ruled out. Three days after treatment was discontinued he developed ventricular fibrillation and died.

The authors suggested that patients taking antimony compounds should be observed cautiously for signs of cardiological and hematological changes.

Myocarditis with electrocardiographic changes has been well described, but the risk of dysrhythmias is usually small. There have been reports of severe cardiotoxicity, leading in some cases to death (23,24). This may largely be due to changes in physicochemical properties of the drug; one cluster of cases was associated with a high-osmolarity lot of sodium stibogluconate (23).

Because of concerns regarding the cardiac adverse effects of antimonials, it is good practice to admit patients for the duration of therapy whenever practicable. This may mean admitting otherwise fit young patients for several weeks for treatment of a non-healing ulcer. To address the safety of outpatient management, a recent small study of 13 marines in the UK showed that they could be safely managed as outpatients with daily stibogluconate injections, provided there was close monitoring of electrocardiograms and blood tests to provide early warning of bone marrow toxicity (25). Three patients developed minor electrocardiographic changes and one developed thrombocytopenia. All these adverse effects resolved when treatment was withdrawn. Patients with a predisposition to dysrhythmias (such as some with ischemic heart disease) are best treated with pentavalent antimonials as inpatients to identify and manage adverse effects early when resources allow.

The cardiac toxicity of antimony has been explored in cultured myocytes (26,27). Potassium antimony tartrate disrupted calcium handling, leading to a progressive increase in the resting or diastolic internal calcium concentration and eventual cessation of beating activity and cell death. An interaction with thiol homeostasis is also involved. Reduced cellular ATP concentrations paralleled toxicity but appeared to be secondary to other cellular changes initiated by exposure to antimony.

Even the normal dose of sodium stibogluconate can lead to both cardiotoxicity and hemotoxicity, because of its cumulative effects.

- Fatal accumulation of sodium stibogluconate occurred in a 4-year-old boy with visceral leishmaniasis treated with intravenous sodium stibogluconate 20 mg/kg (1200 mg/day) and oral allopurinol 16 mg/kg/day (100 mg tds) (22). On day 3 he reported chest pain and persistent cough, and the drugs were withdrawn. Three days later he developed a petechial rash on the legs and died with ventricular fibrillation.

Respiratory

Antimonate ore caused chronic bronchitis in 16 of 100 miners exposed (28). The chronic bronchitis was

© 2006 Elsevier B.V. All rights reserved.

characterized by a mild slow course with ventilation disturbances. There were no cases of pneumoconiosis.

Nervous system

Headaches are common during treatment with antimony. Generalized neuralgia was reported in one study, with an incidence of 4% (SEDA-13, 838) (SEDA-16, 311).

Peripheral sensory neuropathy has been described after the use of sodium stibogluconate for cutaneous leishmaniasis (SEDA-21, 300).

Sensory systems

A metallic taste due to antimonials is uncommon but probably under-reported (SEDA-16, 311).

Hematologic

Autoimmune hemolytic anemia has been described with meglumine antimoniate (29).

Thrombocytopenia has been reported in a patient with *Leishmania donovani* infection and AIDS after stibogluconate therapy for 7 days (SEDA-13, 838). There have been two further reports, one involving a patient with cutaneous leishmaniasis (occurring after 19 days of treatment), the second a man with kala-azar (who became thombocytopenic 11 days after starting therapy); in kala-azar a low platelet count is common and the count normally rises with treatment (SEDA-18, 294).

Gastrointestinal

Anorexia, nausea, and vomiting are common with antimonials (30).

Liver

Hepatotoxicity has been described, but the disease itself may play an overriding role. In 16 patients with mucosal leishmaniasis treated with meglumine antimoniate 20 mg/kg intravenously for 28 days, there were raised liver enzyme in conjunction with electrocardiographic abnormalities and/or musculoskeletal complaints in three subjects (SEDA-16, 311).

Pancreas

Pancreatitis has occasionally been reported with antimonials. In 1993, four cases were described in three reports; two of the patients were immunocompromised. One was asymptomatic, while the other three complained of abdominal pain. Rechallenge with half of the standard dose was carried out in one case and resulted in a renewed increase of serum amylase activity.

Acute pancreatitis developed during treatment with meglumine antimoniate for visceral leishmaniasis in a young boy (31).

- A 2-year-old boy with a history of intermittent high-grade fever, sweating, and abdominal distension developed visceral leishmaniasis. He was given meglumine antimoniate (Glucantime®, Rhone Poulenc, France) 5 mg/kg/day, and the dose was doubled every other day to reach 20 mg/kg/day. Two days after he had reached the full dose, his temperature returned to normal, his general condition improved, and his liver and spleen began to shrink. However, the serum amylase increased to 254 U/l. Because he was asymptomatic, treatment with meglumine antimoniate was continued. However, on day 10 he complained of vomiting and abdominal pain with rebound tenderness. Acute pancreatitis was confirmed by serum amylase and lipase values up to 1557 and 320 U/l respectively and by ultrasound findings of dilatation and edema of the pancreatic ducts. Meglumine antimoniate was withdrawn and the pancreatitis was managed conservatively. Two days later his fever increased and the spleen and liver began to enlarge. He was given allopurinol (20 mg/kg/day) and ketoconazole (5 mg/kg/day) and became afebrile; the spleen and liver began to shrink, his pancytopenia improved, and the albumin:globulin ratio and serum amylase and lipase activities returned to normal. The acute pancreatitis resolved uneventfully.

The mechanism and frequency of this adverse effect are unknown. It has been suggested that immunocompromised patients may be at a higher risk (SEDA-18, 294), but pancreatitis is in any case seen more often in patients with AIDS, irrespective of drug treatment.

Urinary tract

- Septic shock with oliguria developed soon after the first intramuscular administration of meglumine antimoniate 20 mg/kg (equivalent to 510 mg of antimony) to a patient with visceral leishmaniasis and normal renal function (32). Creatinine clearance fell to 23 ml/min. Treatment was withdrawn, and antimony urinary excretion was measured. After the initial dose, 500 mg of antimony was recovered in the urine over 8 days (98% of the dose); 66% was eliminated within the first 48 hours. Nine days after the dose, meglumine antimoniate was reintroduced in a dosage of 11.7 mg/kg (equivalent to 300 mg of antimony) every 48 hours, with good tolerance. At that time creatinine clearance had returned to 88 ml/min. By day 14 of therapy the dosage interval was reduced to 24 hours and from day 17 to day 31 the dosage was increased to 16.6 mg/kg/day (equivalent to 425 mg of antimony). The patient eventually completely recovered, with normal renal function. Although there are no specific guidelines for dosage adjustment in renal insufficiency, monitoring antimony urinary excretion indicates that the kidneys are the almost exclusive route of elimination.

Musculoskeletal

Arthralgia is a common complaint during treatment with pentavalent antimonials and is usually dose-related (30). Muscle pain and bone pain have also been described.

- A palindromic arthropathy with effusion and pancreatitis occurred in association with stibogluconate treatment for kala-azar in a 30-year-old man on hemodialysis for chronic renal insufficiency (SEDA-16, 311).

Immunologic

As an industrial and environmental toxin, antimony trioxide can cause disturbances of immune homeostasis.

© 2006 Elsevier B.V. All rights reserved.

Workers in antimony trioxide manufacture had reduced serum concentrations of cytokines (interleukin 2, gamma interferon) and immunoglobulin (IgG1, IgE) (33).

Death

Antimony has been suggested to be a causal factor in sudden infant death syndrome, since fungal transformation of fire retardants containing antimony in cot mattresses will lead to the formation of stibine (SbH_3). However, the involvement of stibine in cot death is most unlikely (5,6).

Sudden death has been reported during the use of stibocaptate (SEDA-11, 599) (34).

Long-Term Effects

Drug tolerance

The treatment of cutaneous leishmaniasis has been reviewed, including the use of pentavalent antimonials (35). Antimony-resistant strains continue to emerge (36), leading to the use of higher dosages of antimonials or combinations of antimonials with other compounds, such as paromomycin or gamma interferon (37).

Drug–Drug Interactions

Amiodarone

A pharmacodynamic interaction has been described between amiodarone and meglumine antimoniate, both of which prolong the QT interval; the interaction resulted in torsade de pointes (38).

- A 73-year-old man with visceral leishmaniasis was given meglumine antimoniate intramuscularly 75 mg/kg/day. At that time his QT_c interval was normal at 0.42 seconds. Three weeks later his QT_c interval was prolonged to 0.64 seconds and he was given metildigoxin 0.4 mg and amiodarone 450 mg intravenously over 8.25 hours; 12 hours later he had a cardiac arrest with torsade de pointes, which was cardioverted by two direct shocks of 300 J and lidocaine 100 mg in two bolus injections. Because he had frequent episodes of paroxysmal atrial fibrillation, he was given amiodarone 100 mg over the next 40 hours, and developed recurrent self-limiting episodes of torsade de pointes associated with QT_c interval prolongation, which responded to intravenous magnesium 1500 mg. After withdrawal of amiodarone there was no recurrence and a week later the QT_c interval was 0.48 seconds. The plasma potassium concentration was not abnormal in this case.

In view of this report it is probably wise to avoid co-administration of antimonials and amiodarone.

Amphotericin

Amphotericin can worsen stibogluconate-induced cardiotoxicity; a gap of at least 10 days between sodium stibogluconate and amphotericin is recommended (24).

Antituberculosis drugs

See also Individual agents

General Information

Antituberculosis drugs are classified as first-line and second-line.

First-line drugs

- ethambutol
- isoniazid
- pyrazinamide
- rifampicin
- streptomycin

Second-line drugs

- capreomycin
- clofazimine
- cycloserine
- ethionamide and propionamide
- fluoroquinolones
- kanamycin
- *para*-aminosalicylic acid
- rifabutin
- thiacetazone

As a rule, a regimen of two, three, or four of the five first-line antituberculosis drugs (isoniazid, rifampicin, pyrazinamide, ethambutol, and streptomycin) is used in tuberculosis (1). The 6-month short-course regimen consists of isoniazid, rifampicin, and pyrazinamide for 2 months, followed by isoniazid and rifampicin for 4 months (1). It may be advisable to include ethambutol in the initial phase when isoniazid resistance is suspected or if the prevalence of primary resistance to isoniazid is over 4% in new cases. A 9-month regimen consisting of isoniazid and rifampicin is also highly successful (1). Treatment should always include at least two drugs to which the mycobacteria are susceptible.

© 2006 Elsevier B.V. All rights reserved.

Careful monitoring and the addition of pyridoxine to isoniazid have reduced the number of adverse drug effects in tuberculosis. Awareness of potentially severe hepatotoxic reactions is vital, because hepatic failure may be a devastating and often fatal condition. Fulminant hepatic failure caused by rifampicin, isoniazid, or both has been described (2).

Treatment problems that can arise are mainly of two types: adverse reactions (collateral, toxic, or hypersusceptibility reactions), and initial or acquired resistance of *Mycobacterium tuberculosis*, *Mycobacterium bovis*, or non-tuberculous mycobacteria to one or more of the antituberculosis drugs. The latter probably only occurs when the patient has not taken the full combination or the full doses of the drugs all the time. Combination formulations are thus particularly useful. Multidrug-resistant tuberculosis, defined as resistance against at least isoniazid and rifampicin, is the most clinically relevant form of resistance to treatment worldwide.

Observational studies

An increasing number of patients with multidrug-resistant tuberculosis are being treated with second-line drugs worldwide, often in places with poor resources. The number of drugs used is large (4–7) and treatment is prolonged (1–2 years). There is justifiable concern over patients' tolerance of such regimens and their adverse effects, which determine adherence to treatment. Treatment has to be individualized according to the WHO guidelines for a DOTS-plus strategy.

It is therefore encouraging to read a report from Lima, Peru, where 60 patients from a shanty town tolerated a median of eight antituberculosis drugs fairly well for a median duration of 20 months (3). All received a parenteral aminoglycoside daily for 6 months, cycloserine, and a fluoroquinolone, and most also took *para*-aminosalicylic acid and ethionamide. Of 60 patients, 23 took clofazimine, 23 pyrazinamide, 25 isoniazid, and 3 rifampicin. Commonly encountered adverse effects included dermatological effects, including bronzing of the skin (many of these patients were taking clofazimine and fluoroquinolones), depression, anxiety, and peripheral neuropathy. All complained of mild gastritis. There were no cases of serious hepatic or renal toxicity. This may have been because only a few patients took rifampicin. Absence of eighth nerve toxicity was striking, and can be attributed to close monitoring of patients by physicians with experience of DOTS-plus regimens.

In a similar report from Turkey, adverse reactions to drugs led to withdrawal of one or more drugs in 62 of 158 patients (39%) (4). Outcomes were favorable and cultures became negative in 95% of the patients within 2 months.

General adverse reactions

Adverse reactions are often due to the combined effects of two or more drugs used simultaneously (5). Hypersusceptibility reactions can occur even to more than one agent. The incidence of adverse reactions to drugs used in the treatment of tuberculosis is higher in elderly patients, who are more likely to have intercurrent illnesses and a lower lean body mass than younger patients. In two studies from Hong Kong in patients being treated for tuberculosis with rifampicin, the incidence of adverse reactions was higher with regimens containing rifampicin; furthermore, patients taking rifampicin had a higher steady-state plasma concentration of isoniazid (1,6).

Some simple rules about which drugs are more likely to cause which reactions reflect the principle that the most probable causative agent (or agents) must be stopped.

Nervous and sensory systems

Ethambutol is the most likely drug to cause visual disturbances. Isoniazid is associated with polyneuritis and reactions of the central nervous system. Streptomycin can cause eighth nerve toxicity.

Liver

Hepatotoxicity is consistently the most common serious adverse reaction in patients taking antituberculosis drugs. Hepatic necrosis is the most important adverse effect of first-line antituberculosis drug therapy (2). Asymptomatic rises in transaminases are common and are not by themselves justification for withdrawing medication, since they settle spontaneously in most patients while treatment continues. All patients taking antituberculosis drugs should be told to report all new illnesses, especially when associated with vomiting. Hepatitis B carriers were no more likely to react adversely to antituberculosis drugs than non-carriers (7).

If liver damage occurs, isoniazid is probably an important factor and it should be stopped before rifampicin or pyrazinamide (8). Prediction of hepatotoxicity is possible (9). In a case-control study of 60 patients in India, conducted in order to identify features predicting hepatotoxicity, the body mass index was significantly lower (17.2 kg/m^2) in patients who experienced hepatotoxicity than in controls (19.5 kg/m^2) (10).

Urinary tract

In cases of renal insufficiency, streptomycin and ethambutol or second-line antituberculosis drugs with renal toxicity should be immediately withdrawn.

Skin

Adverse reactions to all types of medication are more common in HIV-positive individuals; skin reactions are especially frequent and often severe. Thiacetazone is well recognized as a cause of severe reactions, some of them fatal, but even in combination antituberculosis drug regimens that exclude thiacetazone, the incidence of adverse skin reactions is much higher in HIV-positive than HIV-negative patients: 23% against 1% in one study from Cameroon (11).

Immunologic

In allergic reactions, the drug most probably responsible can be difficult to identify, since the same kind of reaction can occur independently of the chemical nature of the drug. For evaluation of allergic drug reactions, the analysis of time relations (duration of exposure, reaction time, drug-free interval before re-exposure) is extremely

© 2006 Elsevier B.V. All rights reserved.

important. Particularly in allergic reactions to rifampicin, intermittent treatment or re-exposure after a drug free-interval favors sensitization and occurrence. Depending on the severity of the adverse effects, one, two, or all drugs must be stopped until the adverse reaction has completely disappeared. The use of second-line antituberculosis drugs may sometimes be necessary. In patients with drug fever or common rashes, specific desensitization may be attempted, at least with isoniazid (12). In more severe reactions, with anaphylactic shock, agranulocytosis, thrombocytopenia, toxic epidermal necrolysis, or Stevens–Johnson syndrome, specific desensitization should not be considered and the drug should be discarded from the combination.

Organs and Systems

Liver

Hepatotoxicity is the most important adverse effect of antituberculosis drug therapy. Isoniazid, rifampicin, and pyrazinamide are the main culprits. There is wide variability in the risk of hepatotoxic reactions reported from different parts of the world or in different populations (for example African-American women in the postpartum period) (SEDA-24, 353).

Risks

The risks of hepatotoxicity differ with different antituberculosis drug combinations.

Rifampicin plus isoniazid

There are mild to moderate increases in liver transaminases during treatment with rifampicin plus isoniazid in most patients. However, biochemical hepatitis is diagnosed when transaminase activities increase to more than four times the upper limit of the reference ranges on two occasions at least 1 week apart, or more than five times on any single occasion. This calls for withdrawal of all potentially hepatotoxic drugs (rifampicin, isoniazid, and pyrazinamide) until the enzymes return to the reference ranges. During this period, streptomycin plus ethambutol, with or without cycloserine and a fluoroquinolone, is recommended in seriously ill patients.

Hepatotoxicity is generally considered to be rare among children who receive antituberculosis drugs. However, a report from Japan has suggested that this might not be the case, at least in Asia (13). The authors noted high activities of transaminases, more than five times the upper end of the reference range, in eight of 99 children aged 0–16 years who received various combinations of drugs, including rifampicin and isoniazid; 18 children were excluded because of baseline abnormalities in liver function. Age under 5 years and pyrazinamide in the drug regimen were risk factors for hepatotoxicity. There have been few other reports of the risk of hepatotoxicity in children.

Pyrazinamide plus rifampicin

There is continuing concern about the hepatotoxicity of the combination of pyrazinamide with rifampicin for the treatment of latent pulmonary tuberculosis. Among 148 who were given the combination for 2 months, grade 3 hepatotoxicity (transaminases more than 5–20 times the upper limit of the reference range) and grade 4 hepatotoxicity (transaminases more than 20 times the upper limit of the reference range) were reported in 10 and four patients respectively (14). The risk of hepatotoxicity was associated with female sex (OR = 4.1; 95% CI = 1.2, 14) and presumed recent infection (OR = 14.3; 95% CI = 1.8, 115). The investigators recommended caution in using the combination of pyrazinamide with rifampicin in populations in whom its safety has not been established.

Others consider that this combination is useful for high-risk, traditionally non-adherent patients, such as alcoholics and the homeless, but have also emphasized the need for careful monitoring for toxicity (15). This suggestion is based on the presumption that the combination regimen, although toxic, is more likely to be completed by high-risk patients than 6 months of isoniazid alone. However, others observed similar completion rates for the two regimens in a multicenter study (61% and 57%) (16), and the safety and cost-effectiveness of this combination in the treatment of latent tuberculosis has been questioned (17).

Two cases of severe and fatal hepatitis have been reported to the CDC from New York and Georgia among patients taking rifampicin and pyrazinamide for latent tuberculosis (18). Between February and August 2001, another 21 patients had severe hepatotoxicity following treatment with rifampicin plus pyrazinamide for 2 months for latent tuberculosis, as reported to the CDC; five died of fulminant hepatic failure, two of whom had recovered from isoniazid-induced hepatitis (19). This report led to revision of previous guidelines of the American Thoracic Society. According to the revised guidelines, isoniazid for 9 months is the preferred treatment for latent tuberculosis infection in HIV-negative subjects, followed by isoniazid for 6 months or rifampicin for 4 months. Rifampicin plus pyrazinamide for 2 months can be used with caution in these patients, especially if they are taking other medications that are associated with liver injury, and those who drink a lot of alcohol. This combination is not recommended for those with underlying liver disease or who have had isoniazid-associated liver damage. Liver function tests should be measured at baseline and at 2-weekly intervals thereafter for 6 weeks. Only two non-fatal cases of severe liver injury have been reported to the CDC since the publication of revised guidelines as of November 2002 (20).

Susceptibility factors

Acetylator status and other genetic factors, old age, pre-existing hepatic dysfunction, alcoholism, co-infection with hepatitis virus, and malnutrition are important potential susceptibility factors for the development of liver damage in patients taking antituberculosis drugs (21), but there have been inconsistent findings with regard to some of these risk factors in different studies.

Genetic factors

The issue of hepatic dysfunction and acetylator status during treatment with isoniazid plus rifampicin has been re-examined in 77 Japanese patients with pulmonary

© 2006 Elsevier B.V. All rights reserved.

tuberculosis (22). There was a marked increase in the risk of hepatotoxicity amongst slow acetylator NAT2* genotypes (a combination of mutant alleles) compared with the rapid acetylator genotype (homozygous NAT2*4). Using Taylor's series analysis it can be calculated that the relative risk was 28 (95% CI = 4.1, 192). Despite a small sample size (seven slow acetylator genotypes, 42 intermediate, and 28 rapid) the relative risk was highly significant, which is not surprising if all seven of the slow acetylators and only one of the 28 rapid acetylators developed hepatotoxicity.

A unique feature of this study was the determination of acetylator status by genotyping rather than phenotyping. There is generally good concordance between the two methods, but in the presence of hepatic dysfunction the phenotype assessment may not reflect the genotype. Furthermore, 42 of the 77 patients were assigned to the intermediate acetylator genotype, based on heterozygosity for NAT2*4 and a mutant allele. However, phenotyping by estimation of concentrations of metabolites of the commonly used probes does not consistently result in identification of intermediate acetylators. The Japanese are mostly fast acetylators (~90%) compared with Caucasians or Indians (40–50%). It is unlikely, however, that the observed association between slow acetylator genotype and the high risk of hepatic dysfunction was affected by any of these considerations. The dose of isoniazid was rather large (~8 mg/kg/day) and this may have increased the risk of hepatotoxicity. Furthermore, hepatotoxicity was defined as an increase in transaminases to one and a half times the top of the reference range. This degree of hepatic dysfunction is not uncommon in patients taking antituberculosis drugs, and is no indication for withdrawal or modification of treatment. It is not possible to assess the risk of severe hepatotoxicity during treatment, owing to lack of detailed information in the published report.

A case-control study has suggested that there is also an increased risk of antituberculosis drug-induced hepatotoxicity in individuals with a glutathione-*S*-transferase M1 "null" mutation (23). Reduced glutathione transferase activity could theoretically predispose individuals to adverse effects of toxic metabolites and xenobiotics. These observations need to be confirmed.

Old age

Old age and the presence of hepatic dysfunction on baseline evaluation are the most consistent predictors of hepatotoxicity during antituberculosis therapy. The association between hepatotoxicity and hepatitis C virus and HIV seropositivity has been reviewed (SEDA-23, 324). A report from Hong Kong has suggested that the risk is much greater in hepatitis B virus carriers taking antituberculosis drugs (24). Even after excluding patients who had raised baseline alanine transaminase activity or with HbeAg seroconversion during the phase of hepatic dysfunction, the risk of hepatotoxicity was still significantly higher in hepatitis B carriers taking antituberculosis drugs compared with non-carriers (26% versus 8.8%). These observations are of considerable importance in regions of the world in which the prevalence of hepatitis B infection as well as tuberculosis is high, such as South-East Asia and sub-Saharan Africa.

Liver transplantation

Enhanced hepatotoxicity of conventional antituberculosis regimens has been reported in recipients of orthotopic liver transplants, which is not unexpected, because of bouts of organ rejection (25). The authors recommended ofloxacin for these patients on the basis of favorable outcome in six cases. A conventional antituberculosis induction regimen was used initially until hepatotoxicity developed in all six patients. Thereafter they were treated with a combination of ofloxacin and ethambutol, with apparent cure in all. It should be noted that most of the patients took isoniazid + rifampicin for almost 2 months, which is the usual period when hepatotoxic reactions occur. Perhaps one should evaluate substitution of rifampicin with ofloxacin from the very beginning in order to minimize hepatotoxicity, as well as interference with ciclosporin leading to graft rejection noted in an earlier study (26).

Prevention

One of the most important predictors of hepatotoxicity during antituberculosis drug therapy is an abnormal liver function test at baseline. It is reasonable to avoid potentially hepatotoxic drugs in the management of patients with pre-existing liver disease.

The use of ofloxacin instead of rifampicin in antituberculosis drug regimens for patients with underlying chronic liver disease has been reported to be associated with a significantly lower risk of hepatotoxicity (27). Similar observations have been reported among carriers of hepatitis B and liver transplant recipients by other investigators.

Management

There are four issues related to the management of patients who develop hepatotoxicity during treatment with antituberculosis drugs:

1. whatthe preferred treatment regimen should be for patients with significantly abnormal liver functions at baseline;
2. when treatment should be stopped/modified if hepatic dysfunction develops;
3. what antituberculosis treatment, if any, should be used until liver function improves;
4. what a safe regimen is for re-treatment of these patients.

Several herbal products have been claimed to mitigate drug-induced hepatitis caused by antituberculosis agents. However, few of them have undergone rigorous randomized controlled trials.

- Glycyrrhizin is widely used in Japan for the treatment of chronic hepatitis, but in a non-randomized trial in 24 patients who developed drug-induced hepatitis while undergoing antituberculosis chemotherapy, there was no difference in the time required for recovery between the patients who were treated with or without intravenous glycyrrhizin 40 ml/day (28).
- *Moringa oleifera*, commonly known as "drumstick," has been mentioned in the treatment of various illnesses in Indian folk medicine, and an ethanolic extract of the

© 2006 Elsevier B.V. All rights reserved.

leaves had a hepatoprotective effect in a rat model of antituberculosis drug-induced liver injury (29).
- Russian investigators have reported a hepatoprotective effect of a plant product "Galstena" in a rat model and have extended their observations to a clinical trial, with favorable results; however, few data were given in this report (30).

It cannot be denied that there is a need for continuing research in this area, but it is necessary to undertake well-conducted scientific studies before claims of hepatoprotective effects of herbal products can be accepted.

There is a lack of consensus on the best re-treatment protocol for patients who develop hepatotoxicity during treatment with standard antituberculosis agents. Investigators from Turkey have reported a high risk of recurrence of hepatitis (in six of 25 patients) on re-introduction of all drugs in full doses after recovery from hepatitis (31). This risk was less when rifampicin and isoniazid were re-introduced sequentially in increasing doses and when pyrazinamide was replaced by streptomycin.

Long-Term Effects

Drug tolerance

Primary and secondary bacterial resistance to antituberculosis drugs represents a major problem. This can be demonstrated by resistance tests, if available. When testing is not done, primary or secondary resistance can only be suspected when drug treatment fails. The incidence of bacterial resistance varies enormously from country to country and from population to population. In Tanzania (32), where the WHO and the International Union Against Tuberculosis and Lung Diseases (IUATLD) has developed antituberculosis programs, primary resistance to isoniazid and/or streptomycin is found in 10% of cases (33). In contrast, South-East Asian and African patients harbor resistant bacteria markedly more often (SED-10, 572); resistance tests therefore remain mandatory for good epidemiological and therapeutic control. Recent reports from the WHO drug resistance surveillance network have allowed an overview of the current situation worldwide and facilitate the choice of medication according to the origin of the patients (34).

Multidrug-resistant tuberculosis generally results from inadequate therapy or lack of compliance with therapy. A strain of mycobacteria is called resistant when it is insensitive to one of the first-line drugs. It is called multiresistant when it is insensitive to both isoniazid and rifampicin. In this case other antituberculosis drugs may also be ineffective (35). In practice, at least two second-line antituberculosis drugs, selected on the basis of individual drug susceptibility, are given in combination with a fluoroquinolone (36).

Drug malabsorption may contribute to the emergence of acquired drug resistance. It has been described in HIV-infected patients with advanced disease (37), and also in immunocompetent patients (38). Thus, in addition to the use of directly observed therapy to ensure compliance, it is advisable to monitor antimycobacterial drug concentrations routinely in such patients. Practical proposals for the choice of antituberculosis drugs in special circumstances, including drug resistance, have been made (39).

Susceptibility Factors

Age

Increasing age predisposes to hepatotoxicity from antituberculosis drugs. Workers from Florida have reported a five-fold increase in the likelihood of drug-induced hepatotoxicity in patients who are hepatitis C-positive and a four-fold increase in patients who are HIV-positive, compared with seronegative patients treated for tuberculosis (40). In all, 134 patients taking antituberculosis drugs were monitored for drug-induced hepatotoxicity, defined as an increase in aspartate transaminase and/or alanine transaminase activity from normal to at least three times normal and/or an increase in bilirubin above normal. Of the 22 patients who developed drug-induced hepatotoxicity, only six developed drug-induced hepatotoxicity on re-introduction of treatment after an interval in which the abnormalities had resolved. Four of the six had liver biopsies, which showed active inflammation, attributed (at least in part) to hepatitis C. These were then treated with interferon alfa, with improvement of liver chemistry. On improvement, antituberculosis drug therapy was successfully re-introduced in the form of isoniazid and rifabutin, the latter being considered to be less hepatotoxic than rifampicin.

Antrafenine

See also Non-steroidal anti-inflammatory drugs

General Information

Antrafenine closely resembles glafenine and floctafenine (SED-9, 153) (SEDA-7, 116) (SEDA-11, 96) (1). The same adverse effects must be expected and some have been described, for example nephrotoxicity (SEDA-4, 69) (2). Gastrotoxicity is claimed to be less than with aspirin (3), again no doubt merely because it is a weak anti-inflammatory drug.

© 2006 Elsevier B.V. All rights reserved.

Apiaceae

See also Herbal medicines

General Information

The genera in the family of Apiaceae (formerly Umbelliferae) (Table 1) include a variety of spices and vegetables, such as angelica, anise, carrot, celery, chervil, coriander, cumin, dill, fennel, parsley, and parsnip.

Food allergy to spices accounts for 2% of all cases of food allergies but 6.4% of cases in adults. Prick tests to native spices in 589 patients with food allergies showed frequent sensitization to the Apiaceae coriander, caraway, fennel, and celery (32% of prick tests in children, 23% of prick tests in adults) (1). There were 10 cases of allergy related to the mugwort-celery-spices syndrome: coriander ($n = 1$), caraway ($n = 2$), fennel ($n = 3$), garlic ($n = 3$), and onion ($n = 1$).

Scratch tests with powdered commercial spices in 70 patients with positive skin tests to birch and/or mugwort pollens and celery were positive to aniseed, fennel, coriander, and cumin, all Apiaceae, in more than 24 patients (2). Spices from unrelated families (red pepper, white pepper, ginger, nutmeg, cinnamon) elicited positive immediate skin test reactions in only three of 11 patients. Specific serum IgE to spices (determined in 41 patients with a positive RAST to celery) up to class 3 was found, especially in patients with celery-mugwort or celery-birch-mugwort association. The celery-birch association pattern was linked to positive reactions (RAST classes 1,2) with spices from the Apiaceae family only.

Ammi majus and *Ammi visnaga*

Ammi majus is also known as bishop's weed or large bullwort, and *Ammi visnaga* as toothpick weed. They have numerous active ingredients, including ammirin, angenomalin, kellactone, majurin, and marmesin, furanocoumarins (psoralen, bergapten, isopimpinellin, imperatorin, umbelliprenin, xanthotoxin), and flavonol triglycosides (kaempferol, isorhamnetin). In modern times they have been used to treat vitiligo, since they contain psoralens, and have several different pharmacological effects in experimental animals, including hypoglycemic effects (3), antischistosomal effects (4), and inhibition of nephrolithiasis (5).

Table 1 The genera of Apiaceae

Aciphylla (fierce Spaniard)	*Levisticum* (levisticum)
Aegopodium (goutweed)	*Ligusticum* (licorice-root)
Aethusa (aethusa)	*Lilaeopsis* (grasswort)
Aletes (Indian parsley)	*Limnosciadium* (dogshade)
Ammi (ammi)	*Lomatium* (desert parsley)
Ammoselinum (sand parsley)	*Musineon* (wild parsley)
Anethum (dill)	*Myrrhis* (myrrhis)
Angelica (angelica)	*Neoparrya* (neoparrya)
Anthriscus (chervil)	*Oenanthe* (water dropwort)
Apiastrum (apiastrum)	*Oreonana* (mountain parsley)
Apium (celery)	*Oreoxis* (oreoxis)
Arracacia (arracacia)	*Orogenia* (Indian potato)
Berula (water parsnip)	*Osmorhiza* (sweetroot)
Bifora (bishop)	*Oxypolis* (cowbane)
Bowlesia (bowlesia)	*Pastinaca* (parsnip)
Bupleurum (bupleurum)	*Perideridia* (yampah)
Carum (carum)	*Petroselinum* (parsley)
Caucalis (burr parsley)	*Peucedanum* (peucedanum)
Centella (centella)	*Pimpinella* (burnet saxifrage)
Chaerophyllum (chervil)	*Podistera* (podistera)
Cicuta (water hemlock)	*Polytaenia* (hairy moss)
Cnidium (snow parsley)	*Pseudocymopterus* (false spring parsley)
Conioselinum (hemlock parsley)	*Pteryxia* (wavewing)
Conium (poison hemlock)	*Ptilimnium* (mock bishop weed)
Coriandrum (coriander)	*Sanicula* (sanicle)
Cryptotaenia (honewort)	*Scandix* (scandix)
Cuminum (cumin)	*Selinum* (selinum)
Cyclospermum (marsh parsley)	*Seseli* (seseli)
Cymopterus (spring parsley)	*Shoshonea* (shoshonea)
Cynosciadium (cynosciadium)	*Sium* (waterparsnip)
Daucosma (daucosma)	*Smyrnium* (smyrnium)
Daucus (wild carrot)	*Spermolepis* (scaleseed)
Dorema (dorema)	*Sphenosciadium* (sphenosciadium)
Erigenia (erigenia)	*Taenidia* (taenidia)
Eryngium (eryngo)	*Tauschia* (umbrellawort)
Eurytaenia (spreadwing)	*Thaspium* (meadowparsnip)
Falcaria (falcaria)	*Tilingia* (tilingia)
Ferula (asafetida)	*Tordylium* (tordylium)
Foeniculum (fennel)	*Torilis* (hedge parsley)
Glehnia (silvertop)	*Trachyspermum* (Ajowan caraway)
Harbouria (harbouria)	*Trepocarpus* (trepocarpus)
Heracleum (cow parsnip)	*Turgenia* (false carrot)
Hydrocotyle (hydrocotyle)	*Yabea* (yabea)
	Zizia (zizia)

Adverse effects

Injudicious use of the fruit of *A. majus* in combination with skin exposure to the sun can cause severe phototoxic dermatitis, owing to the presence of psoralens (6).

- IgE-mediated rhinitis and contact urticaria were caused by exposure to bishop's weed in a 31-year-old atopic female florist (7). A skin prick test with bishop's weed flowers gave an 8 mm wheal, and the bishop's weed-specific serum IgE concentration was 9.7 PRU/ml (RAST class 3).

Prolonged use or overdosing of the fruit of *A. visnaga* can cause nausea, dizziness, constipation, loss of appetite, headache, pruritus, and sleeping disorders.

Angelica sinensis

Angelica sinensis, known in China as "dong quai" or "dang gui," contains antioxidants (8), inhibits the growth of cancer cells in vitro (9) and stimulates immune function in experimental animals (10). It has been used to treat amenorrhea (11) and menopausal hot flushes (12), and to reduce pulmonary hypertension in patients with chronic obstructive pulmonary disease (13).

Adverse effects

Angelica sinensis can cause hypertension (14).

- A 32-year-old woman, 3 weeks post-partum, developed acute headache, weakness, light-headedness, and vomiting. Her blood pressure was 195/85 mmHg. She had taken dong quai for postpartum weakness and said that she had not been taking any other medicines. Her 3-week-old son's blood pressure was raised to 115/69. Dong quai medication of the mother and breast-feeding of the child were discontinued and the blood pressure normalized in both patients within 48 hours.

Conium maculatum

Conium maculatum (hemlock) contains the poisonous piperidine alkaloid, coniine, and related alkaloids, *N*-methyl-coniine, conhydrine, pseudoconhydrine, and gamma-coniceine. It has well-established teratogenic activity in certain animal species.

Adverse effects

The symptoms of hemlock poisoning are effects on the nervous system (stimulation followed by paralysis of motor nerve endings and nervous system stimulation and later depression), vomiting, trembling, difficulty in movement, an initially slow and weak and later a rapid pulse, rapid respiration, salivation, urination, nausea, convulsions, coma, and death (15).

Coriandrum sativum

Coriandrum sativum (coriander) has traditionally been used as a stimulant, aromatic, and carminative, and to disguise the taste of purgatives. In experimental animals it has hypolipidemic effects (16) and hypoglycemic effects (17).

Adverse effects

Respiratory

Occupational asthma has been attributed to various spices from botanically unrelated species, including coriander.

- A 27-year-old man developed rhinitis and asthma symptoms 1 year after starting to prepare a certain kind of sausage (18). He had positive immediate skin prick tests with paprika, coriander, and mace, and specific IgE antibodies to all three. He had immediate asthmatic reactions to bronchial inhalation of extracts from paprika, coriander, and mace, with maximum falls in FEV_1 of 26, 40, and 31% respectively, but no late asthmatic reactions.

Endocrine

Adrenal insufficiency has been attributed to *C. sativum* (19).

- A 28-year-old woman took an extract of *C. sativum* for 7 days to augment lactation while breastfeeding. She developed severe stomach pain and diarrhea and 15 days later resented with dark skin, depression, dehydration, and amenorrhea. A diagnosis of adrenal dysfunction was made, the herbal remedy was withdrawn, and she was treated with dexamethasone, prednisolone, and an oral contraceptive. Her symptoms resolved within 10 days.

Skin

Contact dermatitis from coriander has been described (20).

Immunologic

An anaphylactic reaction has been described in a patient who was sensitized to coriander (21).

Ferula assa-foetida

Ferula assa-foetida (asafetida) contains coumarin sesquiterpenoids, such as fukanefuromarins and kamolonol, which inhibit the production of nitric oxide and relax smooth muscle.

Adverse effects

Methemoglobinemia occurred in a 5-week-old infant treated with a gum asafetida formulation (22).

Asafetida may enhance the activity of warfarin (23).

Apocynaceae

See also Herbal medicines

General Information

The genera in the family of Apocynaceae (Table 1) include dogbane, oleander, and periwinkle.

Rauwolfia serpentina

The root of *Rauwolfia serpentina* (snakeroot) contains numerous alkaloids, of which reserpine and rescinnamine are said to be the most active as hypotensive agents (1).

Adverse effects

Inexpert use of *R. serpentina* can lead to serious toxicity, including symptoms such as hypotension, sedation, depression, and potentiation of other central depressants.

Table 1 The genera of Apocynaceae

Adenium (desert rose)
Allamanda (allamanda)
Alstonia (alstonia)
Alyxia (alyxia)
Amsonia (blue star)
Anechites (anechites)
Angadenia (pineland golden trumpet)
Apocynum (dogbane)
Carissa (carissa)
Catharanthus (periwinkle)
Cycladenia (waxy dogbane)
Dyera (dyera)
Echites (echites)
Fernaldia (fernaldia)
Forsteronia (forsteronia)
Funtumia (funtumia)

Apomorphine

General Information

Apomorphine, a very potent non-selective dopamine agonist, which acts on both D_1 and D_2 receptors, has been used with some success in Parkinson's disease, particularly in patients with severe long-term adverse effects of levodopa. Because of first-pass metabolism it has to be used subcutaneously, sublingually, or intranasally. Its adverse effects resemble those of levodopa.

Yawning, somnolence, nausea, and vomiting can all result from the use of apomorphine; they respond to naloxone.

Local reactions to subcutaneous infusion of apomorphine in the nose and throat include swelling of the nose and lips, stomatitis, and buccal mucosal ulceration.

© 2006 Elsevier B.V. All rights reserved.

Persistent nodules cause major problems in about 10% of patients after 3 or more years. One solution is to give the drug intravenously using an indwelling cannula. Six patients, who had responded well to subcutaneous apomorphine before nodules developed, had such cannulae inserted (1). The apomorphine was given at a mean rate of 9.0 mg/hour to a total mean dose of 257 mg/day, very similar to the subcutaneous dosage. The intravenous therapy virtually abolished "off" periods, reduced oral antiparkinsonian drug dosages by 59%, and produced a marked (but unquantified) reduction in dyskinesias and an improved quality of life. However, there were major problems. Two patients receiving high doses of apomorphine (450 and 290 mg/day, in the latter case a deliberate overdose) developed thromboembolic complications, following crystal formation, in one case to the right lung and in the other with obstruction to the superior vena cava. Both required surgical intervention. Both recovered fully, but the authors understandably commented that this therapeutic approach still needs further development.

Organs and Systems

Nervous system

A paradoxical akinetic response has been reported in a middle-aged man, probably with nigrostriatal degeneration, who became both immobile and mute 15 minutes after taking 4 mg of apomorphine; the effect was seen again on rechallenge with doses as low as 2 mg (2). The mechanism was not clear.

Psychological, psychiatric

Four men with Parkinson's disease underwent long-term treatment with apomorphine and developed dose-related psychosexual disorders (3).

Sexual function

There have been reports that apomorphine causes penile erections in both Parkinsonian and healthy men (4–6).

Aprindine

See also Antidysrhythmic drugs

General Information

The pharmacology, clinical pharmacology, clinical uses, efficacy, and adverse effects of aprindine have been extensively reviewed (1–5).

The adverse effects of aprindine most commonly affect the central nervous system. However, other less common but serious and potentially fatal adverse effects (neutropenia and liver damage) occur, and these limit its usefulness.

Aprindine is metabolized by CYP2D6, and one would therefore expect interactions with drugs that inhibit this isozyme or are metabolized by it.

Comparative studies

In a comparison of oral aprindine and propafenone in 32 patients (25 men and 7 women, aged 43–82) with paroxysmal or persistent atrial fibrillation, aprindine was effective in five of 29 and propafenone in six of 28; adverse effects were not reported (6).

There has been a multicenter, randomized, placebo-controlled, double-blind comparison of aprindine and digoxin in the prevention of atrial fibrillation and its recurrence in 141 patients with symptomatic paroxysmal or persistent atrial fibrillation who had converted to sinus rhythm (7). They were randomized in equal numbers to aprindine 40 mg/day, digoxin 0.25 mg/day, or placebo and followed every 2 weeks for 6 months. After 6 months the Kaplan–Meier estimates of the numbers of patients who had no recurrences with aprindine, digoxin, and placebo were 33, 29, and 22% respectively. The rates of adverse events were similar in the three groups. This suggests that aprindine has a very small beneficial effect in preventing relapse of symptomatic atrial fibrillation after conversion to sinus rhythm. Furthermore, recurrence occurred later with aprindine than with placebo or digoxin (about 60% recurrence at 115 days compared with 30 days).

Organs and Systems

Respiratory

Pneumonitis has been attributed to aprindine (SEDA-16, 179).

Nervous system

Aprindine can cause adverse effects in the central nervous system (SEDA-1, 156).

Hematologic

The incidence of leukopenia has been estimated at about 2 cases per 1000 patient-years (8).

Liver

Aprindine can cause liver damage (9).

Aprotinin

General Information

Aprotinin is a fibrinolytic agent, a naturally occurring serine protease inhibitor derived from bovine lung. It is a polypeptide of 58 amino acids, with a molecular weight of 6512, which inhibits the action of several serine proteases, including trypsin, chymotrypsin, plasmin, and kallikrein. It is extracted on a commercial basis from bovine lung. By inhibiting kallikrein, aprotinin inhibits the formation of activated factor XII indirectly. It thus inhibits the initiation of both coagulation and fibrinolysis induced by the contact of blood with a foreign surface. It does not affect platelet function. In cardiac surgery, aprotinin reduces the risk of bleeding (1,2).

Aprotinin is not effective after oral administration, but is administered intravenously as a loading dose followed by a continuous infusion. Its activity is expressed as kallikrein inactivation units (KIU). The conventional (Munich) dose regimen consists of an initial 2×10^6 KIU bolus, a similar initial dose to prime the bypass machine, and then 0.5×10^6 KIU/hour by continuous infusion thereafter. The half-life of aprotinin is about 2 hours. Plasma concentrations of 125 KIU/ml are necessary to inhibit plasmin, but a higher concentration of 300–500 KIU/ml is needed to inhibit kallikrein.

During normal fibrinolysis, inactive circulating plasminogen binds to fibrin through an active site that binds lysine. The bound plasminogen is then converted to plasmin by activators (such as tissue plasminogen activator, t-PA) and converted to plasmin, which breaks down the fibrin. Aminocaproic acid (EACA, 6-aminohexanoic acid, Amicar®) and tranexamic acid (Cyklokapron®) are structural analogues of lysine, which bind irreversibly to the lysine-binding sites on plasminogen, inhibiting binding to fibrin and thus the whole process of fibrinolysis (3,4). These agents inhibit the natural degradation of fibrin and so stabilize clots.

Uses

Aprotinin is widely used to inhibit fibrinolysis during cardiac surgery and orthotopic liver transplantation, and reduces the risk of bleeding (1,2). In addition, it is added as a constituent of several commercial formulations of fibrin sealants (“fibrin glues”), such as Quixil. The use of aprotinin in cardiopulmonary bypass surgery was pioneered by Royston, an anesthesiologist in London, who found that it reduced blood loss after both primary and repeat operations (5). It is also effective in operations normally characterized by particularly large blood losses, such as those in patients taking aspirin (6) and patients undergoing cardiac transplantation (7). It is also used to control blood loss in the setting of orthotopic liver transplantation (8,9), where accelerated fibrinolysis is an important component in the abnormalities of hemostasis, which can contribute to perioperative bleeding. Aprotinin is of value in controlling hemorrhage associated with hyperplasminemia (which can, for example, occur after thrombolytic therapy or in association with promyelocytic leukemia). A combination of aprotinin with tranexamic acid can prevent or delay rebleeding after rupture of an intracerebral aneurysm. Clinical trials have not confirmed any benefit from the use of aprotinin in acute pancreatitis.

General adverse effects

Some adverse reactions are associated with all antifibrinolytic agents, reflecting their effect on clot stability. Dissolution of extravascular blood clots may be resistant to physiological fibrinolysis. These drugs should not be used to treat hematuria due to blood loss from the upper urinary tract, as this can provoke painful clot retention and even renal insufficiency associated with bilateral ureteric obstruction (10,11).

Caution should be exercised in the administration of antifibrinolytic agents in disseminated intravascular coagulation (12,13).

Organs and Systems

Cardiovascular

The issue of whether the use of aprotinin is associated with an increased risk of vein graft thrombosis in cardiac bypass surgery has not been resolved (14,15). The use of

© 2006 Elsevier B.V. All rights reserved.

aprotinin was not associated with an increased rate of early occlusion of saphenous vein or internal mammary artery grafts in controlled studies with coronary angiography (16–19).

In a randomized, placebo-controlled, multicenter study of aprotinin in coronary artery bypass surgery, there was no increase in mortality or the incidence of myocardial infarction (20).

There was no evidence of an increased risk of venous thromboembolism in patients receiving aprotinin in a small study after hip replacement (21).

Psychological, psychiatric

Psychotic reactions, including delirium, hallucinations, and confusion, have also been reported in patients given aprotinin, but it is possible that the symptoms were due to underlying pancreatitis (22).

Hematologic

It has been postulated that aprotinin potentiates a prothrombotic state (2). However, in randomized, controlled studies, there were no significant differences between aprotinin and placebo (2).

Disseminated intravascular coagulation can be aggravated by aprotinin, particularly in elderly people (13).

Urinary tract

Aprotinin has a high affinity for renal tissue; 80–90% is stored in the proximal tubule cells after 4 hours and is excreted over 12–24 hours (2). It has been hypothesized that aprotinin causes reversible overload of tubular reabsorption, resulting in transient renal dysfunction (2). It has also been postulated that aprotinin has a direct toxic effect on the proximal tubule cells or alters intrarenal blood flow, through inhibition of renin and kallikrein activity (2).

Immunologic

As might be expected with a bovine protein, allergic reactions can occur, and repeated exposure can even result in anaphylactic reactions. In view of this, some have advocated a strategy of using aprotinin only if excessive bleeding is a problem after surgery (23).

- An aphylactic reaction has been described after the use of fibrin glue as a sealant after mastectomy, probably due to the presence of bovine aprotinin (24).

In one study of 248 patients undergoing cardiac surgery, seven had allergic reactions, ranging from skin flushing to severe circulatory depression (25). Most of the reactions occurred when aprotinin was given a second time within 6 months after the first exposure. However, anaphylaxis has been documented after primary exposure (26). The reported incidence of anaphylactic reactions in other studies has ranged from 0.3 to 0.6% after a single exposure, rising to almost 5% with prior aprotinin exposure (1).

Up to 1980, 32 cases of non-fatal shock attributed to aprotinin had been reported to the Japanese Ministry of Health and Welfare, most concerning patients treated for pancreatitis (27). Although these patients survived, fatal anaphylaxis has been reported (28). Other apparently allergic reactions reported include erythema, urticaria, bronchospasm, nausea and vomiting, diarrhea, muscle pains, and blood pressure changes (29). A case of allergic pancreatitis attributed to aprotinin has also been reported (30).

There is evidence that severe allergic reactions to aprotinin are mediated by IgE, and preoperative screening for the presence of aprotinin-specific IgE antibodies can be of value in identifying patients at risk (31,32).

The sera of 150 patients who had undergone cardiac surgery and were receiving aprotinin for the first time have been studied before and after the operation. At 3.5 months after surgery, the prevalence of aprotinin-specific IgG antibodies was 33% (15/45) after local, 28% (13/46) after intravenous, and 69% (41/59) after combined exposure (33). The authors concluded that local administration of aprotinin induces a specific immune response and reinforces that of intravenous exposure; they therefore recommended that any exposure in a patient should be documented.

Allergic reactions, including anaphylaxis, can occur on re-exposure to aprotinin. The incidence rates of aprotinin-related reactions are 2.7% in re-exposed adults (5/183) and 1.2% in children (3/354), with an overall incidence of 1.8% (8/437). The following advice has been given to reduce the risk and severity of these reactions (1,2):

- give a test dose of aprotinin
- delay the first bolus injection until the surgeon starts the procedure
- give an antihistamine before re-exposure
- avoid re-exposure within the first 6 months after the last exposure.

Infection risk

Inevitably, concern has recently been expressed about the possibility of transmission of the prion believed to be responsible for bovine spongiform encephalopathy (BSE) and new variant Creutzfeldt-Jakob disease. However, the manufacturers of aprotinin have stated that the bovine lungs used as the source of aprotinin are collected in countries in South America (principally Uruguay) in which no cases of transmissible spongiform encephalopathy have been recorded. There is no evidence that any patient with new variant Creutzfeldt-Jakob disease has received aprotinin. Furthermore, in vitro experiments involving spiking of material with mouse-associated scrapie agent have demonstrated an 18-log reduction of the added prions during the manufacturing process (34).

Second-Generation Effects

Teratogenicity

There is no evidence from animal studies and clinical experience of teratogenicity or other adverse effects of aprotinin (35).

© 2006 Elsevier B.V. All rights reserved.

Drug–Drug Interactions

Suxamethonium

Aprotinin slightly reduces plasma cholinesterase activity and would be expected to prolong the action of suxamethonium in combination with other factors. However, re-paralysis has been reported when aprotinin was used after operations during which suxamethonium had been given alone or in combination with normal doses of D-tubocurarine (36).

Araliaceae

See also Herbal medicines

General Information

The genera in the family of Araliaceae (Table 1) include aralia, ginseng, and ivy.

Ginseng

Ginseng is an ambiguous vernacular term, which can refer to *Panax* species such as *Panax ginseng* (Asian ginseng) and *Panax quinquefolius* (American ginseng), *Eleutherococcus senticosus* (Siberian ginseng), *Pfaffia paniculata* (Brazilian ginseng), or unidentified material (for example Rumanian ginseng).

Asian ginseng (*P. ginseng*) contains a wide variety of flavonoids, saponins, steroids, sesquiterpenoids, and triterpenoids. These include ginsenolides and ginsenosides, protopanaxadiol, panaxadiol, panaxatriol, and panasinsene.

The botanical quality of ginseng preparations is problematic (1). For instance, when a case of neonatal androgenization was associated with maternal use of Siberian ginseng tablets during pregnancy, botanical analysis showed that the incriminated material almost certainly came from *Periploca sepium* (Chinese silk vine) (2).

Brazilian ginseng (*P. glomerata*) has been found to be contaminated with cadmium and mercury (3).

Table 1 The genera of Araliaceae

Aralia (spikenard, angelica)
Cheirodendron (cheirodendron)
Dendropanax (dendropanax)
Eleutherococcus (ginseng)
Fatsia (fatsia)
Hedera (ivy)
Kalopanax (castor aralia)
Meryta (meryta)
Munroidendron (munroidendron)
Oplopanax (oplopanax)
Panax (ginseng)
Polyscias (aralia)
Pseudopanax (pseudopanax)
Reynoldsia (reynoldsia)
Schefflera (schefflera)
Tetraplasandra (tetraplasandra)
Tetrapanax (tetrapanax)

There is no good evidence that ginseng confers benefit for any indication (4).

Adverse effects

The various adverse effects that have been attributed to ginseng formulations include hypertension, pressure headaches, dizziness, estrogen-like effects, vaginal bleeding, and mastalgia. Prolonged use has been associated with a "ginseng abuse syndrome" including symptoms like hypertension, edema, morning diarrhea, skin eruptions, insomnia, depression, and amenorrhea. However, most reports are difficult to interpret, because of the absence of a control group, the simultaneous use of other agents, insufficient information about dosage, and lack of botanical authentication (1).

The authors of a review of the adverse effects associated with *P. ginseng* concluded that it is generally safe but at high doses can cause insomnia, headache, diarrhea, and cardiovascular and endocrine disorders (5). Inappropriate use and suboptimal formulations were deemed to be the most likely reason for adverse effects of ginseng. The authors of a systematic review reached similar conclusions and showed that serious adverse effects of ginseng seem to be true rarities (6).

Cardiovascular

The WHO database contains seven cases from five countries of ginseng intake followed by arterial hypertension (7). In five of them no other medication was noted. In four cases the outcome was mentioned, which was invariably full recovery without sequelae after withdrawal of ginseng.

Nervous system

- A 56-year-old woman with previous affective disorder had an episode of mania while taking ginseng (8). She was treated with neuroleptic drugs and benzodiazepines and ginseng was withdrawn. She made a rapid full recovery.

Ginseng has also been associated with a case of cerebral arteritis (9).

Psychiatric

A woman with prior episodes of depression had a manic episode several days after starting to take *P. ginseng* (10).

Skin

Stevens–Johnson syndrome occurred in a 27-year-old man who was a regular user of *P. ginseng* (11).

Musculoskeletal

Aggravation of muscle injury has been attributed to ginseng (SED-13, 1461) (12).

Drug interactions

- A 74-year-old man had increased serum digoxin concentrations without signs of toxicity while taking Siberian ginseng (13). Common causes of increased serum digoxin were ruled out, and the association with ginseng use was confirmed by dechallenge and rechallenge. The rise in serum digoxin concentration could have been due to

© 2006 Elsevier B.V. All rights reserved.

cardiac glycosides contained in *Periploca sepium*, a common substitute for *E. senticosus* (14).

Diuretic resistance has been reported in a patient consuming a formulation containing germanium and ginseng (species unspecified) (15).

Interactions of antidepressants with herbal medicines have been reported (16). Ginseng has been reported to cause mania, tremor, and headache when used in combination with conventional monoamine oxidase inhibitors.

In one case the concomitant use of *P. ginseng* and warfarin resulted in loss of anticoagulant activity (17). However, in an open, crossover, randomized study in 12 healthy men ginseng did not affect the pharmacokinetics or pharmacodynamics of *S*-warfarin or *R*-warfarin (18).

Arecaceae

See also Herbal medicines

General Information

The genera in the family of Arecaceae (Table 1) include various types of palm.

Areca catechu

Areca catechu (areca, betel) contains piperidine alkaloids, such as guvacine, guvacoline, and isoguvacine, and pyridine alkaloids, such as arecaidine, arecolidine, and arecoline.

Many of the world's population (more than 200 million people worldwide) chew betel nut quid, a combination of areca nut, betel pepper leaf (from *Piper betle*), lime paste, and tobacco leaf. The major alkaloid of the areca nut, arecoline, can produce cholinergic adverse effects (such as bronchoconstriction) (1) as well as antagonism of anticholinergic agents (2). The lime in the betel quid causes hydrolysis of arecoline to arecaidine, a central nervous system stimulant, which accounts, together with the essential oil of the betel pepper, for the euphoric effects of chewing betel quid.

Adverse effects

Glycemia and anthropometric risk markers for type 2 diabetes were examined in relation to betel usage. Of 993 supposedly healthy Bangladeshis 12% had diabetes. A further 145 of 187 subjects at risk of diabetes (spot glucose over 6.5 mmol/l less than 2 hours after food or over 4.5 mmol/l more than 2 hours after food) had a second blood glucose sample taken; 61 were confirmed as being at risk, and had an oral glucose tolerance test; nine new diabetics were identified. Spot blood

Thrinax (thatch palm)
Washingtonia (fan palm)

glucose values fell with time after eating and increased independently with waist size and age. Waist size was strongly related to use of betel, and was independent of other factors such as age. The authors suggested that betel chewing may contribute to the risk of type 2 diabetes mellitus (3).

The saliva of betel nut chewers contains nitrosamines derived from areca nut alkaloids (4), and the use of areca nuts has been widely implicated in the development of oral cancers.

Serenoa repens

S. repens (American dwarf palm tree, cabbage palm, sabal, saw palmetto) has mainly been used to treat benign prostatic hyperplasia. In placebo-controlled and comparative studies its efficacy in benign prostatic hyperplasia and lower urinary tract symptoms has been demonstrated (5). Numerous mechanisms of action have been proposed, including an antiandrogenic action, an anti-inflammatory effect, and an antiproliferative influence through inhibition of growth factors.

A systematic review and meta-analysis of randomized trials of *S. repens* in men with benign prostatic hyperplasia showed that saw palmetto extracts improve urinary symptoms and flow measures to a greater extent than placebo, and similar improvements in urinary symptoms and flow measures to the 5-alpha-reductase inhibitor finasteride with fewer adverse effects (6).

Adverse effects

Hematologic

- A 53-year-old man, who had self-medicated with a saw palmetto supplement for benign prostatic hyperplasia, had profuse bleeding (estimated blood loss 2 liters) after resection of a meningioma and required 4 units of packed erythrocytes, 3 units of platelets, and 3 units of fresh frozen plasma (7). Postoperatively his bleeding time was 21 minutes (reference range 2–10 minutes), but all other coagulation tests were normal. He made an uneventful recovery.

The authors concluded that the cyclo-oxygenase inhibitory activity of saw palmetto had caused platelet dysfunction, which had resulted in abnormal bleeding.
