Indapamide

See also Diuretics

General Information

Indapamide is a thiazide-like diuretic. Although it was introduced as a specific antihypertensive drug without appreciable diuretic action, the effects of indapamide are no different from those of bendroflumethiazide.

Organs and Systems

Sensory systems

Transient myopia associated with diffuse choroidal thickening has been described in a 38-year-old white man who had taken indapamide for hypertension; it resolved after withdrawal (1).

Metabolism

The metabolic effects of indapamide appear to be as common as those of thiazides (SEDA-14, 185) (SEDA-15, 216). The metabolic effects of hydrochlorothiazide 25 mg/day and indapamide 2.5 mg/day for 6 months have been compared in a randomized, double-blind study in 44 patients with mild to moderate hypertension (2). There was little difference between the effects of the drugs on a wide range of lipid parameters, glucose, and potassium. The purported metabolic differences with indapamide are unlikely to be of sufficient magnitude to warrant its preferential use in hyperlipidemia.

Electrolyte balance

Cases of severe indapamide-induced hypokalemia have been reported (SED-11, 424) (SEDA-15, 213).

Liver

Severe acute hepatitis associated with indapamide has been reported (3). Serum bilirubin and liver enzymes were greatly raised. All normalized over 6 months after withdrawal of indapamide.

Urinary tract

Interstitial nephritis leading to acute renal insufficiency has been reported with indapamide (4).

Skin

Hypersensitivity to indapamide can provoke serious adverse skin reactions (SEDA-17, 260) (SEDA-18, 234).

One patient had several episodes of fixed drug eruption during treatment with indapamide (5). The diagnosis was confirmed by positive controlled oral challenge.

Pemphigus foliaceus has been described in relation to indapamide (6).

Drug–Drug Interactions

Sulfamethoxazole

The possibility of cross-reactivity with other sulfonamide derivatives was investigated by controlled oral challenge tests with sulfamethoxazole, sulfadiazine, and furosemide. The test with sulfamethoxazole was positive.

Indinavir

See also Protease inhibitors

General Information

Indinavir is an HIV protease inhibitor.

Organs and Systems

Cardiovascular

A hypertensive crisis caused a secondary reversible posterior leukoencephalopathy in a patient taking indinavir-containing antiretroviral therapy (1).

- A 40-year-old man, who had taken stavudine 30 mg bd, lamivudine 150 mg bd, and indinavir 800 mg qds, developed an occipital headache, nausea, and vomiting. His blood pressure was 220/140 mmHg and he had bilateral papilledema. His blood pressure was controlled and his symptoms disappeared. An MRI scan of the brain showed lesions in the periventricular white matter; the nuclei semiovale and occipital asta were most severely affected. Indinavir was withdrawn and replaced by nelfinavir; his blood pressure returned to normal and the MRI white matter lesions disappeared.

In a retrospective analysis of 198 normotensive patients in a protease inhibitor comparison study, 30% of those who took indinavir developed stage I or worse hypertension, compared with none of the patients who took nelfinavir, ritonavir, or saquinavir (2).

Respiratory

Shock and respiratory failure have been attributed to indinavir (3).

- A 36-year-old HIV-positive man had started to take zidovudine and zalcitabine 9 months earlier together with co-trimoxazole as primary prophylaxis against *Pneumocystis jiroveci*, but switched to indinavir, stavudine, and lamivudine. Two hours after the first dose of indinavir he developed a high fever, generalized myalgia, and malaise and started to vomit. After the second dose he developed shock and cyanosis. A chest X-ray was compatible with adult respiratory distress syndrome. All cultures were negative for bacterial, viral, mycobacterial, and fungal pathogens. He recovered in 6 days and antiretroviral treatment without indinavir was reintroduced without recurrent problems.

The authors suggested that the severe shock and respiratory distress syndrome had been due to an idiosyncratic reaction to indinavir.

Nervous system

There has been a report of painful neuropathy in two patients who took ritonavir and indinavir respectively (4).

Paraparesis due to epidural lipomatosis has been attributed to indinavir (5).

- A 35-year-old man, who had taken indinavir 2400 mg/day, lamivudine 300 mg/day, and stavudine 80 mg/day for 10 months, developed a slowly progressive paraparesis, with sensory disturbances in the legs. An MRI scan was consistent with epidural lipomatosis. On withdrawal of indinavir, the symptoms gradually resolved.

Although indinavir can cause abnormal fat accumulation, this is thought to have been the first report of epidural lipomatosis.

Metabolism

Protease inhibitors are associated with hyperglycemia and possible diabetes mellitus. In a prospective study in 12 patients indinavir caused hyperglycemia and reduced insulin sensitivity (6).

Hematologic

Indinavir has been associated with severe hemolytic anemia (7).

- A 32-year-old Caucasian, who was taking lamivudine, stavudine, and indinavir for HIV infection, presented with pallor following a period of fatigue and headache (8). His hemoglobin was 8.2 g/dl and there were no clinical findings to suggest bleeding. The reticulocyte count was 3.5% and a direct Coombs' test was negative. A diagnosis of hemolytic anemia secondary to indinavir was made, the indinavir was stopped, and he was transfused with concentrated erythrocytes. The other antiretroviral drugs were continued, saquinavir was added, and a normal hemoglobin concentration was maintained.

Indinavir has been associated with thrombocytopenia (9).

Liver

Indinavir has been compared with abacavir in a randomized equivalence trial in 562 patients who were also taking lamivudine and zidovudine (10). The only significant difference in adverse effects was that there was hyperbilirubinemia in 8% of those taking indinavir and 2% of those taking abacavir. It has been postulated that indinavir-induced hyperbilirubinemia is due to inhibition of bilirubin UDP glucuronyl transferase activity, since it is more common in individuals with Gilbert's syndrome (11).

© 2006 Elsevier B.V. All rights reserved.

Urinary tract

Indinavir causes nephrolithiasis as a result of precipitation of indinavir crystals in the urinary tract (12,13). It is dose-related and can be prevented by adequate hydration. In 615 patients (18 864 person-years of follow-up) who did not have risk factors for nephrolithiasis, the incidence was 8.6 episodes per 1000 person-years (14).

Several reports have suggested that patients using indinavir may also develop a syndrome consisting of back or flank pain, accompanied by crystalluria, renal function abnormalities, and evidence of tubulointerstitial nephritis on renal biopsy, but without obvious renal calculus formation (15–17).

In a French analysis of 22 510 urinary calculi performed by infrared spectroscopy, drug-induced urolithiasis was divided into two categories: first, stones with drugs physically embedded ($n = 238$; 1.0%), notably indinavir monohydrate ($n = 126$; 53%), followed by triamterene ($n = 43$; 18%), sulfonamides ($n = 29$; 12%), and amorphous silica ($n = 24$; 10%); secondly, metabolic nephrolithiasis induced by drugs ($n = 140$; 0.6%), involving mainly calcium + vitamin D supplementation ($n = 56$; 40%) and carbonic anhydrase inhibitors ($n = 33$; 24%) (18). Drug-induced stones are responsible for about 1.6% of all calculi in France. Physical analysis and a thorough drug history are important elements in the diagnosis.

The incidence of urolithiasis with indinavir has been estimated at 9% (19) but, according to some, may be as high as 20%. Indinavir calculi are often radiolucent and may be missed on CT scan rather than by using a contrast medium (which is itself not without risk) (20,21). It may therefore be that in some cases in which other renal complications with indinavir have been described there was in fact undetected renal stone formation. Any patient taking indinavir who develops renal colic should be suspected of having renal stones (22).

In two cases long-term use of indinavir appeared to have been responsible for renal atrophy (23), and again one wonders whether crystals may have been present but radiologically invisible.

Reversible renal insufficiency (which again could have been due to crystalluria) has been reported with indinavir (24).

- A 38-year-old man developed renal insufficiency while taking indinavir. His serum creatinine increased over a period of about 1 year, but urinalysis was persistently normal. A renal biopsy showed marked tubular crystal deposition. The indinavir was withdrawn, and after 2 months his serum creatinine returned to normal.

Since the basic problem in many such cases is probably crystalluria, it should be possible to treat it with rehydration, perhaps supplemented by brief interruption of therapy; this has been the conclusion of a study in which the unwanted renal effects of indinavir were prominent (25). Of 74 individuals infected with HIV-1 and taking indinavir 2.4 g/day orally, 15 had indinavir-related urological adverse effects (19 episodes), most commonly dull flank pain and dysuria. Microhematuria occurred in 16 of the 19 episodes. Four patients had urinary tract distension on ultrasonography as a possible indirect sign of urolithiasis and one passed a stone. In 4 patients treatment had to be stopped permanently, but in the other 11 it was continued. Some patients required dosage reduction and/or interruption of treatment: only conservative therapeutic measures were required, consisting of rehydration (fluid intake of at least 1.5 l/day) and analgesics.

Of 23 indinavir-treated patients with persistent pyuria, four had interstitial nephritis, seven had urothelial inflammation, 10 had both interstitial nephritis and urothelial inflammation, and two had non-specific urinary tract inflammation (26). In all, 21 patients had multinucleated histiocytes identified by cytological testing of urine specimens. Urine abnormalities resolved in all 20 patients who stopped taking indinavir, and pyuria persisted in the other 3. Six patients had raised serum creatinine concentrations, which returned to baseline when indinavir was withdrawn.

Skin

HIV-positive/AIDS patients using indinavir develop rashes early in treatment, a finding that is familiar with various other drugs used in this condition. This problem has been quantified in a study using data from postmarketing surveillance (27). Of 110 HIV/AIDS patients with a rash, 67% reported that it had occurred within 2 weeks of the start of indinavir therapy. The rash was initially localized in all cases, but in the majority it went on to spread to other body areas, involving all parts of the body in no less than 44%. It was usually pruritic but not accompanied by fever. Relief was often obtained by use of topical antihistamines or oral or topical glucocorticoids. More than half the patients decided to continue therapy despite the rash.

However, cutaneous toxicity can have a major influence on adherence to treatment and can impact adversely on the quality of life. Of 84 patients taking indinavir plus two nucleoside reverse transcriptase inhibitors for 20 months, 48 developed cheilitis, 34 had skin dryness and pruritus, 10 developed asteatotic dermatitis on the trunk, arms, and thighs, and 10 complained of scalp defluvium (28). Severe alopecia was observed in one patient, while six reported that their body hair had become fairer and thinner and shed considerably. Multiple pyogenic granulomas were observed in the toenails of five patients and softening of the nail plate was noted in five. The temporal relation between starting indinavir and the onset of these effects was striking and regression occurred on withdrawal.

Suggested mechanisms for these adverse effects include:

- retinoid-like effects due to homologies of the amino acid sequences of the HIV-1 protease and cytoplasmic retinoic-acid binding protein type 1 (CRABP-1)
- inhibition of CYP3A by indinavir, resulting in reduced oxidation of retinoic acid and hence augmentation of its biological effects.

Hair

Alopecia has been attributed to indinavir in 10 men (29). Of 337 patients who were given indinavir as part of

© 2006 Elsevier B.V. All rights reserved.

combination antiretroviral therapy with nucleoside analogues, five (1.5%) developed severe alopecia a median of 50 days after starting indinavir. Three had diffuse shedding of hair involving the entire scalp, and two were initially aware of circumscribed circular areas of alopecia resulting in complete severe hair loss. Although indinavir was discontinued in all five cases, there was no regrowth a median of 30 days later (30).

Nails

Paronychia associated with indinavir has been reported (31,32). In 288 patients in a retrospective cohort study, paronychia was associated with indinavir, with a hazard ratio of 4.7 (33).

Musculoskeletal

Increased bone mineral density has been documented in patients taking indinavir (34) although in another study protease inhibitor-containing regimens caused accelerated loss of bone density (35).

- Widespread osteosclerosis, accompanied by increased serum concentrations of osteocalcin and C telopeptide, developed in a 56-year-old man who took indinavir 800 mg tds for 27 months (36).

This patient had been taking vitamin A 1 mg/day for 20 years and the authors proposed that the indinavir had also had a vitamin A-like effect.

Frozen shoulder has been attributed to indinavir (SEDA-24, 347) (37). In one case it was associated with Dupuytren's contracture and in one case each with arthralgias and tendinitis (38). An adhesive capsulitis seems to be present.

The results of a questionnaire survey of 878 people with HIV infection treated with antiretroviral drugs confirmed the risk of arthralgias in patients taking indinavir. The authors suggested that crystal deposition in joints, analogous to the crystalluria with nephrolithiasis that indinavir and other protease inhibitors can cause, might be responsible.

Susceptibility Factors

Sex

The pharmacokinetics of indinavir in 220 women and 94 men have been compared; there was no difference (39).

Drug–Drug Interactions

Cannabinoids

The effects of smoked marijuana (3.95% tetrahydrocannabinol; up to three cigarettes per day) and oral dronabinol (2.5 mg tds) on the pharmacokinetics of indinavir 800 mg 8-hourly ($n = 28$) have been evaluated in a randomized, placebo-controlled study in HIV-infected patients (40). On day 14, marijuana reduced the 8-hour AUC of indinavir by 15%, the C_{max} by 14%, and the C_{min} by 34%. However, only the change in C_{max} was significant. Dronabinol had no effects.

Carbamazepine

Failure of combination therapy including indinavir has been attributed to an interaction of indinavir with carbamazepine (41).

- A 48-year-old HIV-positive man taking indinavir, zidovudine, and lamivudine developed *Herpes zoster* infection, which was treated with famciclovir. Postherpetic neuralgia was treated with carbamazepine, and his plasma indinavir concentration fell substantially. The carbamazepine was withdrawn after 2.5 months and 2 weeks later HIV-RNA was detectable in his plasma (6×10^3/ml). His circulating virus was resistant to lamivudine. With a further increase in viral load, his therapy was changed to nevirapine, didanosine, and stavudine.

This treatment failure, and possibly the resistance to lamivudine, was attributed to induction of drug metabolism by carbamazepine.

Didanosine

The absorption of indinavir was not affected by co-administration of didanosine in an encapsulated enteric bead formulation in 24 patients (42).

Levothyroxine

Inhibition of glucuronyl transferase activity by indinavir has been blamed for an interaction of indinavir with levothyroxine, causing hyperthyroidism (43).

- A 36-year-old woman, who had taken levothyroxine for several years, took stavudine, lamivudine, and indinavir for 1 month and developed nervousness, palpitation, restlessness, weakness, and weight loss. She had an undetectable serum TSH concentration and raised unbound serum T4 and T3. The dose of levothyroxine was reduced to one-third and then to one-sixth of the previous dose, and the thyroid function tests returned to normal.

Phenylpropanolamine

In one case the use of phenylpropanolamine with triple drug therapy for HIV prophylaxis led to a hypertensive crisis (44). As the patient had previously tolerated phenylpropanolamine well, one must suspect that one or more of the anti-HIV drugs (probably indinavir) had interfered with the metabolic breakdown of the phenylpropanolamine.

Ritonavir

Using ritonavir as a booster may allow indinavir to be given twice daily and with food. In a cohort survey of 100 patients the combination of indinavir plus ritonavir (400 mg/400 mg or 800 mg/100 mg bd) was a safe and effective option to reduce the tablet burden and improve adherence (45).

Sildenafil

There is good evidence that indinavir can substantially increase plasma concentrations of sildenafil (46). Since HIV infection commonly leads to erectile dysfunction,

© 2006 Elsevier B.V. All rights reserved.

the drugs may well be used together and it will then be prudent to use a lower dose of sildenafil.

Silybum marianum (milk thistle)

The pharmacokinetics of indinavir 800 mg 8-hourly have been studied in the presence and absence of milk thistle 175 mg (containing silymarin 153 mg) tds for 3 weeks in an open study in 10 healthy volunteers; milk thistle had no significant effect except a small reduction in $C_{min.ss}$ (47).

Venlafaxine

Venlafaxine 50 mg 8-hourly reduced the AUC of a single dose of indinavir 800 mg by 28% in nine healthy subjects (48).

Diagnosis of Adverse Drug Reactions

The adverse effects of indinavir have been retrospectively evaluated and correlated with indinavir trough concentration in 63 patients taking indinavir + ritonavir 800/100 mg bd (49). The median indinavir trough concentration of 1446 ng/ml was associated with 60% of measured toxicity. Of 49 patients with an indinavir trough concentration over 500 ng/ml, 46 had at least one dosage adjustment; the main reason for dosage adjustment was toxicity ($n = 43$). The common adverse effects affected the skin (vitamin A-like reactions; $n = 39$), kidneys (renal colic, nephrolithiasis, renal insufficiency; $n = 35$), gastrointestinal tract (nausea, vomiting, and diarrhea; $n = 32$), and liver ($n = 14$). After dosage adjustment, the median indinavir trough concentration was 459 ng/ml, which was associated with 8% of toxicity. Trough concentrations over 500 ng/ml correlated with increased toxicity. The authors concluded that indinavir trough concentrations below 500 ng/ml are safe, and that an optimal concentration range for indinavir trough concentration could be 150–500 ng/ml in patients taking twice daily indinavir + ritonavir.

Indometacin

See also Non-steroidal anti-inflammatory drugs

General Information

Indometacin is the best-known and most thoroughly tested indoleacetic acid derivative. It is one of the most effective NSAIDs, and most of its toxic and therapeutic effects appear to be due to marked inhibition of prostaglandin synthesis. Because of its potency, its clinical efficacy is comparable, if not superior, to any other NSAID, but for precisely the same reason its adverse effects on the gastrointestinal tract and the nervous system inevitably limit its use. However, patients who tolerate it reasonably well are naturally not anxious to exchange it for any newer drugs with fewer problems but less potency. A meta-analysis of patients' preference in 37 crossover comparisons of indometacin with newer NSAIDs did not provide evidence of a trend to replace indometacin with newer NSAIDs (1).

Tropesin is the tropic acid ester of indometacin, and its adverse effects profile is similar to that of indometacin (SEDA-17, 113).

General adverse reactions

Adverse effects, in up to 60% of patients, are closely related to indometacin's strong anti-inflammatory potency. Gastric irritation, including ulcers, bleeding, and perforation, predominates. Nervous system complications are related to cerebral edema. Headache is common. Hematological effects are infrequently reported. Nephrotoxicity is exacerbated by pre-existing renal impairment. Ocular toxicity can follow long-term use.

Cross-reactivity with aspirin has been reported (2). The hazards of administering topical indometacin to asthmatic patients should be widely known (3).

Tumor-induced effects have not been demonstrated.

Organs and Systems

Cardiovascular

Clinical experience and reports have provided little evidence that indometacin precipitates angina or myocardial infarction. However, an individual angina-provoking

© 2006 Elsevier B.V. All rights reserved.

effect has been documented (4), and there are grounds for believing that it can happen.

Intravenous administration of indometacin increases blood pressure, coronary vascular resistance, and myocardial oxygen demands, decreasing coronary flow. A controlled short-term study showed that indometacin increased blood pressure in patients with mild untreated essential hypertension (SEDA-17, 108). In view of the increasing use of parenteral administration, the acute hemodynamic effects of indometacin may now occur more often, especially in the elderly (5). The mechanism is poorly understood, but apparently a direct action is exerted on the resistance vessels in various regions. This is probably independent of indometacin's action on prostaglandin formation. The clinical relevance is largely unknown, but other NSAIDs should probably be prescribed for patients with occlusive vascular diseases affecting the cerebral and/or coronary vessels.

Other systemic cardiovascular adverse effects are due to salt and fluid retention and also to a reduction in the vasodilator action of circulating prostaglandins E_2 and I_2 (6).

Unlike other NSAIDs, indometacin acts as a cerebral vasoconstrictor. It reduces cerebral flow by up to 35% and the response to hypercapnia disappears (SEDA-10, 79). It also reduces blood flow in the splanchnic vascular bed, by increasing local vascular resistance, but does not impair circulation in the forearm and leg muscles.

Respiratory

Inhibition of prostaglandin synthesis explains indometacin's ability to provoke or aggravate asthma in hypersensitive patients (7). Indometacin in ophthalmic solution reportedly caused such deterioration in asthmatic patients as to require mechanical ventilation (3,8). Cross-sensitivity between indometacin and aspirin has been observed.

Nervous system

Adverse reactions to indometacin involving the central nervous system are frequent and come second in importance only to gastrointestinal effects. They are attributed to salt and water retention. Up to 60% of patients experience headache (often migraine-like), frontal throbbing, and vertigo. Vomiting, tinnitus, ataxia, tremor, dizziness, and insomnia follow. Somnolence, confusion, hallucinations (especially in the elderly), and psychotic symptoms have been described. Coma, clonic seizures, and myoclonic spasms (SEDA-18, 101) can develop. Muscle weakness and paresthesia, that is, peripheral neuropathy, may develop in elderly patients, but recede after withdrawal (9,10).

Indometacin is used for non-invasive closure of symptomatic ductus arteriosus in the preterm infant. Intravenous administration causes an instant reduction in cerebral blood flow, increasing cerebral vascular resistance. The clinical significance for the nervous system of these hemodynamic changes is unknown (11,12), but they seem to be linked to the effects seen in the central nervous system. Advantage has been taken of this effect for reducing intracranial hypertension in patients with severe head injury (SEDA-15, 99).

Indometacin is also used in preterm infants as prophylaxis against intraventricular hemorrhage. In a prospective, randomised, placebo-controlled trial in 431 preterm neonates, low-dose indometacin prevented intraventricular hemorrhage without adverse cognitive or motor outcomes at 36 months (13).

Low-dose indometacin (0.1 mg/kg), begun in the first 24 hours of life and given every 24 hours for 6 doses, was not associated with adverse neurodevelopmental outcome at 36 months corrected age (14).

Sensory systems

Prolonged therapy can cause a number of adverse reactions in the eyes. Trivial effects are ocular discomfort, conjunctival pain, and increased ocular tension, but mydriasis, photophobia, blurred vision, diplopia, amblyopia, and loss of vision can occur. The most serious complications are retinopathy with reduced retinal sensitivity, and corneal and retinal pigmentation. They are reversible, but improvement is slow. A report on indometacin retinopathy has added more doubt than certainty to the question of the frequency and severity of retinal toxicity (SEDA-14, 93). Patients taking prolonged therapy should have regular ophthalmic examinations.

Metabolism

Indometacin reduces the area under the corticotropin (ACTH) plasma concentration–time curve after insulin in normal men, possibly because of the role of prostaglandins in the control of ACTH secretion (15).

One report has described low plasma ascorbic acid concentrations during indometacin treatment, and a case of hyperglycemia has been reported (16).

Electrolyte balance

Hyperkalemia has been reported in patients with preexisting renal disease treated with indometacin (SEDA-4, 65) (SEDA-5, 90) (SEDA-6, 93) and in a patient with Bartter's syndrome receiving concomitant oral potassium chloride (SEDA-11, 92) (17). Indometacin caused a high serum potassium concentration in a young athlete (SEDA-14, 93).

Mineral balance

During indometacin therapy, urinary excretion of zinc and calcium can increase significantly (18). The clinical relevance is not known.

Fluid balance

Salt and fluid retention is an adverse effect of indometacin, although it is less important than with the pyrazolone derivatives. Indometacin can antagonize antihypertensive agents, including beta-adrenoceptor antagonists (19,20). The effect on blood pressure in normotensive patients has not been adequately studied.

Severe water intoxication caused by inappropriate ADH secretion has been described in an elderly woman taking indometacin (SEDA-17, 108).

© 2006 Elsevier B.V. All rights reserved.

Hematologic

Anemia caused by repetitive gastrointestinal bleeding is a relatively frequent, although indirect, hematological adverse effect.

Blood dyscrasias, sometimes fatal aplastic anemia (21), isolated granulocytopenia, and agranulocytosis have been reported (22). The International Agranulocytosis and Aplastic Anemia study showed that indometacin was significantly associated with agranulocytosis and aplastic anemia (23).

Since indometacin is an inhibitor of platelet aggregation, impairment of thrombocyte function is frequent, but thrombocytopenia is rare. Severe clotting defects due to inhibition of platelet aggregation in premature infants have been described (24). Postoperative bleeding is significantly more frequent in indometacin-treated patients. Indometacin should probably not be used postoperatively in patients at increased risk of bleeding (SEDA-8, 103).

Gastrointestinal

Gastrotoxicity is the main adverse effect of indometacin, and symptoms range from abdominal discomfort to ulcer penetration and perforation (25). The phenomenon of gastric mucosal adaptation has been evoked to explain the relatively low incidence of severe adverse effects, compared with the acute gastric damage that occurs in short-term studies. In healthy volunteers, indometacin produced acute gastroduodenal damage in all cases, but resolved in almost all, despite continuing administration. The author hypothesized that the severity of mucosal damage depends on the reduction in mucosal blood flow (SEDA-16, 108) (SEDA-17, 108).

Small bowel ulceration with thickening of the bowel wall and stricture formation in the terminal ileum and the ileocecal junction occurred in a patient with rheumatoid arthritis taking long-term indometacin (SEDA-12, 84). This is one reason why prolonged courses of indometacin should be avoided whenever possible, especially in elderly women.

Osmosin, a formulation that contains potassium bicarbonate and releases indometacin osmotically, was withdrawn because of reports of intestinal irritation, bleeding, perforation, and even death. These adverse effects were most probably caused by the very high local concentrations of indometacin and potassium in the lower part of the gastrointestinal tract produced by the tablet, which shifted the adverse reactions from the stomach to the intestine (SEDA-8, 103) (26).

Like other NSAIDs, a diaphragm-like right-sided colonic stricture has been described in a woman taking indometacin suppositories (27). Perforation of colonic diverticula has been described (28).

The use of indometacin suppositories can be associated with rectal irritation, mucosal inflammation, or necrosis with bleeding (29). The local effect on the gastric mucosa is less important than the systemic one, and suppositories do not cause fewer gastric lesions than oral formulations (30).

Liver

Despite reversible changes in liver enzyme tests (31) and a fatal case of acute hepatocellular necrosis, which may have been related to indometacin, the drug is rarely hepatotoxic (32). Indometacin-associated cholestatic liver injury has been described. The reaction was not severe and recovery was rapid and uneventful (33).

Urinary tract

Indometacin nephrotoxicity is rare in patients with normal renal function, but indometacin can aggravate preexisting renal impairment, as has been observed in patients with glomerulonephritis, nephrotic syndrome, systemic lupus erythematosus, and cirrhosis complicated by ascites (SED-8, 219) (SEDA-4, 65) (SEDA-7, 108) (SEDA-11, 85). Severe but reversible loss of renal function in patients with systemic lupus erythematosus in the absence of active renal disease suggests that mesangial contraction in the glomerulus could significantly reduce the capillary surface area available for filtration and hence reduce the glomerular filtration rate (34,35). There is a significant reduction in the glomerular filtration rate and a concomitant drop in renal excretion of sodium and water in patients with compensated cirrhosis without ascites treated with indometacin (SEDA-18, 101).

Probable indometacin-induced renal papillary necrosis has been described in two patients with chronic juvenile arthritis (SEDA-8, 103).

Reversible acute renal insufficiency with eosinophilia has been described (36).

The harmful effect of indometacin on renal function has been used therapeutically to induce medical nephrectomy (SEDA-7, 108).

Skin

Reactions to indometacin range from urticaria and pruritus to fixed rashes, purpura, and maculopapular and morbilliform eruptions. Toxic epidermal necrolysis has also been described (37). The frequency of skin reactions is lower than with pyrazolone derivatives. There is cross-sensitivity with aspirin.

Whether indometacin exacerbates psoriasis is not certain, but one report (38) suggests that it can.

Indometacin can exacerbate dermatitis herpetiformis (SEDA-10, 81).

Musculoskeletal

Progressive destruction of large weight-bearing hip joints was first observed during long-term indometacin therapy more than 25 years ago (SEDA-11, 87) (39). In one comparison of the effects of azapropazone and indometacin, the osteoarthritic process in the hip progressed more quickly in patients treated with indometacin, no doubt a further indication of its powerful inhibitory effect on prostaglandin synthesis (40). The mechanisms responsible for the harmful effect of NSAIDs on osteoarthritic joints have been reviewed (SEDA-11, 87).

Sexual function

Inhibition of prostaglandin synthesis can cause impotence. A healthy man became impotent while taking short-term indometacin 150 mg/day (SEDA-5, 101).

© 2006 Elsevier B.V. All rights reserved.

Immunologic

Masking of infection and abnormal immune reactions have been reported (41). It is not clear whether this has any clinical significance.

Second-Generation Effects

Fertility

Ovulation was inhibited by indometacin at high doses in the preovulatory period (SEDA-16, 109).

Pregnancy

The use of indometacin in late pregnancy has been much debated. Because of its ability to inhibit prostaglandin synthesis it can be used to arrest premature labor for a short time, although there is no evidence that it reduces the incidence of premature delivery. The hazards of using it as a tocolytic agent seem to outweigh any theoretical advantage, since there are many reports of serious adverse neonatal effects after the treatment of preterm labor with indometacin. They include premature closure of the ductus arteriosus, pulmonary hypertension with persistent fetal circulation, fetal anuria, severe oligohydramnios, necrotizing enterocolitis, perinatal death, and severe respiratory distress syndrome resulting in oxygen dependence for several days (SED-11, 179) (42–44) (SEDA-5, 101) (SEDA-6, 93) (SEDA-7, 108) (SEDA-8, 102) (SEDA-9, 88) (SEDA-12, 84) (SEDA-15, 99) (SEDA-16, 109) (SEDA-17, 108). The risks might be linked to the duration of use, but one study provided evidence that short-term indometacin can cause closure of the ductus arteriosus, even if several weeks elapse between treatment and delivery (45).

The risks involved in longer-term use are multiple, as several studies have shown. The use of indometacin and ibuprofen for more than 72 hours in 67 women in preterm labor was significantly associated with more oligohydramnios than either ritodrine or magnesium sulfate. Oligohydramnios developed in 70% of 37 women treated with indometacin, in 27% treated with ibuprofen, and in 2 controls (46).

Pregnant women taking beta-blockers for hypertension in pregnancy should not be given indometacin, as it can raise the blood pressure (47).

Teratogenicity

Indometacin in pregnancy is probably safe, provided its use is limited to the first 32 weeks of gestation. However, a possible teratogenic effect has been ascribed to it (48).

Cerebral ischemia has been described in premature twins following maternal use of indometacin (49).

The incidence and type of cerebral lesions were studied by ultrasound in 159 preterm infants: 76 fetuses were exposed to indometacin used as a tocolytic agent; in the other 83 pregnancies, tocolysis was either not started or limited to fenoterol. The incidence of periventricular leukomalacia was increased in infants exposed to any tocolytic agent; cystic lesions occurred more often in those exposed to indometacin (50).

Oligohydramnios and renal dysgenesis developed in one identical twin exposed to early prolonged high-dose indometacin. As indometacin causes oligohydramnios and renal dysgenesis in fetal monkeys, it may also have caused the abnormalities in this patient (51).

Antenatal indometacin therapy has been extensively reviewed (SEDA-18, 102). Data from a retrospective cohort study of 57 premature infants, born between the 24th and 30th weeks of gestation, whose mothers had been treated unsuccessfully with indometacin for preterm labor, confirmed several fetal and neonatal complications (52). However, the overall results provided inconclusive or contradictory data on the benefit to harm balance of indometacin as a tocolytic agent or as treatment for hydramnios (SEDA-18, 102).

Fetotoxicity

The possible association of indometacin tocolysis with neonatal necrotizing enterocolitis has been the subject of a case-control study (53). All cases of proven necrotizing enterocolitis were ascertained and four controls for each case were randomly identified. During 18 months there were 24 cases of necrotizing enterocolitis. Indometacin as a single tocolytic agent was not associated with necrotizing enterocolitis (OR = 1.0, 95% CI = 0.2, 4.8).

Lactation

The effects of indometacin during lactation are unclear. Convulsions in a breast-fed infant were linked to indometacin in the milk (54).

Susceptibility Factors

Age

Children

Pharmacokinetic factors (slow metabolism) may underlie the marked effect of indometacin on platelet aggregation in premature infants and small children. The use of indometacin in children with patent ductus arteriosus can be followed by a severe general reaction. Nephrotoxicity, abdominal distension, hemorrhagic enteritis, and necrotizing enterocolitis have been observed (SEDA-10, 81) (24,55). No retrospective study has shown that indometacin-treated infants have a higher incidence of retrolental hyperplasia or visual problems (56). Reopening of the ductus after indometacin-induced occlusion has been described (SEDA-18, 101), but the risks of using intravenous indometacin are few and it is more efficacious and safer than ligation.

Elderly people

Elderly patients are susceptible to the adverse effects of NSAIDs on the nervous system. A psychotic reaction has been described in one elderly man taking indometacin (57) and behavioral changes in another (58).

Gastrotoxicity is more frequent in this age group. Of 125 516 residents of US nursing homes during 1992–1996, patients who received at least one prescription for aspirin (n = 19 101) or NSAIDs (n = 9777) were identified (59). NSAID exposure increased the overall gastrointestinal-event-related hospitalization rate. The rates were highest in those taking sulindac, naproxen, or indometacin.

© 2006 Elsevier B.V. All rights reserved.

Other features of the patient

Patients with asthma or allergic rhinitis may be hypersensitive to indometacin and can develop severe general allergic reactions, especially if they are allergic to aspirin.

Indometacin should probably not be used postoperatively in patients with an increased risk of bleeding (SEDA-8, 103), because of its anti-platelet activity.

In athletes in training for a marathon, the use of indometacin may be dangerous, since it can provoke hyperkalemia and there is a risk of serious dysrhythmias (SEDA-14, 93).

Drug Administration

Drug formulations

Indometacin in eye-drop form can cause burning sensations, pruritus, local congestion and irritation, corneal epithelial changes, and edema of the eyelids (60).

Osmosin (Indosmos)

Osmosin (Indosmos) was an osmotic pump version of indometacin, which after a brief career, was withdrawn from the market in the summer of 1982. Indometacin, as a potent NSAID, found itself at the beginning of the 1980s facing heavy competition from a series of newer drugs that were about to be introduced; all were under patent, whereas some of the indometacin patents were about to expire, which could lead to a substantial fall in prices; some of the newer drugs (notably benoxaprofen, itself soon withdrawn, and piroxicam) were suitable for use as a single daily oral dose, which provided at least a marketing advantage; several were claimed, rightly or wrongly, to be relatively well-tolerated by the stomach. One possible answer to these problems seemed to be offered by developing an osmotic pump form of indometacin; in this form, the drug could be released relatively slowly, perhaps prolonging its duration of action and improving its gastric tolerability.

In fact, the question as to whether this form of indometacin really had these advantages has never been satisfactorily settled. The literature (61–64) does not appear to have shown a reduction in gastric adverse effects, at least not if one assesses the papers in question with the critical eye that must be brought to bear on claims of this type. On the other hand, it is clear that if a drug that has a potentially irritant action on the gastrointestinal tract is put into a modified-releasing form, tolerability problems may be displaced from the stomach to the lower parts of the gastrointestinal tract.

In the course of 1982, serious suspicions arose that this was indeed happening. In August, the UK's Committee on Safety of Medicines (CSM) stated that it had received 200 reports of adverse reactions to the product, which was considered a relatively high reporting level for a new drug, though more than 400 000 prescriptions had been issued over the previous 7 months. Many of the reports were of effects traditionally associated with indometacin (such as headache and gastrointestinal problems) and these did not seem to be less frequent with the new system. Two of the reports were of intestinal perforation distal to the duodenum, an unusual site for damage by NSAIDs. The CSM remarked that the release characteristics of the system might expose certain areas of the bowel to higher concentrations of indometacin than usual. It was also noted that the formulation contained potassium bicarbonate, a known bowel irritant (26).

It subsequently became clear that a fair number of cases of intestinal irritation, bleeding, perforation, and probably even death were attributable to the new formulation, leading to the product's withdrawal in countries where it had already been introduced.

The proposed mechanism of small bowel damage due to Osmosin is that the tablets adhered to the intestinal wall (or became lodged in diverticula), resulting in much higher local concentrations of indometacin and potassium than usual.

Indometacin-farnesil

Limited early experiences with indometacin-farnesil, a lipid-soluble indometacin derivative esterified with farnesol, suggested an adverse-effects profile similar to the indometacin, even though the compound was synthesized to reduce gastrotoxicity (SEDA-17, 109).

Drug administration route

Intravenous administration (in the treatment of ureteric colic) is effective and well tolerated. However, in 90% of patients who receive slow (5 minutes) intravenous injection, hypertension, nausea, vertigo, vomiting, and peptic ulcer symptoms have been documented (65). Intravenous administration should be avoided in patients with heart failure.

Intramuscular indometacin causes few adverse effects at the site of injection (redness, pain, induration) (SEDA-8, 102) and seems to have better systemic tolerability than intravenous indometacin: 26% of 388 patients treated with indometacin 100 mg/day developed an adverse effect (gastrointestinal or nervous system-related) and 4.6% interrupted treatment (66).

Drug–Drug Interactions

ACE inhibitors

Although lisinopril in association with indometacin reduced proteinuria in a small group of patients with nephritic syndrome, the combination also caused impairment of renal function and hyperkalemia in many patients (SEDA-16, 109).

Anti-platelet drugs

Indometacin potentiates the effect of anti-platelet drugs and anticoagulants (67).

Aspirin

Indometacin reduces the absorption of aspirin (68).

Beta-blockers

Attenuation of the hypotensive effect of propranolol and thiazide diuretics by indometacin was shown several years ago in a double-blind, placebo-controlled study of patients with essential hypertension (SEDA-6, 94).

© 2006 Elsevier B.V. All rights reserved.

Two women with pre-eclampsia treated with pindolol and propranolol became extremely hypertensive when indometacin was added for premature contractions (47). Pregnant women taking beta-blockers for hypertension in pregnancy should not be given indometacin, as it can raise the blood pressure (47).

Cyclophosphamide

Synergy between indometacin and cyclophosphamide has been advanced as the cause of a life-threatening acute water intoxication and severe hyponatremia observed in a patient with multiple myeloma and normal renal function (SEDA-15, 99).

Dipyridamole

Marked water retention has been observed during acute administration of dipyridamole in combination with indometacin (SEDA-13, 79).

Diuretics

Indometacin reduces the effect of diuretics (69). Combination of indometacin with Moduretic (co-amilozide; amiloride + hydrochlorothiazide) results in hyperkalemia (70).

Metformin

Renal insufficiency and severe metabolic acidosis developed in a patient with diabetes mellitus taking metformin after recent treatment with indometacin (SEDA-22, 118).

Muronomab

The interaction of indometacin with the immunosuppressive agent muromonab, a monoclonal antibody to CD3, is characterized by an increased risk of encephalopathic or psychotic features (71).

Probenecid

Probenecid inhibits the tubular secretion of indometacin (SEDA-4, 66).

Indoprofen

See also Non-steroidal anti-inflammatory drugs

General Information

Indoprofen is one of several NSAIDs that have been withdrawn because of adverse effects. The UK Licensing Authority suspended the product licence on grounds of safety in 1983, and in 1984 the Italian manufacturers decided to withdraw it from the world market. The UK decision was taken because there was a high rate of adverse drug reactions in a voluntary postmarketing surveillance study and the spontaneous adverse reaction reporting system had noted 217 serious adverse effects, mainly gastrointestinal bleeding and perforation. According to the manufacturers, the adverse effects profile in the UK did not emerge in other countries (1). A survey of adverse reactions in 6764 patients, mostly treated for 1 month or less, showed that life-threatening events were rare. A postmarketing surveillance study in 3823 osteoarthritic patients showed that serious adverse reactions were even less frequent (2).

Organs and Systems

Hematologic

The fact that indoprofen prolongs bleeding time and reduces platelet aggregation could result in indirect interactions with anticoagulants (3).

Gastrointestinal

When the UK Licensing Authority suspended the product licence the spontaneous adverse reaction reporting system had received 217 reports of serious adverse effects, mainly gastrointestinal bleeding and perforation.

Death

There were 46 deaths associated with indoprofen in three countries (UK 34, Italy 7, Germany 5), but only 11 were judged to be probably or possibly drug-related. Nine of these deaths were caused by gastrointestinal reactions.

Long-Term Effects

Tumorigenicity

The manufacturers' ultimate reason for worldwide withdrawal was the finding of carcinogenicity in long-term animal studies. To what extent the clinical events actually played a role in their decision is not clear.

Indoramin

See also Alpha-adrenoceptor antagonists

General Information

Indoramin is a postsynaptic selective alpha$_1$-adrenoceptor antagonist that is chemically distinct from the quinazolines. Unlike some other alpha-blockers, indoramin lowers blood pressure without a resulting reflex tachycardia or postural hypotension (1). However, it has largely been supplanted by more modern drugs, such as doxazosin, prazosin, and terazosin.

Organs and Systems

Nervous system

Indoramin penetrates the nervous system significantly and is reported to have a relatively high incidence of adverse effects, including sedation, dizziness, depression, headache, palpitation, dry mouth, and constipation (2). In a comparison with prazosin, prazosin produced a lower incidence of sedation, which is the most common adverse effect of indoramin, usually transient, in about 19% of cases (1). Other adverse effects that have sometimes led to withdrawal of indoramin have been dry mouth, dizziness, and failure of ejaculation. These adverse effects can be reduced by starting therapy with small doses and titrating gradually.

Drug–Drug Interactions

Alcohol

The sedative effect of indoramin is enhanced by alcohol (3).

Infliximab

See also Monoclonal antibodies

General Information

Infliximab, a monoclonal chimeric human/murine antibody directed against tumor necrosis alfa, has been used in the treatment of severe active Crohn's disease (1,2), rheumatoid arthritis (3), and ankylosing spondylitis (4). From the available data submitted for Crohn's disease to the US and European regulatory agencies, the most significant acute adverse reactions were infusion reactions, defined as symptoms within 2 hours after intravenous infusion. The symptoms consisted of fever, chills, urticaria, dyspnea, chest pain, or hypotension, and occurred in 16% of infliximab-treated patients versus 6–7% of placebo-treated patients. Several adverse effects, such as upper respiratory tract infections, headaches, rash, or cough, were more common than with placebo, but severe adverse effects were only slightly more frequent (3.6 versus 2.6%). Clinical trials also showed an increase in the prevalence of antinuclear antibodies or the development of double-stranded DNA antibodies (9% of patients). Although there were clinical features suggestive of the lupus-like syndrome in only very few patients, this issue needs to be further investigated. Also of great concern is the report in several patients of lymphoma (5) or severe opportunistic infections (6). Patients taking concomitant immunosuppressive drugs should be carefully observed for such complications.

Organs and Systems

Cardiovascular

The preliminary results of a phase II trial in patients with moderate to severe congestive heart failure showed a higher incidence of worsening congestive heart failure and death in patients treated with infliximab compared with placebo (7). This led to warnings from regulatory agencies and to the limited use of infliximab in patients with congestive heart failure.

Death due to worsening of cardiac insufficiency in patients with congestive heart failure has been reported (SEDA-26, 401).

Respiratory

Allergic granulomatosis of the lung has been described after a second infusion of infliximab in one of 35 patients with active ankylosing spondylitis (8). The clinical and radiological symptoms resolved 8 weeks after withdrawal, but no other details were given.

- A 32-year-old man with Crohn's disease developed an eosinophilic pleural effusion soon after a second infusion of infliximab (9). He recovered within 8 weeks, but the effusion recurred after infliximab re-treatment 1 year later.

Nervous system

Features of aseptic meningitis have been reported after multiple infliximab injections (10).

- A 53-year-old man with severe rheumatoid arthritis and mixed type III cryoglobulinemia received his first four injections of infliximab uneventfully, but 4 hours after the fifth injection had severe muscle pain in the lower limbs, which required morphine and abated within 3 days. Similar symptoms were observed after the sixth injection. There were no signs of meningitis, the cerebrospinal fluid contained lymphocytes and increased concentrations of protein and IgG. Cultures were negative and MRI scans of the brain and the spine were normal. The CSF was normal 1 month later.

The authors speculated that the most likely explanation for these observations was linked to the lack of transfer of high-molecular weight soluble receptors and IgG across the blood–brain barrier, implying that control of brain tumor necrosis factor alfa cannot be obtained with monoclonal antibodies. They thought that neurological complications in diseases other than multiple sclerosis might be related to control of tumor necrosis factor alfa in the periphery, resulting in an enhanced contribution of brain-derived tumor necrosis factor alfa or other cytokines, such as interleukin-1.

Neurological events suggestive of demyelinating disorders in patients treated with tumor necrosis factor alfa antagonists and reported to the FDA's Adverse Events Reporting System have been reviewed (11). These included 17 cases temporarily associated with etanercept and two with infliximab, but complete information was lacking in a number of cases. The various hypothetical mechanisms by which tumor necrosis factor alfa antagonists might produce demyelinating events have been discussed (12). Briefly, they cause an increase in peripheral T cell autoreactivity, and their inability to cross the blood–brain barrier may account for exacerbation of central demyelinating disorders.

Sensory systems

Optic neuropathy has been described in patients with rheumatoid arthritis taking infliximab. In three patients aged 54–62 years, blurred vision or visual field loss in one or both eyes occurred after the third dose (13).

© 2006 Elsevier B.V. All rights reserved.

Ophthalmic examination showed anterior optic neuropathy in all three patients and MRI scanning ruled out demyelinating optic neuritis. In one patient an additional infusion of infliximab produced similar symptoms in the previously unaffected eye; vision failed to improve despite infliximab withdrawal and steroid treatment.

- Retrobulbar optic neuritis was diagnosed after the ninth dose of infliximab in a 55-year-old woman (14). MRI scanning showed demyelination of the left optic nerve and the visual field defect improved after treatment with prednisone.

Hematologic

The possible role of infliximab in the development of hypercoagulability disorders has been discussed in the context of a case of arterial thrombosis (15).

- A 72-year-old woman with refractory sarcoidosis developed venous thrombosis at a catheter site and extensive multiple thromboses in small arteries in her legs after receiving a third dose of infliximab for severe enteropathy. Anticardiolipin antibodies were detected, but antinuclear and anti-double-stranded DNA antibodies were negative.

Although infliximab has been associated with autoantibody production, it is not known whether it contributed to hypercoagulability in this patient.

Liver

Acute hepatitis with infliximab has been described (16).

- A 44-year-old woman, who had used oral contraceptives for many years and had taken mesalazine, mercaptopurine, and prednisone for Crohn's disease for 7 years, developed clinical and biological signs of acute mixed hepatitis 19 days after a single dose of infliximab 5 mg/kg. There were no symptoms suggestive of hypersensitivity and liver histology showed cholestasis without inflammation or eosinophilia. Other causes, such as a recent viral infection (hepatitis A, B, C, cytomegalovirus, *Herpes simplex*) or gallstones, were ruled out. Among various autoantibodies, only antinuclear antibody titers were slightly raised. Complete normalization was observed 2 months later.

Although the patient took other potentially hepatotoxic drugs, the time-course suggested that infliximab was the cause.

Skin

Skin reactions, including erythema multiforme in three patients and a lichenoid eruption in one, were attributed to infliximab (17). One patient had similar lesions after etanercept. Patch tests with infliximab in three patients were negative, but produced a flare-up of lesions in one patient and recurrence of malaise and nausea in another patient, suggesting that infliximab is well absorbed percutaneously.

- A 72-year-old man developed bullous skin lesions the day after receiving his fourth dose of infliximab for rheumatoid arthritis (18). Human antichimeric antibodies were positive, as were antinuclear antibodies, and he completely recovered after treatment with prednisone.

In three patients with severe Crohn's disease who required digestive surgery, infliximab before or immediately after surgery was discussed as an additional possible cause of postoperative poor wound healing with serious complications (19).

Patients with congestive heart failure has been reported (SEDA-26, 401).

Immunologic

Antibodies to infliximab

Treatment with infliximab can be associated with the formation of human antichimeric antibodies. Such antibodies were rarely detected in patients with rheumatoid arthritis who were also taking methotrexate, and low titers were detected in about 13% of patients with Crohn's disease. Their clinical relevance is unclear, although their presence has sometimes been associated with an increased risk of infusion reactions, the occurrence of serum sickness-like reactions after delayed re-treatment, and a shorter duration of response.

In a randomized, placebo-controlled trial in 573 patients with Crohn's disease, who responded to an initial infusion of infliximab and were then given repeated infusions, antibodies to infliximab were found in 14%; there was a trend toward a lower incidence of antibodies in patients taking concurrent glucocorticoids and immunosuppressive drugs (20). The incidence of infusion reactions was also higher in patients positive for antibodies to infliximab compared with patients without antibodies (16 versus 8%) and lower in patients who were taking both glucocorticoids and immunosuppressants compared with patients who were receiving neither (8 versus 32%).

The clinical significance of antibodies to infliximab has also been explored in 125 patients with Crohn's disease who were given infliximab, of whom 61% had antibodies after the fifth infusion; however, there was no further increase in incidence after subsequent treatment (21). The presence of antibodies was associated with a 2.4-fold increase in the risk of infusion reactions, lower serum infliximab concentrations, and a shorter duration of clinical response, compared with patients with no infliximab antibodies. Patients who received concomitant immunosuppressive therapy had a lower incidence of infliximab antibodies, higher infliximab serum concentrations, and a longer duration of clinical response. Pretreatment with glucocorticoids may reduce the risk of antibody formation, but it is not known whether a pretreatment test for human antichimeric antibodies has a predictive value for adverse reactions (22). However, there were technical issues relating to the antibody assay and definition of clinically relevant antibody titers in this study.

Autoantibodies and autoimmunity

Infliximab may increase the risk of autoimmunity, but the presence of antibodies did not predict the risk of lupus-like syndrome. In trials, the incidence of infliximab-induced anti-double-stranded DNA antibodies ranged from 5 to 34% of patients, depending on the assay method

© 2006 Elsevier B.V. All rights reserved.

used and the duration of exposure (20–24). However, these abnormalities were rarely associated with clinical manifestations. In two large randomized trials in more than 900 infliximab-treated patients, only three developed a lupus-like syndrome, with no evidence of systemic organ involvement (20–24). However, since then, several reports have detailed infliximab-induced, lupus-like syndrome in patients with Crohn's colitis or rheumatoid arthritis, with improvement on withdrawal of infliximab (25,26).

Of 40 patients who had received multiple doses of an investigational liquid formulation of infliximab 2–4 years before, 10 had a severe delayed hypersensitivity reaction within 3–12 days after the first or the second re-infusion (27). This reaction mostly included myalgia, rash, fever, polyarthralgia, and pruritus. Although the six patients tested were negative for antibodies to infliximab before re-infusion, these antibodies were consistently raised after the reaction.

Infliximab binds to tumor necrosis factor alfa on cell surfaces and produces apoptotic cell death, releasing the nucleosomal autoantigens that induce autoantibody formation (28).

- A 69-year-old woman with a 5-year history of rheumatoid arthritis developed drug-induced lupus after receiving infliximab for 23 weeks. She had initially been given methotrexate and prednisone for 4 years. Then, because of lack of efficacy, infliximab was introduced. After three infusions of infliximab and only partial remission the dose was increased to 5 mg/kg, with success. However, before the sixth infusion she developed fever, polyarthralgia, myalgia, and general malaise. Serology excluded viral infection. Autoantibody assessment was positive, confirming the diagnosis of drug-induced lupus.

Hypersensitivity reactions

Both acute and delayed hypersensitivity reactions to infliximab have been reported in clinical trials (SEDA-24, 439).

Immediate infusion reactions to infliximab are usually defined by any significant adverse effect that occurs during or within 1–2 hours after the infusion. The symptoms mostly consist of flushing, rash, shortness of breath, wheeze, hotness, chest pain, vomiting, and abdominal pain.

Delayed reactions are defined by the occurrence of arthralgia and joint stiffness (that is a serum sickness-like reaction) in the days after infliximab administration; they have mostly been observed in patients with Crohn's disease who have received episodic treatment. In one patient the complication was associated with acute respiratory distress syndrome, which only became evident 10 days after re-treatment (22).

Incidence

Immediate hypersensitivity reactions to infliximab occur in 6–19% of adults.

In a retrospective evaluation of 165 patients (479 infliximab infusions) with Crohn's disease, the overall incidence of infusion reactions was 6.1% (29 episodes) (29). Acute infusion reactions within 24 hours of infusion were the most frequent (26 episodes) and delayed infusion reactions from 1 to 14 days after treatment were noted in three instances only. Prophylaxis with diphenhydramine and paracetamol and the use of a test dose of infliximab allowed additional infusions without consequences in patients with mild or moderate previous acute infusion reactions. Three of the four patients who had acute severe reactions received the same prophylaxis plus corticosteroids before re-treatment: one had a similar severe acute reaction, while the other two had no recurrences. This study also suggested that acute infusion reactions are probably not IgE-mediated, as tryptase and IgE serum concentrations were not raised.

Of 86 patients with Crohn's disease receiving infliximab 14% of patients experienced severe systemic reactions, with a significant difference between adults (21%) and children (3%), the reason for which was unclear (30).

There were severe infusion reactions, defined by any significant change in vital signs or the development of chest pain, wheeze, dyspnea, vomiting, abdominal pain, or rash, in 16 of 100 patients with refractory Crohn's disease (31). Half of them occurred during the first infusion, and the rate of infusion reactions was similar in patients taking concurrent immunosuppressants or glucocorticoids compared with those who were not. One patient had anaphylactic shock, five had significant hypotension, six had acute pulmonary symptoms, two had pruritus, flushing, or rash, and one had vomiting. The final patient, who had a previous history of chronic pancreatitis, had acute pancreatitis within 1 hour of treatment.

Immediate hypersensitivity reactions

Acute hypersensitivity reactions can mimic an anaphylactic reaction, but specific IgE antibodies have not so far been identified. A dose-escalation protocol has been proposed to desensitize patients who have had acute systemic reactions (32), but this has not always been successful (33). Although most reported anaphylactic reactions to infliximab have been mild, severe reactions can occur.

- A 36-year-old man with Crohn's disease became refractory to standard anti-inflammatory treatment (glucocorticoids, mercaptopurine, methotrexate, ciclosporin, tacrolimus) (33). Remission over 8 months was achieved with a single infusion of infliximab. With the onset of relapse he was given another infusion of infliximab and had an anaphylactic-like reaction within 1 minute.
- A 35-year-old woman with known hypersensitivity to mesalazine had severe symptoms, namely chest pain, dyspnea, productive cough, skin rash, and hypotension, during a third infusion of infliximab, and died 6 hours later from refractory hypotension and respiratory failure (34). Specific IgE or human antichimeric antibodies were not checked.
- A 33-year-old man with a 3-year history of Crohn's disease had previously received a well-tolerated single infusion of infliximab. When, 14 months later, he received a second infusion for exacerbation of the disease he had no immediate adverse effects, but complained of myalgia, arthralgia, nausea, and vomiting 7 days later and received diphenhydramine. After 3 days he had dyspnea, fever, and chills. An open lung biopsy showed features of eosinophilic pneumonia and no

© 2006 Elsevier B.V. All rights reserved.

infections or other obvious causes were found. He subsequently worsened and required intubation and mechanical ventilation for 13 days. He was given glucocorticoids and quadruple antituberculosis drug therapy and recovered completely within 2 months. Human antichimeric antibodies were raised (13 times normal).
- A 73-year-old woman had three separate episodes of vascular purpura (with leukocytoclastic vasculitis during the third episode) during each sequence of treatment with etanercept; she later developed similar cutaneous lesions after a third injection of infliximab (35).

Delayed hypersensitivity reactions

Delayed hypersensitivity reactions were mostly observed in patients with Crohn's disease who received episodic treatment. In one patient, this complication was associated with acute respiratory distress syndrome, which became evident only 10 days after retreatment (22).

Susceptibility factors

Susceptibility factors for the development of severe systemic reactions after infliximab retreatment have been analysed in 52 adults and 34 children with Crohn's disease (30). Acute severe systemic reactions were defined by symptoms of anaphylactic reactions that required pharmacological treatment, and delayed severe systemic reactions were defined by the occurrence of arthralgia and joint stiffness (that is serum sickness-like symptoms) requiring glucocorticoids in the days after infliximab retreatment. According to these definitions, severe systemic reactions developed in 14% of patients (four acute and eight delayed) during retreatment. They were significantly more frequent in adults than in children (21 versus 3%), and delayed systemic reactions were observed exclusively in adults. These reactions mostly occurred during the second infusion of infliximab, and particularly when retreatment was distant from the first infusion, that is beyond a 20-week interval. This suggested a higher potential for delayed hypersensitivity reactions when repeated doses are given within a longer time interval, and led the authors to recommend multiple early infusions if future infliximab retreatment is anticipated.

In a retrospective review of 361 infliximab infusions in 57 children with inflammatory bowel disease there were 35 episodes of infusion reactions (36). Female sex, previous episodes of infusion reactions, and the use of immunosuppressive therapy for less than 4 months were significant predictors of subsequent infusion reactions.

Infection risk

Infliximab can increase the susceptibility of patients to severe infections, and in particular opportunistic infections (SEDA-26, 402). In patients who received repeated infusions of infliximab, infections requiring antimicrobial treatment occurred in about 30% of patients and severe infections in 4% (20).

Bacterial infections

Blockade of tumor necrosis factor alfa impairs resistance to infections with intracellular pathogens such as mycobacteria, *Pneumocystis jiroveci*, *Listeria monocytogenes*, and *Legionella pneumophila* (37,38). Severe streptococcal and staphylococcal infections have also been observed. Case reports with very severe or fatal outcomes have usually been reported in patients taking concomitant immunosuppressants and have included:

- necrotizing fasciitis due to streptococcal infection (39)
- septicemia due to *Staphylococcus aureus* (40)
- *Listeria monocytogenes* infection (41)
- disseminated tuberculosis (42)
- listeriosis (37).

The safety and efficacy of infliximab have been assessed in 40 patients with severe active spondylarthropathy in a double-blind, randomized, placebo-controlled trial (43). One 65-year-old patient improved but 3 weeks after the third infusion developed a systemic illness. He had enlarged mediastinal lymph nodes and nodular lesion of the liver and spleen. Biopsy of the mediastinal lymph nodes showed tuberculosis, which was confirmed by culture. He was treated and recovered slowly.

Reactivation of latent tuberculosis is a major concern with infliximab (SEDA-26, 402), and accounts for about one-third of infections in these patients. According to data from the manufacturers, 130 cases of active tuberculosis were notified up to October 2001. Many of the cases were disseminated or extrapulmonary tuberculosis, and several patients died. Several case reports have provided detailed information in at least seven other patients, including three who developed miliary tuberculosis and one who developed *Mycobacterium tuberculosis* enteritis (44–48). A detailed analysis of 70 cases of tuberculosis reported to the FDA has been published (49). Two-thirds of the cases were noted after three or fewer infusions and 57% of the patients had extrapulmonary disease. There were 64 cases from countries with a low incidence of tuberculosis. From these reports and the number of patients treated with infliximab, the estimated rate of tuberculosis in patients with rheumatoid arthritis treated with infliximab was four times higher than the background rate. Patients with evidence of active infection should not receive infliximab until the infection is under control; all should be screened for tuberculosis before starting infliximab (50). From these and other data it has been estimated that the risk of tuberculosis in the first year of infliximab treatment is 0.035 in US citizens and 0.2% in non-US citizens. Further investigations, such as a chest X-ray and a Mantoux test, and prophylactic treatment with isoniazid, will show whether the incidence can be reduced in patients taking anti-TNF treatment (51).

In a multicenter trial in 70 patients with ankylosing spondylitis given infliximab, treatment had to be withdrawn in three patients because of systemic tuberculosis, allergic granulomatosis of the lung, or mild leukopenia; after withdrawal all three recovered (8). However, the allergic granulomatosis of the lung was probably due to a hypersensitivity reaction.

- An 11-year-old boy with Crohn's disease received infliximab and 3 days later developed fever, signs of cardiac failure, and *S. aureus* sepsis (52). At surgery an intramyocardial para-aortic abscess with destruction of the aortic valve was found, suggesting chronic infection, possibly activated by the use of infliximab.

© 2006 Elsevier B.V. All rights reserved.

Crohn's disease can lead to vasculitic changes of the aorta, which may have favored the development of the intramyocardial abscess in this case. The size of the abscess suggested persistence for several weeks.

Severe necrotizing fasciitis has been reported in a patient who was given infliximab (39).

- A 54-year-old man with rheumatoid arthritis for 12 years was given infliximab, with remission. He then developed a painful, confluent, erythematous, pustular rash over his trunk and limbs. Skin biopsy showed an acute pustular dermatitis. Five hours later he collapsed with a tachycardia (140/minute) and a blood pressure of 120/70 mmHg. He was apyrexial. His left leg was very tense, painful, and swollen, and he had a disseminated intravascular coagulopathy. There was marked necrosis of his adductor compartment and fascia of his left thigh and necrotic muscles were debrided. Blood cultures and skin swabs grew group A hemolytic streptococci. He then became unstable and died, despite efforts at resuscitation.

Viral infections

Infliximab can compromise antiviral defence mechanisms. There have been detailed reports of cytomegalovirus retinitis (53) and life-threatening disseminated cytomegalovirus infection (54). Most of these patients were taking concomitant immunosuppressants at the time of diagnosis.

- A 67-year-old woman with a 5-year history of rheumatoid arthritis, who had taken prednisone and methotrexate, was given infliximab (55). Her rheumatoid arthritis improved, but she developed multiple bilateral lesions of molluscum contagiosum on the upper and lower eyelids, despite normal CD4 and CD8 counts. She had had similar lesions during a previous course of infliximab. Excision biopsy confirmed the diagnosis.

Protozoal infections

There has been a detailed report of *P. jiroveci* pneumonia (56).

Fungal infections

In a review of 10 cases of histoplasmosis in patients treated with infliximab ($n = 9$) or etanercept ($n = 1$) the infection occurred within 1 week to 6 months after the first dose (57). Of these 10 patients, nine required treatment in an intensive care unit and one died. All lived in regions in which histoplasmosis was endemic. It was not possible to determine which patients had new infections or reactivation of previous infections.

In 41 patients with rheumatic disease who received a total of 300 infusions of infliximab over 9 months there were severe adverse effects in 15%, one of which was a case of histoplasmosis (58).

- A 28-year-old woman with unresponsive rheumatic disease developed histoplasmosis after a second infusion of infliximab. She had pet birds, and the authors thought that she had had reactivation of an infection rather than a new infection.

There have been other reports of histoplasmosis (59), invasive pulmonary aspergillosis (60), and extensive pulmonary coccidioidomycosis (61).

Death

- A 64-year-old man without heart failure was found dead 18 hours after a single infusion of infliximab for rheumatoid arthritis (62). No obvious cause was found at autopsy, except that the patient was known to have had frequent intervention by a pacemaker that had been implanted for several years.

Long-Term Effects

Tumorigenicity

There is great concern about the potential development of malignancy after blockade of tumor necrosis factor alfa, and it is biologically plausible. However, it is unclear whether this is a drug-related or a disease-related phenomenon.

There have been several cases of lymphoproliferative disease (B cell non-Hodgkin's lymphoma and nodular sclerosing Hodgkin's disease) in the 9 months after infliximab infusion in patients with Crohn's disease (63). The FDA received reports of 26 cases of lymphoproliferative disorders in patients treated with etanercept ($n = 18$) or infliximab ($n = 8$) over 20 months (64). Although this reporting rate does not exceed the age-adjusted incidence of lymphomas in the USA, spontaneous reporting underestimates the true incidence. In addition, several findings were similar to those reported in patients taking immunosuppressive drugs after transplantation. For example, 81% of the reported cases were non-Hodgkin's lymphomas. Also, the median time to occurrence after the start of anti-TNF-alfa treatment was only 8 weeks. Finally, lymphoma regressed in two patients after withdrawal and without specific cytotoxic therapy. Although the actual incidence of neoplasia was low, additional long-term data that take into account concomitant or previous immunosuppressive treatment are needed before firm conclusions can be reached.

Influenza vaccine

See also Vaccines

General Information

Influenza vaccine viruses are propagated in embryonated chicken eggs. The virus-containing extra-embryonic fluid is harvested, purified, and inactivated with formalin. Inactivated flu vaccine is produced either as whole virus vaccine or ether-disrupted split or subunit preparations. However, many other new or modified influenza vaccines are already available or are expected to appear in the near future, for example vaccines containing new adjuvants, live attenuated vaccines, and vaccines administered by alternative routes.

Comparisons of reactogenicity (and immunogenicity) of different vaccine types have been provided (SEDA-8, 299) (SEDA-10, 290) (SEDA-11, 290) (SEDA-12, 282) (SEDA-13, 286) (SEDA-14, 284) (SEDA-15, 351) (SEDA-16, 386) (SEDA-17, 375) (SEDA-18, 335) (1). In most of these trials the investigators found little difference in reactogenicity between the various vaccines.

The safety and immunogenicity of an inactivated subunit influenza vaccine containing MF59 (oil-in-water emulsion, squalene, and Tween 80 and sorbitan trioleate as stabilizers) as an adjuvant has been described in two studies of 92 and 211 elderly persons (65 years of age and over) (2,3). Investigations were carried out during three consecutive influenza seasons. Compared with a commercial non-adjuvant subunit vaccine containing the same influenza strains recommended by the World Health Organization, geometric mean titers and seroconversion rates were higher after the use of the newly developed vaccine. The adjuvant vaccine caused more local reactions than the conventional vaccine. However, the reactions were mild and limited to the first 2–3 days after immunization. Systemic reactions were not significantly different, except for mild transient malaise. Considering the better immunogenicity of the adjuvant vaccine, the authors recommended it particularly for elderly people, who are at greatest risk of developing severe influenza disease. The vaccine manufactured by Chiron Behring has been already licensed for persons of 65 years of age and over in Italy and Germany.

The results of several clinical trials with a liposomal influenza vaccine have been reviewed (4). This trivalent liposomal influenza vaccine consists of purified influenza hemagglutinin inserted into a membrane of phosphatidylcholine and phosphatidyl-ethanolamine; it contains 15 micrograms of hemagglutinin per viral strain per dose. The trials included two randomized studies (in 126 healthy nursing home residents aged 63–102 years and 72 elderly individuals aged 60–98 years) and four double-blind studies (in a total of 831 elderly persons aged 67–71 years and younger adults aged 28–38 years); further studies included 24 children and adults with cystic fibrosis and 49 children at high risk of influenza. In all of these studies, the liposomal vaccine was compared with commercially available whole and subunit influenza virus vaccines. In general, seroconversion rates were significantly higher with the liposomal vaccine than with the commercially available vaccines. Local adverse reactions, such as pain at the injection site (up to 62% of children and up to 11% of adults), local induration and swelling (33% of all vaccine recipients), or redness (5% of adults and 20% of children) were transient and usually mild. One child with cystic fibrosis and two elderly persons had severe pain. Between 68 and 100% of children with cystic fibrosis reported at least one systemic reaction (fatigue, cough, coryza, headache) after the liposomal vaccine compared with 23–50% after the commercially available subunit vaccine. Fatigue (up to 19%), malaise (up to 14%), headache (up to 10%), and cough (up to 8%) were the most common systemic reactions reported by young adults and elderly people. There were single cases of severe fatigue, cough, and diarrhea in children with cystic fibrosis, young adults, and elderly people. Liposomal influenza vaccine did not induce a mean anti-phospholipid antibody response in the elderly volunteers.

In a randomized, double-blind study, trivalent, live, attenuated, cold-adapted intranasal influenza vaccine (FluMist) has been compared with intranasal placebo plus a trivalent injected inactivated influenza vaccine (5). The 200 patients were aged 65 years and over and had chronic cardiovascular or pulmonary conditions or diabetes mellitus. During the 7 days after immunization, sore throat was reported on at least one day by significantly more of the FluMist recipients (15 versus 2%). The increased frequency of sore throat may have been attributable to direct or indirect effects of vaccine virus replication. No other symptom was associated with FluMist. These findings were consistent with evaluations of other live, attenuated, cold-adapted influenza vaccine formulations in older adults. However, further studies of the safety of FluMist are warranted.

The immunogenicity and safety of inactivated intranasal influenza vaccine have been reviewed (6). The author concluded that the vaccine is highly immunogenic and well tolerated by most vaccinees, in terms of both local nasal symptoms and possible vaccine-mediated systemic symptoms. The symptoms were primarily mild, occasionally moderate, and in a few cases more severe; in most cases they lasted for only 1–2 days.

In 1997, an avian influenza A/Hongkong/97 (H5N1) virus emerged as a pandemic threat. A non-pathogenic variant influenza A/duck/Singapore/97 (H5N3) was identified as a leading vaccine candidate, but the non-adjuvanted antibody response was poor; however, the addition of the adjuvant MF59 (oil-in-water suspension) boosted the antibody responses to protective levels. In 65 volunteers who received either the non-adjuvanted or the adjuvanted vaccine, both vaccines were well tolerated and did not differ significantly. There was pain at the injection site of varying intensity in nine of the 32 volunteers who received the adjuvanted vaccine, and in none of the volunteers who received the non-adjuvanted vaccine (7).

General adverse effects

Local adverse reactions after flu immunization are few and infrequent. Slight to moderate tenderness, erythema, and induration at the injection site lasting 1–2 days occur in 15–30% of recipients. Fever, malaise, myalgia, and other symptoms of toxicity are rare (about 2%) and most often affect persons with no prior exposure to the flu antigens in the vaccine, for example young children. These reactions usually begin 6–12 hours after immunization and can last 1 or 2 days. They have been attributed to the vaccine, although the virus is inactivated. On the other hand, cases of respiratory diseases among vaccinees are coincidental. Although current flu vaccines are highly purified, they can cause hypersensitivity reactions such as hives or angioedema, perhaps due to residual egg protein (8,9). Notwithstanding the fact that the egg protein content is small, asthma or anaphylactic reactions with vascular purpura and encephalopathy can occur in those who are sensitive to the material (10,11).

Incidence

A nationwide surveillance system covering illness after flu immunization in the USA in 1976–77 among over 48 million persons immunized in 1976 with A/New Jersey/76 influenza vaccine (swine flu vaccine) resulted in a total of 4733 reports of illness, including reports of 223 deaths (12). Since most of the deaths occurred within 48 hours of immunization, the figures for deaths per 100 000 vaccinees (by diagnosis) were compared with the expected death rate (by the same diagnosis) per 100 000 population for a 2-day period. In general, the crude expected death rate was much higher than the death rate among vaccinees. Other than Guillain–Barré syndrome and rare cases of anaphylaxis, no serious illnesses seemed to be causally associated with flu immunization. However, widespread under-reporting of illness and death in the passive phase of this surveillance system impaired the validity of the study. Allergic skin reactions were reported at a rate of 0.3 per 100000 vaccinees and severe anaphylaxis at a rate of 0.024 per 100000. There was a cluster of four cases of encephalitis within 1 week of vaccine administration in one state. There were three deaths from cardiovascular disease in chronically ill persons over 70 years of age immunized in one clinic. It was not possible to establish a causative link between immunization and death. Persons immunized in the clinic died at rate of 5 per 100000 per day, in contrast to the expected rate of 17 per 100000 per day for people aged 65 years and older in the respective state.

Case reports of complications temporarily connected with the administration of flu vaccine have been

© 2006 Elsevier B.V. All rights reserved.

published. They include reports of acute disseminated encephalitis (13), acute thrombocytopenic purpura (14), acute transverse myelitis (15), aseptic meningitis (16), bullous pemphigoid (SEDA-21, 334), encephalopathy (17), erythromelalgia (18), optic neuritis (19) with reversible blindness (SEDA-4, 226) (SEDA-21, 334), optic atrophy (SEDA-6, 287), pericarditis (SEDA-7, 324), polymyalgia rheumatica (20), microscopic polyangiitis involving the skin and joints (21), acute symmetrical polyarthropathy with orbital myositis and posterior scleritis (22), systemic vasculitis (23), a trigeminal neuralgia-like symptoms (24), and vascular purpura with histological features of cutaneous necrotizing vasculitis (25).

The current status of adjuvanted influenza vaccines has been reviewed (26). The authors concluded that the vaccine produces a higher titer of antibodies than non-adjuvanted or virosomal vaccines. Local reactions occur more often, but are mild and transient. The results of a trial with two doses of an intranasally administered inactivated virosome-formulated influenza vaccine containing *Escherichia coli* heat-labile toxin as a mucosal adjuvant in 106 volunteers aged 33–63 years have been reported (27). About 50% of vaccinees had local adverse reactions (44% after the first dose and 54% after the second dose) or systemic adverse reactions (48 and 46%) after administration of the vaccine. Rhinorrhea, sneezing, and headache were the most common reactions; they were mild and transient and resolved within 24–48 hours. No febrile reactions were associated with immunization. Between 77 and 92% of vaccinees developed protective hemagglutination inhibition antibody titers against the two influenzae A strains of the vaccine, whereas protective antibody titers against the B strain of the vaccine were achieved in only 49–58%.

Organs and Systems

Cardiovascular

Influenza infection has been a significant problem in cardiac transplant patients; immunization of such patients could therefore be beneficial. However, its use has been limited by concern that stimulation of the immune system might in principle cause an increased risk of cardiac rejection. In the renal transplant experience, influenza infection itself can trigger an immunological response to cause graft rejection, as well as predisposing to other infections. Another concern is whether an immunosuppressed cardiac transplant recipient could seroconvert sufficiently. In a case-control study in 18 cardiac transplant recipients and 18 control patients 6 months or more beyond transplant surgery, there were no differences in the incidence of cardiac rejection or immune responses (28).

There have been reports of pericarditis (29,30) in temporal relation to influenza vaccine.

Respiratory

Of 109 children with asthma aged 6 months to 18 years immunized with trivalent subvirion influenza vaccine, 59 vaccinees had no asthma symptoms on the day of immunization, but 50 had an exacerbation requiring prednisone (31). Antibody responses were not different in the two groups. Adverse effects, including local swelling at the injection site, fever, rash, and headache, were not different in the two groups.

Nervous system

Adverse effects of flu immunization on the nervous system range from polyneuropathy to meningoencephalitis and Guillain–Barré syndrome (32).

Examination of new cases of multiple sclerosis among the 45 million swine flu vaccine recipients indicated no excess over the expected frequencies. Inactivated swine flu vaccine did not influence the onset or exacerbation of the disease (33).

Guillain–Barré syndrome

Guillain–Barré syndrome was observed during the 1976/7 mass immunization campaign in the USA. The vaccine then used was A/New Jersey/76 (H1N1) flu vaccine (swine influenza). The overall incidence of cases of Guillain–Barré syndrome attributed to the use of vaccine at that time was 4.9–5.9 per million vaccinees (34). Various authors tried to settle the question of a cause and effect relation. Detailed reports have been published (SEDA-10, 289) (SEDA-11, 290) and the resulting litigation has been reviewed (35). In an analysis of computerized summaries of 1300 cases, immunized cases with extensive paresis or paralysis occurred in a characteristic epidemiological pattern, suggesting a causal relation between immunization and Guillain–Barré syndrome (34). Cases with limited motor involvement showed no such pattern. Unlike the 1976 swine flu vaccine, vaccines used subsequently have not been associated with an increased frequency of Guillain–Barré syndrome. It has been calculated that the risk of polyneuropathy following immunization is one in 200 000, compared with a population incidence of spontaneous Guillain–Barré syndrome of one in 1 000 000 (36).

The original Centers for Disease Control study of the relation between A/New Jersey/876 (swine flu) vaccine and Guillain–Barré syndrome showed a statistically significant association and suggested a causal association between the two events. In an evaluation of the medical records of all previously reported adult patients with Guillain–Barré syndrome in Michigan and Minnesota from 1 October 1976 to 31 January 1977, the relative risk during the 6 weeks after flu immunization in adults was 7.10 (excess cases attributed to the vaccine: 8.6 per million vaccinees in Michigan and 9.7 per million vaccinees in Minnesota), comparable to the relative risk of 7.60 found in the original study (37). There was no increase in the relative risk of Guillain–Barré syndrome beyond 6 weeks after immunization.

A retrospective study (1980–88) conducted to determine if the US Army's mass influenza immunization program was associated with an increased incidence of Guillain–Barré syndrome found no temporally related increase (38).

The number of reports of influenza vaccine-associated Guillain–Barré syndrome to the US Vaccine Adverse Event Reporting System increased from 37 in 1992–93 to 74 in 1993–94, raising concerns about a possible increase in vaccine-associated risk. Detailed data analyses

© 2006 Elsevier B.V. All rights reserved.

showed that the relative risk of Guillain–Barré syndrome associated with influenza immunization, adjusted for age, sex, and vaccine season, was 2.0 for the 1992–93 season and 1.5 for the 1993–94 season. For the two seasons combined, the adjusted relative risk of 1.7 suggested that there was slightly more than one additional case of Guillain–Barré syndrome per million vaccinees. An accompanying editorial also referred to the occurrence of Guillain–Barré syndrome during the swine flu immunization campaign in 1976. The authors considered the results of this study as epidemiological evidence that immunization against strains of influenza other than swine flu may increase the risk of Guillain–Barré syndrome, albeit minimally (39).

Sensory systems

Four patients with corneal transplants developed ocular manifestations (bilateral graft rejection in two cases, uveitis, and epithelial and stromal herpetic kerato-uveitis) at 3 days to 6 weeks after the receipt of inactivated influenza vaccine (40). Whereas case reports of ocular manifestations after influenza immunization are known, this is perhaps the first report of vaccine-related herpetic recurrence. The authors advised caution when influenza immunization is considered for patients who have had a corneal transplant.

Urinary tract

There has been a report of minimal-change nephrotic syndrome (41) in temporal relation to influenza vaccine.

Skin

Influenza vaccine is one of at least 30 drugs believed to cause bullous pemphigoid or cicatricial pemphigoid (42).

- A 90-year-old woman developed a generalized bullous eruption resembling bullous pemphigoid 12 hours after influenza immunization (43).

Influenza vaccine can also cause pemphigus (44).

Musculoskeletal

There has been a report of rhabdomyolysis (45) in temporal relation to influenza vaccine.

Immunologic

Changes in the lymphocyte population similar to those observed during virus infections occurred within the first 2 weeks after immunization (46). There were no reports describing more severe courses of infectious diseases during this period.

The question of whether egg allergy is a justified contraindication to influenza immunization has been studied in 80 individuals with egg allergy and 124 control subjects, who received influenza vaccine containing ovalbumin/ovomucoid 0.02, 0.1, or 1.2 μg/ml (47). The individuals with egg allergy received the vaccine in two doses 30 minutes apart; the first dose was one-tenth and the second dose nine-tenths of the recommended dose. The patients with egg allergy, even those with significant allergic reactions after egg ingestion, safely received influenza vaccine in this two-dose protocol with vaccine containing no more than 1.2 μg/ml of egg protein.

There have been reports of individual cases of giant cell arteritis (48) and polymyalgia rheumatica (49,50) in temporal relation to influenza vaccine.

- A 70-year-old man, previously healthy, developed giant cell arteritis 5 days after influenza immunization (51).

The authors mentioned another case reported in 1976.

Drug Administration

Drug dosage regimens

Current recommendations for the use of influenza vaccine in adults are based on a single injection. This may not be valid in case of a new pandemic caused by an antigenic shift of the influenza virus. Currently, the only group for whom a second dose is recommended comprises children who have never been immunized. However, when two-dose regimens in adults have been studied, the second dose of vaccine has not been associated with higher rates of reactions than the first. People who have a stronger local reaction after a first injection are more likely to have another such reaction after a second injection (31).

Drug administration route

The intranasal administration of influenza vaccines has been reviewed (52). Trivalent cold-adapted intranasal influenza vaccine was used to immunize 1602 healthy children aged 15–71 months in a randomized, double-blind, placebo-controlled trial (53). One year later 1358 were reimmunized. The vaccine provided efficacy of 92% during 2 years against virologically confirmed influenza. Transient, minor symptoms of respiratory illness (rhinorrhea, nasal congestion, low-grade fever) were reported more often in vaccinees than in controls; no significant differences were noted after dose 1 and dose 2.

Drug–Drug Interactions

Anticoagulants

In a prospective study of the effect of flu immunization on the prothrombin time in eight patients taking long-term anticoagulant treatment the prothrombin time was prolonged by 40%. In healthy subjects there was no significant effect on warfarin metabolism (SEDA-10, 289).

- An 81-year-old patient who had been well controlled by anticoagulants for 12 years had an episode of gastrointestinal bleeding associated with influenza immunization (54).

However, others did not confirm this effect (55), and the lack of a clinical interaction with warfarin has also been confirmed by a report of the US Immunization Practices Advisory Committee (9).

Anticonvulsants

In a study of serum concentrations of the anticonvulsants phenytoin, phenobarbital, and carbamazepine, before and after mentally retarded patients received flu vaccine, the

© 2006 Elsevier B.V. All rights reserved.

authors concluded that serum concentrations of these drugs may increase as a result of flu immunization and that dosage adjustments may be necessary (56).

Benzodiazepines

The metabolism of lorazepam and chlordiazepoxide was not altered by flu immunization (57).

Theophylline

After influenza immunization there was a reduction in blood theophylline concentrations in patients and healthy volunteers (58). The authors concluded that flu vaccine may influence the pharmacokinetics of several drugs, and a second group found that theophylline oxidation was significantly reduced at 1 day, but not at 7 days, after immunization (57). However, others did not confirm these effects (55,59). The lack of a clinical interaction with theophylline has also been confirmed by a report of the US Immunization Practices Advisory Committee (9).

Inhaler propellants

General Information

Pulmonary delivery of drugs is the administration route of choice in respiratory diseases such as chronic obstructive pulmonary disease and asthma. Different devices are available, including metered-dose inhalers, dry powder inhalers, and nebulizers, and nearly 80% of asthmatic patients worldwide use metered dose inhalers (1). Chlorofluorocarbons have been used as an aerosol propellant in metered-dose inhalers; however, they deplete the ozone layer and are being replaced by more environment-friendly propellants, even though the contribution of aerosols of this type to the total global burden of chlorofluorocarbons is less than 0.5%. The first chlorofluorocarbon-free metered-dose inhaler for asthma treatment was approved by the FDA in 1996 (2) and the European Union has set 2005 as a target date for the withdrawal of all chlorofluorocarbon-based inhalers (1). In the USA, prescriptions for chlorofluorocarbon-free medications rose from 16.4 million in 1996 to 33.8 million in 2000 (2). Most of the chlorofluorocarbon-free medications were steroids for nasal use (27.2 million). However, chlorofluorocarbon-containing medications still represented two-thirds of all prescriptions and increased from 63.0 to 67.6 million dispensed (2).

Specific propellants

Freons (chlorofluorocarbons)

The multidose pressurized aerosols using chlorofluorocarbon propellants have been widely used.

In animal experiments, plasma concentrations of Freon 11 and Freon 12 of 20–35 μg/ml sensitized the heart to adrenaline and exercise. Severely ill asthmatic subjects (mean oxygen tension = 55 mmHg, range 50–80) were studied following therapeutic doses of a beta$_2$-adrenoceptor agonist pressurized aerosol. Plasma concentrations of

© 2006 Elsevier B.V. All rights reserved.

Freon 11 up to 4.53 μg/ml and of Freon 12 up to 4.73 μg/ml were measured after two inhalations. It was concluded that a toxic concentration could only be reached if the aerosol was taken on every breath for over 12 consecutive breaths (3).

Other excipients

The effects of other constituents present in multidose pressurized aerosols have been investigated in 11 850 asthmatic patients. Three aerosols were compared. Two placebo multidose pressurized aerosols contained the same chlorofluorocarbons but different dispersing chemicals, oleic acid (MDI-OA) and lecithin NF (MDI-L). Another contained salmeterol xinafoate (0.025 mg) plus lecithin NF (MDI-S). Peak expiratory flow rate was measured before and 5 minutes after inhalation. A 20% fall in peak expiratory flow rate was defined as clinically significant bronchoconstriction. A total of 180 (1.5%) patients developed bronchoconstriction, 43 in the MDI-S group, 67 in the MDI-L group, and 70 in the MDI-OA group. Bronchoconstriction was significantly less with the salmeterol aerosol. It was suggested that one of the inert constituents is the likely irritant causing occasional acute bronchoconstriction. The risk of this effect increased with age and decreasing pretreatment peak expiratory flow rate (4).

Preservatives

Inhalation of distilled water will cause bronchoconstriction in 60% of infants with a history of wheeze (SEDA-17, 212). If nebulizer solutions are hypotonic or hypertonic or contain preservatives (such as benzalkonium chloride, edetic acid, sulfites and metabisulfite) they can cause paradoxical bronchoconstriction. It has been recommended that all nebulizer solutions should be isotonic and free of preservatives (SEDA-13, 132). Unit dose vials are available in which the drug solution is isotonic and preservative-free. However, multidose formulations are still available and are widely used, as the cost per dose is less.

Benzalkonium chloride at concentrations greater than 0.005 mg/ml causes histamine release from mast cells in vitro. At a concentration of 0.03 mg/ml an excess of 90% of the histamine content is released (5). This is in the range of the minimum concentration of benzalkonium chloride recommended as a disinfectant (0.025 mg/ml). Inhalation of benzalkonium chloride nebulizer solution causes concentration-related falls in FEV_1 in patients with asthma (6). Benzalkonium chloride 0.3 mg also causes a temporary increase in airway reactivity to histamine. This amount of benzalkonium chloride is similar to that in a 2.5 mg dose from a multidose vial of salbutamol (7). Ipratropium containing benzalkonium chloride 0.25 mg/ml causes bronchoconstriction in a proportion of patients with asthma. Bronchodilatation is seen when 2 ml (0.5 mg) of preservative-free ipratropium bromide solution is inhaled (8). Benzalkonium chloride 0.1 mg/ml does not alter the bronchodilator effect of salbutamol. The difference between salbutamol and ipratropium may be the lower concentration of benzalkonium chloride in the salbutamol solution (0.1 versus 0.25 mg/ml) and the greater potency and more rapid onset of the bronchodilator response to salbutamol (9). Individual case reports suggest that multiple doses of nebulized salbutamol (containing benzalkonium chloride) can cause serious deterioration in severe asthma. This can be reversed by changing to a benzalkonium chloride-free formulation (10).

EDTA (edetate) is also used as a preservative in nebulizer preparations and produces a concentration-related bronchoconstriction (11).

Hydrofluoroalkanes

The search for ozone-friendly propellants has concentrated on two hydrofluoroalkanes with physicochemical properties similar to the chlorofluorocarbons: hydrofluoroalkane 134a and hydrofluoroalkane 227 (1). A new generation of chlorofluorocarbon-free metered dose inhalers has been designed by the pharmaceutical industry to be equivalent to the currently marketed chlorofluorocarbon-containing inhalers in terms of efficacy, safety, and dose delivery. This goal was achieved by using the Modulite technology, by dissolving the drug in the propellant with the aid of a glycerol-like co-solvent (12).

$Beta_2$-adrenoceptor agonists

The therapeutic effects of salbutamol and salmeterol were unaffected by hydrofluoroalkane 134a, and there were no clinically significant differences in safety parameters (13,14). The safety of the hydrofluoroalkane 134a salbutamol sulfate inhaler, Airomir, has been evaluated in a postmarketing surveillance study (15). A non-randomized study has been performed in 6614 patients with obstructive airways disease taking metered doses of salbutamol delivered by inhalers using either hydrofluoroalkane or chlorofluorocarbon as the propellant. There were no significant differences between the groups in the rate of hospital admissions for the condition for which salbutamol was prescribed, in visits to accident and emergency departments, or in unscheduled home visits. There were adverse events in 25% of patients in both groups. The most common adverse events were infection, bronchospasm, and upper respiratory tract infection. Adverse events attributed to the medication occurred in 3.1% of the patients who used the hydrofluoroalkane propellant and 0.7% of those who used the chlorofluorocarbon. This difference was significant (OR = 4.34; 95% CI = 2.22, 8.52). In contrast, serious adverse events occurred more often with the chlorofluorocarbon (3.7%) than with the hydrofluoroalkane (2.7%), but this difference was not significant.

More patients using the hydrofluoroalkane (18%) withdrew from the study than patients using the chlorofluorocarbon (4.8%). Most of the withdrawals in both groups were unrelated to safety (9 and 3.2% respectively). The reasons for withdrawal included intercurrent illness, loss to follow-up, and inadvertent prescription errors. More patients using the hydrofluoroalkane withdrew because of an adverse event or because of the taste of the inhaler, 3.8 versus 0.9% and 3.1 versus 0.2% respectively. The authors concluded that the data supported the evidence already obtained in clinical trials that reformulation of salbutamol in a hydrofluoroalkane propellant does not result in changes in safety compared with a chlorofluorocarbon formulation.

Hydrofluoroalkane 134a and chlorofluorocarbon have been compared in two randomized, double-blind, placebo-controlled studies with salbutamol. Salbutamol 180 μg in

© 2006 Elsevier B.V. All rights reserved.

hydrofluoroalkane 134a given 30 minutes before an exercise challenge was as safe and effective as 180 μg in chlorofluorocarbon in 24 patients with documented exercise-induced bronchospasm (16). In 63 patients with mild to moderate asthma salbutamol in hydrofluoroalkane 134a or chlorofluorocarbon were of comparable efficacy without any difference in the incidence of adverse events (17).

Glucocorticoids

Beclomethasone dipropionate and budesonide Modulite formulations have been compared with equivalent chlorofluorocarbon products in small groups of healthy volunteers and asthmatic patients (18): there was no significant difference in morning serum cortisol or urinary cortisol excretion, suggesting that the systemic availability of the inhaled corticosteroids with different propellants is similar. Moreover, plasma profiles of beclomethasone dipropionate and B17MP were similar after inhalation of beclomethasone dipropionate Modulite and beclomethasone dipropionate-chlorofluorocarbon, suggesting that pulmonary delivery to the lung is comparable with the two propellants (18).

There have been three randomized, double-blind studies in adult asthmatics of the efficacy and safety of a beclomethasone dipropionate-hydrofluoroalkane 134a formulation, equivalent in dose per actuation to the currently marketed beclomethasone dipropionate chlorofluorocarbon products (19–21). Daily doses of beclomethasone dipropionate hydrofluoroalkane 134a 1000 μg over 12 weeks given by metered-dose inhaler (19) or a spacer jet device (20) were equivalent in terms of safety and efficacy compared with beclomethasone dipropionate chlorofluorocarbon 1000 μg. The same was true for doses of 400 μg (21).

In another study, different doses of flunisolide hydrofluoroalkane were tested in 21 healthy adult volunteers for 4.5 days (170, 340, and 680 μg); there was a dose-related response after both single- and multiple-dose administration (22). There was no accumulation of flunisolide with repeated dosing, suggesting that the systemic availability of flunisolide hydrofluoroalkane is low. A randomized, double-blind, placebo-controlled study with daily doses of 80 and 160 μg over 12 weeks in 353 asthmatic children gave similar results (23).

These results suggest that the transition from chlorofluorocarbon-containing to chlorofluorocarbon-free metered-dose inhalers is possible without concerns about safety and efficacy.

Infection risk

Certain problems are peculiar to the use of wet nebulization inhalation devices. There is a risk of contamination of the airways with bacterial flora, which increases when treatment is given in a hospital (SEDA-2, 154). In one series of 41 patients in an intensive care unit who were being ventilated and were receiving nebulized salbutamol, all developed respiratory tract infections due to *Burkholderia* (*Pseudomonas*). The same organism (confirmed by molecular fingerprinting) was isolated from nebulizers and a multiple-dose bottle of salbutamol used for several of the patients. Appropriate infection control measures resolved the problem (SEDA-20, 185).

Inosine pranobex

General Information

Inosine pranobex is a synthetic product, also known as isoprinosine or inosine dimepranol acedobene, with antiviral properties that are assumed to be related to its effect on T cell-mediated immunity rather than to direct antiviral activity. It has been tried in a wide range of viral diseases and also in rheumatoid arthritis (1), multiple sclerosis (2), and alopecia (3). However, clinical trials have mostly shown only modest therapeutic benefit or none at all (1,4), and no specific adverse effects, except for an increase in serum uric acid concentrations (5), reflecting the metabolic pathways of purines (6).

Organs and Systems

Immunologic

Anecdotal reports have attributed aggravation of polymyositis (7) and generalized *Herpes zoster* virus infection to inosine pranobex (8).

Drug–Drug Interactions

Zidovudine

Inosine pranobex increased zidovudine plasma concentrations and half-life (9).

Insulin

General Information

Insulin is used for substitution therapy in patients with an absolute or relative deficiency of insulin. Most of the insulins now prescribed are either human or highly purified insulins of animal origin or synthetic insulins closely related to human insulin. The use of insulin of lesser purity is declining, but it is still used in considerable quantities in Eastern and Central Europe and in less developed countries. In some countries, both highly purified insulins of Western origin in concentrations of 100 U/ml, and locally produced less pure insulins in concentrations of 20, 40, or 80 U/ml are available at the same time, creating confusion. Patients have to realize that the syringe used for injection has to be concordant with the specific strength of insulin for which it has been made. The manner and the site of administration, the variation in duration of action of the various insulin formulations, the grade of purification, and differences in concentration cause specific problems.

The effects of insulin are modified by various factors. The speed and extent of absorption of insulin depends, for example, on the site of injection (1), the depth of the subcutaneous injection, skin temperature (2), the presence of lipodystrophy, and variation in the extent of inactivation of injected insulin. The disposal of insulin depends on many factors. Exercise and hard work lower the blood glucose and thereby increase the effect of

© 2006 Elsevier B.V. All rights reserved.

insulin. Infections and obesity reduce its effect. The timing of food intake and the composition of meals are also related to the action of insulin. A thin layer of fat, as sometimes occurs in the upper arm or in the thighs of thin men, can result in intramuscular injection, leading to faster absorption of long-acting insulins. This can reduce the absorption time by half (3). The major factors that affect the fate of injected insulin (and thereby also its risks) are listed in Table 1 (4).

Insulin has a half-life of only a few minutes when injected intravenously. It is therefore prepared in different formulations for subcutaneous injection, with different half-lives of absorption, giving different durations of action. The main formulations, with their approximate durations of action are given in Table 2.

An alternative method of altering the duration of action of insulin is to use analogues in which there are amino acid substitutions. Analogues are listed in Table 3. Insulin aspart, insulin detemir, insulin glargine, and insulin lispro are all covered in separate monographs.

General adverse effects

The major adverse effect of insulin is hypoglycemia, which is specifically dangerous when the patient's awareness of hypoglycemia is reduced or when long-acting formulations are used. Allergic reactions, although less common with newer formulations, regularly occur (5).

Table 1 The major factors that affect the fate of injected insulin

Variable	Clinical relevance
Insulin formulation	Ultra-short-acting insulin (half-life 0.5–2 hours) Regular insulin (half-life 2–4 hours) Intermediate-acting insulin (half-life 16–20 hours) Prolonged-acting insulin (half-life 36 hours and over) Intraindividual variation in absorption up to 50% Interindividual variation from day-to-day up to 25%
Insulin species	Of minimal importance
Injection technique	Contributes to variance
Injected region	Absorption faster from abdominal region than from femoral and gluteal regions; exercising the injected limb speeds up absorption (applies especially to regular insulin)
Subcutaneous blood flow	A major determinant of absorption rate and clinically significant for regular insulin (influenced by smoking, ambient temperature, exercise, and local massage)
Subcutaneous degradation of insulin	Usually of no clinical significance; in rare cases after insulin need exceeds 120 IU/day it might explain brittleness
Insulin antibodies	Increase unpredictably the circulating fraction of insulin and prolong its half-life; a rare cause of insulin resistance

Table 2 Formulations of human insulin (all rINNs) and their durations of action

Type of insulin	Onset of action (hours)	Maximum action (hours)	Duration of action (hours)
Ultra-short-acting			
Insulin aspart, insulin lispro	0.05–2	0.5–1.5	4
Short-acting			
Neutral insulin injection	0.3–0.5	1–3	5–8
Intermediate-acting			
Insulin zinc suspension (amorphous) (semilente)	1–2	6–10	12–16
Isophane insulin (Neutral Protamine Hagedorn, NPH)	1–2	4–6	11–20
Globin zinc insulin suspension	1–2	6–10	10–18
Compound insulin zinc suspension (lente)	2–4	3–12	14–24
Long-acting			
Protamine zinc insulin injection	4–6	16–24	24–36
Insulin zinc suspension (crystalline) (ultralente)	4–6	16–24	24–36
Insulin glargine, insulin detemir	0.5–1	1–24	22–28
Combined formulations			
Diphasic insulin injection	0.7–1	3–18	12–24

Rare complications are lipoatrophy or hypertrophy and insulin edema. Insulin has to be given by injection, with pumps or specific devices for intensive therapy, which all generate specific problems. Other ways of administrating insulin are still experimental.

Additives introduced as preservatives or to change the duration of action of insulin can also cause adverse effects.

Table 3 Insulin analogs

Analogue	Comments
Insulin aspart	Rapid-acting, short-acting; the proline at site 28 of the B chain is replaced by aspartate (B28Asp)
Insulin defalan	Prepared from insulin by removal of the terminal phenylalanine
Insulin detemir	Long-acting; the threonine is deleted at B30 and the lysine at B28 is acylated with a miristoyl side-chain (B29Lys (ϵ-tetradecanoyl)desB30)
Insulin glargine	Long-acting; the asparagine at A21 is replaced by glycine and two arginines are added to the C terminus of the B chain (A21Gly,B31Arg,B32Arg)
Insulin glulisine	Rapid-acting, short-acting; the asparagine at B3 is replaced by lysine and the lysine at B29 is replaced by glutamic acid (B3Lys,B29Glu)
Insulin lispro	Rapid-acting, short-acting (2–4 hours); the lysine at site 29 and the proline at site 28 of the B chain are interchanged (B28Lys,B29Pro)

Organs and Systems

Nervous system

Cerebral edema has been described during therapy of diabetic ketoacidosis with a large volume of fluid, resulting in rapid changes in plasma osmolality, mostly in young patients (SEDA-26, 462). However, in 10 adults with ketoacidosis, no signs of cerebral edema (supported by CT scans) were found (6).

Susceptibility factors for cerebral edema during ketoacidosis in children have been investigated in 61 cases of cerebral edema during 6977 hospital admissions (7). They were matched with two types of controls for each case: three children with ketoacidosis randomly selected and three children matched for age (within 2 years), onset of diabetes, blood pH, and serum glucose at entry. The results suggested that high initial serum urea concentrations and a low $PaCO_2$ are associated with an increased probability of cerebral edema. Children with these abnormalities should be monitored for signs of neurological deterioration, and hyperosmolar therapy should be immediately available. Treatment with bicarbonate was associated with an increased risk and should be avoided. In an accompanying editorial it was stated that high doses of insulin, hypotonic fluids, and bicarbonate are often seen as culprits, but it is also possible that it is an idiosyncratic response to diabetic ketoacidosis; there is no proof of either theory (8).

Metabolism

Hypoglycemia

The most frequent complication of insulin therapy is inadvertent hypoglycemia (9–11). Over 5% of deaths in diabetes can be attributed to hypoglycemia. The frequency increases with rigorous maintenance of normoglycemia (12,13). In the Diabetes Control and Complications Trial (DCCT) (14) the frequency of serious hypoglycemia was more than three times increased in the intensively treated group, and the frequency of the attacks was related to the concentration of HbA_{1c} (15). The UK Prospective Diabetes Study in patients with type 2 diabetes also showed an increased risk of hypoglycemia with more intensive treatment (16).

Attacks of hypoglycemia are often preceded by less marked attacks, which are unnoticed or not reported to the family or physician. Attacks can be caused by reduced resistance to insulin or switch to a type of insulin with a different duration of action. The reasons for hypoglycemia can be inaccurate or excessive insulin injections, heavy physical exercise, or omission of meals. The action of highly purified insulins and some new analogues, even when in long-acting form, is somewhat faster and shorter compared with less pure formulations. Errors in injection techniques, such as superficial subcutaneous injections, forming nodules or causing bleeding, can introduce variation in the absorption of insulin, resulting in an increase in the mean administered dose and in inadvertent hypoglycemia. Twice-daily isophane insulin for 6 months has been compared with once-daily ultralente insulin in 60 patients (17). Isophane was associated with fewer attacks of hypoglycemia, lower HbA_{1c}, lower evening glucose concentrations, and greater patient satisfaction.

The Somogyi effect, unnoticed hypoglycemia during sleep, causes a rebound increase in morning blood glucose with accompanying glycosuria. When, in response to this, the evening dose of long-acting insulin is increased, the risk of nocturnal hypoglycemia also increases, creating a vicious cycle. Blood glucose monitoring late at night helps to establish the diagnosis. Of 39 poorly controlled patients with insulin-treated diabetes aged 9–66 years, 22 had recurrent nocturnal hypoglycaemia, the best clinical clue to which was intermittent symptoms, however mild and infrequent they appeared to be (18).

Hypoglycemia can also be induced by concomitant diseases, for example renal disease, hepatic disease (cirrhosis), hypopituitarism, hypoadrenocorticalism, hypoglucagonism, hypothyroidism, malnutrition, anorexia nervosa, pregnancy, termination of pregnancy, recovery from infections, operations, or stress.

Frequency

In a review of 102 consecutive drug-induced, hospital-related cases of coma, 23 were caused by insulin only, 14 by insulin + glibenclamide, and 3 by insulin + metformin (19). The likelihood of readmission for hypoglycemia after a previous admission was 2.9 times greater.

Of 546 Spanish diabetic children and teenagers, 14% had one period of hypoglycemia and 21% had more than one episode (20). The highest incidence was in the morning, possibly related to the frugal Spanish breakfast and abundant food intake in the evening.

Hypoglycemia was retrospectively monitored in 1055 patients who had had type 2 diabetes for more than 2 months, and who visited the clinic at least twice in 6 months (21). They all received aggressive treatment to reach near-normal blood glucose concentrations. Symptoms of hypoglycemia were mentioned by 12% of those treated with diet alone, 16% of those using oral agents, and 30% of those using any form of insulin. In only five patients, all using insulin, was there severe hypoglycemia. A low HbA_{1c} concentration at follow-up, symptoms of hypoglycemia at the initial visit, and younger age were independently associated with an increased incidence of symptoms.

During 12 months, 244 episodes of severe hypoglycemia in 166 patients were recorded in a district with a population of 367 051 people (8655 with diabetes); there were 69 (7.1%) episodes in people with type 1 diabetes, 66 (7.3%) in people with type 2 diabetes using insulin, and 23 (0.8%) in those taking a sulfonylurea. Age, duration of diabetes, and lower social class were risk factors. The total cost of emergency treatment was estimated to be no more than $92 078 per year (22). In a German study in a comparable group of 200 000 people, there were 92 cases in those with type 1 diabetes and 146 cases in those with type 2 diabetes during 3 years (23). The estimated costs were lower: $88 676 per year for type 2 diabetes and $16 258 for type 1 diabetes.

In 28 children aged 3.1–8.3 years using twice- or thrice-daily insulin, blood glucose was measured with a subcutaneous continuous glucose monitoring system on 3 consecutive days and nights (24). Hypoglycemia was defined as a blood glucose concentration below 3.3 mmol/l for longer than 15 minutes. The prevalence

© 2006 Elsevier B.V. All rights reserved.

of hypoglycemia was 10% and it was more common at night than during the day (19 versus 4.4%). Hypoglycemia at night had a longer duration (median 3.3 hours) and was asymptomatic in 91% of the episodes. The highest prevalence occurred at between 04.00 and 07.30. On a thrice-daily insulin injection regimen, nightly hypoglycemia was less frequent, but the frequency was higher on the following morning. With increasing age there was less hypoglycemia.

Mechanisms

The concentrations of the counter-regulatory hormones adrenaline and glucagon were higher before treatment of coma in insulin-treated persons admitted to hospital for hypoglycemia than in the fasting state. However, concentrations of adrenaline, glucagon, cortisol, and growth hormone are lower during a hypoglycemic episode in a diabetic than when these hormones are measured during induced hypoglycemia in non-diabetics (25). There was an inverse correlation between glucose and adrenaline in hypoglycemia, but no direct relation between the other hormones and blood glucose concentrations. The addition of intramuscular glucagon during intravenous glucose therapy did not result in different glucose concentrations at any time (25). In type 2 diabetes counter-regulatory hormones are reduced compared with controls, but the patients release the hormones at higher blood glucose concentrations than type 1 diabetics, and the glucagon response is not blunted (26,27).

- Low responses of counter-regulatory hormones during induced hypoglycemia in a 27-year-old woman with poorly controlled diabetes (HbA_{1c} 11%), with frequent hypoglycemic instances of which she was not aware, improved dramatically after 3 months of good regulation (28); only growth hormone showed no reaction.

Hypoglycemia increased beta-adrenoceptor sensitivity in healthy subjects but reduced it in type 1 diabetes (29).

In 20 insulin-treated diabetic patients with episodes of severe hypoglycemia in 1982–84, re-evaluated in 1992–94, emergency visits were reduced from 1.05/year to 0.42/year between 1984 and 1994 (30). There were no cases of fatal hypoglycemia. There was no association with HbA_{1c}. Multiple daily insulin doses reduced the frequency of hypoglycemia to one-third. In 1984, unawareness was a predisposing factor and most of the patients had deficient counter-regulation (adrenaline). Most patients had a long history of insulin injections (mean 29 years). In 1994, six patients were partly and eight patients totally retested and compared with 10 matched control patients with type 1 diabetes. When hypoglycemia was induced by insulin the patients with frequent hypoglycemia reached values under 3.0 mmol much faster, and in six patients the test had to be stopped before the normal duration of 3 hours for hypoglycemia; this never happened in the control patients. Counter-regulation was deficient in both 1984 and 1994, indicating that reduced counter-regulation can be permanent and does not only depend on specific circumstances.

In 86 intensively treated patients with type 1 diabetes aged 7–18 years, the incidence of severe hypoglycemia correlated with the serum activity of acetylcholine esterase. Patients with acetylcholine esterase activity at the median or above reported 3.0 events/year and those with acetylcholine esterase activity below the median reported 0.5 events/year, suggesting that a genetic factor may play a role in the emergence of severe hypoglycemia (31).

Presentation

Symptoms of hypoglycemia have to be expected when the blood glucose concentration is below 2.6 mmol/l. The effects of hypoglycemia vary from patient to patient and can vary in the same patient. The symptoms and signs are of two types: adrenergic effects, due to release of catecholamines, and neuroglycopenic effects, due to the effects of hypoglycemia on the nervous system.

- *Adrenergic effects* Hunger, restlessness, profuse sweating, palor, tachycardia, and palpitation.
- *Neuroglycopenic effects* Headache, confusion, drowsiness, fatigue, difficulties in finding words, frequent yawning, anxiety, blurred vision, diplopia, and numbness of the nose, lip, and fingers.

Some patients do not experience the noradrenergic symptoms of hypoglycemia. They are taken by surprise, may lose consciousness and have hypoglycemic blood glucose concentrations without any preceding symptoms. After frequent episodes of hypoglycemia, there is altered awareness of hypoglycemia (18,32,33). It is difficult to substantiate altered awareness. Neuroendocrine responses and symptoms of hypoglycemia, but not cognitive dysfunction, are shifted to lower plasma glucose concentrations after recent hypoglycemia (34). Repeated episodes of hypoglycemia reduce the awareness of symptoms of hypoglycemia. This is accompanied by a lower blood glucose concentration, to elicit the response of counter-regulatory hormones (35). Beta-blockers also suppress the adrenergic symptoms, apart from sweating, which is mediated by sympathetic cholinergic transmission. Training increases awareness (36). Intensively treated patients may have reduced preservation of higher brain functions (37). Some groups, mainly in the UK, have suggested that transfer from animal to human insulin increases unawareness (SEDA-15, 452) (38), but this was not substantiated in other studies (39–41).

Every patient treated with insulin (or with hypoglycemic agents) who develops a neurological or psychiatric disorder has to be considered to be hypoglycemic until proven otherwise.

A rapid fall in blood glucose in a diabetic patient can cause symptoms of hypoglycemia, even when blood glucose concentrations are still normal or above normal. Experience with pumps has shown that many patients continue to feel hypoglycemic for a long time after normoglycemia has been restored. After an attack of hypoglycemia, patients often felt less well for a period of up to 48 hours. Headache, tiredness, and lack of initiative may disappear only gradually. These symptoms in the morning may indicate unnoticed hypoglycemic periods during sleep. Wet pyjamas or sheets may also indicate unnoticed hypoglycemia. During anesthesia, profuse sweating may indicate hypoglycemia.

© 2006 Elsevier B.V. All rights reserved.

A rise in C reactive protein has been observed during spontaneous attacks of hypoglycemia in diabetics and after experimental hypoglycemia in healthy controls (42).

Cardiovascular effects of hypoglycemia

The cardiovascular effects of hypoglycemia include angina pectoris, dysrhythmias, electrocardiographic changes, and coronary thrombosis. Raised concentrations of catecholamines and reduced concentrations of potassium contribute to cardiac damage during hypoglycemia.

Respiratory effects of hypoglycemia

- A 19-year-old woman with diabetes developed hypoglycemia with pulmonary edema (43). This has previously been seen as a complication of insulin shock therapy for psychiatric illnesses.

Nervous system effects of hypoglycemia

When hypoglycemia does not resolve spontaneously or is not terminated, cerebral dysfunction becomes manifest as confusion or reduced consciousness. Lethargy and depression or obstructive behavior develop and are accompanied by loss of consciousness, snoring, deep respiration, and facial paralysis. Neurological involvement can appear as cramps, paralysis, hemiplegia, or paraplegia. Epileptic seizures can accompany attacks of hypoglycemia. In deep coma the pupils are dilated, but they may react to light. Coma can develop very rapidly.

In a teaching hospital in Edinburgh, 56 admissions of 51 patients for hypoglycemia were registered during 12 months; 41 patients had diabetes mellitus and 33 were using insulin (44). There was a high incidence of neurological effects. Psychiatric illness or alcoholism was common. Four patients died but only one as a direct consequence of hypoglycemia. A further six patients died within 15 months, not related to hypoglycemia.

In 37 drivers with type 1 diabetes, fewer corrective actions were taken when the blood glucose was below 2.8 mmol/l (45). This was related to increased neuroglycopenic symptoms and increased electroencephalographic theta-wave activity. The authors suggested that diabetics should not begin to drive when the blood glucose concentration is in the 4.0–4.5 mmol/l range. In two editorials, the possibility of further restricting driving licenses in people with diabetes has been discussed (46,47). However, there is no evidence of higher accident rates in drivers with diabetes.

A retrospective questionnaire was sent to 195 consecutive patients addressing questions of severe hypoglycemia, coma, awareness of hypoglycemia, and fear of hypoglycemia (48). The mean duration of diabetes was 20 years and 82% had received intensive therapy. Coma was reported in 19% and severe hypoglycemia in 41%. Coma was independently related to neuropathy, beta-blockers, and alcohol.

In reaction to a report of pulmonary edema and hypoglycemia (SEDA-24, 488) it has been noted that in many cases, one or more seizures precede pulmonary edema (acute respiratory distress syndrome), suggesting a neurogenic mechanism (49).

In 304 insulin-treated patients, 8.2% of those with type 1 diabetes and 2.2% of those with type 2 diabetes had blood glucose concentrations below 4 mmol/l on arrival in the clinic (50). None had complained of symptoms of hypoglycemia or had taken glucose, but when questioned, 59% had autonomic symptoms and 12% had neuroglycopenic symptoms; 29% were asymptomatic.

Autonomic failure can occur as a result of hypoglycemia, since antecedent hypoglycemia causes both defective glucose counter-regulation and lack of awareness of hypoglycemia. The role of the brain in lack of awareness of hypoglycemia and the question of whether the brain is the primary site for sensing hypoglycemia has been discussed (51). In older people, markedly fewer autonomic symptoms are reported and there is greater slowing of psychomotor performance. In young children, hypoglycemia can lead to more mood and behavioral disturbances than in adults, although they also occur in the latter. It may be that the cortical responses to recurrent hypoglycemia are less plastic and reversible than the hypothalamic and glucose-sensing functions (52).

Psychological and psychiatric effects of hypoglycemia

Using evidence from auditory-evoked brain potentials and hypoglycemic clamps, it has been argued that antecedent hypoglycemia not only reduces awareness, but also that several aspects of cognitive function are attenuated during subsequent hypoglycemia 18–24 hours later (53). However, there were no effects of repeated hypoglycemia on cognitive function in patients included in the DCCT, a large American study that included more than 1400 patients, which showed that normalization of blood glucose prevents or delays the development of secondary (microvascular) complications in type 1 diabetes (54).

Nevertheless, long periods of hypoglycemia can cause permanent brain damage. There is concern that frequent attacks of hypoglycemia impair brain function but there are few hard data.

Hypoglycemic coma due to insulin with extensive mental changes has been reported, including a review of six comparable cases in patients aged 37–56 years, whose coma lasted from 36 hours to 31 days (55).

- A 37-year-old man could not be wakened in the morning. He had injected insulin without eating. His blood glucose was 1.5 mmol/l and he did not improve with intravenous glucose 16 g. In hospital he remained unconscious with a blood glucose of 12.2 mmol/l. There was no alcohol in the blood, his pH was 7.35, and he had a normal anion gap (18 mmol/l). His serum creatinine concentration was 288 μmol/l and his creatine kinase activity was high, suggesting rhabdomyolysis. A brain CT scan was normal and repeated electroencephalography showed slow waves with reduced voltages but no focal changes or irritation. He gradually recovered and was discharged after 6 days. Because of the dissociation between physical and mental improvement he was checked after 6 months and still had antegrade memory loss and problems with memory, complaining that he needed reminders on paper, and had less vitality and reduced emotionality.

© 2006 Elsevier B.V. All rights reserved.

Of the six reviewed patients, two died in coma; the other four had neuropsychological problems that did not improve after 6 months and up to 2 years. They had comparable electroencephalographic changes. During coma there was hypokalemia and hypocalcemia combined with increased lipolysis; this may have accounted for the permanent cerebral changes.

Of 20 patients with severe hypoglycemic coma and 20 with no or light coma, those with hypoglycemia had chronic depression and anxiety and performed persistently more poorly in several cognitive tests (56).

In 42 patients with at least two episodes of severe hypoglycemia in the previous 2 years and 51 patients with no episodes, low blood glucose, hypoglycemia-impaired ability to do mental subtractions, and awareness of neuroglycopenia and hypoglycemia predicted future severe attacks of hypoglycemia (57). In another study, blood glucose awareness training increased adrenaline responses to hypoglycemia (58). However, in a reanalysis of data from the Diabetes Control and Complications Study, a large study relating the development of secondary complications to less strict control of blood glucose (14), there was no effect of repeated hypoglycemia (54).

The effect of hypoglycemia on cognitive function has been investigated in 142 children aged 6–15 years with type 1 diabetes intensively treated for 18 months; 58 had 111 periods of treatment. There were no effects on cognitive functions (59). In 29 prepubertal children, with diabetes for at least 12 months and using twice-daily mixed insulin, observed for two nights, asymptomatic hypoglycemia occurred in 13 children on the first night and in 11 children on the second night; cognitive performance was not altered, but mood was reduced (60).

In healthy volunteers hypoglycemia caused significant deterioration in short-term attention, whereas sustained attention and intelligence scores did not deteriorate (61).

Sensory effects of hypoglycemia

Temporary blindness after severe coma (62,63) and retinal damage by gazing in the sun during hypoglycemia (64) have been reported.

Differential diagnosis

When a patient does not react rapidly to sufficient therapy, other diagnoses have to be considered during suspected attacks of hypoglycemia.

Alcohol can confuse the diagnosis of hypoglycemia (SEDA-5, 386). Alcohol inhibits gluconeogenesis. It makes the patient more susceptible to hypoglycemia and can even cause hypoglycemia in healthy individuals. The symptoms of alcohol abuse and hypoglycemia are almost identical. If hypoglycemia is predominant, glucose administration will help. In attacks of hypoglycemia, the symptoms disappear rapidly after glucose intake.

Vascular episodes in older diabetics can mimic attacks of hypoglycemia. True epilepsy or strokes can cause comparable symptoms or accompany hypoglycemia.

Differentiation of hypoglycemia from hyperglycemic coma is usually not difficult. The development of hyperglycemic coma takes a longer time and the blood glucose concentration is high. However, urine testing may show positive glycosuria, if urine produced before the hypoglycemic period is still in the bladder. Even ketonuria may be present if a patient has been fasting for a long period.

Timing

The emergence of attacks of hypoglycemia depends on the times and amounts of food eaten and the duration of action of the insulin used (see Table 2). When only one type of insulin is used, the symptoms of hypoglycemia mostly occur at the end of the period of maximal insulin activity. Modern insulin therapy involves using a combination of long-acting and short-acting insulins. Long-acting insulins are given once or twice a day in combination with and/or in addition to short-acting insulins, which are given 2–4 times a day. Hypoglycemia can then develop at times when the combined effects are most prominent. Hypoglycemia in the mid-morning can be a consequence of the action of the long-acting insulin of the previous day and the short-acting insulin given earlier in the same morning. Hypoglycemia during the night or in the early morning can be caused by too much long-acting insulin or by short-acting insulin late at night without sufficient food. Repeated symptoms of hypoglycemia at the same time of the day indicate that the timing of the insulin injection or the relative proportions of long-acting and short-acting insulins have to be changed. If the interval between insulin injection and the subsequent meal is very short, the effective insulin concentration in the blood will still be low when glucose is absorbed from the gut. This will cause very high postprandial glucose concentrations. An increase in the dose of insulin will then cause hypoglycemia at a later time. It is therefore advisable to try first to increase the interval between the injection and start of the meal. New synthetic insulins, like lispro insulin, give a more rapid increase and fall of insulin concentrations than regular insulin; in that case, postprandial hypoglycemia can occur 1–3 hours after the injection (65).

Susceptibility factors

Hypoglycemia is an important problem in children (66–68). Children do not always establish the connection between the symptoms of threatening hypoglycemia and the danger involved. Overdosage of insulin is relatively common (SEDA-7, 406).

Older patients are particularly susceptible to hypoglycemia (69). Factors such as cerebral blood flow, blood PO_2 and PCO_2, permeability of the blood–brain barrier, and the presence of underlying neurological defects influence the hypoglycemic effects.

Hypoglycemic periods are often seen in "brittle diabetics," many of whom are overtreated with insulin. Changes in the insulin regimen (reduced use of long-acting insulin, frequent small injections of short-acting insulin) or the use of continuous infusion pumps can often lead to better results, but not everyone with brittle diabetes responds in that way (SEDA-7, 405). Apparently brittle diabetes may in fact be due to factitious hypoglycemia, the hypoglycemic periods of which are caused by surreptitious self-injection of insulin, Munchausen syndrome by proxy (SEDA-18, 413), or manipulation of the prescribed doses. In factitious hypoglycemia, low blood

© 2006 Elsevier B.V. All rights reserved.

glucose concentrations are accompanied by high insulin concentrations but low concentrations of C peptide (70). Suicide attempts with insulin may be less uncommon than is often thought. A Medline search between 1966 and 1999 identified 46 papers containing 69 cases of factitious hypoglycemia; 46 were women, 52 were not diabetic, 29 had no close links with diabetes in their environment (71). In 47 the hypoglycemia was induced by insulin. Two patients died and one had severe impairment of intellectual function and short-term memory. In 32 cases unnecessary surgical procedures were performed.

Impaired hypoglycemic awareness was associated with an increased rate of severe hypoglycemia in 130 children and adolescents (aged 3–17 years) (72). One-third of the severe episodes developed without warning symptoms. Impaired awareness, young age, and recent attacks of hypoglycemia were independent susceptibility factors.

The authors of a systematic review of whether there is a difference in the frequency and awareness of hypoglycemia induced by human or animal insulins identified 52 randomized, controlled trials; 37 were double-blind (73). They found no support for the supposition that human insulin per se affects the frequency, severity, or symptoms of hypoglycemia. In a few studies, mainly of less rigorous design, there was an effect when people were transferred from animal to human insulin, indicating increased frequency or reduced awareness of hypoglycemia.

A questionnaire about the prevalence of severe hypoglycemia in relation to susceptibility factors was answered by 387 patients in 1984 and by 641 patients in 1998; 178 patients answered both questionnaires (74). The following changed significantly from 1984 to 1998: multiple injection therapy increased from 71 to 98%, daily self-monitoring from 17 to 48%, episodes of nocturnal hypoglycemia from 76 to 83%, and lack of awareness from 40 to 55%; HbA_{1c} fell from 7.6 to 7.4%.

Awareness of hypoglycemia

Avoidance of hypoglycemia for 3 months can improve hypoglycemic awareness for a period of over 3 years (75). In contrast, supervised induction of brief hypoglycemia twice weekly reduced clinical awareness of hypoglycemia by 33% and reduced the important adrenaline response, so reducing the behavioral and physiological defences against hypoglycemia (76).

Management

Patients have to be instructed to have a rapidly absorbed form of carbohydrate (for example dextrose tablets) available at all times and to use it when the first symptoms of hypoglycemia are felt. Often they fail to do so (77). If patients are used to self-monitoring, it is advisable that they monitor blood glucose first, although they should be told that a rapid drop in blood glucose concentration without reaching hypoglycemic values can cause a hypoglycemic reaction. Hypoglycemic reactions are sometimes difficult to discriminate from other feelings of malaise. Carbohydrate will always give rapid relief if the diagnosis is hypoglycemia and it is always safe to try taking it.

The conscious patient should take oral glucose at once. The treatment of choice in hypoglycemic coma is immediate intravenous injection of 20–50 g of dextrose. The patient may try to resist the injection, and help with the immobilization of the arm may therefore be needed. Injection of concentrated glucose solution outside a blood vessel leads to inflammatory and necrotic reactions. If intravenous injection of glucose is impossible, 1 mg of glucagon can be injected subcutaneously. However, in patients with residual insulin secretion (type 2 diabetes) glucagon may elicit extra insulin secretion and perpetuate hypoglycemia (78). The Epipen (a pen filled with a solution of adrenaline) is not a good substitute for the glucagon pen (in which glucagon must be dissolved before it can be used) in the treatment of hypoglycemia (79).

When the patient has taken high doses of long-acting insulin, hypoglycemia may relapse after a single dose of glucose has provided temporary relief, and monitoring should continue for a longer period. After hypoglycemic reactions elicited by long-acting insulins or oral hypoglycemic drugs the patient should be observed for possible recurrence during the next few days (80). The longer the duration of coma, the poorer the prognosis. Persistent posthypoglycemic coma can be due to cerebral edema. Fever can accompany this severe form of coma, which requires treatment with intravenous mannitol and glucocorticoids. Severe coma can last for several days and require intensive management. Encephalopathy with neurological symptoms can be the consequence.

Infusion of too much glucose over an extended period in the treatment of hypoglycemia is dangerous (81). Glucose utilization in the postabsorptive state is 2 mg/kg/minute and can increase, if insulin concentrations are high, to 6 mg/kg/minute (about 600 g/day in a 70 kg individual). It is better to infuse glucose in concentrations of 10 or 20% rather than 40%.

The opinion of experts about when and how to treat asymptomatic hypoglycemia in children varies greatly (82). Hypoglycemia in children is often undetected. Using a subcutaneous continuous glucose monitoring system (83) or the non-invasive Glucowatch biographer (84), hypoglycemic periods were more frequent and prolonged than when only fingerprick testing was available. For treating hypoglycemia in children, small doses of glucagon are suggested. The contents of a 1 mg/ml ampoule can be drawn into a 1 ml U100 syringe. For children under 2 years, 20 micrograms should be given initially; 10 micrograms is added for every year, up to 150 micrograms at age 15. When the effect is insufficient, the dose can be repeated once or twice (85).

Fat metabolism

- A 14-year-old adolescent girl, who had only used regular insulin developed lipoatrophy (86). Histology showed lipoblastoma-like cells, a possible sign of dedifferentiation. Skin tests showed no signs of allergy. The concentrations of immunoglobulins and TNF-alfa were normal.

© 2006 Elsevier B.V. All rights reserved.

Body weight

The DCCT Research Group has reported that patients in the intensive treatment group had substantial excess weight gain (87). In the first 9 months a group of patients who received intensive treatment gained 3.3 kg, compared with 1.2 kg in the control group; the percentage of people who gained more than 5 kg/m^2 was consistently higher with intensive therapy. This weight gain was related to both lean body mass and fat.

Fluid balance

Insulin edema is a rare complication, more often seen in the earlier years of insulin therapy (SEDA-11, 364). It is mostly seen when dysregulated patients with progressive weight loss are treated with relatively high amounts of insulin. Reduced sodium excretion (88), sodium reabsorption, and water retention by a possible direct action of insulin on the kidney may be involved (89). The role of aldosterone or of inhibition of the renin–angiotensin–aldosterone system in insulin edema is unclear. Insulin edema is a specific adverse effect, but it can aggravate pulmonary edema, congestive heart failure, and hypertension. Treatment consists of reduction of the insulin dose, after which the edema resolves within 3–4 days.

Insulin edema has been described in children with newly discovered diabetes (90).

- A 13-year-old girl with diabetes was given insulin 2 U/kg/day. She developed generalized edema and gained 20 kg over 2 weeks. With less insulin, furosemide, and later ephedrine the edema disappeared within 1 month.
- A 14-year-old girl with diabetes was given insulin up to 1.5 U/kg/day and gradually developed edema and gained 8.5 kg over 9 days. With furosemide, the edema gradually disappeared in 1 month.

Both of these children received rather high doses of insulin and they lacked the extreme acidosis that often occurs in young people when diabetes first appears.

Liver

Hepatic damage by regular human insulin has been reported (91).

- A 45-year-old man, who drank alcohol 60 g/day until diabetes was diagnosed, had mild liver function test abnormalities 6 months earlier, but only the gamma-glutamyl transpeptidase was raised (167 IU/l). When insulin was given, the transaminases also increased. Liver function normalized after withdrawal of insulin. Reinstitution of insulin and a switch to another human insulin formulation again increased the liver enzymes. He was managed with glibenclamide and liver biopsy was not performed. Lymphocyte stimulation tests gave negative results to all insulin formulations. All hepatitis-related virus markers were negative.

As the changes in this case were seen with different types of insulin, it is improbable that additions to the formulation were responsible. It is possible that the use of alcohol made the liver more sensitive to the damaging effects of exogenous insulin.

Skin

Hypertrophy of the subcutaneous tissues after insulin injections leads to delayed and variable insulin absorption. Of 282 children (160 boys and 122 girls, median age 12 years) prospectively evaluated for 3 months, 29% had mild skin hypertrophy and 18% had massive hypertrophy (92). The latter had higher HbA_{1c} concentrations and longer durations of diabetes and required more daily injections. There was no relation to the length of the needles used.

Amyloid-like deposition in the skin has been reported in a patient using porcine insulin (93).

- A 34-year-old man with a 17-year history of type 1 diabetes developed a 7 cm firm mass, distinct from adjacent areas of lipohypertrophy, and numerous smaller lesions of the same consistency. The lump consisted of acellular waxy material that appeared to be amyloid, formed by insulin. He had used porcine insulin for a long time.

This complication has been described before (SEDA-14, 373).

Musculoskeletal

A specific complication of the use of large amounts of insulin during hyperosmolar diabetic coma is rhabdomyolysis (94). Low intramuscular phosphate and potassium concentrations, often masked by relatively high blood glucose concentrations, may be important contributory factors.

Immunologic

Insulin allergy is quite common (SEDA-7, 403) (95–97). Allergy has been reported to human insulin and protamine (98) and to human insulin (99,100).

- A 41-year-old woman became allergic to all types of insulin (beef, pork, human, lente, etc.). She had used insulin for the first time during pregnancy and was intermittently treated unsatisfactorily with oral agents. She used lispro insulin for more than 6 months without an allergic reaction.
- A 54-year-old woman with gestational diabetes was later found to be allergic to chromium, pollen, dust, penicillin, acarbose, and metformin (101). She was treated with diet and glibenclamide, but later required insulin. With Humulin N insulin she developed a wheal of 15 mm immediately after the injection, which resolved in a few hours. However, a painful itchy induration appeared 2–3 hours after the injection and lasted a few days. She had an immediate reaction to isophane insulin, with induration, but insulin lispro was well-tolerated.
- A 5-year-old child with diabetes, Pierre Robin syndrome, cleft palate, allergic rhinitis, recurrent sinusitis, and obstructive sleep apnea, who had previously had skin rashes after penicillin, sulfonamides, and clindamycin, was given soluble and isophane human insulins (102). Three years later she developed local reactions, 2–5 cm areas, 30–120 minutes after injection. Skin-prick tests were negative for the diluent, isophane, and soluble insulin, but intradermal testing was positive with

© 2006 Elsevier B.V. All rights reserved.

both insulins. Cetirizine and dexamethasone added to the insulin gave temporary relief. She was then given insulin lispro by pump. After about 8 months, she started to develop local reactions again but with cetirizine and the pump her reactions were manageable.

- A 6-year-old boy developed recurrent generalized urticaria 1 year after he started to use human Mixtard insulin (103). The rash started 10 minutes after injections in the arms, thighs, and buttocks, at sites where earlier injections had been given, and disappeared within 12 hours. When he was changed to insulin lispro he had three urticarial reactions in the first 2 weeks and then sporadically. The reactions were treated with chlorphenamine for 2 years.

Presentation

Although serious systemic reactions are rare, local reactions at the site of injection are not infrequent. They appear as reddening, swelling, heat, burning, and itching, with or without frankly painful sensations. They can set in immediately or after some hours. The lesion can extend gradually and persist for variable periods. Some immediate reactions are related to IgE (or IgE/IgG) concentrations (104), but a direct relation between allergic reactions and a specific IgG fraction cannot be established (105).

- A 45-year-old woman who had used insulin for 4 years had a biphasic hypersensitivity reaction to human insulin (or another component of the injection fluid) (106). Within 20 minutes after the injection a swelling developed and in a later phase papular lesions with lichenoid features and post-inflammatory hyperpigmentation emerged. Histologically, there was neutrophilic infiltration with erythrocyte extravasation and eosinophilic amorphous material, surrounded by neutrophilic infiltrate. Saline injection did not elicit an effect. IgE anti-insulin antibodies were not found. There was no Arthus reaction (type IV allergy).

Other reactions are of the tuberculin granulomatous type or of the local vasculitis Arthus type. The local reactions can be accompanied, preceded, or followed by a generalized reaction, such as urticaria, nausea, vomiting, diarrhea, angioedema, wheezing, or anaphylactic shock. The last of these is rare, but sometimes fatal.

Insulin can induce local, painful lumps at injection sites. Sclerosing granulomata are occasionally seen (107) perhaps due to zinc (108). Such reactions are most commonly a consequence of an incorrect injection technique, generally the use of too short a needle or too superficial an injection. General edema (SEDA-11, 364) or abscesses (SEDA-7, 406) generated by insulin injections are extremely rare.

Lipodystrophy, lipoatrophy, or lipohypertrophy can be a consequence of chronic local insulin reactions that can be elicited by less pure as well as by highly purified preparations (109), but such reactions can also develop at sites distant to the injection.

Leukocytoclastic vasculitis has been attributed to human insulin.

- A 48-year-old woman with type 1 diabetes developed tender induration within 2–6 hours and persisting for 1–3 days after injection of both isophane and regular insulins (110). This was followed by intense itching and redness, but no wheal-and-flare reaction. Switching to semisynthetic insulin and other insulin analogues or continuous subcutaneous insulin infusion had no effect. After 3 years the condition became incapacitating. Humalog 5–6 times a day, including an injection at 0300 hours was the best tolerated regimen. Intradermal tests showed allergy to human, porcine, and bovine insulins, but no reaction to protamine or other additives. Skin biopsies showed a leukocytoclastic vasculitis. Prednisolone 10 mg/day plus azathioprine 50 mg/day, later replaced by methotrexate 7–15 mg/week, produced complete resolution within 8 weeks.

Pathogenesis

Allergic reactions to insulin were originally thought to be caused by impurities present in the formulation. However, after the introduction of monocomponent insulins and human synthetic insulins, these reactions continued to be seen, even in patients without a history of treatment with other insulins (111). Switching from animal to human insulin can paradoxically cause allergic reactions, which subside when treatment with animal insulin is re-introduced (112). In patients who have never used other types of insulin, allergic reactions can be seen when human insulin is used and anti-insulin antibodies can be demonstrated (113). Antibodies against human insulin have also been found in sera collected from patients before human insulin was available (114). However, insulin antibodies can be found during or before the emergence of type 1 diabetes. Circulating insulin-binding antibodies can increase insulin resistance (115) and extend insulin action by slowing release. The titers of antibodies fall when purified insulins or human insulin are used, but they can be demonstrated even when modern insulins of high purity have been used exclusively. Anti-receptor antibodies are seldom seen.

In India, insulin antibodies have been investigated in 25 patients with type 1 diabetes, 19 patients with so-called malnutrition-related diabetes, and eight patients with fibrocalculous pancreatopathy, who used bovine insulin because it was cheaper (116). Antibodies appeared within 3 months of treatment. The development of antibodies was not related to the type of diabetes. There was a fall in antibody titer with increased duration of treatment. There was no correlation between daily insulin requirement and antibody titers.

Allergic reactions can also be elicited by excipients in insulin formulations, such as Surfen (aminoquinuride) (117), zinc (118), and protamine (119,120). Remnants of fluids used for cleansing the skin can be co-injected in micro-amounts and elicit allergic reactions (121). Allergy to latex in vial tops or syringes can become manifest during insulin treatment (122). In excised (infected) lumps, amyloid fibrils, proteins containing intact insulin, were demonstrable (123). Plastic syringes can release silicone particles, which can diminish the effect of insulin (124) or themselves induce granulomatous reactions (125).

It has been suggested that increased concentrations of corticotropin-releasing hormone, which has an immunomodulatory effect and causes vasodilatation and mast cell

© 2006 Elsevier B.V. All rights reserved.

degranulation, could play a role in urticaria that develops during hypoglycemic periods in type 1 diabetes (SEDA-13, 381). Adrenal hyperandrogenemia is found in many diseases with hypersensitivity (126).

Susceptibility factors

Intermittent insulin administration seems to favor the development of allergic reactions to insulin (SEDA-6, 369).

Continuous intraperitoneal infusion of insulin causes increased insulin immunogenicity, but it is not known if this is accompanied by an increased frequency of autoimmune diseases. Antibodies against insulin, thyroglobulin, thyroperoxidase, gastric parietal cells, smooth muscle, mitochondria, liver and kidney microsomes, endomysium, and gliadin, and antinuclear antibodies were determined before and yearly after transfer to continuous intraperitoneal infusion of insulin in 28 patients; 19 remained negative for all investigated antibodies and in the other 9 the anti-insulin titer increased but other antibody titers remained constant or fluctuated (127). The authors concluded that during continuous intraperitoneal infusion of insulin in type 1 diabetes the frequency of other autoimmune diseases like hyperthyroidism was not increased. However, this conclusion was criticized, as the small numbers did not allow a positive or negative conclusion (128).

Treatment

In 95% of cases the local reactions disappear spontaneously. A switch to less immunogenic, highly purified insulin, or insulin lispro (129), is necessary if the reactions persist. For local allergic reactions, antihistamines or the addition of hydrocortisone 2 mg along with the insulin are seldom needed. Hydrocortisone suppresses local allergic reactions. For generalized reactions, skin testing is often necessary to establish allergic desensitization. One should start with low intradermal doses and, if necessary, add hydrocortisone.

For therapy of local lumps, extravasation, etc., one should first seek to improve the injection technique. Substitution with highly purified insulin is recommended. Injection with purified insulin into the affected area may speed up resorption of the lumps. Lipodystrophy or lipoatrophy improve after switching to highly purified human or insulin lispro. Lipohypertrophy, on the other hand, often fails to respond to changes in the insulin regimen (130). Varying the injection site may help, but differences in absorption rate then have to be taken into account.

Insulin resistance is said to be present when more than 200 U/day have to be injected; it is generally due to insulin antibodies. In general, antibody titers fall when highly purified insulins are used, but they sometimes persist after the switch. Some diseases, such as infections, endocrine hyperfunctional states (acromegaly, Cushing's syndrome, thyrotoxicosis), leukemia, or stress, can contribute to insulin resistance. Recombinant IGF-I (insulin-like growth factor I), which has a structure comparable to insulin, may help to overcome insulin resistance (131); adverse effects are burning at the injection site, hypoglycemia, fluid retention, facial edema, increased heart rate, arthralgia, myalgia, parotid gland tenderness, and dyspnea.

Continuous subcutaneous insulin infusion with fast-acting insulin has been used in two cases.

- A 43-year-old man with type 1 diabetes developed local pruritus, redness, and swelling 4–5 times a week, 15–20 minutes after an injection, subsiding within 1–2 hours (132). Later he had a generalized urticarial reaction 5 minutes after an injection. Insulin lispro did not help. When checked for allergens, he was positive for all types of insulin and negative for additives. With oral mizolastine the local reactions abated for a week, but then reappeared with every injection. Generalized urticaria recurred later. With continuous subcutaneous insulin infusion the local reactions immediately disappeared and metabolic control was improved.
- A 79-year-old man used mixed insulin for 2 months and developed swelling at injection sites, lasting 48 hours (133). The lesions persisted despite switching to various types of insulin. He was allergic to insulin, as shown by a raised eosinophil count, a markedly increased IgE concentration, and antibodies to human, bovine, and porcine insulins in the RAST test. He was not allergic to needles or additives. With subcutaneous bolus doses of insulin lispro and Humulin he developed induration and wheal-and-flare reactions. When hydrocortisone 10 mg was added to each injection, the allergic reactions disappeared, but they recurred after 2 months. With continuous subcutaneous insulin infusion there were no allergic responses for 3 months. His raised IgE concentrations fell.

Long-Term Effects

Drug tolerance

Insulin resistance has been reported with continuous subcutaneous infusion.

- Diabetes mellitus in a 36-year-old man with acute pancreatitis could not be controlled with continuous subcutaneous insulin infusion, even with doses up to 1800 U/day, because of insulin resistance (134). Intravenous insulin by pump had to be stopped because of a catheter infection. The continuous subcutaneous infusion of freeze-dried insulin and the addition of aprotinin, a protease inhibitor, soluble dexamethasone or prednisolone, and intravenous immunoglobulin was ineffective. An implantable pump for intraperitoneal delivery established good regulation at a dosage of 30 U/day.
- A 23-year-old diabetic woman had severe subcutaneous insulin resistance for 11 years (135). Continuous subcutaneous insulin infusion with regular or insulin lispro did not prevent periods of fluctuating responses to insulin. The addition of heparin to insulin lispro in the pump improved serum insulin concentrations and metabolic control. The addition of heparin to regular insulin gave no improvement.

Heparin may improve the transport of insulin lispro but not of regular insulin.

Second-Generation Effects

Pregnancy

In a longitudinal cohort survey of 278 pregnant women with type 1 diabetes, the frequency of severe hypoglycemia increased two to three times compared with the last 4 months before pregnancy (25%, including 9% with hypoglycemic coma, before pregnancy and 41%, including 19% with coma, during pregnancy) (136). A history of severe hypoglycemia before pregnancy, a longer duration of diabetes, an HbA_{1c} concentration of 6.5% or less, and a daily insulin dose of over 0.1 U/kg were indicators of increased risk.

Continuous subcutaneous insulin infusion in pregnancy has been studied retrospectively in a nested case-control study (137). Those who used the pump had higher fasting blood glucose concentrations at the start, came sooner to the pregnancy clinic, used more insulin, put on more weight, and were more likely to have the baby admitted to the special baby care unit. Birth weights and neonatal hypoglycemia were similar.

- A 37-year-old nurse with type 1 diabetes was adequately treated with lispro and isophane insulin during her first pregnancy (138). In her second pregnancy, 3 years later, she had frequent episodes of hypoglycemia with the same regimen, for which she sometimes needed an injection of glucagon during the night. When the isophane in the evening was changed to glargine she had no more serious episodes of hypoglycemia.

Teratogenicity

In animals, teratogenicity of insulin during pregnancy has been observed (SEDA-8, 908) (139). No proof has been given that this also holds good in humans. A statistical significant relation found between insulin use for or during pregnancy and musculoskeletal anomalies (140) may also be caused by increased blood glucose or other to diabetes related factors.

Susceptibility Factors

Age

In 3805 children and adolescents with type 1 diabetes in 21 pediatric centers in 17 countries, feedback was given on the overall mean HbA_{1c} concentration in all the centers (141). After 3 years insulin therapy was more intensive, but glycemic control improved in only three centers. The relative risk of severe hypoglycemia was lowest in the center with the best glycemic control.

Drug Administration

Drug formulations

The formulation of insulin differs in various countries. A strength of 100 U/ml (U100) is increasingly used in many countries, but in other countries strengths of 20, 40, or 80 U/ml (U20, U40, and U80) are still in use. The increased frequency of travelling and tourism has increased the importance of the problem. In some countries in various parts of the world, both U40 insulin of variable purity and highly purified U100 insulin are available at the same time. U100 insulin used in U40 syringes causes severe unexpected hypoglycemia and the reverse induces apparent insulin resistance (SEDA-6, 367).

Drug contamination

A skin reaction to latex in rubber associated with an insulin formulation has been reported (142).

- In a 35-year-old woman, pruritic, erythematous, urticated plaques occurred at insulin injection sites, and persisted for 48 hours, after the use of a prefilled cartridge pen containing Humulin (Lilly) and Human Monotard (Novo Nordisk) aspirated from a punctured vial, but not when the insulin was taken directly from the vial. She had positive skin-prick tests to latex solutions. Both the cartridge bungs and the vial bungs contain butyl rubber with added natural rubber latex. Switching to latex-free vials alleviated the problem.

Drug administration route

The American Diabetes Association has published revised guidelines on insulin administration, including storage of insulin, use and reuse of needles, alternatives to syringes, injection techniques, and patient management related to dosing of insulin, self-monitoring, and hypoglycemia (143).

Developments in the administration of insulin through the skin, the mouth, the nose, and the lung have been reviewed (144). Methods of absorption other than subcutaneous, such as nasal insulin, buccal insulin, rectal insulin, and insulin in enteric-coated capsules, are still experimental. A problem in nasal administration is still how to get a daily reproducible dose (145). The frequency of hypoglycemia is comparable to the frequency with subcutaneous insulin (146). Nasal irritation, sometimes with congestion, and dyspnea (147) can occur. Pulmonary insulin, delivered by aerosol inhalation, is another experimental method. No lung obstruction was reported, but the uptake varied considerably (148).

Insulin syringes

Disposable syringes can release silicon particles into the insulin vials, reducing the effectiveness of insulin (149). This can happen when insulin is injected back into the vial, during correction for the desired dose, and is specifically seen when low doses are used for long periods. Flocculation of insulin, found before the expiry date, may be related to this problem (SEDA-12, 360).

Insulin pens

Insulin pens are being increasingly used for intensive insulin therapy. For low doses, pens are more accurate than syringes (150). In 48 children and adolescents pen devices were more accurate than syringes when under 5 U of insulin had to be injected; for higher doses pens and syringes were comparable (151).

© 2006 Elsevier B.V. All rights reserved.

Long-acting isophane insulin in pens can be insufficiently resuspended before an injection, resulting in a great variation in the dose of insulin per injection; in one study isophane content ranged from 5 to 214% (151). Only 10% of 109 patients tipped and rolled the pen more than 10 times. There was no relation between inadequate suspension and the number of attacks of hypoglycemia. It was mechanically proven that 20 cycles are necessary for good suspension. After education, suspension errors were less common in 80% of the patients. They had fewer attacks of hypoglycemia, but HbA_{1c} did not change.

A warning has been given that over 0.3 μl of blood (and viruses) can reflux in insulin cartridges in pen-like injectors. Reflux was measured using a rubber tube containing a dye solution. A questionnaire study in 193 patients using cartridges showed that 20 patients sometimes noted a reddish cartridge and that two patients shared their cartridges with other patients (152).

After injecting insulin, the pen has to be kept in place for some time. Many pens leak from the tip of the needle when the pen is removed from the injection site 7 seconds after the injection is finished. In one study only the Novopen 1.5 ml and Novolet 1.5 ml showed no leakage; eight of twenty 3 ml BD pens and Novo pens, 16 of 20 Novolets 3 ml and 19 of 20 Saline pens 3 ml (Lilly) leaked 4.0, 4.7, 5.9, and 9.2 mg respectively (153). It is necessary to keep the needle in place for 10–30 seconds after injection. Measured by ultrasonography, 86% of injections with needles of 12.7 mm and 38% of injections with needles of 8 mm in diabetic children with a BMI below the 60 percentile were intramuscular instead of subcutaneous (154). The injection changed from intramuscular to subcutaneous in half of the injections in the arm and in two-thirds of injections in the thigh when 8 mm needles were used. Nowadays, 6 mm needles are available in many countries.

In general, intensive therapy produces lower blood glucose concentrations and HbA_{1c} concentrations. This may result in worsening of proliferative retinopathy (155), or weight gain M14.42.9]. Pens can develop inaccuracies in rare instances, which may be unnoticed by the patient (156). Clogging of the system is often the cause. The result is diabetic coma or ketoacidosis, but this is not more frequent than with other systems. When needles are not regularly renewed, infections may emerge.

Insulin pumps

The usefulness of devices for constant subcutaneous, intravenous, or intraperitoneal insulin administration is well established. To establish feedback systems reliable, constantly functioning insulin sensors are essential, but they have been in a developmental phase for more than 25 years, and no long-acting glucose sensors for non-experimental use are yet available (157). Experience with pumps in large groups of patients has been reported (158–160). When starting intensive therapy, temporary worsening of secondary complications, mostly retinopathy, but sometimes nephropathy, has been reported (SEDA-14, 374). Weight gain is also a complication. The major candidates for insulin pump therapy include patients with type 1 diabetes, pregnant women, some types of brittle diabetics, patients wanting to become pregnant, and children.

Most pumps deliver insulin subcutaneously. Implantable pumps delivering insulin intraperitoneally with remote control devices are increasingly used (161,162). Pumps provide signals to alert users to malfunction, but leakage of connections often does not activate the alarm. Since the patient has no natural reserve of insulin, breakdown of the pump, leakage, or intercurrent infection without adjustment of the dose rapidly leads to ketoacidosis. The sudden release of insulin from a "runaway" pump is an exceptional event. Hypoglycemic deaths, infections (for example with *Mycobacterium fortuitum*) (163), local allergic reactions and infections, thrombosis in intravenous systems, allergy to nickel in needles (164), skin infections (165), needle breakage (SEDA-13, 382), problems with bad batteries, breakdown of the pump, leakage in delivery systems, or wrong insertion of the needle have all been described (SEDA-7, 405) (166). Pumps with sealed reservoirs (waterproof) can expel more insulin when used at high altitudes (skiing, mountaineering, pressurized cabins in airplanes) inducing serious hypoglycemia (SEDA-16, 486) (167); adapters that allow pressure equilibrium obviate this. Pumps that deliver insulin intravenously are almost obsolete, since they can cause thrombosis, vasculitis, and septicemia.

Efficacy

Continuous subcutaneous insulin infusion has been reviewed (168,169). Probably more than 100 000 patients in the USA are using it. Some studies have shown no difference in mean glucose concentration or HbA_{1c} compared with intensive treatment, but most have shown a slight difference favoring continuous subcutaneous infusion. With fast-acting analogues the postprandial glucose peaks are lower. In one study, when insulin delivery was intentionally interrupted, the increase in glucose concentrations or the development of ketonuria was later with regular insulin, but in another study there was no difference in the development of hyperglycemia or beta-hydroxybutyric acid between fast-acting analogues and regular insulin. Patients preferred to continue treatment with pumps.

Insulin delivery by a pump may be superior to glargine insulin. Continuous subcutaneous insulin infusion was compared with intensive therapy with insulin glargine plus insulin lispro in 19 patients (170). The patients who received insulin glargine were exposed to glucose concentrations under 3.9 mmol/l overnight for three times as long as those who used continuous subcutaneous insulin infusion.

In a meta-analysis of the metabolic and psychosocial impact of pumps, 52 studies were found; 22 were published before 1987 and 13 after 1993, the year in which the results of the DCCT were published (171). The authors stated that therefore conclusions about efficacy are not definitive. All pump malfunctions were reported before 1988. All types of changes were reported when the frequency and severity of hypoglycemia were compared with prepump times. Infection and skin irritation were expressed in different ways in the various studies. The risk of diabetic ketoacidosis fell after 1993. Most users preferred to continue pump treatment, mainly because of more flexibility, greater freedom, and improved glycemic control.

When continuous subcutaneous insulin infusion and sulfonylureas were compared in nine normolipidemic

© 2006 Elsevier B.V. All rights reserved.

patients with type 2 diabetes, HbA_{1c} was not different but triglycerides and small LDL particles were reduced by the continuous infusion (172).

Continuous subcutaneous insulin infusion treatment is feasible in obese patients (BMI over 30 kg/m^2) with type 2 diabetes and severe insulin resistance, as has been shown in a study in 10 patients over 40 weeks (173). HbA_{1c} improved from 12 to 9.6% and weight was reduced by 2.5 kg. There were no adverse effects.

Use in children

In a randomized, crossover study in 10 children aged 7–10 years who used subcutaneous insulin pumps only in the evening and at nighttime, fasting, and 0300 hours, concentrations of blood glucose and fructosamine were improved (174). There was a better quality of life and a reduced fear of hypoglycemia. Children of this age may not be capable of handling a pump during the day.

In 95 patients aged 4–18 years with a median follow-up of 28 months, continuous subcutaneous insulin infusion produced no change in medical complications (diabetic ketoacidosis, visit to the emergency department), but there was a reduction in the number of episodes of hypoglycemia (175). HbA_{1c} was significantly lower than pre-pump values, but gradually increased in the first year and then remained stable.

In 118 children aged 1.5–18 years treated with continuous subcutaneous insulin infusion, HbA_{1c} in preschool children fell from 7.1 to 6.5%, in school children from 7.8 to 7.3%, and in adolescents from 8.1 to 7.4% (176). Daily insulin consumption did not increase and the frequency of severe episodes of hypoglycemia fell.

General adverse effects

Continuous intraperitoneal insulin infusion with implantable pumps has been assessed in 34 patients with poorly controlled diabetes (177). In two patients, the pump was explanted: in one patient with Werner's syndrome (no subcutaneous fat) the pump was explanted because of infection in the pocket, and one pump was explanted because the patient had local complaints and psychological problems. One patient refused to be included. Patients were followed for 58 months. HbA_{1c} fell from 10.0 to 9.0% in the first year and remained there. Median days in hospital fell from 45 to 13 after 1 year. The quality of life was relatively low and many had psychiatric problems. Although long-term glycemic control improved and lengths of hospital stay were reduced, normal glucose control and normal quality of life could not be achieved.

Local adverse effects

Implantable insulin infusion pumps have been reviewed (178,179), as has the use of pumps in children (180). In 31 centers, 914 pumps were implanted, representing 2121 patient-years. Some commonly reported pump complications were (178):

- hematoma or seroma, usually resolved by needle aspiration;
- pump migration, the frequency lessening with experience; surgical intervention is necessary;
- rare pump pocket infections; the causes were difficult to determine, but in two patients, coagulase-negative staphylococci were found, suggesting contamination with skin flora during refill;
- progressive thinning of the skin, 1–30 months after implantation in 2 per 100 patient-years; pain and skin erosion often followed; the cause is unclear; only a correlation with physical activity could be found.

Catheter malfunction was the most frequent event (obstruction, total occlusion, and peritoneal adhesions: 13, 10, and 3.1 events per 100 patient-years respectively). Flushing sometimes prevented occlusion. Better tip design had a big effect. Adhesion formation decreased with daily injections of heparin. The frequency of ketoacidosis was comparable to that reported with continuous subcutaneous insulin infusion and was usually related to catheter obstruction. It diminished during the review period. Episodes of severe hypoglycemia were fewer than during intensive subcutaneous therapy.

The tendency of insulin molecules to aggregate in concentrated solutions sometimes requires specific insulin or insulin lispro for pumps. There is a difference of opinion about whether insulin absorption kinetics change (improve) during placement of the catheter (SEDA-16, 488) (SEDA-18, 412). Changing the injection site and renewing the infusion system every 2–4 days is important in preventing clogging, local allergy, and infection at the insertion site.

In implanted pumps, catheters for continuous intraperitoneal insulin infusion can be obstructed by deposits of fibrin on the catheter tip. They mostly reappear after the plug is blown out, necessitating replacement (181). Hematoma, skin erosions, infections (182), pain, pump migration, and pocket complications are not rare (SEDA-20, 397) (183). Erosion of the cecum, mimicking appendicitis, is reported (184). During the start of pump therapy, some patients feel as if they are constantly hypoglycemic, even though low blood glucose concentrations cannot be objectified.

There was no macrophage activation in 10 patients with obstructed ($n = 3$) or non-obstructed ($n = 7$) catheters in implantable pumps (185).

When insulin delivery stops during continuous subcutaneous insulin infusion, ketoacidosis can develop rapidly, but it can be easily corrected if ketoacidosis has developed recently, although exceptions occur (186).

- A 32-year-old woman with well-regulated diabetes, using about 35 U/day of insulin by continuous subcutaneous infusion, tried a sauna for the first time when her blood glucose was 7 mmol/l. She stayed for about 45 minutes and the temperature reached 70°C for 10 minutes. The blood glucose concentration rose to 11 and 17 mmol/l, despite a bolus of insulin 6 units. She felt sick and vomited during the night; the next morning her blood glucose was 21 mmol/l and she had ketonuria, abdominal cramps, and extreme fatigue. Insulin 25 units by pump produced no improvement, but after opening a new vial, the situation improved; within 6 hours she was normoglycemic, and her ketonuria disappeared within 16 hours.

© 2006 Elsevier B.V. All rights reserved.

It is not clear in this case whether insulin had formed aggregates and fibrils due to the high temperature or if the action of counter-regulatory hormones induced by hyperthermia was increased, or both.

Problems with insulin delivery in implanted pumps are difficult to correct. A change in Hoechst 21 pH-neutral semisynthetic insulin 400 U/ml in accordance with regulations of the European Pharmacopoeia (SEDA-20, 397) resulted in more frequent clogging when this insulin was used in the Minimed 2001 implantable pump (MIP 2001). From October 1995 to October 1996, 17 pumps were implanted (187). The refilling period was reduced from 90 to 30–45 days and the reservoirs were washed with insulin-free buffer before each refill. Backflow was seen in 13 pumps after a mean period of 7.2 months. Modification of the manufacturing process produced 21PH ETP insulin (human semisynthetic insulin, Genapol-stabilized) 400 U/ml, Hoechst, with improved stability since July 1997. All pumps were specifically cleaned before the new insulin was used for refill. The refill period was increased from 38 to 78 days. In 16 pumps, only one backflow was seen after 14 months. The incidence of catheter blockage did not change. The better stability of this insulin for implantable pumps has been confirmed in a study in which 88 pumps were refilled every 45 days and 108 pumps every 90 days (188).

Pump failure

Almost all pumps are programmable and pump failure is rare (2 per 100 patient-years) (178).

Risk of hypoglycemia

Continuous subcutaneous insulin infusion in 75 youths aged 12–20 years has been compared with multiple daily injections over 12 months (189). HbA_{1c} was lower, and the number of attacks of hypoglycemia in the pump group was 50% less. Ketoacidosis seldom occurred: once during intensive therapy and twice during pump therapy. Weight increased more during pump treatment. Coping with diabetes was less difficult with pump therapy.

In 103 patients who used continuous subcutaneous insulin infusion for 2 years, the incidence of severe hypoglycemia fell from 0.70 cases/patient/year before treatment to 0.06 cases/patient/year during treatment, and HbA_{1c} improved from 7.7 to 7.2% (190). The incidence of abscesses was 0.1 cases/patient/year and of ketoacidosis 0.01 cases/patient/year. The patients with HbA_{1c} concentrations above 8.5% had a higher incidence of serious hypoglycemia and abscesses. Quality of life assessments showed great improvements. The reasons for continuous subcutaneous insulin infusion were optimization of metabolic control, greater flexibility, or prevention of severe hypoglycemia.

In 138 patients treated with continuous subcutaneous insulin infusion for 7 years, there was a fall in the incidence of episodes of serious hypoglycemia (from 0.31 to 0.09 cases/patient/year) and ketoacidosis (from 0.41 to 0.11 cases/patient/year); the number of infections was unchanged (0.2 infections/patient/year) (191).

When continuous subcutaneous insulin infusion was instituted in patients with long-standing poor glycemic control during a crossover study in 79 patients for 32 weeks, 17 dropped out after the first crossover, making it impossible to use the second arm. HbA_{1c} and quality of life both improved. There were more episodes of mild hypoglycemia with continuous subcutaneous insulin infusion (192). The authors of an editorial concluded that continuous subcutaneous insulin infusion can anticipate changes in insulin need, which is important for diabetics with a variable lifestyle or an exaggerated dawn phenomenon (193). For a large group the increase in cost and the hassle of continuous subcutaneous insulin infusion do not offset that, and multiple daily injections with glargine as basal insulin (see below) can be equally effective.

Continuous subcutaneous insulin infusion was found to be feasible in 56 children and adolescents (aged 7–23 years) (194). HbA_{1c} improved in 36 and deteriorated in 6. The rate of severe attacks of hypoglycemia fell, but not significantly. Hypoglycemia and seizure frequency were less overall in the group, with better HbA_{1c} concentrations. One patient had a catheter infection and was treated with local antibiotics and a new infusion system at another site.

Suitable types of insulin

Short-acting neutral buffered insulin by pump is sometimes ineffective. Treatment with non-buffered insulin can make things worse, but short-acting acidified insulin can improve HbA_{1c}. This type of insulin is well tolerated for over 3 years. The acid insulin may contain more monomers than neutral insulin, which may act less rapidly, as it contains more polymers (195).

Insulin lispro is sometimes less beneficial in continuous subcutaneous insulin infusion (196).

- A 58-year-old man with diabetes and unawareness of hypoglycemia had 53 emergency hospital admissions in 2 years before he started regular continuous subcutaneous insulin infusion. His attacks of hypoglycemia were reduced to one every 2–3 weeks. His mean blood glucose was 7.0 mmol/l. When insulin lispro was introduced in the pump he had an attack every 2–3 days for 68 days and hospital admission was required seven times. The mean blood glucose was 6.3 mmol/l. After he used soluble insulin instead of insulin lispro, the number of attacks of hypoglycemia fell substantially. The mean blood glucose was 6.4 mmol/l.

It may be that the more rapid diffusion and absorption of insulin lispro in diabetics who achieve tight metabolic control and have hypoglycemia unawareness destabilizes glycemic control.

Continuous subcutaneous insulin infusion with insulin lispro has been reported to give variable control (197).

- A 12-year-old boy with type 1 diabetes had problems with insulin lispro in his pump. After multiple daily injections, he started continuous subcutaneous insulin infusion with insulin lispro and could freely adjust his eating schedule; he had fewer episodes of hypoglycemia and his HbA_{1c} was 5.4%. Later, he developed a pattern of variable responsiveness to insulin, starting with increased responsiveness on the day on which he changed his subcutaneous needle, followed by reduced sensitivity and hyperglycemia on the third day. The infusion site was changed and Velosulin was added to insulin lispro, making it possible for him to use his injection site for 3 days

© 2006 Elsevier B.V. All rights reserved.

consistently; the HbA_{1c} was 7.2%. After 2.5 years he started using insulin aspart. It then became possible to change the infusion site every 4–5 days, when the cartridge was empty. The HbA_{1c} fell to 6.2%.

Continuous subcutaneous insulin infusion has been compared with short-acting insulins plus glargine or isophane as long-acting insulins for 1 year in 32 patients with poor control (198). Four of them had serious attacks of hypoglycemia. There were no differences in HbA_{1c} or other metabolic parameters (including lipids). In those treated with continuous subcutaneous insulin infusion, the reduction in the amount of insulin required was larger.

Hoechst 21 pH-neutral insulin in intraperitoneal pumps increases the production of antibodies to insulin, in contrast to the same insulin in subcutaneous pumps (199). It is not clear whether the intraperitoneal route or modification of insulin during storage in the implanted reservoir causes greater antigenicity. When a newly designed side-port catheter on the Minimed pump was used in 40 patients for 450 days per patient, there was one catheter encapsulation, one clogging, and six cases of catheter/pump related underdelivery (200). This was comparable to the position before 1994, when the formula of the Hoechst 21 pH-neutral insulin was changed for the first time.

Other devices

Other devices, such as long-term subcutaneous catheters (201,202), which have to be renewed every 4 days (203), or intraperitoneal catheters (204) for pumps, pose the same types of problems as subcutaneous catheters for pumps, except that the catheters are indwelling for longer periods. The jet-stream injector, introduced as an alternative for people who are afraid of injections, has given problems with delayed pain and bleeding. The advantages of these methods are questionable.

Oral administration

Metabolism of insulin and the lack of a specific carrier to transport insulin through the gut made the oral route impossible (144).

Inhaled insulin

In the lungs, insulin has to be absorbed from the alveoli (144). Enhancers to give the particles the right size and constituency to reach the alveoli improve systemic availability (205). The relative potency of inhaled insulin is about 10%, which means that a 10-fold increase in dose is necessary. The effects of inhaled insulin are comparable to those of injected regular or fast-acting insulins or even faster. However, it is difficult to get a good action profile. The anatomy of the pharynx affects the transport of the particles. In smokers, the permeability of the lung epithelium is much greater and absorption from the alveoli is faster and higher than in non-smokers; during actual smoking, uptake is reduced. In the short term the excipients in the sprays have no adverse effects. More participants in a study of inhaled human insulin were satisfied with inhaled insulin than they were with subcutaneous insulin (206).

Ten severely hyperglycemic patients with type 2 diabetes taking oral agents were treated at random with two injections of isophane daily or with lyophilized nasal insulin before each meal, with an added injection of subcutaneous isophane when necessary (207). The periods were separated by 2 months. Nasal insulin produced control of diabetes comparable to isophane, except in three patients. Adverse effects included transient pruritus, sneezing and rhinorrhea, and chronic nasal crusts. One patient was withdrawn because of cough and dizziness after each nasal dose.

Inhaled insulin has been studied in 72 patients in an open, parallel-group, randomized trial for 12 weeks; 35 used inhaled insulin (152). The inhaled insulin was given three times before meals with isophane insulin at bedtime. Controls used their regular insulin two or three times a day with a long-acting insulin at bedtime. HbA_{1c} did not differ between the groups and there was no difference in the frequency or severity of attacks of hypoglycemia. Pulmonary function tests were stable and showed no differences between the groups. There were no serious or major adverse effects.

The dose of inhaled insulin is about 10 times higher than the subcutaneous dose that produces the same hypoglycemic effect. In an open, randomized, crossover study subcutaneous insulin was compared with a 10 times higher dose of inhaled insulin in 15 non-smoking patients with type 2 diabetes (208). The peak action of inhaled insulin was earlier. Apart from that, the effects were similar. There were no differences in FEV_1 at baseline or at 4 or 8 hours after treatment. Absorption of inhaled insulin is significantly higher in smokers (209). In non-diabetics, absorption is reduced in asthma (210). Inhaled insulin may increase the titer of insulin antibodies (211).

Nasal administration

Insulin is rapidly absorbed after nasal administration, but even with absorption enhancers its systemic availability is low and its metabolic effect very short (144).

Gelified nasal insulin has been compared with twice daily isophane insulin and three times daily subcutaneous regular insulin in 16 patients with type 1 diabetes (207). Three patients had to withdraw because of nasal burning and one because of persistent sinusitis. One patient had purulent sinusitis after 6 months. The efficacy of gelified insulin was comparable to that of regular insulin.

Transdermal administration

Application to the skin, a highly efficient general barrier, did not result in sufficient and reproducible absorption (144).

Drug overdose

- Insulin overdose has been reported in patients without diabetes (212) and in a 25-year-old man with Munchausen's syndrome (213).
- Suicide by insulin has been reported in a 68-year-old, non-diabetic physician who had also taken metoprolol and alcohol. The blood metoprolol concentration was 0.4 microgram/ml (usual target range 0.035–0.5 microgram/ml) and alcohol 122 mg/dl (27 mmol/l). C-peptide could not be detected, serum insulin was 1849 μU/ml (normal fasting concentration below 16 μU/ml) (214).

© 2006 Elsevier B.V. All rights reserved.

Hypokalemia, hypophosphatemia, and hypomagnesemia can occur after insulin overdose (215).

- A 47-year-old man with type 2 diabetes attempted suicide by taking a bottle of wine, triazolam 2 mg, zoplicone 75 mg, and subcutaneous insulin (soluble 300 U and isophane 1800 U). His blood glucose was 1.5 mmol/l, potassium 2.4 mmol/l, phosphate 0.74 mmol/l, and magnesium 1.06 mmol/l. After 80 ml of 50% glucose and gastric lavage he needed a glucose infusion 6.6 mg/kg/minute for 24 hours to keep his blood glucose at 5.5–11.1 mmol/l. There was no brain damage on neurological examination or CT scan.

Acute liver damage has been attributed to insulin overdose followed by excessive glucose administration (79).

- In a suicide attempt, a 48-year-old woman took clomipramine 225 mg, diazepam 50 mg, oxazepam 150 mg, flurazepam 120 mg, and aspirin 10 g and injected insulin subcutaneously (1000 U short-acting and 1000 U long-acting). Her blood glucose was undetectable. She was intubated and given 40% glucose 20 ml and an infusion of 20% glucose (total 100 g over 2 hours). She continued to receive intravenous glucose 40% with potassium chloride for 36 hours (total 4430 g) in spite of high glucose concentrations. Her aspartate and alanine transaminase activities rose to 420 and 610 U/l respectively, the total bilirubin to 147 μmol/l (mainly unconjugated), the alkaline phosphatase to 178 U/l, and the serum lactate to 6.8 mmol/l. An ultrasound scan of the liver was normal. When the glucose infusion was stopped, everything normalized rapidly.

Acute steatosis of the liver may have explained this presentation. In insulin overdose, the combination of greatly increased hepatic production of triglycerides from glucose and reduced production of apolipoprotein B 100 results in an insufficient increase in the transport of triglycerides in VLDL particles from liver to muscle and adipose tissue and contributes to the steatosis.

Drug–Drug Interactions

ACE inhibitors

Whether ACE inhibitors aggravate or generate hypoglycemia is debated (216). In a case-control study of 404 cases and 1375 controls, the risk of hypoglycemia was 5.5 times greater (95% CI = 4.0, 7.6) in insulin versus sulfonylurea users and was not influenced by use of ACE inhibitors overall (217). However, the use of enalapril was associated with an increased risk of hypoglycemia (OR = 2.4; 95% CI = 1.1, 5.3).

Beta-blockers

Beta-blockers have various effects on glucose metabolism, but these are usually too small to be of clinical significance (217,218). However, beta-blockers can block the adrenergic symptoms of hypoglycemia.

- A 68-year-old woman with diabetes and hypertension using 42 units of isophane insulin and propranolol 20 mg qds died with a blood glucose concentration below 1.4 mmol/l without any symptoms of hypoglycemia (219).

Clozapine

Severe insulin resistance with ketoacidosis (pH 6.9) has been reported with clozapine (220). After withdrawal, insulin requirements fell. Reinstitution of clozapine induced an identical increase in insulin need.

Glucocorticoids

Glucocorticoids are counter-regulatory and can cause increased insulin requirements. Conversely, reducing the dose of a glucocorticoid, without changing the dosage of insulin, can cause hypoglycemia.

Maprotiline

- Maprotiline, a tetracyclic antidepressant, repeatedly induced hypoglycemia in a 39-year-old woman with type 1 diabetes, even when the insulin dosage was reduced from 20 U/day to 4–10 U/day. Maprotiline seems to prolong the half-life of insulin. A glucagon stimulation test showed a maximum C-peptide concentration of only 0.22 nmol/l (221).

Olanzapine

Olanzapine has been reported to have precipitated diabetes (222).

- A 31-year-old man with a treatment-refractory psychiatric disorder without prior diabetes was given olanzapine 10 mg/day. After 3 months he developed hyperglycemia and an acidosis (pH 7.11). After treatment he needed at least 64 U/day of insulin, but 15 days after stopping olanzapine his insulin requirements fell and 15 days later insulin was withdrawn.

Interference with Diagnostic Tests

Blood glucose measurement

Three diabetic patients on chronic ambulatory peritoneal dialysis (CAPD) had symptoms of hypoglycemia when glucose readings on strips were higher than 4 mmol/l (223). Venous testing showed glucose concentrations as low as 1.8 mmol/l. Large amounts of glucose are used in CAPD, which not only affects the regulation of diabetes but can also affect the peritoneal wall. Since 1999, icodextrin has been used in dialysis fluids. Icodextrin is glucose-free and reduces the need for insulin. However, it is also absorbed systematically and can be metabolized to maltose and maltotriose. Paper systems that use either glucose oxidase or glucose dehydrogenase overestimate glucose readings when icodextrin is used, and patients and their carers are not able to measure low blood glucose concentrations. Another factor is that during end-stage renal insufficiency, insulin catabolism is reduced. This contributes to the problems when CAPD is changed to automated (overnight) peritoneal dialysis, in which daytime hypoglycemia can be prevented by reducing the amount of insulin used during the day.

Monitoring Therapy

Frequent self-control by pricking the fingertips can cause anemia (224) or pyoderma gangrenosum and fingertip ulceration (225).

Problems with the use of blood glucose measurement systems are reported from time to time. For example, it is easy to read glucose meters wrongly (SEDA-25, 508). Hypoglycemia was missed when a patient inadvertently switched the glucose meter from mmol/l to mg/dl and read 266 mg/dl as 26.6 mmol/l and 158 mg/dl as 15.8 mmol/l (226).

- An 89-year-old man wrongly read the glucose concentrations in his home glucose meter (227). The meter read 561 mg/dl and 591 mg/dl but testing in the clinic 2 hours later showed concentrations of 175 mg/dl and 188 mg/dl. He had read the digital display upside down: 591 instead of 165 and 561 instead of 195.

Patients should be instructed about the correct orientation of digital meters.

In Raynaud's phenomenon, blood glucose concentrations measured by finger prick are often lower than the real values (50). The arm reacts more slowly to rapid changes in glucose concentrations. When glucose is monitored in the arm, changes in glucose concentrations are later seen than when monitored by finger prick (228). Rubbing the arm reduces the differences (229).

The development of glucose sensor systems has been reviewed (230). An automated device for sampling in the arm (231) and a microdialysis-based glucose sensor system (232) have been developed.

Insulin aspart

See also Insulin

General Information

Insulin aspart is a rapid-acting synthetic insulin in which proline is replaced by aspartate at position 28 in the B chain. Insulin aspart has been reviewed (1). Its adverse effects do not differ from those of soluble human insulin and it has a similar effect on the blood glucose concentration (2).

A new development is the binding of two 9-fluorenylmethoxy-carbonyl moieties to two amino acids in the structure of aspart insulin, phenylalanine and lysine (3). This compound has no biological activity but gradually releases its groups and keeps diabetic animals in a good metabolic state over 2–3 days. Experiments in humans have not yet been reported.

Aspart insulin and biphasic insulin aspart (30% soluble rapid-acting insulin and 70% protamine-bound aspart insulin) have been reviewed (4).

Comparative studies

In a double-blind, crossover study of insulin aspart or soluble human insulin before meals and protamine zinc insulin before bedtime, 90 of 104 patients with type 1 diabetes completed the trial (5). Insulin aspart improved postprandial control by reducing hyperglycemic and hypoglycemic variations, but night-time control was inferior. There were 547 hypoglycemic episodes in the aspart period compared with 615 in the regular insulin period (no significant difference). However, there were only 20 major hypoglycemic events in 16 patients using aspart versus 44 events in 24 patients using human insulin. One patient was withdrawn with fatigue and anorexia during aspart. Convulsions during hypoglycemia occurred once in each group.

Insulin aspart had an increased maximal effect compared with regular insulin in euglycemic clamps in nondiabetics (6).

In an open comparison of insulin aspart and regular human insulin for 6 months in 882 patients with type 1 diabetes and extended to 714 patients for another 6 months, postprandial glucose concentrations were lower with insulin aspart (7). HbA_{1c} was slightly but significantly lower (7.78 versus 7.93%). There were no differences in hypoglycemic periods or adverse events.

Insulin aspart has been compared with regular insulin in 1065 patients for 26 weeks (8). HbA_{1c} improved significantly with aspart. The number of major attacks of hypoglycemia fell in the aspart group from 11 to 8%; there were no other differences.

Insulin aspart has been compared with buffered regular insulin by continuous subcutaneous infusion (9). There was some crystal formation with both formulations, but less with insulin aspart. Patients who used aspart required a slightly higher basal dose of insulin but had fewer unexplained attacks of hypoglycemia.

Frequent addition of isophane to a regimen of insulin aspart is unnecessary, as has been shown in a multicenter, multinational, randomized, open study in 368 patients

© 2006 Elsevier B.V. All rights reserved.

followed for 64 weeks (10). Frequent addition of isophane up to four times daily to insulin aspart did not improve HbA_{1c} or change the number of episodes of hypoglycemia compared with regular insulin combined with isophane. Only postprandial blood glucose concentrations were reduced.

When insulin lispro and insulin aspart were compared in a single-blind, randomized, crossover study in 14 patients with type 1 diabetes, insulin lispro had a faster onset of action but a shorter duration (11). However, in another study the pharmacokinetic and the pharmacodynamic profiles of insulin aspart compared with human insulin were the same in 24 healthy Japanese as in non-Japanese (12). Insulin aspart and insulin lispro were equally effective in another 24 patients with type 1 diabetes (13).

Combination with long-acting insulin

In a multinational study for 6 months in 448 patients with type 1 diabetes, two-thirds were given the long-acting insulin detemir and one-third received isophane, both in addition to premeal rapid-acting insulin aspart (14). HbA_{1c} concentrations were comparable, but in the detemir group the risk of hypoglycemia was 22% less and the risk of nocturnal hypoglycemia was 34% lower. There were two cases of severe hypoglycemia with detemir and one with isophane. Three patients who used detemir developed reactions at the injection site (pain, myalgia, redness, or lipodystrophy) compared with one who used isophane (itching). One potentially allergic reaction was possibly related to detemir.

The new, short-acting insulins can be bound to protamine, allowing the preparation of mixed formulations. In an open, randomized, single-dose, three-way, crossover trial biphasic insulin aspart 30 (30% aspart plus 70% protaminated aspart, BIAsp 30), biphasic insulin lispro 25 (25% lispro plus 75% protaminated lispro, Mix 25), and biphasic human insulin 30 (30% regular plus 70% isophane insulin, BHI 30) were compared in 45 patients (15). Biphasic insulin aspart improved postprandial control better. There were 23 episodes of hypoglycemia with BIAsp 30, 19 with Mix 25, and 11 with BHI 30; two episodes with BIAsp 30, five with Mix 25, and two with BHI 30 required third-party intervention.

When 30% insulin aspart plus 70% protamine aspart was compared with the same mixture of regular plus isophane insulins, both injected twice-daily for 12 weeks, in 294 patients with type 1 and type 2 diabetes, control was better with the aspart mixture (16). There were fewer episodes of major hypoglycemia (20 versus 42) but the same number of minor episodes (362) with aspart.

Placebo-controlled studies

In a double-blind, crossover study with insulin aspart and human insulin in type 1 diabetes, human insulin was given 30 minutes before a meal with placebo immediately before the meal, or placebo was given 30 minutes before the meal with aspart insulin or human insulin immediately before the meal (17). On average, insulin aspart was absorbed twice as fast as human insulin. Postprandial glucose control improved on aspart. There were no episodes of serious hypoglycemia.

Organs and Systems

Immunologic

When short-acting insulins are given to patients who are allergic to regular insulin the allergic reactions can disappear. Although the short-acting insulins often have the same immunogenic epitopes, rapid dissociation of the fast-acting insulins into monomers can reduce their antigenic effects. Insulin lispro is known to be beneficial, and this has also been reported for aspart insulin (18).

- A 45-year-old man with type 2 diabetes treated with glibenclamide and metformin received combined chemotherapy for non-Hodgkin's lymphoma and was given premixed insulin. He developed local wheal-and-flare reactions immediately after the injections. Skin prick tests were positive for various types of insulin but weakly positive for lispro and negative for insulin aspart. He tolerated aspart insulin without any allergic reactions.

A few patients treated with insulin aspart developed antibodies, which cross-reacted with antibodies against human insulin and fell after 3 months (19). In lipodystrophy with lipoatrophic diabetes high insulin resistance is often found, for which leptin deficiency is one contributory factor.

Allergic reactions have been described with insulin aspart.

- A 53-year-old woman had type 2 diabetes that was not well controlled with diet and oral hypoglycemic drugs (20). She took intermediate-acting insulins, and after 2 months noticed redness and itching at injection sites. When she used insulin aspart and insulin lispro successively, the local reactions continued. She had a high serum concentration of total IgE (748 IU/ml; reference range below 400) and insulin-specific IgE (20 IU/ml; reference range below 0.34), positive insulin antibodies, and positive prick tests for insulin lispro, insulin aspart, human insulin, porcine insulin, and protamine. With intensive nutrition therapy and oral drugs her HbA_{1c} fell to 5.5%.
- A 29-year-old woman with raised insulin concentrations during therapy had lipodystrophy and high insulin antibody titers with high binding capacity and high affinity (21).

Insulin antibodies are rarely found in patients with lipodystrophy.

Insulin detemir

See also Insulin

General Information

Insulin detemir is a long-acting insulin analogue that lacks threonine at the B30 position and is acylated with a 14-carbon myristoyl fatty acid side-chain at the epsilon-amino group of the lysine in the B28 position. This stimulates binding to albumin and increases the half-life, extending its duration of action.

Comparative studies

In healthy volunteers, there was a dose-related increase in blood insulin concentrations after the administration of insulin detemir (1). However, there was no clear dose-response metabolic effect and individual variability was high.

Insulin detemir has been compared with protamine zinc insulin in 59 patients with type 1 diabetes (2). All used insulin detemir for 6 weeks and protamine zinc insulin for 6 weeks in a randomized order. About 2.35 times higher doses of detemir were necessary than protamine zinc insulin. Fasting blood glucose concentrations were lower at the end of the detemir period and there were fewer attacks of hypoglycemia.

In a 6-month, multinational, open, parallel-group comparison of insulin detemir and protamine zinc insulin in 448 patients with type 1 diabetes, the two treatments produced comparable HbA_{1c} concentrations and fasting plasma glucose concentrations with less within-subject variation in fasting blood glucose with insulin detemir (3). The risk of hypoglycemia was 22% lower with insulin detemir and 34% lower for nocturnal hypoglycemia.

Combination with short-acting insulin

In a multinational study for 6 months in 448 patients with type 1 diabetes, two-thirds were given insulin detemir and one-third received isophane, both in addition to premeal rapid-acting insulin aspart (3). HbA_{1c} concentrations were comparable, but in the detemir group the risk of hypoglycemia was 22% less and the risk of nocturnal hypoglycemia was 34% lower. There were two cases of severe hypoglycemia with detemir and one with isophane. Three patients who used detemir developed reactions at the injection site (pain, myalgia, redness, or

© 2006 Elsevier B.V. All rights reserved.

lipodystrophy) compared with one who used isophane (itching). One potentially allergic reaction was possibly related to detemir.

Organs and Systems

Immunologic

An unspecified allergic reaction to insulin detemir has been reported (3).

Insulin glargine

See also Insulin

General Information

Insulin glargine is a new long-acting human insulin analogue, in which phenylalanine is removed from site 30 of the C terminal of the B chain and two arginine molecules replace it, adding two positive charges; asparagine on site 21 of the A chain is replaced by the more stable glycine to avoid deamination. Older long-acting insulins, such as protamine zinc insulin and insulin zinc suspension (crystalline) (ultralente), had a maximal hypoglycemic effect after about 20 hours (in the middle of the night), and the glucose-lowering action then abated gradually. The newer analogues have a more constant profile of action (1–3).

The binding of insulin analogues to insulin and IGF-I receptors and their metabolic and mitogenic properties have been evaluated in vitro (4). In general the metabolic potencies correlated with insulin receptor binding and the mitogenic properties correlated with IGF-I receptor binding. The rapid-acting analogues resembled insulin, except that the binding of insulin lispro to the IGF-I receptor was slightly increased. Insulin glargine had a 6- to 8-fold greater affinity for IGF-I and mitogenic potency than human insulin (suggesting greater growth-stimulating potential). In insulin detemir the balance between the metabolic and mitogenic potency was not changed, but receptor affinity was reduced, which may explain its lower efficacy on a molar base in humans.

Insulin glargine has been reviewed (5,6). The general conclusion was that it is an effective long-acting insulin with no pronounced peaks of action. Patients using insulin glargine have a reduced risk of hypoglycemia. Insulin glargine, which is metabolically active for at least 24 hours, could have an overlapping effect after a second injection. However, there was no evidence of accumulation when insulin glargine, mean dose 24 U/day, was used in combination with insulin lispro for 11 days (7). In reaction to comments, and discussing whether fluctuations in insulin concentrations still occur during the administration of insulin glargine, the authors agreed that the dose should be constant for at least 2 days before a change is made. It is also not clear whether higher doses of insulin glargine could accumulate because of slower inactivation (8).

Comparative studies

The absorption of insulin glargine was delayed compared with protamine zinc insulin in a study using radioactive tracers (9).

In single-dose, double-blind, euglycemic clamp studies, insulin glargine had a smoother metabolic effect with a peakless profile of action starting at 2–4 hours and continuing over 24 hours than protamine zinc insulin, whose peak occurred at 4 hours and whose activity subsequently fell (10).

In a randomized, parallel-group study, there were fewer episodes of nocturnal and serious hypoglycemia when insulin glargine was compared with once- or twice-daily protamine zinc insulin (11,12). Other adverse reactions and reactions at the injection sites were identical.

Insulin glargine did not cause a peak in blood insulin concentration, compared with protamine zinc insulin and crystalline insulin zinc suspension (ultralente); the effect lasted 24 hours, almost comparable to continuous subcutaneous infusion of a short-acting insulin (13).

In general, one daily injection of insulin glargine gives more constant insulin concentrations and fewer nightly attacks of hypoglycemia than protamine zinc insulin. Treatment satisfaction was constantly better with insulin glargine in 517 patients (14). There was a consistent mean reduction in the perceived frequency of attacks of hypoglycemia. Other adverse effects were not mentioned.

- A 60-year-old man with type 2 diabetes received radiation therapy for a carcinoma of the esophagus and needed continuous enteric tube feeding (15). One daily injection of glargine controlled his diabetes well: his HbA_{1c} concentration was 6.1% and he had no episodes of hypoglycemia for almost 4 months. This made continuous infusion of a short-acting insulin unnecessary.

However, control can be inadequate with a once-daily injection.

- A 53-year-old man with type 1 diabetes needed tube feeding after a stroke and received glargine insulin once daily (16). He had marked hyperglycemia after 22 hours and when the dose was divided into two equal doses every 12 hours, the hyperglycemia was reduced.

© 2006 Elsevier B.V. All rights reserved.

Insulin glargine and protamine zinc insulin have been compared in 349 children and adolescents in a multicenter, open, randomized study (17). Besides the usual thrice-daily regimen of regular insulin they took either insulin glargine at bedtime or protamine zinc insulin at bedtime or twice daily. HbA_{1c} did not differ. The target for fasting blood glucose was 4.4–8.8 mmol/l, and 5% more patients who used insulin glargine reached the target (44% compared with 39% of the patients who used protamine zinc insulin). Symptomatic hypoglycemia was similar with the two treatments.

Six children were treated with insulin glargine and six with protamine zinc insulin as the long-acting insulin component (18). After 3 months, unbound insulin concentrations were lower during the night with insulin glargine. There were three cases of hypoglycemia with protamine zinc insulin and one with insulin glargine.

Combination with short-acting insulin

Insulin glargine plus a short-acting insulin has been compared with isophane insulin for 4 weeks in a double-blind study in 256 patients with type 1 diabetes (19). The patients were all taking once- or twice-daily isophane insulin and continued to do so or switched to insulin glargine with added zinc 30 or 80 micrograms/ml at bedtime. The patients who used insulin glargine had more attacks of hypoglycemia at the start of the study than those who used isophane insulin, but this tended to equalize during the 4 weeks. Fasting plasma glucose was lower in those who used insulin glargine. HbA_{1c} concentrations were not reported.

The combinations insulin lispro + insulin glargine and regular + isophane have been compared in a randomized, crossover study for 32 weeks in 25 patients (20). HbA_{1c} was not different, but the total insulin dose was lower with insulin lispro + insulin glargine and there were fewer episodes of nocturnal hypoglycemia.

Organs and Systems

Metabolism

In 619 patients with type 1 diabetes treated with protamine zinc insulin and insulin lispro, randomized to once-daily insulin glargine or to once-daily or twice-daily protamine zinc insulin for 16 weeks in an open study, there was no difference in the frequency of hypoglycemic episodes, severe hypoglycemia, or HbA_{1c} (21). Fasting plasma glucose concentrations were lower with insulin glargine.

In 518 patients with type 2 diabetes using protamine zinc insulin, with or without short-acting insulin, randomized to insulin glargine or protamine zinc insulin, there was less nocturnal hypoglycemia with insulin glargine (22). HbA_{1c} and mild symptomatic hypoglycemia was the same in both groups.

In 426 patients with type 2 diabetes poorly controlled with oral therapy, randomized to protamine zinc insulin or insulin glargine, glucose concentrations after dinner were lower with insulin glargine and there were significantly fewer attacks of hypoglycemia (23). HbA_{1c} was 8.2 and 8.1% with insulin glargine and protamine zinc insulin respectively.

Immunologic

Insulin glargine solved a problem in a man with type 1 diabetes after pork, beef, and human insulins had elicited allergic reactions (24). Antihistamines ameliorated the reactions but did not resolve them. Insulin glargine elicited no reactions, even when regular insulin was given. This case suggests that the A chain, which is modified in insulin glargine, is part of the allergic epitope. Tolerance to insulin glargine appeared to suppress allergy to regular insulin.

Drug Administration

Drug formulations

In contrast to most medium- and long-acting formulations, insulin glargine is a clear solution. In two cases, patients gave themselves rapid-acting insulin instead of glargine.

- A 25-year-old woman and a 52-year-old woman injected lispro instead of insulin glargine (25). The first realized her mistake and managed to prevent severe hypoglycemia by eating continuously, despite a fall in blood glucose to 3.7 mmol/l. The other had a blood glucose of 3.1 mmol/l and recovered after intravenous dextrose.

Four other mistakes have been reported (26,27). The authors advised the use of pens for injection of short-acting insulins, as all the mistakes were made by patients who used vials and syringes to administer both types of insulin.

Insulin lispro

See also Insulin

General Information

Insulin lispro induces more rapid and constant release of insulin from the injection site, since it consists of monomeric insulin. The change of one or more amino acids in the insulin molecule prevents insulin from forming dimers or hexamers. More rapid absorption, rapid availability, and rapid inactivation make the action better than that of endogenously secreted insulin. When the interval between meals is long, the premeal blood glucose concentration increases rapidly.

After the administration of insulin lispro it is not necessary to delay a meal until sufficient insulin is absorbed. Insulin lispro can be given immediately before or during a meal and can be used when rapid action is important, as in outpatient treatment of ketonuria (1) or in continuous subcutaneous insulin infusion (2). Insulin lispro can be successful in patients with subcutaneous insulin resistance (3).

Observational studies

During Ramadan, insulin lispro reduced the number of attacks of hypoglycemia and reduced postprandial blood glucose (4). It also reduced post-snack raised blood glucose concentrations when sugar-rich snacks were used (5).

Combination with long-acting insulin

The combinations insulin lispro + insulin glargine and regular + NPH have been compared in a randomized, crossover study for 32 weeks in 25 patients (6). HbA_{1c} was not different, but the total insulin dose was lower with insulin lispro + insulin glargine and there were fewer episodes of nocturnal hypoglycemia.

The new short-acting insulins can be bound to protamine, allowing the preparation of mixed formulations. In a randomized, open, crossover study for 24 weeks, a 50% mixture of insulin lispro and protamine lispro injected immediately before each meal plus NPH in the evening gave a comparable profile to regular insulin injected 30 minutes before each meal plus NPH in the evening (7). There were no differences in HbA_{1c} or

© 2006 Elsevier B.V. All rights reserved.

episodes of hypoglycemia. When Mix25TM (25% insulin lispro plus 75% protamine lispro) was compared with 30/70 human insulin in an open, randomized, crossover study during Ramadan, the daily average blood glucose concentration was better with the insulin lispro combination. The number of hypoglycemic episodes was the same with the two formulations (8).

In an open, randomized, single-dose, three-way, crossover trial, biphasic insulin aspart 30 (30% aspart plus 70% protaminated aspart, BIAsp 30), biphasic insulin lispro 25 (25% lispro plus 75% protaminated lispro, Mix 25), and biphasic human insulin 30 (30% regular plus 70% NPH insulin, BHI 30) were compared in 45 patients (9). Biphasic insulin aspart improved postprandial control better. There were 23 episodes of hypoglycemia with BIAsp 30, 19 with Mix 25, and 11 with BHI 30; two episodes with BIAsp 30, five with Mix 25, and two with BHI 30 required third-party intervention.

Comparative studies

In an open, randomized, crossover study, 113 patients with at least 6 months of continuous subcutaneous insulin infusion before the study were treated with regular insulin or insulin lispro (2). Postprandial blood glucose was lower and HbA_{1c} fell more with insulin lispro. There were no differences in catheter obstruction, hypoglycemic episodes, or other adverse effects. Satisfaction with treatment was better with insulin lispro.

There were no differences between human protamine zinc insulin and human ultralente insulin when either was added once or twice daily to insulin lispro (10).

When either insulin lispro or regular insulin was given during the evening meal in a randomized, double-blind study in insulin-using adolescents, insulin lispro reduced the number of hypoglycemic episodes at night but redistribution of evening carbohydrate might be necessary to reduce postprandial hypoglycemia (11).

Premeal hyperglycemia is common. The short action of insulin lispro can then be extended by the addition of protamine zinc insulin. In a 3-month study in addition to a once-daily injection of protamine zinc insulin, at each meal insulin lispro or insulin lispro + protamine zinc insulin was injected; the postprandial blood glucose concentration was lower, but the post-absorptive glucose concentration was higher in the insulin lispro-only group; there was no difference in HbA_{1c}. The addition of protamine zinc insulin (30% at breakfast, 40% at lunch, and 10% at dinner) improved post-absorptive glucose and HbA_{1c} (12).

Insulin Mix 25 (25% insulin lispro and 75% neutral protamine zinc insulin) reduced the glucose response to a standardized breakfast meal better than premixed 30% regular + 70% protamine zinc insulin when 22 patients with type 2 diabetes were studied three times in a double-blind fashion (13). Protamine zinc insulin mixed with insulin lispro has the same action profile of insulin lispro, with the continuing action of the long-acting component (14). The same mixture given three or four times daily provides acceptable control (15), but gives no possibility of adjusting the short-acting insulin regularly. Protamine zinc insulin must be mixed with insulin lispro in the syringe immediately before the meal (16). The mixture is not stable for longer as there is partial exchange of the rapid-acting analogue and the protamine-bound human insulin. Instant mixing is no solution when pens are used.

The use of insulin lispro instead of regular insulin reduced the frequency of nocturnal attacks of hypoglycemia but did not change HbA_{1c} (17). This was confirmed by the UK Prospective Diabetes Study (18), which also found a fall in postprandial glucose with an increase in fasting and preprandial glucose.

In an open, crossover, randomized study in 33 patients with type 1 diabetes who used regular or insulin lispro, the latter was associated with a lower incidence of severe hypoglycemia, mostly due to reduced nocturnal hypoglycemia; HbA_{1c} was not different (19).

A crossover comparison of regular insulin + protamine zinc insulin at bedtime with insulin lispro + multiple protamine zinc insulin showed no effect on overall hypoglycemia but there was less frequent severe hypoglycemia with the second treatment (20). The reduction in HbA_{1c} was small and not significant. Insulin doses were the same. Patients preferred the second treatment.

In an open, randomized, multicenter study, 33 women with type 1 diabetes for at least 2 years were randomized to preprandial lispro or regular insulin in week 15 of their pregnancy; both groups used NPH insulin as well (21). HbA_{1c} concentrations fell at the same rate. One patient in the regular group had one episode of severe hypoglycemia and one had three episodes. Biochemical hypoglycemia (under 3.0 mmol/l) was significantly more frequent in the lispro group (5.5 versus 3.9%). Retinopathy progressed during pregnancy in three of the 16 who used lispro and six of the 17 who used regular insulin; retinal aneurysms were seen at the beginning of the study in 10/16 and 5/17 patients respectively. There were no differences in the neonates.

When insulin lispro and insulin aspart were compared in a single-blind, randomized crossover study in 14 patients with type 1 diabetes, insulin lispro had a faster onset of action but a shorter duration (22). However, in another study, the pharmacokinetic and pharmacodynamic profiles of insulin aspart compared with human insulin in 24 healthy Japanese were the same as those in non-Japanese subjects (23).

Insulin aspart, insulin lispro, and buffered regular insulin in continuous subcutaneous insulin infusion have been compared in an open, randomized, parallel-group study in 146 patients (24). HbA_{1c}, hypoglycemic episodes, and blockages of pumps or infusion sets did not differ.

Insulin lispro and insulin aspart were equally effective in 24 patients with type 1 diabetes (25).

Insulin lispro and repaglinide were given to seven patients with diabetes related to cystic fibrosis (26). They had normal fasting blood glucose and insulin concentrations, but postprandial glucose concentrations were substantially raised. Insulin lispro had a larger and more sustained effect in lowering postprandial glucose than repaglinide. However, the doses of insulin lispro (0.1 U/kg) and repaglinide (1 mg) may not have been comparable.

Organs and Systems

Metabolism

Hypoglycemic events in 24 controlled trials of rapid-acting insulin analogues have been analysed (27). In 22 trials, insulin lispro was used, 19 studies were open and unblinded, and five were double-blind. In five of 22 studies there was a significant reduction in mild hypoglycemia, but there were no changes in the frequency of severe hypoglycemia in 10 of 12 studies that reported these events; there was a fall in nocturnal hypoglycemia in 6 studies, but in 18 studies there was no fall. The author stated that rapid-acting insulins are only appropriate in intensive therapy, which involves well-educated and well-motivated patients.

Lipoatrophy is rare with human recombinant insulin. Two cases of lipoatrophy induced by insulin lispro during continuous subcutaneous insulin infusion have been reported (28).

- An 8-year-old girl was switched to continuous subcutaneous insulin infusion using insulin lispro for better regulation after 4 years of diabetes. After 12 months she developed lipoatrophy of the abdominal wall, which progressed during the next months. When she changed to neutral buffered regular human insulin, no further lipoatrophy developed, but the existing atrophy did not improve either.
- A 51-year-old woman started to use continuous subcutaneous insulin and after 2 years the insulin was changed to insulin lispro. She developed lipoatrophy in the abdomen and buttocks 1 year later and there was an increase in the time before the bolus started to peak. Buffered regular human insulin stopped progression of the lipoatrophy.

Skin

Insulin lispro can cause lipoatrophy, but it was less extensive in a case in which it had occurred with regular insulin, perhaps because of the greater solubility of insulin lispro.

- Several combinations of regular and NPH insulin reduced the risk of hypoglycemia and optimized blood glucose in a 29-year-old woman who had had type 1 diabetes for 6 years (29). Continuous subcutaneous insulin infusion with regular insulin reduced the risk of hypoglycemia, but after 7 months she developed lipoatrophy. Changing the site of the cannula did not help. She was given insulin lispro instead and after 11 months a new, less extensive area of lipoatrophy emerged, which did not disappear.

Immunologic

The long-term antigenicity of insulin lispro and cross-reactivity with human insulin antibodies over 4 years has been investigated in 1221 patients with both type 1 and type 2 diabetes, either insulin-naïve or with prior insulin treatment, in a multicenter combination of controlled and non-controlled open studies (30). Like recombinant human insulin, insulin lispro elicited a low immunogenic response. The reversal of amino acids in B28 and B29 is in a relatively non-immunogenic area. Moreover, antigenicity often correlates with residence of insulin in subcutaneous tissues, and insulin lispro has a short residence time. The patients did not develop increased dosage requirements. Intermittent treatment did not increase specific or cross-reactive responses. The antibody responses were slightly higher in type 1 than in type 2 diabetes. In lipodystrophy with lipoatrophic diabetes, high insulin resistance is often found, for which leptin deficiency is one contributory factor.

Second-Generation Effects

Pregnancy

Rapid improvement of regulation by insulin lispro during pregnancy causes proliferative diabetic retinopathy more often. In 14 patients treated with insulin lispro to improve control before or at the beginning of pregnancy, six of the 10 patients with normal optic fundi remained negative. However, three patients developed bilateral progressive retinopathy with marked vision impairment, in two cases with vitreous hemorrhage; one patient with a negative examination 6 months before pregnancy, but with minimal lesions 18 months earlier, developed progressive retinopathy with vitreous hemorrhages in spite of multiple coagulations (31). The authors advised care when starting insulin lispro in patients with a history of retinal lesions and to look for those at risk by performing fluorescein angiography, which distinguishes incipient changes better.

In a comparison of premeal regular insulin and premeal insulin lispro in gestational diabetes there were fewer attacks of hypoglycemia, but fasting glucose, postprandial glucose, and HbA_{1c} were similar in the two groups (32). There were no fetal or neonatal abnormalities.

Susceptibility Factors

Age

The newer insulins are not registered for use in children in many countries. A report of the use of postprandial insulin lispro versus preprandial regular insulin in an open, crossover, randomized study in 24 prepubertal children showed no large differences (33). Fasting blood glucose was higher with insulin lispro. The number of hypoglycemic episodes was almost the same with both insulins. There was one case of severe hypoglycemia.

Renal disease

The pharmacodynamic and pharmacokinetic properties of regular soluble insulin and insulin lispro have been investigated in 12 patients with and without nephropathy in a double-blind, crossover study with euglycemic glucose clamping (34). Insulin clearance was reduced by 30–40% in patients with nephropathy, but in both groups the time to reach the maximal effect was shorter with insulin lispro. The overall metabolic effect of regular soluble insulin, but not of insulin lispro, was lower in nephropathy, in which a 50% higher dose of regular insulin may be necessary.

© 2006 Elsevier B.V. All rights reserved.

Drug Administration

Drug administration route

Insulin lispro by repeated injection has been compared with insulin lispro by continuous subcutaneous infusion in 41 patients who were C-peptide negative (35). HbA_{1c}, mean blood glucose concentrations, and mean insulin doses were significantly lower during continuous subcutaneous infusion; the frequency of attacks of hypoglycemia was the same.

Insulin-like growth factor (IGF-I)

General Information

Insulin growth factor (IGF) and the IGF-I receptor are structurally comparable to insulin and the insulin receptor. Recombinant human IGF-I has 54% identity to proinsulin. Insulin and IGF-I can bind to both receptors, but insulin can only transfer 1% of the IGF message on the IGF receptor and IGF-I only 1% of the insulin message on the insulin receptor.

Recombinant human IGF-I is used as an adjunct to insulin therapy in patients with large daily variations in insulin effect. It is sometimes given in insulin resistance syndromes caused by changes in the insulin receptor or in type B insulin resistance syndrome caused by antibodies to the insulin receptor.

In 14 adolescents, the addition of IGF-I to diabetic treatment for 12 weeks did not change leptin concentrations (1).

IGF-I was given as co-therapy with insulin in 223 patients for 12 weeks twice-daily (2). The doses of IGF-I were 40/40, 80/40, or 80/60 micrograms/kg. Patients who received co-therapy were able to reduce their daily doses of insulin. The number of episodes of hypoglycemia was the same, but glucose regulation was tighter during IGF-I co-therapy. The fall in HbA_{1c} concentration was greater with co-therapy (–1.2%) than with intensive therapy only (–0.7%). The dosage regimen of 40/40 micrograms/kg was well tolerated. Higher doses had no greater effect but were associated with edema, jaw pain, headache, palpitation, tachycardia, syncope, or early worsening of retinopathy.

Organs and Systems

Sensory systems

Of 199 patients, 16 developed significant worsening of retinopathy, including neovascularization, over 12 weeks; 12 of the 16 had optic disc swelling, which necessitated laser therapy in three of them (3). This was mostly seen in patients using a high dose of IGF-I, but a long-term effect of low-dose IGF-I could not be excluded either.

Immunologic

IGF-I can cause allergic reactions (4).

- A 75-year-old man with glucose intolerance, severe hyperinsulinemia, and extreme insulin resistance with anti-insulin receptor antibodies had immunosuppressive therapy and plasmapheresis to remove the antibodies, without lasting success. Treatment with hrIGF-I, 0.4 mg/kg/day, reduced HbA_{1c} from 13.8% to 8.0%. After 5 months he developed a generalized skin eruption 20 minutes after the injection. When IGF-I was withdrawn the HbA_{1c} rose again. After careful desensitization with hrIGF-I, 0.1 mg three times a week, IGF-I was continued, with good effect on HbA_{1c}.

Long-Term Effects

Tumorigenicity

A non-Hodgkin's lymphoma developed in the right femur of a 58-year-old man who had used IGF-I 40 micrograms bd (5) in a study of the effect of adding IGF to insulin therapy (SEDA-23, 457).

Interferon alfa

See also Interferons

General Information

Interferon alfa is used as purified natural leukocyte or lymphoblastoid human interferon, or as a recombinant DNA preparation. Work to assign the most frequently observed amino acids at each position has led to a so-called consensus interferon alfa (1). Relatively low doses (3–10 MU three times a week) are now being used in most indications, except in AIDS-related Kaposi's sarcoma (up to 30 MU/day). Although the half-life is only 4–5 hours, its biological effects persist for 2–3 days.

Observational studies

Considerable efforts have been made to improve the efficacy of interferon alfa in patients with chronic hepatitis C. Currently used regimens, including long-term interferon alfa alone or in combination with ribavirin, produce a sustained response rate of 40–50%. Other possibly effective strategies include a longer duration of treatment, higher fixed doses, and high-dose induction (2). A longer duration of treatment has been evaluated in patients with chronic hepatitis B. In 118 patients, treatment for 32 rather than 16 weeks enhanced the virological response to hepatitis B without increasing the severity of adverse effects, except for hair loss, which was more frequent during prolonged therapy (3).

A wide range of persistent symptoms has been reported during interferon alfa treatment for chronic hepatitis C. An analysis of 222 patients from the USA and France, enrolled in a multicenter trial, suggested that pretreatment symptoms were an important predictor of moderate or severe (defined as debilitating) adverse effects during treatment with interferon alfa (4). Compared with baseline, the incidences of moderate and severe fatigue, myalgia, arthralgia, headache, dry eyes, and dry mouth increased significantly after 6 months. In each case, the development of these debilitating adverse effects was associated with the presence of that symptom at baseline. They were more often reported in patients who received interferon alfa daily than three times weekly, and in US than French patients, suggesting possible differences in cultural attitudes toward illness. There was also increased use of antidepressants during the 6-month survey.

Low daily doses of interferon alfa have been used with small doses of cytarabine in the treatment of early chronic myelogenous leukemia (5). With doses sufficient to obtain a good cytogenetic response (for example 3.7 MU/m^2/day plus cytarabine 7.5 mg/day) toxicity was considered acceptable. There was significant fatigue in 43% of cases, significant neurological changes in 27%, weight loss in 19%, and oral ulcers in 4%.

Comparative studies

Interferon alfa, in combination with ribavirin, is currently first-line therapy for patients with chronic hepatitis C and compensated liver disease, and its use has been extensively reviewed (6). A meta-analysis of trials in patients who were previously non-responsive to interferon alfa alone showed that treatment withdrawal for an adverse event was more frequent in patients who received combination therapy (8.8%) compared with interferon alfa monotherapy (4%) (7). However, treatment withdrawal is more frequent in practice. In a retrospective analysis of 441 consecutive patients treated with interferon alfa and ribavirin, 25% of patients discontinued treatment because of adverse effects (8). The study identified female sex, a dose of interferon alfa above 15 MU/week, and naive patients as independent susceptibility factors for premature withdrawal.

Comparisons of different forms of interferon alfa

In a randomized comparison of recombinant interferon alfa-2b and interferon alfa n-3 (9 MU/week for 1 year) in 168 naive patients with chronic hepatitis C, there was no significant difference in clinical outcomes and the incidence or type of adverse effects between the groups (9). There was a non-significant trend toward more severe leukopenia and a higher incidence of severe thyroid disorders in patients who received recombinant interferon alfa-2b.

Pegylated interferon alfa-2a is a modified form of interferon alfa; it produces higher serum concentrations and has greater efficacy. In 1530 patients with chronic hepatitis C, pegylated interferon alfa-2b had a similar profile of adverse effects to unmodified interferon alfa-2b, but with more frequent dose-limiting neutropenia (10). Two other studies have shown that peginterferon alfa-2a once weekly is more effective than unmodified interferon alfa-2a three times weekly in patients with chronic hepatitis C (11,12). The frequency and severity of adverse effects with the two treatments were very similar and were consistent with the known adverse effects of interferon alfa. In one study, a neutrophil count below 0.5×10^9/l was more frequent with peginterferon alfa than with unmodified interferon alfa (12/265 versus 4/261), but none of these patients required treatment withdrawal or had serious infections in relation to neutropenia (12). In the other study, the proportion of patients who required dosage modification because of thrombocytopenia was also higher with peginterferon alfa (18 versus 6%), but no patients had clinically significant bleeding disorders (11). Taken together, these studies suggest that pegylated interferon alfa may produce more frequent or more severe hemotoxic effects than unmodified interferon alfa.

In 1530 patients with chronic hepatitis C, pegylated interferon alfa-2b had a similar profile of adverse effects to unmodified interferon alfa-2b, but with more frequent dose-limiting neutropenia (10). No particular adverse effect has emerged since the use of this new formulation.

General adverse effects

The adverse effects of interferon alfa have mostly been reported after systemic administration, as intranasal use was not associated with more frequent adverse effects than placebo (13). Almost all patients treated with interferon alfa have experienced adverse effects, most of which are mild to moderate in intensity and easily manageable without withdrawal of treatment (14). The incidence and profile of adverse effects reported with the available types

© 2006 Elsevier B.V. All rights reserved.

of interferon alfa are very similar (SEDA-21, 369) (SEDA-22, 399), but they differ with the dose, schedule of administration, and the disease. At least 4–5% of patients with chronic hepatitis C had to discontinue treatment because of adverse effects, and dosage reduction was required in 9–22% of those receiving 9–15 MU/week (15). In a large retrospective evaluation of 11 241 patients with chronic viral hepatitis, the incidence of fatal or life-threatening adverse effects related to interferon alfa was one in 1000; events included irreversible liver failure, severe bone marrow depression, and attempted suicide (16). Overall, severe adverse effects were observed in 1% of patients, and comprised mostly thyroid disorders, neuropsychiatric manifestations, and cutaneous adverse effects. In other studies in patients with chronic hepatitis, the incidence of major adverse effects was 25% in 659 patients (17); in Japan, dosage reduction or withdrawal was necessary in 31% of 987 patients receiving relatively high dosages of interferon alfa (18–70 MU weekly) (18). The safety of interferon alfa in children appears to be similar to that in adults (19). The pathogenesis of most adverse effects observed with interferon alfa is poorly understood, but two main mechanisms are commonly postulated, namely a direct toxic effect or an indirect immune-mediated effect.

During the first days of treatment, virtually all patients have a flu-like syndrome with fever, chills, tachycardia, malaise, headache, arthralgias and myalgias, but tachyphylaxis usually develops after 1–2 weeks of treatment (20). Late febrile reactions are rarely noted (21). Although the severity increases with the dose, the flu-like syndrome is rarely treatment-limiting and it can be partly prevented by the prophylactic administration of paracetamol (acetaminophen). The acute release of fever-promoting factors, for example the eicosanoids, IL-1, and TNF alfa, secondary to interferon alfa is the suggested mechanism.

Although the adverse effects profiles of the currently available formulations of interferon alfa are very similar, patients who have adverse effects with one formulation can be successfully re-treated with another type of interferon alfa. This has been shown in 22 patients in whom lymphoblastoid interferon alfa was withdrawn because of severe adverse effects (leukopenia, thrombocytopenia, thyroid disorders, and psychiatric disturbances) and were successfully re-treated with similar dosages of leukocyte interferon alfa (22). Only one of these patients had severe leukopenia again.

Organs and Systems

Cardiovascular

Hypotension or hypertension, benign sinus or supraventricular tachycardia, and rarely distal cyanosis, have been reported within the first days of treatment in 5–15% of patients receiving high-dose interferon alfa (20). These adverse effects are usually benign, except in high-risk patients with a previous history of dysrhythmias, coronary disease, or cardiac dysfunction.

Cardiac complications

Severe or life-threatening cardiotoxicity is infrequent and mostly reported in the form of a subacute complication in patients with cancer, and in those with pre-existing heart disease or receiving high-dose interferon alfa. Atrioventricular block, life-threatening ventricular dysrhythmias, pericarditis, dilated cardiomyopathy, cardiogenic shock, asymptomatic or symptomatic myocardial ischemia or even infarction, and sudden death have been observed (SED-13, 1091) (SEDA-20, 326) (SEDA-22, 369) (23). The combination of high-dose interleukin-2 (IL-2) with interferon alfa enhanced cardiovascular complications, namely cardiac ischemia and ventricular dysfunction (24).

Cardiomyopathy has been attributed to interferon alfa in an infant (25).

- A 3-month-old boy was given interferon alfa (2.5–5.5 MU/m^2) for chronic myelogenous leukemia. After 7.5 months he developed progressive respiratory distress, with anorexia, irritability, and nocturnal sweating. A chest X-ray showed cardiomegaly, an echocardiogram showed a markedly dilated left ventricle, and an electrocardiogram showed left ventricular hypertrophy with abnormal repolarization. Viral cultures and serology for cytomegalovirus, parvovirus B19, and enterovirus were negative. Infectious diseases and metabolic disturbances were excluded. Interferon alfa was withdrawn and digoxin, furosemide, and an angiotensin-converting enzyme inhibitor were given. One year later, he was asymptomatic without further cardiac treatment.

Similar, but anecdotal reports were also described in patients without evidence of previous cardiac disease and receiving low-dose interferon alfa (SEDA-20, 326). In chronic viral hepatitis, only seven of 11 241 patients had severe cardiac adverse effects (16). The exact risk of such cardiovascular adverse effects is unknown. In patients with chronic viral hepatitis, cardiovascular test results were not modified when patients were re-examined after at least 6 months of treatment, even where there was an earlier cardiac history (26), but there was a potentially critical reversible reduction in left ventricular ejection of more than 10% in another prospective study (27).

Myocardial dysfunction can completely reverse after withdrawal of interferon alfa and does not exclude further treatment with lower doses (28).

- A 47-year-old man with renal cancer and no previous history of cardiovascular disease developed gradually worsening exertional dyspnea after he had received interferon alfa in a total dose of 990 MU over 5 years. Echocardiography and a myocardial CT scan confirmed a dilated cardiomyopathy, with left ventricle dilatation and diffuse heterogeneous perfusion at rest. He improved after interferon alfa withdrawal and treatment with furosemide, quinapril, and digoxin. Myocardial scintigraphy confirmed normal perfusion. He restarted low-dose interferon alfa (6 MU/week) 1 year later and had no recurrence of congestive heart failure after a 1-year follow-up period.

Patients with pre-existing cardiac disease are more likely to develop cardiovascular toxicity while receiving interferon alfa, but these complications are rare. Among 89 patients with chronic hepatitis C, 12-lead electrocardiography monthly during a 12-month treatment period and follow-up for 6-months showed only minimal and non-specific abnormalities in five patients (two had right

© 2006 Elsevier B.V. All rights reserved.

bundle branch block, one left anterior hemiblock, and two unifocal ventricular extra beats) (29). None of these disorders required treatment withdrawal, and complete noninvasive cardiovascular assessment was normal. Overall, the role of interferon alfa was uncertain and the 5.6% incidence of electrocardiographic abnormalities was suggested to be similar to that expected in the general population. Nevertheless, severe cardiac dysrhythmias are still possible in isolated cases, as illustrated by the development of third-degree atrioventricular block, reversible on withdrawal, in a 57-year-old man with lower limb arteritis but no other cardiovascular disorder (30).

Peripheral vascular complications

Raynaud's phenomenon

Raynaud's phenomenon can occur, particularly in patients with chronic myelogenous leukemia (SEDA-20, 326) (31), and severe cases were complicated by digital necrosis (SEDA-20, 326) (SEDA-21, 369).

In 24 cases of Raynaud's syndrome, interferon alfa was the causative agent in 14, interferon beta in 3, and interferon gamma in 5 (32). There was no consistent delay in onset and the duration of treatment before the occurrence of symptoms ranged from 2 weeks to more than 4 years. The most severe cases were complicated by digital artery occlusion and necrosis requiring amputation. Few patients had other ischemic symptoms, such as myocardial, ophthalmic, central nervous system, or muscular manifestations. Severe Raynaud's phenomenon was also reported in a 5-year-old girl with hepatitis C (33).

Cryoglobulinemia

Although most patients with mild-to-moderate clinical manifestations of hepatitis C virus-associated mixed cryoglobulinemia improved during treatment with interferon alfa, acute worsening of ischemic lesions has been reported in three patients who had prominent cryoglobulinemia-related ischemic manifestations (34). All three had acute progression of pre-existing peripheral ischemia or leg ulcers within the first month of treatment, and transmetatarsal or right toe amputations were required in two. The lesions healed after interferon alfa withdrawal. It was therefore suggested that the antiangiogenic activity of interferon alfa may also impair revascularization and healing of ischemic lesions in patients with initially severe ischemic manifestations.

Venous thrombosis

Whereas clinically insignificant coagulation abnormalities have been documented in patients receiving high-dose continuous interferon alfa (35), isolated cases of venous thrombosis have been observed (SEDA-20, 329) (36). Interferon alfa can also induce the production of antiphospholipid antibodies (SEDA-20, 329) (SEDA-21, 371). In one study, antiphospholipid antibodies were found in five of 12 patients with melanoma treated with interferon alfa alone or with interferon alfa plus interleukin-2; deep venous thrombosis occurred in four patients with antiphospholipid antibodies (37). Although the underlying neoplasia undoubtedly played a role in the further development of venous thrombosis, the causative role of interferon alfa was suggested by the absence of antiphospholipid antibodies and venous thrombosis in eight patients treated with interleukin-2 alone.

Other vascular complications

Other anecdotal reports included acrocyanosis and peripheral arterial occlusion (SED-13, 1095) (SEDA-22, 400). Although the causal relation is unclear, interferon alfa was considered as a possible cause in the triggering of acute cerebrovascular hemorrhage or ischemic neurological symptoms in few patients (SEDA-21, 370) (SEDA-22, 400). The pathogenic mechanisms of these vascular effects are still unclear; vasculitis, hypercoagulability, vasospasm, a paradoxical anginal effect of interferon alfa, or an underlying cardiovascular disease have all been suggested as underlying processes.

Respiratory

The respiratory adverse effects of interferon alfa include interstitial pneumonitis (38), which is rare. Since the first description of interstitial pneumonitis associated with interferon alfa in Japanese patients who also used the popular "Sho-saiko-t" herbal formulation, similar cases have been described in Western patients, suggesting that interferon alfa can be the sole cause in some patients (SED-13, 1091) (SEDA-20, 326) (SEDA-21, 370) (39,40).

Interferon alfa was also suspected to be involved in one case of biopsy-proven bronchiolitis obliterans-organizing pneumonia (41). Clinical symptoms of pneumonitis appeared 3–12 weeks after the onset of interferon alfa therapy, and after withdrawal of treatment they usually completely resolved, either spontaneously or after a short course of glucocorticoid treatment. Immune-mediated pulmonary toxicity involving the activation of T cells was considered as a likely mechanism. The uncommon features of bronchiolitis obliterans-organizing pneumonia have been reported in three other patients who received interferon alfa together with ribavirin or cytosine arabinoside (42,43).

In four patients with hematological malignancies who developed symptoms suggestive of pneumonitis (that is a dry cough and dyspnea) after 1 week to 38 months of interferon alfa treatment, there was a marked reduction in carbon monoxide diffusion capacity in all cases, whereas there were pathological findings in ordinary chest X-rays in only two (44). What the authors called ultracardiography and high-resolution CT scanning were suggested to have higher sensitivity in evaluating pulmonary symptoms. In three patients, complete reversal was obtained after interferon alfa withdrawal, either spontaneously or after corticosteroid treatment, although one patient required long-term glucocorticoid treatment.

In a retrospective review of 70 patients with hepatitis C enrolled in four clinical trials, there were four cases of significant pulmonary toxicity (two of bronchiolitis obliterans and two of interstitial pneumonitis) (45). Three recovered completely, but one still required glucocorticoids for exertional dyspnea that persisted 17 months after interferon alfa withdrawal. The authors suggested that there was an increased risk with high-dose interferon, because three of these patients received high doses (5 MU/day) or pegylated interferon alfa. In contrast, they were unaware of any significant pulmonary

© 2006 Elsevier B.V. All rights reserved.

toxicity in any of their approximately 500 patients with hepatitis C.

Interferon alfa can cause exacerbation of asthma (SED-14, 1248).

- Acute exacerbation of asthma has been reported in two men aged 27 and 57 years with a previous history of mild asthma (46). They developed progressive aggravation of asthma within 8–10 weeks of treatment for chronic hepatitis C, and finally required emergency treatment with systemic glucocorticoids and inhaled beta$_2$ adrenoceptor agonists. Severe asthma recurred 2–3 weeks after interferon alfa rechallenge in both patients.

Although these cases are anecdotal, they strongly suggest that interferon alfa should be regarded as a possible cause of asthma exacerbation in predisposed patients.

- Sustained and isolated dry cough has been attributed to interferon alfa in a 49-year-old woman (47). The symptoms disappeared after withdrawal, recurred on readministration, and again resolved after withdrawal. No other cause was found after thorough investigation.

Pleural effusion has been attributed to interferon alfa (48).

- A 54-year-old man received interferon alfa-2a, 9 MU/day, for chronic hepatitis C. He developed an asymptomatic right pleural effusion after 14 days. Although his serum titer of antinuclear antibodies was slightly increased, a more complete screening for autoimmune disease was negative. An infectious origin was also ruled out. The pleural effusion spontaneously disappeared after interferon alfa withdrawal and did not recur.

Although the mechanism of this adverse effect was purely speculative, it was suggested that interferon alfa might have induced a reaction similar to the immunopathological mechanism involved in serositis associated with systemic lupus erythematosus.

Pulmonary artery hypertension has been attributed to interferon alfa (49).

- A 23-year-old man taking hydroxycarbamide 1.5 g/day and interferon alfa-2b (less than 10 MU/day) for chronic lymphocytic leukemia had progressive dyspnea and a non-productive cough after about 5 months. The electrocardiogram showed right-axis deviation, incomplete right bundle-branch block, and right ventricular hypertrophy. The estimated pulmonary artery pressure by echocardiography was 80 mmHg and there were signs of right heart failure. Respiratory function tests showed a restrictive defect, and the chest X-ray showed pulmonary congestion without infiltrates. The patient's clinical status and respiratory function tests improved rapidly after withdrawal of interferon alfa while hydroxycarbamide was continued, and a mean pulmonary artery pressure of 34 mmHg was measured by right heart catheterization 1 month later. At 6 months, the systolic pulmonary artery pressure estimated by echocardiography had fallen to 35 mmHg and the electrocardiogram returned to normal after 1 year.

The authors mentioned that intravenous interferon alfa in sheep had caused an increase in pulmonary artery pressure.

Nervous system

Peripheral neuropathy

Dose-related distal paresthesia occurred in as many as 7% of patients (20), but new onset or worsening of neuropathy has rarely been attributed to interferon alfa. A sensorimotor polyneuropathy was the most frequent presentation (50). The symptoms usually developed after 2–28 weeks of treatment. Such reports were mostly described in patients who received high cumulative doses of interferon alfa, but induction or exacerbation of peripheral sensorimotor axonal neuropathy, particularly in patients with chronic hepatitis C and mixed cryoglobulinemia, was also observed after long-term or low-dose treatment (SED-13, 1092) (SEDA-20, 327) (SEDA-21, 370) (51). Nerve biopsy showed necrotizing vasculitis or axonal degeneration. Most patients stabilized or improved slowly over several months after interferon alfa withdrawal and/or treatment with corticosteroids. Several patients also required plasmapheresis or cyclophosphamide. Although several authors have suggested an autoimmune process, the underlying pathogenic mechanism is unclear.

Other rare forms of neuropathy (SED-13, 1092) include mononeuropathy multiplex (52), acute axonal polyneuropathy (53), anterior ischemic optic neuropathy (54), trigeminal sensory neuropathy (55), bilateral neuralgic amyotrophy (56), brachial plexopathy (57), and symptoms suggestive of leukoencephalopathy (58).

Cranial nerve palsies

There have been reports of interferon alfa-induced cranial nerve palsies, including Bell's palsy.

Two patients, one of whom also received ribavirin, had facial nerve palsy after 5 and 8 months of interferon alfa therapy (59). The palsy resolved completely in one patient after withdrawal and the administration of prednisolone; however, in the other case, the palsy resolved without drug withdrawal, suggesting coincidence.

Two other cases of Bell's palsy, which reversed after interferon alfa withdrawal, have been reported (60). Although the delay in onset (7.5 and 8 weeks) suggested that interferon alfa might be the cause, one patient had no recurrence after rechallenge. A coincidental adverse event cannot therefore be completely ruled out.

Demyelination

Various forms of interferon alfa-induced neuropathy have been reported (SED-14, 1249), but chronic inflammatory demyelinating polyneuropathy has seldom been described (61,62).

- In two patients with chronic hepatitis C or malignant melanoma, paresthesia and tiredness occurred after 6 weeks and 9 months of treatment respectively. Despite withdrawal of interferon alfa, the neurological symptoms worsened initially and a diagnosis of chronic inflammatory demyelinating polyneuropathy was finally confirmed several weeks later. One patient improved after an extended course of plasma exchange and the other required immunoglobulins and prednisolone. Mild to moderate neurological abnormalities persisted at follow-up in both patients.

© 2006 Elsevier B.V. All rights reserved.

Multiple sclerosis has been attributed to interferon alfa (63).

- A 29-year-old woman received interferon alfa-2b (6–10 MU/day) for chronic myeloid leukemia, and about 3 years later developed headaches, back pain, progressive visual disturbance, and a sensory deficit in the legs. MRI scans of the brain and spinal cord suggested a first episode of multiple sclerosis. In addition, the myelin basic protein concentration was slightly raised, and perimetry showed bilateral optic neuritis. Most of her neurological symptoms, except central vision impairment, improved after interferon alfa withdrawal and treatment with high-dose methylprednisolone. As a major partial cytogenetic response had been obtained with interferon, she was given natural interferon alfa (3 MU/day) 2 months later. After 2 days of treatment, she complained of transient but severe pain in the back and the legs, and developed acute paraplegia and loss of micturition desire. Again, interferon was withdrawn and she was given high-dose methylprednisolone. There was no further neurological deterioration at follow-up.

This account is reminiscent of the various autoimmune diseases that can be unmasked or exacerbated by interferon alfa.

Extrapyramidal effects

Extrapyramidal effects have been occasionally reported as a manifestation of persistent neurotoxicity induced by interferon alfa. This issue has been addressed in a report of severe refractory akathisia (64).

- A 28-year-old man received interferon alfa (5 MU/day for 28 days) for chronic hepatitis B. At the end of treatment he developed a slight parkinsonian gait, and 8 days later had a fever with vomiting, insomnia, restlessness, and raised serum creatine kinase activity (4946 IU/l). He had severe akathisia with psychomotor excitement and parkinsonism. Despite treatment with clonazepam, thioridazine, propranolol, trihexyphenidyl, and bromocriptine, his condition progressively worsened. He was finally given intravenous levodopa for 8 days and recovered dramatically within the next few days.

This report, together with previous experimental data, suggests that levodopa might be useful in alleviating some of the manifestations of persistent interferon alfa-induced neurotoxicity.

In two other patients, akathisia occurred shortly after they had started to take interferon alfa; one improved after the frequency of injections was reduced (65). Unfortunately, this report did not provide sufficient convincing evidence for a causal relation; the development of akathisia may have been coincidental.

Chorea is a very rare manifestation of interferon alfa neurotoxicity (SEDA-20, 327).

- A 68-year-old woman developed progressive personality changes and 2 months later permanent choreic movements of the four limbs (66). She had taken interferon alfa-2b (3 MU/day) and hydroxyurea 50 mg/kg/day for chronic myeloid leukemia for 2 years and had no history of psychiatric disorders. Neuropsychological testing showed frontal subcortical dysfunction. There were no abnormalities in the Huntington disease gene. She progressively worsened over the next 6 months. The electroencephalogram was disorganized, with diffuse slow waves, and she was bedridden. Interferon alfa was withdrawn. The chorea ceased 1 month later and she completely recovered cognitive function. Electroencephalography was normal 6 and 12 months later.

The authors attributed these events to antidopaminergic effects of interferon alfa.

Seizures

Although generalized tonic-clonic seizures have occasionally been described during trials of high doses of interferon alfa, they have also been reported after the use of intermediate or even low doses (67–69). There was a 1.3% incidence of generalized seizures in a retrospective study of 311 patients treated with low doses for chronic viral hepatitis (70). In another study, tonic-clonic seizures were identified in 4% of children treated for chronic hepatitis B (71). As seizures occurred only in children under 5 years of age with fever or potential perinatal nervous system injury, immaturity of the nervous system was suggested to be an additional factor for interferon alfa-induced neurotoxicity in children.

- In three patients, seizures occurred after a cumulative dose of 266–900 MU (72,73). Two were retreated with a lower dose and remained free of seizures, so that the strength of the causal relation was debatable (72). However, a dose-related effect was still possible.
- Another patient with a history of bipolar mood disorder experienced had his first four episodes of seizures with a prolonged delirious state 1 week after withdrawal of interferon alfa (73).

Reversible photosensitive seizures have also been reported (74).

- A 62-year-old man without a personal or family history of epilepsy received interferon alfa (3 MU three times a week) for 2 years for multiple myeloma. He had frequent episodes of myoclonic jerks in the face, especially when the sun was shining while driving his car. He also had one generalized seizure. Electroencephalography showed a paroxysmal response to intermittent photic stimulation and magnetic resonance imaging was normal. The seizures disappeared and his electroencephalogram normalized after interferon alfa withdrawal.

In this case, the possible role of interferon alfa was suspected only late during treatment, indicating that patients should be regularly questioned about neurological symptoms, because more severe complications might have occurred.

In a prospective study of the effect of interferon alfa (56 MU/day for 4 weeks then 27 MU/week for 20 weeks) in 56 patients with chronic hepatitis C, there was diffuse electroencephalographic slowing at 2 and 4 weeks of treatment, suggesting mild encephalopathy (75). These changes completely reversed after withdrawal. However, the dosage used in this Japanese study was relatively high compared with the dosages currently used in Western countries. In addition, the clinical relevance of these electroencephalographic changes was not investigated.

Neuromuscular function

A number of reports have confirmed that interferon alfa can induce or unmask underlying silent myasthenia gravis (SED-13, 1097) (SEDA-20, 327) (SEDA-21, 370). The diagnostic criteria for myasthenia gravis were clearly fulfilled in these reports, and an autoimmune reaction was the most likely mechanism, as each patient had positive serum anti-acetylcholine receptor antibodies and required permanent anticholinesterase drugs long after interferon alfa withdrawal. Myasthenia gravis developed in two patients treated with interferon alfa-2b for chronic hepatitis C, one of whom also took ribavirin (76,77). Both had an increase in acetylcholine receptor antibody titers and required permanent pyridostigmine and immunosuppressant treatment. These findings suggest that interferon alfa does not cause myasthenia gravis but unmasks it.

Sensory systems

Eyes

Ophthalmic disorders can occur during interferon alfa treatment (78–84) and some of the literature has been reviewed (85). Retinopathy consisting of cotton-wool spots and/or superficial retinal hemorrhages has been reported with a variable incidence (18–86%), and the available data suggest that the increased incidence can be influenced by an initial high dose of interferon alfa. Whereas diabetes mellitus and systemic hypertension have been identified as possible susceptibility factors, the incidence of retinopathy was not significantly increased in 19 patients with chronic renal insufficiency, compared with 17 patients without chronic renal insufficiency (86). However, it was felt that renal insufficiency may be associated with the most severe cases, that is those requiring dosage reductions.

In one study, in which prospective ophthalmic examinations were made before and at regular 2-week intervals after the beginning and end of treatment, 28 of 81 patients who received a uniform total dose of natural interferon alfa (478 MU) for chronic hepatitis C developed the typical findings of interferon-induced asymptomatic retinopathy (cotton-wool spots and/or retinal hemorrhages) (84). In contrast, there were no lesions in the 25 patients with chronic hepatitis C who did not receive interferon alfa or in the 20 with diabetes mellitus and/or hypertension but without chronic hepatitis C. Most of the cases were observed within 4 months of treatment, and the lesions always abated after withdrawal or even despite continuation, suggesting that treatment can be continued unless patients develop symptoms. Indeed, most patients with retinopathy associated with interferon alfa remained asymptomatic.

The pathogenesis of retinopathy associated with interferon alfa is unclear. In 45 patients with chronic hepatitis C (25 treated with interferon) there was an association between retinal hemorrhages caused by interferon alfa (six patients) and a concomitant significant increase in plasma-activated complement (C5a), compared with baseline C5a serum concentrations (87). However, the signification and contribution of raised C5a concentrations in the pathogenesis of ocular complications needs to be clarified, although it has been suggested that retinal hemorrhage could be predicted on the basis of raised C5a concentrations (88).

Although most patients with interferon alfa retinopathy remain asymptomatic, ocular complications, such as reduced vision or complete visual loss due to occlusive vasculitis, central retinal artery occlusion, or anterior ischemic optic neuropathy, continue to be reported in a very few patients (SED-13, 1096) (82,85,89–93). However, subclinical but eventually long-lasting or even irreversible abnormally long visual evoked responses have been identified in 24% of patients (SEDA-22, 403). Regular ophthalmological monitoring to detect retinal changes, even though the patient is still asymptomatic, is therefore strongly recommended in patients receiving interferon alfa.

Other isolated reports of ophthalmic abnormalities refer to optic neuritis with blurring of vision, cortical blindness with fatal encephalopathy, mononeural abducent nerve paralysis, and complete but reversible bilateral oculomotor nerve paralysis (SED-13, 1096) (94–97).

- A 60-year-old smoker was treated with interferon alfa (100 MU/week for 2 months and 9 MU/week for 15 weeks) for cutaneous melanoma. Ocular examination was normal before treatment, but he developed acute loss of peripheral vision in his left eye after 23 weeks. Examination was consistent with anterior ischemic optic neuropathy, and there was optic disc edema, a pupillary defect, and circular visual field constriction in the left eye. There was renal artery constriction in both eyes. Despite treatment with aspirin, high-dose dexamethasone, heparin, and finally withdrawal of interferon alfa, loss of visual function progressed and affected both eyes. Ciclosporin was started, but he was considered to have irreversible loss of visual function.

This report shows that interferon alfa can be a potent precipitator of extremely severe ocular disorders and also argues for careful ocular surveillance in patients receiving adjuvant interferon alfa for high-risk resected melanoma.

Of 57 patients treated with interferon for renal cell carcinoma, two developed multiple retinal exudates associated with visual disturbance; both had taken vinblastine concurrently. The precise role of interferon in this reaction is unknown (98).

Ears

In 49 patients, there was reversible otological impairment with tinnitus, mild-to-moderate hearing loss or both in respectively 8, 16, and 20% of patients after interferon alfa or interferon beta administration (SEDA-19, 336). These disorders tended to occur more frequently in patients on high cumulative doses, but led to withdrawal of treatment in only two patients. Complete but reversible hearing loss, and acute unilateral vestibular dysfunction with spontaneous vertigo and nystagmus have each been reported in one patient receiving interferon alfa (SEDA-21, 372).

Sudden hearing loss has been reported (SEDA-21, 372) and in one case of promptly reversible hearing loss on interferon alfa withdrawal, the presence of anti-endothelial cell antibodies was suggested to have played a role in the development of autoimmune microvascular damage (99).

© 2006 Elsevier B.V. All rights reserved.

Smell

Patients treated with interferon alfa sometimes complain of transient taste or smell alterations, but anosmia has been reported (SEDA-22, 403) (100).

- A 37-year-old man received interferon alfa for chronic hepatitis C. After 2 weeks he complained of smelling difficulties and subsequently developed complete anosmia. There were no other neurological symptoms and complete neurological examination was normal. Anosmia still persisted 13 months after drug withdrawal.
- In both patients, the persistence of anosmia late after interferon alfa was resumed indicates that a causal relation to treatment is purely speculative.

Psychological, psychiatric

Neuropsychiatric complications of interferon alfa were recognized in the early 1980s and represent one of the most disturbing adverse effects of interferon alfa (SED-13, 1091) (SEDA-20, 327) (SEDA-22, 400). Reviews have provided comprehensive analysis of the large amount of experimental and clinical data that have accumulated since 1979 (101,102).

DoTS classification (BMJ 2003; 327:1222–5)
Dose-relation: collateral effect
Time-course: intermediate or delayed
Susceptibility factors: pre-existing psychiatric disorders, organic brain injury, or addictive behavior

Presentation

Within a large spectrum of symptoms, complications are classified as acute, subacute, or chronic.

Acute neuropsychological disturbances are usually associated with the flu-like syndrome and include headache, fatigue, and weakness, drowsiness, somnolence, subtle impairment of memory or concentration, and lack of initiative (20). This pattern of cognitive impairment is similar to changes observed during influenza and has also been described in healthy patients who have received a single dose of interferon alfa (103). More severe acute manifestations (for example, marked somnolence or lethargy, frank encephalopathy with visual hallucinations, dementia or delirium, and sometimes coma) have been almost exclusively described in patients receiving more than 20–50 MU (20); vertigo, cramps, apraxia, tremor and dizziness were also reported.

The subacute or chronic neuropsychiatric effects of long-term therapy are usually non-specific, with cognitive impairment (for example visuospatial disorientation, attentional deficits, memory disturbances, slurred speech, difficulties in reading and writing), changes in emotion, mood, and behavior (for example psychomotor slowing, hypersomnia, loss of interest, affective disorders, irritability, agitation, delirium, paranoia, aggressiveness, and murderous impulses). Post-traumatic stress symptoms have also been reported (SEDA-22, 400). As a result, severe psychic distress can be observed during long-lasting treatment or in patients who are otherwise not severely affected (20,104). The most severe psychiatric complications of interferon alfa include rare cases of homicidal ideation, suicidal ideation, and attempted suicide (105).

The clinical features of mania have been described in four patients with malignant melanoma, with a detailed review of nine other published cases (106). Although seven suffered from depression during treatment, the onset of mania or hypomania was often associated with interferon alfa dosage fluctuation (withdrawal or dose reduction) or introduction of an antidepressant for interferon alfa-induced depression. In these patients, the risk of mood fluctuations persisted for several months after interferon alfa withdrawal, and low-dose gabapentin was considered useful in treating manic disorders and in preventing mood fluctuations. Interferon alfa was suggested as a possible cause of persistent manic-depressive illness for more than 4 years in a 40-year-old man (107). Although the manic episodes may have been coincidental, the negative history and the age of onset are in keeping with a possible role of interferon alfa treatment.

The clinical features, management, and prognosis of psychiatric symptoms in patients with chronic hepatitis C have been reviewed using data from 943 patients treated with interferon alfa (85%) or interferon beta (15%) for 24 weeks (108). Interferon-induced psychiatric symptoms were identified in 40 patients (4.2%) of those referred for psychiatric examination. They were classified in three groups according to the clinical profile: 13 cases of generalized anxiety disorder (group A), 21 cases of mood disorders with depressive features (group B), and six cases of other psychiatric disorders, including psychotic disorders with delusions/hallucinations ($n = 4$), mood disorders with manic features ($n = 1$), and delirium ($n = 1$) (group C). The time to onset of the symptoms differed significantly between the three groups: 2 weeks in group A, 5 weeks in group B, and 11 weeks in group C. Women were more often affected than men. There was no difference in the incidence or nature of the disorder according to the type of interferon used. Whereas most patients who required psychotropic drugs were able to complete treatment, 10 had to discontinue interferon treatment because of severe psychiatric symptoms, 5 from group B and five from group C. Twelve patients still required psychiatric treatment for more than 6 months after interferon withdrawal. In addition, residual symptoms (anxiety, insomnia, and mild hypothymia) were still present at the end of the survey in seven patients. Delayed recovery was mostly observed in patients in group C and in patients treated with interferon beta. Although several patients with a previous history of psychiatric disorders are sometimes successfully treated with interferon alfa, severe decompensation with persistent psychosis should be regarded as a major possible complication (109).

The neuropsychological adverse effects of long-term treatment have been assessed in 14 patients with myeloproliferative disorders using a battery of psychometric and electroneurological tests before and after 3, 6, 9, and 12 months of treatment (median dose 25 MU/week) (110). In contrast to several previous studies, there was no significant impairment of neurological function, and attention and short-term memory improved during treatment. Despite the small number of patients, these results suggest that prolonged interferon alfa treatment did not cause severe cognitive dysfunction, at least in patients with cancer.

Diagnosis

Electroencephalographic (EEG) findings show reversible cerebral changes with slowing of dominant alpha wave activity, and occasional appearance of one and two activity in the frontal lobes, suggesting a direct effect on fronto-subcortical functions. Marked electroencephalographic abnormalities are sometimes observed in asymptomatic patients. The pattern of changes is identical whatever the dose, but the severity of symptoms is dose- and schedule-related. Most patients improve or recover after dosage reduction or withdrawal, and protracted toxicity, with impaired memory, deficits in motor coordination, persistent frontal lobe executive functions, Parkinson-like tremor, and mild dementia, have been occasionally reported (111).

In a study of 67 patients with chronic viral hepatitis, the self-administered Minnesota Multiphasic Personality Inventory (MMPI), which determines the patient's psychological profile, significantly correlated with the clinical evaluation and was a sensitive and reliable tool for identifying patients at risk of depressive symptoms before the start of interferon alfa therapy (112). It was also successfully used to monitor patients during treatment.

Frequency

The most typical psychiatric symptoms reported by patients taking interferon alfa are depressive symptoms, at rates of 10–40% in most studies (113–116). In four clinical studies in a total of 210 patients with chronic hepatitis C, the rate of major depressive disorders during interferon alfa treatment was 23–41% (117–120).

Suicidal ideation or suicidal attempts have been reported in 1.3–1.4% of patients during interferon alfa treatment for chronic viral hepatitis or even within the 6 months after withdrawal (121,122), but the excess risk related to interferon alfa is not known.

Time-course

Subacute or chronic neuropsychiatric manifestations are more typically identified after several weeks of treatment and are among the most frequent treatment-limiting adverse effects (104,115,123–125). The onset can be insidious in patients treated with low doses, or subacute in those who receive high doses. Most patients develop severe depressive symptoms within the first 3 months of treatment (117–120).

Although psychiatric manifestations usually appear during interferon alfa therapy, delayed reactions can occur.

- A 37-year-old man without a previous psychiatric history developed major depression with severe psychotic features within days after the discontinuation of a 1-year course of interferon alfa-2b (126).

In 10 patients with melanoma and no previous psychiatric disorders, depression scores measured on the Montgomery-Asberg Depression Rating Scale were significantly increased after 4 weeks of high-dose interferon alfa (127). Patients whose scores were higher before treatment developed the worst symptoms of depression during treatment. This positive correlation provides striking evidence that baseline and regular assessment of mood and cognitive functions are necessary to detect disorders as early as possible.

Mechanisms

Although very few studies have specifically investigated the role of the underlying disease, the findings of significant neuropsychiatric deterioration during interferon alfa treatment compared with placebo or no treatment in chronic hepatitis C, chronic myelogenous leukemia, or amyotrophic lateral disease strongly suggested a causal role of interferon alfa (128–130).

The mechanism by which the systemic administration of interferon alfa produces neurotoxicity is unclear, and might result from a complex of direct and indirect effects involving the brain vasculature, neuroendocrine system, neurotransmitters and the secondary cytokine cascade with cytokines which exert effects on the nervous system, for example interleukin-1, interleukin-2, or tumor necrosis factor alfa (131). Whether a clinical effect is directly mediated through the action of a given cytokine or results from a secondary pathway through the induction of other cytokines or second messengers is difficult to determine.

A study in 18 patients treated with interferon alfa for chronic hepatitis C has given insights into the possible pathophysiological mechanism of depression (132). Depression rating scales, plasma tryptophan concentrations, and serum kynurenine and serotonin concentrations were measured at baseline and after 2, 4, 16, and 24 weeks of treatment with interferon alfa 3–6 MU 3–6 times weekly. During treatment, tryptophan and serotonin concentrations fell significantly, while kynurenine concentrations rose significantly. Depression rating scales also rose from baseline after the first month of treatment, with continued increases thereafter. In addition, there was a relation between increased scores of depression and changes in serum kynurenine and serotonin concentrations. These changes suggested a predominant role of the serotonergic system in the pathophysiological mechanisms of interferon alfa-associated depression. Accordingly, 35 of 42 patients included in three open trials of antidepressant treatment responded to a selective serotonin reuptake inhibitor drug, such as citalopram or paroxetine, and were able to complete interferon treatment (119,133,134).

Susceptibility factors

Various possible susceptibility factors have been analysed in several studies (118–120,135). Sex, the dose or type of interferon alfa (natural or recombinant), a prior personal history of psychiatric disease, substance abuse, the extent of education, the duration and severity of the underlying chronic hepatitis, and scores of depression before interferon alfa treatment were not significantly different between patients with and without interferon alfa-induced depression. Advanced age was suggested to be a risk factor in only one study (120). Although a worsening of psychiatric symptoms was noted during treatment in 11 patients receiving psychiatric treatment before starting interferon, only one was unable to complete the expected 6-month course of interferon alfa and ribavirin therapy (118).

© 2006 Elsevier B.V. All rights reserved.

Of 91 patients treated with interferon alfa-2b and low-dose cytarabine for chronic myelogenous leukemia, 22 developed severe neuropsychiatric toxicity (136). Their symptoms consisted mostly of severe depression or psychotic behavior, which resolved on withdrawal in all patients. The time to toxicity ranged from as early as 2 weeks to as long as 184 weeks after the start of treatment. Five of six patients had recurrent or worse symptoms after re-administration of both drugs. Several baseline factors were analysed, but only a pretreatment history of neurological or psychiatric disorders was considered to be a reliable risk factor. Severe neuropsychiatric toxicity developed during treatment in 63% of patients with previous neuropsychiatric disorders compared with 10% in patients without. It is unlikely that the combination of interferon alfa-2b with low-dose cytarabine potentiated the neuropsychiatric adverse effects of interferon alfa in this study. Indeed, previous experience with this combination, but after exclusion of patients with a psychiatric history, was not associated with such a high incidence of neuropsychiatric toxicity or any significant difference in toxicity between interferon alfa alone and interferon alfa plus low-dose cytarabine.

Patients receiving high doses of interferon alfa or long-term treatment are more likely to develop pronounced symptoms (123). A previous history of psychiatric disorders, organic brain injury, or addictive behavior are among potential susceptibility factors, but worsening of an underlying psychiatric disease is not the rule, provided that strict psychiatric surveillance and continuation of psychotropic drugs are maintained (137). Other putative susceptibility factors include the intraventricular administration of interferon alfa, previous or concomitant cranial irradiation, asymptomatic brain metastases, and pre-existing intracerebral ateriosclerosis (SED-13, 1092) (115,138–142). Despite early findings, co-infection with HIV has not been confirmed to be a susceptibility factor (SEDA-20, 327).

The occurrence of psychiatric disorders has been prospectively investigated in 63 patients who received a 6-month course of interferon alfa (9 MU/week) for hepatitis C (143). All were assessed at baseline with the Structured Clinical Interview for DSM-III-R (SCID) and monitored monthly with the Hopkins Symptoms Checklist (SCL-90). Most had a history of alcohol or polysubstance dependence, and 12 had a lifetime diagnosis of major depression. There were no significant changes in the SCL-90 scores during the 6-month period of survey in the 49 patients who completed the study, even in those who had a lifetime history of major depression. At 6 months, there was probable minor depression in eight patients and major depression in one; none had attempted suicide.

In a prospective study, 50 patients with chronic hepatitis B or C who received 18–30 MU/week of natural or recombinant interferon alfa were followed for 12 months (144). The SCID before starting interferon alfa identified 16 patients with a current psychiatric diagnosis and eight with a previous psychiatric disorder; 26 patients free of any psychiatric history constituted the control group. Psychiatric manifestations during treatment occurred in 11 patients (five from the control group), major depression in five, depressive disorders in three, severe dysphoria in two, and generalized anxiety disorder in one. Most of them were successfully treated with psychological support and drug therapy. Overall, 20 patients interrupted interferon alfa (10 in each group), including three for psychiatric adverse effects, but patients with a pre-existing or recent psychiatric diagnosis were no more likely to withdraw from treatment than the controls.

Of 33 patients with chronic hepatitis C treated with interferon alfa, 9 MU/week for 3–12 months, prospectively evaluated using the Montgomery-Asberg Depression Rating Scale (MADRS) before and after 12 weeks of treatment, eight developed depressive symptoms, of whom four had major depression without a previous psychiatric history (145). All four recovered after treatment with antidepressants. This study confirmed that a high baseline MADRS is significantly associated with the occurrence of depressive symptoms.

These studies have confirmed that previous psychiatric disorders are not necessarily a contraindication to a potentially effective treatment. However, patients with depressive symptoms immediately before treatment are still regarded at risk of severe psychiatric deterioration with treatment (113).

Management

The management of the psychiatric complications of interferon alfa has not been carefully investigated, but multiple approaches are theoretically possible. Various pharmacological and non-pharmacological interventions have been discussed (146), and prompt intervention should be carefully considered in every patient who develops significant neuropsychiatric adverse effects while receiving interferon alfa. Depending on the clinical manifestations, proposed treatment options include antidepressants, psychostimulants, or antipsychotic drugs.

Based on a possible reduction in central dopaminergic activity mediated by the binding of interferon alfa to opioid receptors, naltrexone has been proposed as a means of improving cognitive dysfunction (123).

Selective serotonin re-uptake inhibitors have been advocated as the drugs of choice to allow completion of interferon alfa treatment (113), but that was based on very limited experience and the unproven assumption that SSRIs are safe in patients with underlying liver disease. The preliminary results of a double-blind, placebo-controlled study showed that 2 weeks of pretreatment with paroxetine significantly reduced the occurrence of major depression in 16 patients on high-dose interferon alfa for malignant melanoma (147). In a placebo-controlled trial, the preventive effects of paroxetine (mean maximal dose of 31 mg) were studied in 40 patients with high-risk malignant melanoma and interferon alfa-induced depression (148). Treatment started 2 weeks before adjuvant high-dose interferon alfa. Paroxetine significantly reduced the incidence of major depression (45% in the placebo group and 11% in the paroxetine group) and the rate of interferon alfa withdrawal (35 versus 5%). Although the number of patients was small and the duration of the survey short (12 weeks), this suggests that paroxetine effectively prevents the risk of depressive disorders in patients eligible for high-dose interferon alfa. However, these results are

© 2006 Elsevier B.V. All rights reserved.

limited, because patients with melanoma who receive adjuvant high-dose interferon alfa are particularly likely to develop depression. The safety of prophylaxis with paroxetine also requires additional data, because three patients taking paroxetine developed retinal hemorrhages, including one with irreversible loss of vision.

- In contrast to this study, a 31-year-old woman with major depressive disorder, which responded to paroxetine and trazodone, had progressive recurrence of mood disorders after the introduction of interferon alfa for essential thrombocythemia (149).

This suggests that interferon alfa can also reverse the response to antidepressants.

Endocrine

Pituitary

Interferon alfa can stimulate the hypothalamic–pituitary–adrenal axis, with a marked increase in cortisol and adrenocorticotrophic hormone secretion after acute administration (SED-13, 1093). No further stimulation was observed after several weeks of treatment, pointing to possible down-regulation of the ACTH secretory system. As a result, long-term treatment with interferon alfa is not thought to influence pituitary hormones significantly, and the concentration of several hormones, for example calcitonin, LH, FSH, prolactin, growth hormone, ACTH, cortisol, testosterone, and estradiol, were not modified by prolonged interferon alfa treatment (150,151). No clinical endocrinopathies attributable to such disorders in the regulation of these hormones have yet been reported.

Although the rate of growth was significantly lower than predicted in 35% of children receiving long-term treatment for recurrent respiratory papillomatosis (152), only one case of growth retardation has been reported in other settings (SEDA-19, 335). A significant reduction in weight and nutritional status was observed during treatment with interferon alfa for 6 months for chronic viral hepatitis in children aged 4–16 years, but this was transient and not associated with growth impairment (153).

Reversible hypopituitarism with antibodies to pituitary GH3 cells and exacerbation of Sheehan's syndrome have been reported (SED-13, 1093) (SEDA-21, 371).

A syndrome resembling inappropriate antidiuretic hormone secretion has been described in a few patients receiving high-dose interferon alfa (SED-13, 1093) (154).

Thyroid

Since the original 1988 report of hypothyroidism in patients with breast cancer receiving leukocyte-derived interferon alfa (155), numerous investigators have provided clear clinical and biological data on thyroid disorders induced by different forms of interferon in patients with various diseases (21,156–159). Two of these reports also mentioned associated adverse effects that developed concomitantly, namely myelosuppression and severe proximal myopathy (Hoffmann's syndrome).

Presentation and outcomes

The spectrum of interferon alfa-induced thyroid disorders ranges from asymptomatic appearance or increase in antithyroid autoantibody titers to moderate or severe clinical features of hypothyroidism, hyperthyroidism, and acute biphasic thyroiditis. Antithyroid hormone antibodies have also been found in one patient, and this could have been the cause of erroneously raised thyroid hormone concentrations (160).

The clinical, biochemical, and thyroid imaging characteristics of thyrotoxicosis resulting from interferon alfa treatment have been retrospectively analysed from data on 10 of 321 patients with chronic hepatitis (75 with chronic hepatitis B and 246 with chronic hepatitis C) who developed biochemical thyrotoxicosis (161). Seven patients had symptomatic disorders, but none had ocular symptoms or a palpable goiter. Six had features of Graves' disease that required interferon alfa withdrawal in four and prolonged treatment with antithyroid drugs in all six. Three presented with transient thyrotoxicosis that subsequently progressed to hypothyroidism and required interferon withdrawal in one and thyroxine treatment in all three.

Although much work on thyroid autoimmunity associated with interferon alfa has accumulated, little is known about the very long-term outcome of this disorder. In 114 patients with chronic hepatitis C and no previous thyroid disease who were treated with interferon alfa-2a for 12 months, data on thyroid status were retrospectively obtained at the end of treatment, 6 months after withdrawal, and after a median of 6.2 years (162). Among 36 patients who had thyroid autoantibodies at the end of treatment, the authors identified three groups according to the long-term outcome: 16 had persistent thyroiditis, 10 had remitting/relapsing thyroiditis (that is antibodies became negative after 6 months of therapy and were again positive thereafter), and 10 had transient thyroiditis. Therefore, 72% of these patients had chronic thyroid autoimmunity at the end of follow-up and 12 developed subclinical hypothyroidism. In contrast, only one of 78 patients negative for thyroid autoantibodies developed thyroid autoantibodies. Although none of the patients had clinical thyroid dysfunction, this study suggests that long-term surveillance of thyroid disorders is useful in patients who have high autoantibody titers at the end of treatment with interferon alfa.

Although thyroid disorders in patients treated with interferon alfa generally follows a benign course after interferon alfa withdrawal or specific treatment, severe long-lasting ophthalmopathy resulting from Graves' disease has been described in a 49-year-old woman (163).

Time-course

Clinical symptoms usually occur after 2–6 months of treatment and occasionally after interferon alfa withdrawal.

- A middle-aged woman developed subacute thyroiditis by the sixth month of treatment with interferon alfa (164). She also had the classic symptoms of hyperthyroidism, although it is clear that these could easily have been mistaken for adverse effects of interferon alfa itself, for example weakness, weight loss, and palpitation.

After 6 months of treatment, 12% of patients with chronic hepatitis C had thyroid disorders, compared with 3% of patients with chronic hepatitis B. This study also suggested a possible relation between low free triiodothyronine serum concentrations before treatment and the

© 2006 Elsevier B.V. All rights reserved.

subsequent occurrence of thyroid dysfunction. After a follow-up of 6 months after the end of interferon alfa treatment, 60% of affected patients with chronic hepatitis C still had persistent thyroid dysfunction; all had been positive for thyroid peroxidase antibodies before treatment. Long-term surveillance is therefore needed in these patients.

Frequency

In a prospective study, the overall incidence of biochemical thyroid disorders was 12% in 254 patients with chronic hepatitis C randomized to receive ribavirin plus high-dose interferon alfa (6 MU/day for 4 weeks then 9 MU/week for 22 weeks) or conventional treatment (9 MU/week for 26 weeks) (165). There was no difference in the incidence or the time to occurrence of thyroid disorders between the groups. Of the 30 affected patients, 11 (37%) had positive thyroid peroxidase autoantibodies (compared with 1% of patients without thyroid dysfunction), nine developed symptomatic thyroid dysfunction, and only three had to discontinue treatment. There was no correlation between the viral response and the occurrence of thyroid disorders, and only female sex and Asian origin were independent predictors of thyroid disorders.

Data on the incidence of thyroid disorders in interferon alfa-treated patients vary, largely because the follow-up duration, the nature of the study (prospective or retrospective), biological monitoring, diagnostic criteria, and the underlying disease differ from study to study (156). The incidence of clinical or subclinical thyroid abnormalities is generally 5–12% in large prospective studies in patients with chronic hepatitis C treated for 6–12 months, but it reached 34% in one study (21,166). The incidence was far lower in patients with chronic hepatitis B, at 1–3%. A wider range in incidence was found in patients with cancer, with no clinical thyroid disorders in 54 patients treated during a mean of 16 months for hematological malignancies (167), whereas in many other studies there was a 10–45% incidence (156). Even more impressive was the escalating incidence of thyroid disorders in patients with cancer receiving both interferon alfa and interleukin-2 (qv).

Mechanisms

Possible mechanisms need to be clarified. Since thyroid autoantibodies are detected in most patients who develop thyroid disorders, the induction or exacerbation of preexisting latent thyroid autoimmunity is the most attractive hypothesis. This is in accordance with the relatively frequent occurrence of other autoantibodies or clinical autoimmune disorders in patients who develop thyroid disorders (168). However, 20–30% of patients who develop thyroid diseases have no thyroid antibodies, and it is thus not yet proven that autoimmunity is the universal or primary mechanism. In fact, there were subtle and reversible defects in the intrathyroidal organification of iodine in 22% of antithyroid antibody-negative patients treated with interferon alfa (169). In addition, the acute systemic administration of interferon alfa in volunteers or chronic hepatitis patients reduces TSH concentrations (SED-13, 1093) (170), and in vitro studies have suggested that interferon alfa directly inhibits thyrocyte function (SED-13, 1093) (171). Finally, the thyroid autoantibody pattern in patients who developed thyroid dysfunction during cytokine treatment was not different from that of patients without thyroid dysfunction, but differed significantly from that of patients suffering from various forms of spontaneous autoimmune thyroid disease (172).

Susceptibility factors

In addition to the underlying disease, there are many potential susceptibility factors (21,173). There is as yet no definitive evidence that age, sex, dose, and duration of treatment play an important role in the development of thyroid disorders. However, patients with previous thyroid abnormalities are predisposed to develop more severe thyroid disease (SEDA-20, 328). The incidence of thyroid disease was not different between natural and recombinant interferon alfa. Although this should be taken into account, a previous familial or personal history of thyroid disease was generally not considered a major risk factor. Finally, only pre-treatment positivity or the development of thyroid antibodies during treatment seem to be strongly associated with the occurrence of thyroid dysfunction.

In 175 patients with hepatitis B or C virus infections, women with chronic hepatitis C and patients with previously high titers of antithyroid autoantibodies were more likely to develop thyroid disorders (174).

The immunological predisposition to thyroid disorders has been studied in 17 of 439 Japanese patients who had symptomatic autoimmune thyroid disorders during interferon alfa treatment (175). There was a significantly higher incidence of the human leukocyte antigen (HLA)-A2 haplotype compared with the general Japanese population (88 versus 41%), suggesting that HLA-A2 is a possible additional risk factor for the development of interferon alfa-induced autoimmune thyroid disease.

Among other potential predisposing factors, treatment with iodine for 2 months in 21 patients with chronic hepatitis C receiving interferon alfa did not increase the likelihood of thyroid abnormalities compared with eight patients who received iodine alone, but abnormal thyroid tests were more frequent compared with 27 patients who received interferon alfa alone (176). This suggests that excess iodine had no synergistic effects on the occurrence of thyroid dysfunction induced by interferon alfa.

The occurrence of thyroid dysfunction in 72 patients treated with interferon alfa plus ribavirin (1.0–1.2 g/day) has been compared with that of 75 age- and sex-matched patients treated with interferon alfa alone for chronic hepatitis C (177). Of the former, 42 patients, and of the latter, 40 patients had received previous treatment with interferon alfa alone. There was no difference in the rate of thyroid autoimmunity (antithyroglobulin, antithyroid peroxidase, and thyroid-stimulating hormone receptor antibodies) between the two groups, but the patients who received interferon alfa plus ribavirin developed subclinical or overt hypothyroidism more often (15 versus 4%). Similarly, the incidence of hypothyroidism increased to 19% in patients who underwent a second treatment with interferon alfa plus ribavirin compared with 4.8% after the first treatment with interferon alfa alone, while the incidence remained essentially the same in patients who had two consecutive treatments with interferon alfa alone

© 2006 Elsevier B.V. All rights reserved.

(4.7 and 7.1% respectively). Furthermore, there was no higher incidence of thyroid autoimmunity or clinical disorders after a second course of interferon alfa whether alone or combined with ribavirin in patients who had no thyroid autoantibodies at the end of a first course of interferon alfa alone, suggesting that these patients are relatively protected against the development of thyroid autoimmunity.

Management

The management of clinical thyroid dysfunction depends on the expected benefit of interferon alfa. Assay of thyroid antibodies before treatment, and regular assessment of TSH concentrations in treated patients, even after interferon alfa withdrawal, are useful as a means of predicting and detecting the risk of thyroid disorders. Complete recovery of normal thyroid function is usually observed after thyroxine replacement but sometimes requires interferon alfa withdrawal. Sustained hypothyroidism requiring long-term substitution treatment has occasionally been observed (SED-13, 1092) (178), and is more likely in patients with initially severe hypothyroidism and raised thyroid antibody titers (179). By contrast, hyperthyroidism generally requires the prompt withdrawal of interferon alfa, and severe forms may require radical radioiodine therapy. Although not enough data are available on the long-term consequences of interferon alfa-induced thyroid dysfunction, the recurrence of thyroid abnormalities after the administration of pharmacological doses of iodine should be borne in mind (180).

Parathyroid

Exacerbation of secondary hyperparathyroidism occurred in a 20-year-old renal transplant patient who also developed psoriasis during interferon alfa treatment (181). Both disorders resolved after withdrawal.

Adrenal

Of 62 initially autoantibody-negative patients treated with interferon alfa for chronic hepatitis C for a mean of 8 months, three developed antibodies to 21b-hydroxylase, a sensitive assay of adrenocortical autoimmunity (182). However, there were no cases of Addison's disease or subclinical adrenal insufficiency. This study suggested that the adrenal cortex is another potential target organ of autoimmune effects of interferon alfa, along with thyroid and pancreatic islet cells.

Metabolism

Diabetes mellitus

The development or worsening of insulin-dependent diabetes mellitus is limited to isolated case reports in patients treated with interferon alfa or interferon alfa plus interleukin-2 (SEDA-20, 328) (SEDA-21, 371). In chronic hepatitis, diabetes mellitus was noted in only 10 of 11 241 treated patients (16). Although a relation between chronic hepatitis C and the occurrence of glucose metabolism disorders is possible (183), reports of diabetes mellitus in patients treated with interferon alfa were probably more than coincidental. Indeed, there have been reports of prompt amelioration or complete recovery after interferon alfa withdrawal (SED-13, 1092) (184–186) and of successive episodes of diabetes after each course of interferon alfa (SEDA-21, 371).

- In three middle-aged patients, diabetes was diagnosed after 3–7 months of treatment with interferon alfa-2b and ribavirin, and two presented with severe ketoacidosis (187,188). There was a family history of diabetes in one patient and two had high titers of glutamic acid decarboxylase antibodies before treatment. One patient never had diabetes-related serum autoantibodies before or after interferon alfa therapy. All three required permanent insulin treatment despite withdrawal of interferon alfa.
- Insulin-dependent diabetes mellitus has been reported after 2 weeks to 6 months of treatment with interferon alfa in four patients with chronic hepatitis C (189). All discontinued interferon alfa, and one woman who restarted treatment had a subsequent increase in insulin requirements.

A 75 g oral glucose tolerance test was performed before and after 3 months of interferon alfa treatment in 32 patients with chronic hepatitis C, of whom 15 also had an intravenous glucose test (190). Baseline evaluation showed that five patients had mild diabetes mellitus, three had impaired glucose tolerance, and 24 were normal. After 3 months of treatment, two patients with diabetes mellitus shifted to impaired glucose tolerance, and all patients with impaired glucose tolerance had normal glucose tolerance. Only three initially normal patients developed impaired glucose tolerance and none had newly diagnosed diabetes mellitus. From these results, and in contrast to previous reports (SED-14, 1250), it appears that interferon alfa did not have any adverse effects on insulin sensitivity and glucose tolerance after 3 months of treatment.

Interferon alfa may produce more severe changes than interferon beta (191).

- A 39-year-old man with diabetes, stabilized with insulin 22 U/day for 13 years, received interferon beta (6 MU/day) for chronic hepatitis C. His diabetes progressively worsened, necessitating insulin 50 U/day. After 4 weeks, interferon beta was replaced by interferon alfa (10 MU/day). Shortly afterwards he developed severe diabetic ketoacidosis and shock, which reversed after hemodynamic support and continuous hemodiafiltration.

Mechanisms

Autoimmunity was suggested as a likely mechanism, with HLA-DR4 haplotype and/or islet cell antibody (ICA) positivity at the time of diagnosis in several patients. Because the induction of ICA antibodies in patients treated with interferon alfa has never been otherwise demonstrated (21), the triggering, rather than the induction, of a latent autoimmune phenomenon in patients with a genetic susceptibility is probable (192).

More direct interference with glucose metabolism cannot be excluded. Interferon alfa can reduce the sensitivity of peripheral tissues or liver to insulin and accelerate the destruction of stimulated pancreatic beta-cells (193,194); this could be a possible mechanism in patients not exhibiting islet cell antibodies. This is also

© 2006 Elsevier B.V. All rights reserved.

in keeping with rare instances of induction or exacerbation of type II non-insulin dependent diabetes mellitus (SEDA-19, 335).

Insulin antibodies were also found in six of 58 patients treated for chronic viral hepatitis (195) and that was associated with signs of insulin allergy in one patient (SEDA-19, 335).

Susceptibility factors

Patients with obesity and a family or previous history of glucose intolerance should be considered more predisposed to interferon alfa-induced diabetes, but the association is not consistently found (SEDA-20, 328).

Dyslipidemia

Interferon alfa often affects lipid metabolism and produces a reversible reduction in cholesterol and, more consistently, increases in triglyceride concentrations (SEDA-20, 328) (SEDA-21, 371). Meticulous blood lipid investigation showed a significant rise in serum triglyceride and lipoprotein(a) concentrations and reductions in total cholesterol, HDL cholesterol, LDL cholesterol, and apoprotein A1.

Marked hypertriglyceridemia (10–20 μg/ml), which abates when treatment is withdrawn, has sometimes been observed (SED-13, 1093) (196,197). Inhibitory effects of interferon alfa on lipoprotein lipase and triglyceride lipase or increased hepatic lipogenesis have been suggested (198,199). Diet and lipid-lowering drugs have been proposed as means of maintaining acceptable triglyceride concentrations during long-term interferon alfa therapy. Although the possibility of pancreatic or cardiovascular complications should be borne in mind, no secondary clinical consequences of interferon alfa-induced blood lipid disorders have been so far reported.

In a prospective study of lipid changes in 36 patients with chronic hepatitis C treated with interferon alfa for 6 months, the most prominent findings included increases in triglycerides, VLDL cholesterol, and apolipoprotein B, and falls in HLD cholesterol and apolipoprotein A1 (200). Three patients also developed chylomicronemia and two of those had severe hypertriglyceridemia. All three patients had triglycerides over 2 μg/ml before treatment, suggesting that patients with abnormal serum triglyceride concentrations at baseline are more likely to develop marked hypertriglyceridemia.

Porphyria

- A severe acute flare of porphyria cutanea tarda has been reported in a 61-year-old man after 4 months of treatment with interferon alfa-2b plus ribavirin for chronic hepatitis C (201). No further relapse was observed after chloroquine treatment, despite continuation of the antiviral drugs.

This patient had previously had episodes of small blisters that spontaneously resolved, and hereditary porphyria cutanea tarda was demonstrated by chromatographic and mutation analysis.

Hematologic

Hematological toxicity due to interferon alfa commonly includes dose-related leukopenia, neutropenia, and thrombocytopenia, whereas anemia is rare and usually moderate (202).

Reductions in platelet count and leukocyte count were usually in the range of 30–50% compared with baseline, but severe and reversible thrombocytopenia ($<49 \times 10^9$/l) or neutropenia ($<0.9 \times 10^9$/l) were noted in 10 and 20% of patients (203). However, life-threatening neutropenia or thrombocytopenia were reported in only six of 11 241 patients with chronic viral hepatitis (16), and reports of Coombs'-negative hemolytic anemia or complete agranulocytosis are sparse (SED-13, 1094) (SEDA-20, 329).

In a retrospective study of 158 patients with chronic viral hepatitis treated for 6–12 months, lymphoblastoid interferon alfa produced the largest fall in leukocyte and platelet counts (−38 and −32% versus baseline values), recombinant interferon alfa was associated with intermediate toxicity (−32 and −26%), and leukocyte interferon alfa produced the smallest reduction (−27 and −22%) (204). The lowest mean values were observed after an average of 4–5 months. However, the clinical relevance of these differences is probably minimal, because the overall reduction in leukocyte and platelet numbers was small, and no patients developed clinical symptoms of cytopenia.

Mechanisms

Interferon alfa has direct myelosuppressive effects and can also cause hematological disorders by immune blood cell destruction, as suggested by reports of immune-mediated thrombocytopenia, immune hemolytic anemia (205,206), or a positive direct Coombs' test, with or without hemolysis (207–209).

The kinetics of the hemotoxic effects of interferon alfa have been studied in 76 patients with chronic hepatitis C (210). There were significant falls in white blood cell count and platelet count within 12 hours after the first injection, and a second fall in platelet count after 2 weeks, but not further thereafter. This rapid time-course suggests that liver or spleen sequestration of blood cells, rather than direct bone marrow suppression or immune-mediated hematological toxicity, is the most likely explanation for this acute hemotoxic effect, which does not preclude continuation of treatment.

Susceptibility factors

Susceptibility factors for severe hematological toxicity include cirrhosis and hypersplenism.

Prior interferon alfa treatment lasting for more than 6 months and withdrawn for 2–3 months was also one of the most significant factors to explain a reduced yield of peripheral blood stem cells in 88 previously autografted patients with myeloma undergoing G-CSF stimulation for future autotransplantation (211). As suggested by this study, the myelosuppressive effects of interferon alfa may be prolonged to such an extent that a minimum delay of more than 2–3 months after interferon alfa withdrawal should be considered before harvesting bone marrow cells.

Pancytopenia or aplasia, sometimes fatal, have been reported only in patients who had received previous

© 2006 Elsevier B.V. All rights reserved.

chemotherapy, as has severe and even fatal erythrocytosis in patients with hairy cell leukemia (SED-13, 1094) (212–216).

Anemia

Isolated anemia is not a common feature of the hemotoxic effects of interferon alfa, and pure red cell aplasia has been reported in two patients with chronic leukemia for several months (217,218). Both patients improved progressively after replacement of interferon alfa by hydroxyurea. However, one required erythrocyte transfusions for 14 months.

- Pernicious anemia with a low vitamin B_{12} concentration and positive intrinsic factor antibodies has been reported in a 54-year-old woman who was receiving interferon alfa as a maintenance treatment for relapsing chronic hepatitis C (219).

Rapid exacerbation (1–21 days) or delayed (3–38 months) de novo appearance of immune hemolytic anemia has been reported after initiation of interferon alfa treatment in nine patients with lymphoproliferative disorders (220). However, this rare event was identified in only 1% of 581 patients receiving interferon alfa alone or as part of a chemotherapeutic regimen for chronic myelogenous leukemia (221). A mechanism close to that observed with alpha-methyldopa has been thought to be involved (208). The direct antiglobulin test was positive in 32% of 28 chronic myeloid leukemia patients after a median of 1 year of treatment with interferon alfa (222).

Interferon alfa can also induce multiple antibody formation to transfused blood cell antigens, with subsequent massive hemolysis (223).

- A 33-year-old man developed a delayed hemolytic reaction 7 days after red cell transfusion (224). Additional investigations showed the presence of an anti-M antibody, the production of which was supposedly caused by chemoimmunotherapy (interferon alfa, interleukin-2, and 5-fluorouracil) which was begun 24 hours after transfusion.

Leukopenia

The dose of interferon alfa is usually halved when the neutrophil count falls below 0.75×10^9/l or the drug is permanently withdrawn when it falls below 0.5×10^9/l. However, this issue has recently been challenged by a retrospective analysis of 11 patients with compensated cirrhosis, four of whom had severe neutropenia (that is 0.4 to 0.67×10^9/l) during the first 2 months of treatment (225). They remained asymptomatic and the neutropenia spontaneously reversed despite continued treatment.

In one study in 119 patients treated with interferon alfa and ribavirin for chronic hepatitis C, in whom neutropenia was not considered as a cause for exclusion or dosage modification, the neutrophil count fell by an average of 34% (31–74%) (226). During the course of treatment, 32 patients had at least one neutrophil count below 1×10^9/l, 11 had a neutrophil count below 0.75×10^9/l, and 2 had a neutrophil count below 0.5×10^9/l; however, none of these patients required dosage modification because of neutropenia. None of the 22 patients who developed documented or suspected bacterial infections during or immediately after treatment withdrawal had concomitant neutropenia. The three black patients with constitutional neutropenia (pretreatment neutrophil counts below 1.5×10^9/l) had only minimal changes in their neutrophil counts during treatment and no infection, suggesting that these patients can be safely treated.

Thrombocytopenia

Although inhibition of stem-cell proliferation is the most likely mechanism of hematological toxicity, increased platelet hepatic uptake has been suggested to account for thrombocytopenia (227). Raised serum thrombopoietin concentrations were found in patients with interferon alfa-induced thrombocytopenia (228). However, there is evidence that serum thrombopoietin concentrations in patients who have had thrombocytopenia during interferon alfa treatment for chronic viral hepatitis C either do not increase (in patients with compensated cirrhosis) or increase only moderately and less than expected (in non-cirrhotic patients) (229). The authors proposed that interferon alfa impairs liver production of thrombopoietin, raising the possibility of testing thrombopoietin administration in patients with severe thrombocytopenia before or during treatment with interferon alfa (230).

- In a 45-year-old man treated with pegylated interferon alfa-2b for relapsing chronic hepatitis C, thrombocytopenia recovered over 2 months, despite initial treatment with glucocorticoids and immunoglobulin (231).

Interferon alfa-induced immune-mediated thrombocytopenia shares many features with idiopathic thrombocytopenic purpuras and may be therefore coincidental (SED-13, 1094) (SEDA-20, 328) (SEDA-21, 371), but recurrence of thrombocytopenia on interferon alfa readministration strongly supports a causal role of interferon alfa (232). Cross reaction with interferon beta was not found in an isolated report (SEDA-20, 329). Even though severe and even fatal worsening of idiopathic thrombocytopenic purpura has been observed after administration of interferon alfa (SED-13, 1094) (SEDA-20, 328), interferon alfa was not considered harmful in patients with chronic hepatitis C who were previously positive for platelet-associated immunoglobulin G (233).

Thrombotic thrombocytopenic purpura is a possible complication of interferon alfa in patients with chronic myelogenous leukemia, and can develop even after a successful prolonged (2–3 years) treatment (234). Complete recovery is expected after prompt medical management with plasma exchange and glucocorticoids.

Platelet aggregation

The effects of interferon alfa-2b on platelet aggregation have been studied in 29 patients with melanoma who received a low-dose regimen (9 MU/week in five patients) or a high-dose regimen (100 MU/m^2/week intravenously for 4 weeks, then 30 MU/m^2/week subcutaneously for 48 weeks in 24 patients) (235). Compared with pretreatment values and healthy controls, there was significant inhibition of platelet aggregation in the high-dose group, while the effects were minimal in the low-dose group. In the high-dose group, the inhibition was more prominent during the subcutaneous maintenance dose and was still

© 2006 Elsevier B.V. All rights reserved.

detectable 8 weeks after interferon alfa withdrawal in 60% of the tested samples. An increased risk of bleeding should therefore be anticipated in patients who receive high-dose interferon alfa.

Clotting factors

Clotting disorders due to interferon alfa have rarely been reported.

- Asymptomatic prolongation of the activated partial thromboplastin time associated with lupus anticoagulant and a reduction in the coagulation activity of factors IX, XI, and XII occurred after 10 weeks of interferon alfa-2b and ribavirin in a 60-year-old woman with chronic hepatitis C (236). There were no arguments in favor of an antiphospholipid syndrome, and all the abnormalities normalized after withdrawal.

Interferon alfa was suspected of having induced the development of anti-factor VIII autoantibodies in one patient with hemophilia who survived and one without hemophilia who subsequently died from acute hemorrhage (SED-13, 1094) (237,238).

- There was significant bleeding with hematomas in association with an inhibitor of factor VIII in a 58-year-old man who took interferon alfa for 1 year for chronic myelogenous leukemia (239). The factor VIII inhibitor, which was markedly raised, disappeared within 6 weeks of interferon alfa withdrawal and prednisone treatment.

By contrast, in a small uncontrolled study, there was no increase in antifactor VIII antibodies in patients with hemophilia A treated with interferon alfa (240).

Gastrointestinal

Mild and transient gastrointestinal disorders, namely nausea, vomiting, diarrhea or anorexia, were observed in 30–40% of patients, and their severity is typically dose-related (20). Dryness or inflammation of the oropharynx, and moderate stomatitis were sometimes noted, but severe painful oral ulcers recurring after interferon alfa re-administration have been reported (241). More severe forms of digestive disease have been described in isolated case histories with microscopic colitis and the occurrence or the exacerbation of ulcerative colitis (SED-13, 1094) (SEDA-21, 372).

Celiac disease

Celiac disease was observed after 2–3 months of interferon alfa treatment in two patients with chronic hepatitis C aged 34 and 38 years (242). Both had total villous atrophy on distal duodenal biopsy, were positive for antiendomysial antibodies, and responded to a gluten-free diet. Three other cases were reported after 1–5 months of treatment for chronic hepatitis C (37,243). The diagnosis was confirmed in all three patients, based on the presence of total villous atrophy on distal duodenal biopsy, positivity of antiendomysial antibodies, and recovery with a gluten-free diet. Pretreatment antiendomysial antibodies were positive in the two patients tested. As suggested in one patient, interferon alfa can be safely continued providing that a gluten-free diet is strictly respected.

Enteritis

Eosinophilic enteritis has been attributed to interferon alfa (244).

- A 23-year-old man with no previous history of digestive disorders took interferon alfa for chronic hepatitis C. After 2 weeks of treatment, he had severe abdominal pain and diarrhea. The absolute eosinophil count was 7.5×10^9/l, with 40% eosinophils on bone marrow aspiration and a markedly high IgE concentration. Radiological examination showed diffuse jejunal and ileal wall thickening and gross ascites with numerous eosinophils. Complete resolution was obtained after interferon alfa withdrawal and prednisolone treatment. There was no recurrence after prednisolone was withdrawn.
- A 23-year-old man with no previous history of digestive disorders took interferon alfa for chronic hepatitis C. After 2 weeks of treatment, he had severe abdominal pain and diarrhea. The absolute eosinophil count was 7.5×10^9/l, with 40% eosinophils on bone marrow aspiration and a markedly high IgE concentration. Radiological examination showed diffuse jejunal and ileal wall thickening and gross ascites with numerous eosinophils. Complete resolution was obtained after interferon alfa withdrawal and prednisolone treatment. There was no recurrence after prednisolone was withdrawn.

Colitis

Microscopic colitis and new or worsened ulcerative colitis have been attributed to interferon alfa (SED-13, 1094) (SEDA-21, 372). Ischemic colitis has been reported in two of 280 patients treated for chronic hepatitis C (245).

Liver

Asymptomatic and reversible rises in serum transaminases have been reported in 25–30% of patients receiving high-dose interferon alfa (20). Although direct hepatotoxicity has been suspected in isolated and unexplained cases of severe liver failure (SED-13, 1094), most data favored exacerbation of chronic viral hepatitis or latent autoimmuine hepatitis.

Exacerbation of chronic viral hepatitis

In the treatment of chronic hepatitis B, HBe seroconversion was sometimes preceded by transient and moderate worsening of serum transaminases, but severe exacerbation of chronic hepatitis B infection and fatal liver failure can occur. Such fatalities were reported in under 0.5% of patients with hepatitis B (246). Patients with active cirrhosis or a previous history of decompensated cirrhosis are particularly susceptible to these complications (247).

Acute exacerbation of hepatitis is an extremely rare complication of chronic hepatitis C treatment. An exaggerated immune response to hepatitis virus was supposedly the cause of acute icteric hepatitis in two patients (SEDA-21, 372) (248).

- A 43-year-old man had a moderate rise in hepatic transaminase activities after 4 weeks of interferon alfa treatment. His liver tests normalized after withdrawal, but the aspartate transaminase activity increased dramatically shortly after treatment was restarted. His

© 2006 Elsevier B.V. All rights reserved.

condition rapidly deteriorated, with a diagnosis of hepatorenal failure, and he finally required liver transplantation. Histological examination of the liver showed advanced micronodular cirrhosis, a feature not found on pretreatment liver biopsy.

In another study, only four of 11 241 patients treated with interferon alfa died of fulminant liver failure (16).

Autoimmune hepatitis

More disturbing are reports of interferon alfa-induced acute exacerbation of latent autoimmune hepatitis (SED-13, 1094) (249–256). Further analysis showed that these patients were initially misdiagnosed as having hepatitis C, and autoimmune hepatitis reversible by glucocorticoid treatment was later proven to be the correct diagnosis. It was later found that latent chronic autoimmune hepatitis can be present in patients with unequivocal serological evidence of chronic hepatitis C (249,257). The co-existence of serological markers of autoimmune hepatitis and confirmed hepatitis C before treatment with interferon alfa in the same patient is very disturbing, because the distinction cannot readily be made on the basis of biological and histological data. As glucocorticoids can increase the extent of viremia, and since in addition interferon alfa can acutely exacerbate latent autoimmune liver disease, this has raised the question of how to deal with these patients. In those without serological markers of autoimmune liver disease, only close monitoring of liver function to detect any sudden increase in alanine transaminase activity is helpful, because the systematic detection of autoantibodies proves unable to predict the risk of overt autoimmune hepatitis (257). In those with both hepatitis C virus and autoantibodies, there is as yet no consensus on the therapeutic management. Glucocorticoids may actually increase the extent of viremia, while interferon alfa may exacerbate autoimmune hepatitis. As a result, controversies have emerged, with several investigators advocating glucocorticoids as first line treatment and providing a safe option in patients with high antibody titers, whereas others have found interferon alfa to be more appropriate (SED-13, 1094) (SEDA-20, 329) (SEDA-21, 372).

De novo induction rather than exacerbation of autoimmune hepatitis is still possible, as indicated by anecdotal reports in patients with cancer or chronic viral hepatitis (SED-13, 1094) (SEDA-22, 402). Such a very rare event is in keeping with the usual absence of autoantibody specific for autoimmune liver disease after interferon alfa treatment.

Positive serological markers of autoimmune hepatitis before treatment in patients with concomitant chronic hepatitis C are sometimes associated with further exacerbation of an underlying autoimmune liver disease during interferon alfa treatment. Of three patients with raised antimitochondrial antibodies (over 1:160), only the two patients with M2 (with or without M4 or M8) subtypes had biochemical exacerbation of cholestasis and an unfavorable response to interferon alfa (255). Although very few patients were investigated, determination of antibodies against submitochondrial particles may help to identify patients who are likely to have no benefit and even exacerbation of liver disease with interferon alfa.

In 25 children with chronic hepatitis C, pretreatment positivity for liver/kidney microsomal type 1 (LKM-1) antibodies was associated with more frequent treatment-limiting increases in serum alanine transaminase activity (256). Withdrawal of interferon alfa-2b because of hypertransaminasemia was required in three of four LKM-1 positive children compared with two of the 21 LKM-1 negative children. Although none developed features of autoimmune hepatitis, careful surveillance of hepatic function is recommended in LKM-1-positive patients.

Other complications

Interferon alfa-associated macrovesicular steatosis has been reported (258).

- A 50-year-old woman without a history of liver disease, dyslipidemia, diabetes, obesity, or alcoholism started taking interferon alfa (7.5 MU/day) for chronic myelogenous leukemia together with allopurinol and hydroxyurea for 2 weeks. Her liver tests were normal before treatment but transaminase activities were greatly increased after 2 weeks. Serological tests for hepatitis B and C and HIV were negative, as was screening for serum antitissue antibodies. Liver biopsy showed severe macrovesicular steatosis (80% of hepatocytes) without steatohepatitis. Liver tests completely normalized on interferon alfa withdrawal. A few weeks after interferon alfa was restarted in a lower dose (3–5 MU/day), she again had a rise in liver enzymes, and a second liver biopsy showed unchanged findings. Liver tests remained stable despite treatment continuation.

Other adverse liver effects reported with interferon alfa include primary biliary cirrhosis (SEDA-20, 329) and granulomatous hepatitis (SEDA-20, 329) (SEDA-21, 372) (259).

Pancreas

Asymptomatic rises in pancreatic enzymes and reversible acute pancreatitis have been reported in isolated patients, with no mention of hypertriglyceridemia (SEDA-19, 336).

- A 54-year-old man developed abdominal pain from the beginning of interferon alfa treatment (260). Two weeks later his serum amylase and lipase peaked at about three times the upper limit of normal. Careful radiological investigations ruled out pancreatic calcification and biliary or pancreatic lithiasis and showed only pancreatic enlargement. Complete improvement occurred after treatment withdrawal. As in the very few previous cases, there was no hypertriglyceridemia in this patient.

A definite case of pancreatitis proven by positive rechallenge was also briefly cited in a review of drug-associated pancreatitis spontaneously reported to the Dutch adverse drug reactions system (261).

Two cases of interferon alfa-induced acute pancreatitis in patients with chronic hepatitis C were particularly convincing, because other causes were carefully ruled out and clinical symptoms or biological abnormalities recurred after rechallenge in both patients (262). Although one patient also took ribavirin, recurrence was observed

© 2006 Elsevier B.V. All rights reserved.

after re-administration of interferon alfa alone. Lipid disorders were not found in these patients, confirming that interferon alfa-induced pancreatitis is not due to hypertriglyceridemia.

Urinary tract

Mild and usually asymptomatic proteinuria, leukocyturia, microscopic hematuria, or moderate increases in serum creatinine were observed in 15–25% of patients (20). There was moderate deterioration of glomerular and tubular renal function in most interferon alfa-treated patients assessed prospectively with a number of renal function markers (263).

In patients receiving high-dose interferon alfa, severe proteinuria and nephrotic syndrome have sometimes been noted (264).

- A 57-year-old woman developed severe nephrotic syndrome after 3 months of interferon alfa re-treatment, and renal biopsy showed minimal change nephrotic syndrome with T cell-predominant interstitial nephritis (265). Proteinuria persisted despite interferon alfa withdrawal and resolved only after glucocorticoid treatment.
- A 55-year-old woman was treated with interferon alfa and ribavirin for 1 year and developed asymptomatic nephrotic syndrome with focal segmental glomerulosclerosis on renal biopsy (266). Proteinuria slowly improved over the next 21 months.

Interferon alfa-induced acute renal insufficiency is rare and has mostly been reported in patients with underlying renal disease, in those receiving high dosages, or in those with varied malignancies (SED-13; 1095) (SEDA-20, 329) (SEDA-21, 372) (267,268). Very few cases have been described in patients with chronic hepatitis (SEDA-21, 372) (SEDA-22, 402). It has also been reported after intravesical administration (SEDA-21, 372). When available, pathological findings have pointed variously to nephrotic syndrome with minimal-change nephropathy and acute tubulointerstitial nephritis, nephrotic syndrome with severe glomerular changes, membranoproliferative glomerulonephritis, extracapillary glomerulonephritis with crescents, focal segmental glomerulosclerosis, and acute tubular necrosis. Renal dysfunction usually resolves after withdrawal of interferon alfa, but irreversible alteration or incomplete resolution of renal function have occasionally been noted.

A review of 15 other available reports of renal insufficiency and proteinuria in patients with chronic myeloid leukemia or other malignancies confirmed that the histological spectrum of renal lesions associated with interferon alfa is varied, and includes membranous glomerulonephritis, minimal change glomerulonephritis, acute interstitial nephritis, hemolytic–uremic syndrome, and thrombotic microangiopathy. Renal complications were reversible in nine patients; three patients had persistent proteinuria, and four had persistent renal dysfunction, of whom three required chronic hemodialysis. Two-thirds of the patients developed renal complications within 1 month of treatment with interferon alfa, and one-third had received a relatively low dosage of interferon alfa (9–15 MU/week).

The mechanism of interferon alfa nephrotoxicity is probably multifactorial and may involve a direct nephrotoxic effect with a possible additive effect of concomitant NSAID therapy, a T cell-mediated immune effect, immune-complex renal disease, or an autoimmune etiology (SED-13, 1095) (269–274).

Acute renal insufficiency has also occurred as a consequence of interferon alfa-induced hemolytic–uremic syndrome, thrombotic thrombocytopenic purpura, or renal thrombotic microangiopathy (SED-13, 1095) (234,275–278). The diagnosis was made after 7 months to 10 years of treatment (median 50 months) with weekly doses of 15–70 MU. This rare but extremely severe complication has almost exclusively been reported in patients treated for chronic myelogenous leukemia, so that the respective roles of interferon alfa and the underlying hematological malignancy are undetermined. However, at least one case has been reported in a patient with hepatitis C (SEDA-22, 402). From a total of 15 cases, renal prognosis was poor, with early deaths in four patients, chronic hemodialysis in eight, and chronic renal insufficiency in three.

To determine the characteristics of thrombotic microangiopathy associated with interferon alfa, data from eight patients were carefully examined (279). All had chronic myeloid leukemia and had received high-dose interferon alfa (mean 39 MU/week) for a long time (mean 32 months) before diagnosis. Severe arterial hypertension was the most common sign before diagnosis. Five patients had distal ischemic lesions that required amputation in one, and all had typical lesions of renal thrombotic microangiopathy involving both glomeruli and small arterioles. After interferon alfa withdrawal, two recovered normal renal function, three had persistent renal insufficiency, one relapsed 17 months after treatment withdrawal, and two required chronic dialysis. One patient had already had reversible renal insufficiency during a previous course of interferon alfa. From a review of 21 other previously published similar cases, the authors confirmed that interferon alfa-induced thrombotic microangiopathy mostly occurred in patients with chronic myeloid leukemia, whereas only two cases were reported in patients with chronic hepatitis C and one in a patient with hairy cell leukemia. The delayed occurrence of renal toxicity was also suggested to be highly predictive of histological thrombotic microangiopathy.

Possible deleterious effects of interferon alfa on renal graft function are repeatedly reported (280).

- A 43-year-old man with stable renal graft function, taking ciclosporin, methylprednisolone, and azathioprine, developed chronic myelogenous leukemia and received interferon alfa (3 MU/day). Seven weeks later, he became tired and had increased proteinuria and a raised serum creatinine concentration (574 μmol/l). Interferon alfa was withdrawn and he received high-dose methylprednisolone for suspected acute graft rejection. This was unsuccessful and a first renal biopsy showed widespread interstitial edema that could not be correctly interpreted. Hemodialysis was restarted, and he finally developed a catheter infection and died from sepsis. Histology of the explanted renal graft showed severe, predominantly acute, vascular rejection.

The rapid occurrence of renal dysfunction after interferon alfa in this case suggested a causal relation.

Skin

A wide range of skin lesions has been reported, and most include skin dryness, rash, diffuse erythema, or urticaria, occurring in 5–12% of patients (20,281). However, severe dermatological complications are rare. In a prospective survey of 120 patients treated during 6–18 months for chronic viral hepatitis, only three developed lichen planus and one relapsing aphthous stomatitis (282).

Injection site reactions

Subcutaneous interferon alfa sometimes causes local erythema and skin induration, which can be prevented by regularly changing the site of injection. Isolated reports have described more severe local reactions, with inflammatory painful nodules, purpuric papules and vasculitis, local ulceration, and injection site necrosis (SED-13; 1095) (SEDA-20, 330) (SEDA-21, 372) (SEDA-22, 402). Despite previous findings, even patients receiving low-dose interferon alfa can have severe injection site reactions. A localized intradermal bullous eruption, which recurred following each interferon alfa injection, was also reported (283).

Severe injection site reactions have been extensively detailed in six patients who had local cutaneous necrosis or indurated erythema after 1–10 months of treatment with low-dose interferon alfa (284). Four patients had concomitant risk factors known to reduce microcirculation, that is beta-blockers, dihydroergotamine, and cigarette smoking. The lesions healed after medical treatment in five patients, but one required surgical excision. The ulcers healed slowly and full recovery occurred only after a mean of 16 weeks after drug withdrawal. The lesions did not recur after interferon alfa re-administration at the other injection sites.

As with interferon alfa, pegylated interferon alfa has been associated with injection site skin necrosis (285). Severe local reactions after subcutaneous injections mostly consist of ulceration and skin necrosis, but a variety of reactions have been described. Prominent suppuration and granulomatous dermatitis at the injection sites of interferon alfa have been reported in two patients (286). Three patients who had severe rashes while receiving pegylated interferon alfa-2a or 2b had positive intracutaneous tests to both pegylated forms of interferon alfa but not to standard interferon alfa-2a or 2b (287). One of these patients subsequently tolerated standard interferon alfa. Cutaneous ulcers have also been reported in patients treated with peginterferon alfa-2b (288,289). In the latter case, the lesions healed under local therapy and the same dose of interferon was maintained.

Lichen planus

The new occurrence or exacerbation of lichen planus is a well-known complication of interferon alfa, but this has been a source of a considerable debate (SED-13, 1095) (SEDA-20, 330) (SEDA-22, 402). Indeed, most patients have received interferon alfa for chronic hepatitis C, an underlying disease that is controversially thought to be associated with a spontaneously higher incidence of lichen planus (290). In addition, complete reversibility of previous lichen planus was sometimes observed in patients treated with interferon alfa (SEDA-20, 330). Whatever the truth of the matter, the recurrence of lesions after interferon alfa re-administration or reports of lichen planus in patients with cancer (291–293) argues strongly for a direct causal link with interferon alfa. Local treatment and PUVA were sometimes sufficient to alleviate symptoms, but withdrawal of interferon alfa was required in the most severe cases (SED-13, 1095).

Pemphigus and pemphigoid

Bullous pemphigus and pemphigoid with circulating pemphigus-like autoantibodies, pemphigus foliaceus with anti-intercellular IgG antibodies, and paraneoplastic pemphigus due to interferon alfa have rarely been reported (SED-13, 1095), as has extensive oral pemphigus (294).

- A 28-year-old woman developed oral ulcers after a 5-month course of interferon alfa-2a for chronic hepatitis C. She had multiple erosions on both lips, the tongue, the floor of the mouth, the soft palate, the pharyngeal walls, and the laryngeal mucosa, but there were no skin or genital lesions. Raised double-stranded DNA antibody titers were found. Histology showed pemphigus vulgaris, and complete resolution was obtained by withdrawal of interferon alfa and immunosuppressive and local treatment.

This case was thought to have been due to the immunomodulatory effects of interferon alfa.

Psoriasis

The first reports of psoriasis in cancer patients treated with high-dose interferon alfa were followed by a controversial debate (295,296). However, numerous cases have confirmed that interferon alfa can either induce typical psoriasis or worsen pre-existing psoriasis (SED-13, 1095) (297), an observation that is compatible with interferon alfa-induced imbalance toward an increased Th1 response. This was particularly exemplified by the reversibility of the lesions after withdrawal of treatment and the prompt recurrence of symptoms after interferon alfa re-administration. Exacerbation of psoriasis usually occurred within the first month, whereas a minimum of 2–3 months of treatment was required in patients without a past history of psoriasis (297). Psoriatic lesions at the sites of injection were suggested to be potential indicators for further generalization of psoriasis. In more severe cases, there was concomitant development of monoarticular or polyarticular joint symptoms (SED-13, 1095) (SEDA-21, 372). Pustular psoriasis with balanitis and erosive monoarthritis, suggesting incomplete Reiter's syndrome, was also reported in one patient with HLA-B27 (298).

Vitiligo

Vitiligo has sometimes been reported in patients with malignant melanoma, for example in 17–25% of patients receiving interferon alfa alone (SEDA-21, 372). There have also been a few reports of vitiligo in patients with chronic hepatitis C (SEDA-20, 330), and one patient had both scleroderma and vitiligo (SEDA-19, 336).

© 2006 Elsevier B.V. All rights reserved.

Other complications

A spectrum of cutaneous lesions has been described distant from sites of interferon alfa injection. The clinical and histological characteristics of inflammatory skin lesions that occurred away from injection sites have been investigated in 20 patients treated with interferon alfa-2a or 2b plus ribavirin for chronic hepatitis C (299). Cutaneous lesions developed between 2 weeks and 4 months and consisted of pruritic papular erythematous eruptions with occasional vesicles. These eczema-like skin lesions predominated on the distal limbs, the head, and the neck. Photosensitivity was also noted in four patients and mucous lesions in two. Skin biopsy mostly showed non-specific mononuclear infiltrates. The skin lesions were promptly reversible in 10 patients who required treatment withdrawal, while others improved after symptomatic treatment. Two of the three patients who again received the same or another type of interferon alfa had recurrence of their lesions. Skin tests performed in six patients were negative, including the two patients who relapsed after rechallenge with interferon alfa, and were therefore considered unhelpful.

- Radiation recall dermatitis developed in a 29-year-old woman after high-dose intravenous interferon alfa-2b was given 5 days after the completion of radiotherapy for malignant melanoma (300).

The authors suggested that interferon alfa can trigger an inflammatory reaction in patients whose inflammatory response threshold has been lowered by irradiation.

- A 46-year-old woman developed transient facial erythema with telangiectasia after each injection of interferon alfa, resolving within 1–2 days, and completely disappearing after definitive withdrawal of treatment 7 months later (301).
- Two patients treated with pegylated interferon alfa-2b and ribavirin developed cutaneous thrombotic microangiopathy (302).
- A 54-year-old woman had small bullous lesions mainly on the backs of her hands and feet after 6 months of treatment with pegylated interferon alfa-2b plus ribavirin for chronic hepatitis C. The lesions lasted 48 hours and healed rapidly after rupture of the bullae.
- A 62-year-old woman developed generalized pruritus and excoriated lesions after 5 months of treatment with pegylated interferon alfa-2b plus ribavirin. The lesions were maximal on the backs of her hands and feet after 8 months of treatment, but there were no bullae.

Skin biopsies in the last two patients showed microthrombi of the dermal capillaries and a necrotic epidermis. Immunofluorescence showed only fibrinogen. Some bullous lesions were still present 1 month after withdrawal in the first patient, while the second patient responded to local corticosteroids and a reduced dose of pegylated interferon alfa, but continued to have episodes of severe pruritus.

Other dermatological complications have in most instances been reported as single case histories, so that any causal relation with interferon alfa awaits confirmation. These reports have included worsening of lichen myxedematosus, injection site pyoderma gangrenosum, a polymorphous light eruption (SEDA-22, 372), and a fatal case of histiocytic cytophagic panniculitis (SEDA-20, 330).

- Meyerson's phenomenon, multiple focal and transient eczematous eruptions around melanocytic nevi, has been reported in a 24-year-old man when the dosage of interferon alfa for Behçet's disease was doubled (303).
- Bullous lesions with specific infiltrates of mycosis fungoides have been reported in a 67-year-old woman who took interferon alfa for 2 months for mycosis fungoides (304).

Although in the second case the syndrome could not be definitely attributed to interferon alfa, the authors noted that bullous mycosis fungoides is an extremely rare variant of this disease and withdrawal of interferon alfa led to healing of the blisters without further recurrence.

Hair

Moderate and reversible alopecia secondary to telogen effluvium is common (7–30%), and sometimes recedes despite continued treatment (305). Alopecia areata has very occasionally been described (306).

- Injection-site alopecia has been reported in three patients, affecting the thighs in two patients and the abdomen in one (307). A reversible focal telogen effluvium secondary to high local concentrations of interferon alfa was the most likely cause, indicating that rotating injection sites are needed to prevent this adverse effect.
- Alopecia areata after 7 months of interferon alfa, slowly reversible on withdrawal, has also been reported in a 36-year-old woman (308).

In two patients with previously natural curly hairs, the combination of interferon alfa plus ribavirin was suggested to have triggered a rapid change in hair texture, with diffuse straightening hairs, eyelashes, and eyebrow hypertrichosis (309). In one patient, a causal role of treatment was supported by the spontaneous recovery of hair abnormalities after withdrawal and the recurrence of similar abnormalities on rechallenge.

Excessive growth of eyelashes and nail damage due *to Tinea unguium* have been occasionally reported in patients receiving interferon alfa (SED-13, 1095) (SEDA-21, 372). Hypertrichosis of the eyelashes (trichomegaly) developed in two of 36 patients with chronic viral hepatitis who were examined for ocular complications during treatment with high-dose interferon alfa (18–30 MU/week) (86). These two patients had received the highest dose of interferon alfa.

Musculoskeletal

Arthralgia, myalgias, and muscle weakness are typically observed during the early influenza-like reaction (20). Direct muscle toxicity of interferon alfa can result in acute rhabdomyolysis, in some cases fatal after the dose of interferon alfa was increased (SEDA-19, 330) (SEDA-21, 372).

- A 26-year-old man with a malignant melanoma had two episodes of acute severe rhabdomyolysis after each exposure to a chemotherapy regimen containing interferon alfa and dacarbazine (310). As a few cases of

© 2006 Elsevier B.V. All rights reserved.

rhabdomyolysis have been previously reported after interferon alfa alone (SEDA-19, 336) (SEDA-20, 330) (SEDA-22, 403), interferon alfa was suggested as the most likely cause.

- Acute rhabdomyolysis occurred in a 34-year-old woman with a melanoma treated with interferon alfa 20 MU/m^2/day (311). There was no recurrence on retreatment with a lower dose (down to 6.6 MU/m^2/day), suggesting that this was a dose-related complication.
- A 34-year-old man with scleromyxedema had flu-like symptoms and muscle pain after the first injection of interferon alfa 6 MU (312). After three additional injections at 2-day intervals, his muscle symptoms worsened and were associated with mild quadriparesis, reduced deep tendon reflexes, dark urine, confusion, and agitation. Biological findings were consistent with acute rhabdomyolysis, and electromyography showed rare denervation potentials. His symptoms resolved and the laboratory findings normalized within 15 days.

Delayed muscular adverse effects have been occasionally reported including the clinical exacerbation of a latent myopathy (SEDA-19, 336), delayed and severe myopathic changes (313), myositis, polymyositis, and a Lambert–Eaton-like syndrome (SEDA-19, 336) (SEDA-20, 330) (SEDA-22, 403).

- Three patients developed unilateral or bilateral avascular necrosis of the femoral head after 3–54 months of treatment with interferon alfa for chronic myelogenous leukemia (314). One required bilateral hip replacement and two significantly improved after interferon alfa withdrawal. One patient received further interferon alfa without exacerbation.

Although there were risk factors for avascular necrosis in two of the patients (a short course of methylprednisolone and moderate alcohol consumption), the authors did not consider them to be significant. They identified seven other reported cases of avascular necrosis in patients with chronic myeloid leukemia, including two patients who were taking interferon alfa at the time of the complication. One patient with pre-existing avascular necrosis had an acute exacerbation within 1 month of interferon alfa and required hip replacement. Although any causal relation with treatment remains purely speculative, the authors argued that the known antiangiogenic effects of interferon alfa could have predisposed patients to avascular necrosis.

Sexual function

Sexual complaints attributed to interferon alfa, namely decreased libido, impotence, or erectile failure, are usually concomitant to other neuropsychiatric symptoms, and cases of reversible impotence are anecdotal (315). The mechanisms accounting for these adverse effects are unclear, and changes in sex hormone concentrations have not been consistently reported. In one study in healthy women, interferon alfa produced falls in serum progesterone and estradiol concentrations (316), but neither impairment of libido nor impairment of fertility has apparently been reported in women. No evidence of gonadal toxicity or sexual dysfunction was found in 43 men with hairy cell leukemia who received interferon alfa for 2–12 months compared with 33 patients who received no systemic therapy (317). Finally, sexual complaints reported during interferon alfa treatment of chronic hepatitis C were presumably related to fatigue, anxiety, or psychological disorders rather than to endocrinological changes (SEDA-21, 373).

Immunologic

Hypersensitivity reactions

No IgE-mediated immediate-type allergic reactions to interferon alfa have ever been conclusively documented. A recurrent non-IgE-mediated anaphylactic reaction, possibly due to mast cell degranulation, has been described in a patient with mastocytosis (318).

- A 64-year-old man with no history of allergy had progressive fatigue, loss of appetite, and facial edema after 6 months of interferon alfa-2b treatment for chronic hepatitis C (319). Angioedema was diagnosed and it resolved after withdrawal of interferon alfa and a short course of prednisolone. Serum immunoglobulin E and plasma bradykinin concentrations were raised, but the C1 esterase inhibitor and serum complement concentrations were normal.
- A 47-year-old man, who had previously received a 2-month course of interferon alfacon-1 for chronic hepatitis C, started interferon alfa-2b 8 months later (320). He developed mild generalized pruritus the day after the second injection, and dyspnea with diffuse urticaria within a few hours after the third injection. Skin tests were not performed, and IgG but not IgE antibodies to interferon alfa were found.

These cases do not formally show a causal relation with interferon alfa, and at best they suggest that an IgE-mediated reaction is probably not the cause of hypersensitivity reactions to interferon alfa. In the first case, the mechanism may have been similar to that observed with angiotensin-converting enzyme inhibitors.

Cases of contact dermatitis have suggested that interferon alfa-2c can cause cell-mediated delayed hypersensitivity (321,322).

Interferon alfa antibodies

Both binding and neutralizing antibodies to interferon alfa can be detected in interferon alfa-treated patients, and the incidence or clinical significance of these antibodies is the subject of continuous controversy, which has been addressed in a number of studies or general reviews (SED-13, 1096) (SEDA-20, 330) (SEDA-21, 373) (156,323–325).

In various studies, the incidence of antibody formation has ranged from zero to more than 50% of patients. However, any comparison between studies is difficult, because the underlying treated disease, the type of interferon used, the route of administration, the dosage regimen, the schedule of treatment, and the method of assay have differed from one investigation to another. Antibodies to interferon alfa have been reported to be more frequent in patients receiving long-term, instead of short-term, treatment, in patients receiving subcutaneous rather than intravenous interferon alfa, and in patients receiving low rather than high doses (156). Complete disappearance of interferon

© 2006 Elsevier B.V. All rights reserved.

alfa antibodies was usually observed after withdrawal. Interferon alfa formulations also differ in antigenicity. Using the same anti-interferon alfa antibody assay, a higher frequency of antibodies to recombinant interferon alfa-2a has repeatedly been reported compared with other recombinant or natural interferon alfa formulations in patients treated by the same route and with the same treatment schedule. In 296 patients with chronic hepatitis, binding and neutralizing antibodies were found in 45 and 20% respectively of patients receiving recombinant interferon alfa-2a compared with 15 and 6.9% of those receiving recombinant interferon alfa-2b, and 9.4 and 1.2% of those receiving interferon alfa-n1 (326,327). There were similar differences in the immunogenic potential of the two recombinant interferon alfa formulations in 159 patients with chronic myelogenous leukemia (328). Overall, the incidence of binding antibodies is in the range of 20–50% for recombinant interferon alfa-2a, 6–10% for recombinant interferon alfa-2b, and 1–6% for interferon alfa-n1 (324).

The clinical significance of binding antibodies appears to be limited to a possible change in interferon alfa pharmacokinetics. By contrast, neutralizing antibodies, which are usually detected within 2–4 months of treatment, can theoretically reduce the clinical response to interferon alfa and cause interpatient variability in response to treatment, but this is still debated (323–325). Although several studies have failed to detect any loss of therapeutic response, response failure or the reversal of an initial clinical response, simultaneously with (or soon after) the appearance of neutralizing antibodies, have been reported. In large-scale studies, the clinical response to recombinant interferon alfa was significantly less in patients with neutralizing antibodies, and it has therefore been suggested that the appearance of neutralizing antibodies provides the prime explanation for those instances in which there is a relapse or a breakthrough of the disease before the completion of treatment (329–335). In addition, in patients who cease to respond therapeutically after recombinant interferon alfa antibody formation, a change to natural interferon alfa has proved successful in restoring the response in some cases (335–338). This has led to the suggestion that the formation of neutralizing antibodies represents a specific immune response to the recombinant preparations, and that natural interferon alfa can overcome the neutralizing activity of antibodies to recombinant interferon alfa. On the other hand, neutralizing antibodies were not associated with immune complex-associated diseases or hypersensitivity reactions, and exerted no influence on interferon alfa-associated adverse effects. They can even be accompanied by improvement in the flu-like syndrome.

Autoantibodies

Collectively, several antibodies (mostly antinuclear, antithyroid, parietal cell, liver/kidney microsome, and smooth muscle antibodies, and rheumatoid factor) can be detected before interferon alfa treatment in about one-third of patients. Increased titers or the occurrence of various autoantibodies were observed in 4–30% of previously autoantibody-negative patients (21,156). These autoantibodies do not affect the response to interferon alfa treatment (339–341). Although it was initially felt that interferon alfa might facilitate the development of autoimmune disease in patients previously positive for non-organ-specific autoantibodies, the evidence is still limited and the clinical consequences of such autoantibodies are unclear. Except for thyroiditis, large studies in patients with chronic viral hepatitis C receiving interferon alfa did not show a significant increase in overt autoimmune diseases, despite the pre-existence or further positivity of several autoantibodies (SED-13, 1096) (SEDA-20, 330) (SEDA-21, 373) (SEDA-22, 405). However, in 83 patients with chronic hepatitis C there were one or more pre-existing autoantibodies (mostly low-titer antinuclear antibodies) in 35 patients (group I), of whom seven had clinical evidence of immune-mediated disorders, whereas five of 48 patients without pre-existing autoantibodies (group II) had similar disorders (342). After 12–48 weeks of treatment with interferon alfa in 44 patients, there were new immune-mediated disorders in six of the 20 patients in group I (thyroid disorders in three, arthropathy in two, and psoriasis in one), but none in the 24 patients in group II. Patients who are positive for autoantibodies before interferon alfa may therefore be much more likely to develop autoimmune diseases, particularly thyroid disorders, during interferon alfa treatment.

As a result, there is no clear consensus about the management of patients previously positive for non-organ specific autoantibodies, but it is usually considered that low autoantibody titers or the absence of concomitant symptoms suggestive of autoimmune disease is not a contraindication to treatment.

Autoimmune disorders

The possibility of autoimmune disorders during interferon alfa treatment has been addressed by many authors. The spectrum of interferon alfa-induced immune diseases includes organ-specific and systemic autoimmune diseases, such as thyroiditis, diabetes, hematological disorders, systemic lupus erythematosus, rheumatoid arthritis, dermatological disease, and myasthenia gravis (156). Several have been discussed in appropriate sections elsewhere in this monograph. The exact role of interferon alfa is usually difficult to ascertain, because the underlying disease, that is chronic hepatitis C, can also be associated with immune-mediated disease.

Two studies have provided insights into the incidence and risk factors of the immune-mediated complications of interferon alfa in patients with chronic myeloid leukemia. In the first study, 13 of 46 patients had autoimmune manifestations consisting of a combination of autoimmune thyroiditis in four, a direct antiglobulin test without hemolysis in eight, cryoagglutinins in one, Raynaud's phenomenon in two, and chronic autoimmune hepatitis in one (343). Overall, six patients had clinically symptomatic manifestations after a median of 15 months of treatment. In the second study, there were autoimmune diseases in seven of 76 patients after a median of 19 months of treatment, including hypothyroidism in one, immune-mediated hemolysis in two, systemic lupus erythematosus in two, Raynaud's phenomenon in one, and mixed connective tissue disease in one (344). In

© 2006 Elsevier B.V. All rights reserved.

both studies there was a strong association with female sex and it was confirmed that patients who developed clinical autoimmune complications had had relatively long exposures to interferon alfa.

The management of patients with chronic hepatitis C and associated features of autoimmune disease carries the risk of exacerbating the underlying disease. Different treatment strategies, including interferon alfa alone or combined with ribavirin or glucocorticoids, or no treatment, have been discussed (345).

Behçet's disease

Characteristic features of Behçet's disease or isolated positive skin tests were found in one study of patients with chronic myelogenous leukemia treated with interferon alfa (346). No other reports confirmed these findings.

Dermatomyositis

Occasional reports have suggested that interferon alfa can cause dermatomyositis (347).

- A 57-year-old woman received adjuvant high-dose interferon alfa 16 months after removal of a malignant melanoma. About 6 weeks later, she developed hand swelling, fatigue, myalgia, arthralgia, and weakness. Interferon alfa was withdrawn. She had multiple joint involvement, and radiological imaging showed bilateral interstitial pulmonary infiltrates. Anti-Jo antibodies were positive but other autoantibodies were negative. She also had violet eyelid discoloration with edema, tenderness in various muscle groups, and reduced strength in the shoulders. The muscle biopsy showed scattered necrotic fibers and basophilic regenerative fibers. She gradually recovered with methotrexate and corticosteroids, and the titer of anti-Jo antibodies fell dramatically.

Polyarteritis nodosa

Severe polyarteritis nodosa-like systemic vasculitis has been reported (SEDA-20, 330) and cutaneous polyarteritis nodosa has been attributed to interferon alfa (348).

- A 50-year-old woman was given interferon alfa for chronic hepatitis C and primary biliary cirrhosis, and within 2 months became febrile and developed a diffuse nodular erythematous rash. The skin biopsy showed typical features of necrotizing angiitis, and cutaneous periarteritis nodosa was diagnosed. Full recovery was obtained after interferon alfa withdrawal and prednisolone treatment.

According to the authors, it is not known whether this complication was directly due to interferon alfa, represented the triggering of latent periarteritis nodosa in a patient with primary biliary cirrhosis, or whether it was a coincidental adverse event.

Polymyositis

- Polymyositis has very rarely been associated with interferon alfa, but has been reported together with autoimmune thyroiditis in a 48-year-old woman after treatment for 5 months for malignant melanoma (349).

There have been two reports of polymyositis in association with interferon alfa treatment for hematological malignancies (123,350). In both cases, clinical and/or electrophysiological recovery occurred after drug withdrawal, spontaneously or after a short course of glucocorticoids.

Sarcoidosis

The early impression that interferon alfa, alone or in combination with ribavirin, could reactivate or cause new subcutaneous sarcoid nodules and pulmonary or generalized sarcoidosis, has been confirmed by several reports, with prompt recovery after interferon alfa withdrawal (SED-13, 1097) (SEDA-20, 330) (SEDA-22, 404). The incidence may have been underestimated; in one series, 3 patients out of 60 who received interferon alfa alone or combined with ribavirin developed pulmonary sarcoidosis (351). In a review of 27 cases, the time to onset was 15 days to 30 months, and there were dermatological signs in 50% (352). Five patients had also taken ribavirin, but an enhanced T cell immune reaction from the combination of interferon alfa plus ribavirin is speculative. However. the association of cutaneous or systemic sarcoidosis with interferon alfa, alone or in association with ribavirin, has been exemplified by various reports (353,354), including one patient whose sarcoidosis resolved with prednisone despite continued interferon alfa treatment (355).

- A 60-year-old woman receiving interferon alfa developed cutaneous sarcoid foreign body granulomas at the sites of a previously childhood skin injury (356).

This suggests that interferon alfa may facilitate the development of cutaneous sarcoid granuloma from particulate foreign matter.

De novo sarcoidosis has been reported in six patients (357–361) and reactivation of pre-existing disease in one (362). One of these patients had chronic hepatitis B, suggesting that interferon alfa treatment rather than the underlying disease was the most probable triggering factor. Remission was observed in all patients after withdrawal, either spontaneously or after glucocorticoid treatment.

Sjögren's syndrome

One report of Sjögren's syndrome in a patient taking interferon alfa should be regarded with caution (SEDA-20, 330).

Systemic lupus erythematosus and rheumatoid arthritis

The possible role of interferon alfa in the development of rheumatoid arthritis or systemic lupus erythematosus has been described in isolated cases (363,364), and confirmed cases of systemic lupus erythematosus have very occasionally been reported (SED-13, 1096) (SEDA-20, 330). In most of these cases, the predominance of young patients and female sex, the presence of renal or skin involvement, the findings of positive antibodies to double-stranded DNA, and the rapid onset after the start of treatment, as well as persistence of symptoms after interferon alfa withdrawal, are more in keeping with unmasking by interferon alfa of idiopathic lupus rather than with a new drug-induced illness. The reactivation or appearance of inflammatory rheumatological disorders consistent with rheumatoid arthritis or lupus-like polyarthritis were

© 2006 Elsevier B.V. All rights reserved.

also consistently reported (SEDA-20, 330) (365,366). In a review of 37 published cases of interferon alfa-induced arthritis, symmetrical polyarthritis was the most common feature, and antinuclear antibodies or rheumatoid factor were found in 72 and 34%, respectively (367). Although spontaneous improvement was sometimes observed after withdrawal of interferon alfa, more severe cases required anti-inflammatory, antimalarial, or immunosuppressive drugs. In five of eight patients rechallenged with interferon alfa, there was recurrence of arthritis.

There was an unexpectedly high incidence of rheumatoid and lupus-like symptoms (27 of 137 patients), namely arthralgia, arthritis, myalgia, and Raynaud's phenomenon, in patients with myeloproliferative disorders taking interferon alfa alone or combined with interferon gamma (365). However, only a minority of affected patients fulfilled the diagnostic criteria for systemic lupus erythematosus. By contrast, systemic autoimmune diseases appeared to be genuine but very rare complications of interferon alfa in chronic hepatitis C, with only one case of lupus-like syndrome and two cases of polyarthritis in a survey of 677 patients (18).

Other reports included seronegative polyarthritis, acute seronegative monoarthritis of the hip, and seropositive monoarthritis of the metatarsophalangeal of the right foot (SED-13, 1097).

Systemic lupus erythematosus has been reported in two patients given interferon alfa for chronic hepatitis C (363,368). However, it is not known whether this complication was coincidental or treatment-related.

Systemic sclerosis

Systemic sclerosis has been attributed to interferon alfa-2a (369).

- A 52-year-old woman received interferon alfa-2a for chronic myeloid leukemia and after about 2 years developed fever, dyspnea, and limb edema. The erythrocyte sedimentation rate was 50 mm/hour and pulmonary imaging showed pulmonary vascular congestion. She improved after interferon alfa withdrawal and administration of diuretics, but similar symptoms recurred 3 months later. She also had progressive thickening of the skin on the hands and wrists. There was diffuse parenchymal and interstitial fibrosis of the lungs, absence of peristalsis on esophagogastroduodenoscopy, renal impairment, and positive antisclero-70 antibodies. Capillaroscopy showed typical features of scleroderma. Based on these findings, a diagnosis of systemic sclerosis was suggested and she slowly improved over the next months with cyclophosphamide, prednisone, iloprost, and hydroxyurea.

This patient had the HLA-DR11 haplotype, which is associated with systemic sclerosis, and this suggests that interferon alfa may have triggered the autoimmune phenomenon.

Vasculitis with cryoglobulinemia

Interferon alfa can sometimes aggravate hepatitis C-related cryoglobulinemia.

- A fatal exacerbation of hepatitis C-related cryoglobulinemia, preceded by rapid deterioration of neurological status, massive upper gastrointestinal bleeding, and diffuse hemorrhagic gastritis with vasculitic changes on gastroscopy, has been reported within the first 3 weeks of interferon alfa treatment in a 51-year-old woman (370).

However, cryoglobulin-associated vasculitis is a recognized manifestation of hepatitis C infection. Reports of vasculitis in interferon alfa-treated patients should therefore be interpreted with caution (SED-13, 1095) (371). In addition, several isolated reports suggested that exacerbation of cryoglobulinemia might also be the result of interferon alfa treatment (SEDA-19, 337).

Interferon alfa and transplantation

A possibly deleterious effect of pre- or post-transplant interferon alfa therapy in transplant recipients has been emphasized by several studies and case reports. These point to a higher incidence or greater severity of graft-versus-host reactions in patients who have received an allogeneic bone marrow transplant (SED-13, 1097) (372,373), significant deterioration of renal function or an increased risk of glucocorticoid-resistant rejection in renal transplant patients (SED-13, 1097) (374), and a possibly increased risk of acute or chronic rejection in liver transplant patients (375,376). These findings are still the subject of debate, as the available data consist mainly of retrospective or poorly controlled studies with a limited number of patients (377,378). In addition, several other investigators have failed to identify any deleterious influence of interferon alfa treatment in transplant recipients (SEDA-21, 373) (SEDA-22, 403). This issue warrants further large scale, prospective, controlled studies.

Immunosuppressive effects

Isolated reports of *Candida* esophagitis or *Pneumocystis jiroveci* (*Pneumocystis carinii*) infections in immunocompetent patients and the possible decrease in CD4+ T cells with or without opportunistic infections in several HIV-infected patients (SED-13, 1097) (379) suggest that unexpected immunosuppressive effects of interferon alfa can occur. An autoimmune destruction of CD4 cells in patients with a particular HLA haplotype has been proposed as a possible mechanism (380). One patient also had an acute and fatal acute precipitation of infection with *Entamoeba histolytica* (SEDA-22, 403). However, the available evidence is still very limited and no firm conclusion can be drawn on a possible association between interferon alfa treatment and a fall in CD4 cell count or an immunosuppressive effect.

Two patients aged 38 and 54 years with hemodialysis-dependent end-stage renal insufficiency developed severe bacterial infections, osteomyelitis, and prostatitis, within 3 months of interferon alfa-2b treatment for hepatitis C virus infection (381).

Possible exacerbation of latent parasitic infection by interferon alfa has been reported (SEDA-22, 403).

- Two patients receiving interferon alfa plus ribavirin for chronic hepatitis C developed symptomatic strongyloidiasis within 2–3 weeks of treatment (382).

© 2006 Elsevier B.V. All rights reserved.

Because both drugs have immunomodulatory effects, it was not determined which one was the more likely cause.

Graft-versus-host disease

There are still uncertainties about the possible relation between interferon alfa and an increased incidence or severity of acute graft-versus-host disease after bone marrow transplantation. Late-onset, severe, atypical chronic graft-versus-host disease has been attributed to interferon alfa (383).

- A 44-year-old woman received interferon alfa 6 MU/day for relapse of chronic myeloid leukemia 7 years after successful bone marrow transplantation. About 2 years later, interferon alfa was withdrawn because of diffuse erythematous skin lesions with discoid lupus erythematosus on skin biopsy and severe dysphagia with esophagitis and pseudomembranes at endoscopy. Fever, bilateral pulmonary infiltrates, and respiratory distress syndrome subsequently developed, and she required mechanical ventilation. An open lung biopsy showed features of chronic pulmonary graft-versus-host disease. All her symptoms completely resolved with ciclosporin and corticosteroids. An infectious cause was ruled out.

In this case, the clinical presentation was compatible with typical chronic graft-versus-host disease. Whether interferon alfa induced or aggravated chronic graft-versus-host disease in this patient was an open question.

Death

There is a debate as to whether previous interferon alfa adversely affects the outcome of bone marrow transplantation in chronic myelogenous leukemia.

In a retrospective study of 153 patients who underwent bone-marrow transplantation for chronic myelogenous leukemia, pretransplant interferon alfa treatment for more than 12 months was associated with a significant increase in transplant-related mortality during the first 2 years when compared with patients who received pretransplant interferon alfa for less than 12 months (28 of 46 patients versus nine of 38) (384). This adverse outcome was also more frequent in patients who discontinued treatment less than 3 months before transplantation.

Of eight studies, five showed no harmful effect and three suggested an increased risk of post-transplant complications or mortality (SEDA-22, 403) (SEDA-23, 395).

The outcome of bone marrow transplantation in 152 patients (86 on interferon alfa, 66 on chemotherapy) included in two consecutive randomized trials, has been analysed prospectively (385). Whereas the duration of interferon alfa treatment did not influence the outcome of transplantation, there was a significant reduction in survival: the 5-year survival was 45% in the 50 patients who were still receiving interferon alfa within 3 months before bone marrow transplantation and 71% in the 36 patients who were not. According to the authors, interferon alfa should not be prescribed in patients who are likely candidates for early bone marrow transplantation.

Long-Term Effects

Tumorigenicity

Compared with untreated patients and patients treated with busulfan or hydroxyurea, interferon alfa produced a significantly higher frequency of clonal aberrant cytogenetic abnormalities and chronic clonal evolution in patients with chronic myeloid leukemia (386). However, the possible role of interferon alfa in the secondary occurrence of hematological malignancies is purely speculative. Only isolated cases of myeloproliferative syndrome, leukemia, or lymphoma have been attributed to interferon alfa (SED-13, 1098) (SEDA-20, 331) (SEDA-21, 373). There was no increased incidence of second cancers in patients treated for hairy cell leukemia (SEDA-20, 331).

Second-Generation Effects

Teratogenicity

In experimental models there has been no evidence of mutagenic or teratogenic effects of interferon alfa, and placental transfer is unlikely or very low (387). Immediately after delivery, interferon alfa concentrations in the breast milk or in the sera of two newborns were very low compared with maternal serum concentrations (388). Uncomplicated and successful pregnancies have been detailed in several patients treated for hematological malignancies or chronic hepatitis C, with interferon alfa exposure during the first trimester or even the whole of pregnancy (SED-13, 1098) (SEDA-20, 331) (389–392). In only three cases have premature delivery or moderate intrauterine growth retardation been observed, and any direct causal relation to interferon alfa treatment is doubtful. One report mentioned transient and moderate thrombocytopenia in a neonate born to a woman who had received interferon alfa throughout pregnancy (391).

Although no long-term follow-up is as yet available, clinical examination performed up to 2–3 years after delivery in at least seven babies has proved normal. Despite these reassuring data, the safety of interferon alfa during pregnancy still awaits further documentation, and it is advisable to delay therapy of non-life-threatening disease in pregnant women, especially during the first trimester.

Susceptibility Factors

Age

There is little information on the use of interferon alfa in children with chronic hepatitis C. In a review of 19 studies published between 1990 and 2000, there were data on only 366 treated children (105 untreated) and they suggested a higher rate of sustained response than in adults (393). Besides flu-like symptoms, reversible weight loss, neutropenia, and alopecia were the most commonly reported adverse events, but adverse events were not systematically recorded in these studies.

© 2006 Elsevier B.V. All rights reserved.

Although the anti-angiogenic effects of interferon alfa have been successfully used to treat severe hemangiomas in infants, the possibility of spastic diplegia is a matter of concern (SEDA-22, 404). Spastic diplegia developed in five of 26 infants during treatment, with possibly significant functional sequelae (394), and in one of 53 infants treated for a median of 51 weeks (395). Persistent, severe, spastic diplegia occurred after 1 year of treatment in a 5-month-old boy (396). Because the immature central nervous system of infants may be more susceptible to interferon alfa toxicity, it has been stressed that this treatment should be reserved for infants with life-threatening hemangiomas (397). That interferon alfa can play a role in the occurrence of this acute neurological complication has been further substantiated by the finding of abnormally high interferon serum concentrations in 45% of neonates with spontaneous cerebral palsy compared with control children (398).

Renal disease

High daily dosage or serum concentrations of interferon alfa may be associated with more frequent and more severe adverse effects during the treatment of chronic hepatitis C in hemodialysis patients. In one study, three of 10 hemodialysis patients had severe neurological adverse effects (generalized seizures or posterior leukoencephalopathy) (399). In another study, three of six patients receiving daily injections had to discontinue treatment because of depression, loss of consciousness, and persistent high-grade fever, while no serious adverse effects were reported in three other patients who received interferon alfa three times a week (400). In both studies, there were significant changes in interferon alfa pharmacokinetics (higher C_{max}, AUC, and half-life) in hemodialysis patients compared with patients with normal renal function, consistent with altered clearance of interferon alfa.

Drug Administration

Drug formulations

The FDA has expanded the indications for a combination product to include patients with chronic hepatitis C who have not been treated with interferon alfa. This product, Rebetron Combination Therapy (Schering), contains recombinant interferon alfa-2b for injection (Intron A) plus ribavirin (Rebetol) in capsules, and was previously only approved for patients who had relapsed after treatment with interferon alone (401). Serious adverse effects, such as depression, suicidal ideation, and suicide, have occurred with this regimen and patients should be closely monitored.

Drug administration route

The use of intraspinal interferon alfa (1 MU three times a week for 4 weeks) in 22 patients with neoplastic meningitis was associated with frequent adverse effects that mostly manifested as chronic fatigue syndrome in 91% of patients (severe in 45%) and arachnoiditis in 73% (severe in 9%) (402). Interferon alfa-induced immune dysregulation in an immunologically predisposed patient was suggested to account for this complication.

Drug–Drug Interactions

Alcohol

Even moderate but continuing alcohol consumption needs to be taken seriously in patients receiving interferon alfa, and exacerbation of previous acute alcohol hepatitis has been reported in two patients with chronic hepatitis C, despite reduced alcohol consumption (403). Liver transaminases subsequently normalized after withdrawal of interferon alfa in both patients.

Angiotensin-converting enzyme inhibitors

An increased risk of severe and early but reversible neutropenia has been found in patients taking angiotensin-converting enzyme inhibitors (enalapril and captopril) with interferon alfa (404).

Carmustine

Owing to its antineoplastic properties, interferon alfa is sometimes used with cytostatic drugs. In 275 patients randomized to receive radiation and carmustine either alone or with interferon alfa for high-grade glioma, there was no significant improvement in the overall survival and time to disease progression in those given interferon alfa, but a higher incidence of adverse effects, namely fever, chills, myalgia, lethargy, headache, and seizures (405).

13-Cisretinoic acid

The combination of interferon alfa with 13-*cis*-retinoic acid may have potentiated the occurrence of fatal radiation pneumonitis (SEDA-21, 374).

Clozapine

Agranulocytosis was observed when interferon alfa was given to a patient taking long-term clozapine (SEDA-22, 404), but this is a known risk of the latter.

Coumarin anticoagulants

There have been two reports of increased prothrombin time in patients taking warfarin or acenocoumarol (SEDA-19, 337) (SEDA-22, 374).

Cyclophosphamide

Depending on the timing of exposure, interferon alfa may adversely affect the pharmacokinetic and hematological effects of cyclophosphamide. In 10 patients with multiple myeloma, interferon alfa given 2 hours before cyclophosphamide infusion significantly reduced cyclophosphamide clearance and produced less exposure to its metabolite 4-hydroxycyclophosphamide compared with interferon administration 24 hours after cyclophosphamide (406). This resulted in a significantly greater fall in white blood cell count in patients who received interferon alfa after cyclophosphamide.

Erythropoietin

Reduced efficacy of human erythropoietin, requiring increased erythropoietin dosages, has been clearly documented in several patients receiving interferon alfa

© 2006 Elsevier B.V. All rights reserved.

(407–409), an effect that is probably mediated by interferon alfa-induced suppression of erythropoiesis.

5-Fluorouracil

One would expect drugs with myelosuppressive effects to exacerbate the hematological toxicity of interferon alfa. However, even though interferon alfa is increasingly used with other cytotoxic drugs, no specific and unexpected adverse effects have been reported, except for the combination of interferon alfa with 5-fluorouracil, which produced increased serum concentrations of fluorouracil and a significantly higher incidence of severe adverse effects, namely gastrointestinal and myelosuppressive adverse effects (410,411).

Melphalan

Interferon-induced fever has been thought to increase the cytotoxicity of melphalan (412).

Oral hypoglycemic drugs

There has been one report of hypoglycemia in a patient treated with metformin and chlorpropamide (SEDA-21, 374).

Paroxetine

It has been suggested that concomitant treatment with paroxetine may be a susceptibility factor for retinal damage by interferon alfa (82).

Phenazone (antipyrine)

Interferon alfa inhibits several hepatic microsomal cytochrome P_{450} enzymes in vitro and in vivo (SED-13, 1099) (20,413). However, repeated injections of interferon alfa produced conflicting results, with no change in salivary phenazone clearance (SED-13, 1099) (414).

Ribavirin

The combination of interferon alfa with ribavirin is one of the most promising treatments for chronic hepatitis C. However, two patients developed rapid and particularly severe anemia within 4 and 6 weeks of combined treatment (415). One patient required erythrocyte transfusions, and both recovered after withdrawal. The combination of pure red cell aplasia due to interferon alfa and hemolytic anemia due to ribavirin was suggested to have accounted for this possible interaction.

There was an increased incidence of adverse skin effects, mostly eczema, malar erythema, and lichenoid eruptions, in 33 patients who received combination of interferon alfa with ribavirin compared with 35 patients treated with interferon alfa alone (416).

Thalidomide

In 13 patients with metastatic renal cell carcinoma, the combination of interferon alfa-2a (27 MU/week) and thalidomide produced severe neurological toxicity in four patients, an incidence that was considered to be far greater than would be expected with either drug alone (417).

Theophylline

Interferon alfa inhibits several hepatic microsomal cytochrome P_{450} enzymes in vitro and in vivo (20) and reduces theophylline clearance (SED-13, 1099) (418–420).

Zidovudine

Synergistic hemotoxicity has sometimes resulted from the combination of interferon alfa with zidovudine in AIDS-associated Kaposi's sarcoma, but this regimen is considered to be relatively safe (421,422).

Interferon beta

See also Interferons

General Information

Interferon beta is used in the form of natural fibroblast or recombinant preparations (interferon beta-1a and interferon beta-1b) and exerts antiviral and antiproliferative properties similar to those of interferon alfa. Although its efficacy has been debated (1), interferon beta has been approved for the treatment of relapsing–remitting multiple sclerosis, and more recently for secondary progressive multiple sclerosis.

The general toxicity of interferon beta is very similar to that of interferon alfa (2), with no apparent differences between the two recombinant preparations with any route of injection (SEDA-20, 332) (3–6). In multiple sclerosis, fatigue and a transient flu-like syndrome responsive to paracetamol or the combination of paracetamol plus prednisone have been observed in about 60% of patients during the first weeks of treatment, and tachyphylaxis usually developed after several doses (7). Patients with chronic progressive disease are more likely to discontinue treatment because of adverse effects (8).

Clinically relevant adverse effects associated with interferon beta and their management have been lengthily reviewed (9). Interferon beta-1a and beta-1b, the two recombinant available forms of interferon beta, have not been directly compared. From the results of a randomized, crossover study in 12 healthy volunteers, a single injection of interferon beta-1a 6 MU (Rebif) was suggested to produce less frequent and less severe fever than interferon beta-1b 8 MU (Betaseron), but identical pharmacodynamic effects (10).

A flu-like illness is the most common adverse effect of interferon beta. In an open, randomized study of the effects of paracetamol 1 g or ibuprofen 400 mg before and 6 hours after interferon beta injection on interferon beta-induced flu-like symptoms in 104 patients, the two drugs were equally effective (11).

Organs and Systems

Cardiovascular

Cardiovascular adverse effects of interferon beta include isolated reports of severe Raynaud's phenomenon (SEDA-22, 374) and acute myocarditis (SEDA-21, 374).

Fatal capillary leak syndrome has been reported (12).

- A 27-year-old woman had an 8-month history of relapsing–remitting neurological symptoms and a monoclonal gammopathy. She started to take interferon beta-1b for multiple sclerosis, but had marked somnolence 30 hours after a single injection. She rapidly became unresponsiveness, and hemodynamic tests showed low central venous and pulmonary capillary wedge pressures with generalized peripheral edema, ascites, and bilateral pleural effusions. She died within 80 hours after injection from multiple organ failure. At postmortem she was found to have C1 esterase inhibitor deficiency.

In the light of the possible effects of interferon beta on cytokine release and complement activation, a cytokine-mediated reaction was discussed as the cause of the capillary leak syndrome in this case.

Respiratory

Bronchiolitis obliterans with organizing pneumonia has been reported in a patient taking interferon beta (13).

- A 49-year-old man had a progressive unproductive cough and right hemithoracic pain after 3 months of interferon beta-1a 30 micrograms/week for multiple sclerosis. A CT scan showed a right basal pulmonary infiltrate and transbronchial biopsies showed features consistent with bronchiolitis obliterans with organizing pneumonia. The lesions resolved fully on interferon beta-1a withdrawal and prednisone treatment.

Nervous system

Although direct toxic effects of natural interferon beta on the nervous system have been regarded as a possible risk of intraventricular and/or intratumoral injection (14), interferon beta is considered to be markedly less neurotoxic than interferon alfa (15).

Although headache was not specifically identified as an adverse effect of interferon beta in pivotal trials, the frequency, duration, and intensity of headache increased during the first 6 months of treatment in 65 patients (16). There was a 35% probability of aggravated headaches in patients with pre-existing headaches.

The possible deleterious effects of interferon beta-1b on increased spasticity have been examined in 19 patients with primary progressive multiple sclerosis, 19 untreated matched patients, and 10 patients treated with interferon beta-1b for relapsing–remitting multiple sclerosis (17). Patients with primary progressive multiple sclerosis had frequent (68%) and clinically relevant increased spasticity (seven required oral baclofen), usually after about 2 months of treatment, whereas only two (11%) of the untreated patients and none of the patients with relapsing–remitting multiple sclerosis had similar disabling spasticity. Seven patients had to discontinue treatment after 6 months because of spasticity, and symptoms improved over several months after withdrawal. The authors suggested that this possible adverse effect should be taken into account in clinical trials because it could mask the positive clinical effects of interferon beta-1b.

© 2006 Elsevier B.V. All rights reserved.

Neurosarcoidosis has been reported in a patient with chronic hepatitis C who was treated with interferon beta.

- A 56-year-old woman developed numbness and difficulty in swallowing and in closing her left eye several weeks after starting interferon beta for chronic hepatitis C (18). She had facial paresthesia, a left facial nerve palsy, dysphagia, and signs of radiculopathy on the left side. Serum angiotensin-converting enzyme activity was raised. She had bilateral hilar lymphadenopathy without interstitial changes and increased radiogallium uptake in hilar lymph nodes and the parotid glands. Although the cerebrospinal fluid was normal, a diagnosis of neurosarcoidosis was considered, and she recovered completely after interferon beta withdrawal and glucocorticoid therapy.

Moderate exacerbation of multiple sclerosis sometimes occurs in the first 3 months of interferon beta treatment.

- A 21-year-old man had an acute and very severe clinical relapse, with multiple disseminated demyelinating lesions and axonal injury on MRI and cerebral biopsy, after the third injection of interferon beta-1a (19).

Whether this case was due to interferon beta or resulted from spontaneous exacerbation was open to question.

Sensory systems

Retinal complications of interferon alfa in chronic viral hepatitis patients are well known, but few cases have been described with interferon beta.

- Bilateral retinopathy with similar features to those observed with interferon alfa has been reported in a 40-year-old woman treated with interferon beta-1b for multiple sclerosis (20).

In 49 patients, there was reversible otological impairment with tinnitus, mild-to-moderate hearing loss, or both in respectively 8, 16, and 20% of patients after administration of interferon alfa or interferon beta (SEDA-19, 336). These disorders tended to occur more frequently in patients on high cumulative doses, but led to withdrawal of treatment in only two patients.

Psychological, psychiatric

There have been reports of depression, suicidal ideation, and attempted suicide in patients receiving interferon beta (2,8,21). The lifetime risk of depression in patients with multiple sclerosis is high, and there has been a lively debate about whether interferon beta causes or exacerbates depression in such patients. Impressions of a possibly raised incidence of depression among patients treated with interferon beta for multiple sclerosis should be interpreted in the light of the spontaneous tendency to depressive disorders and suicidal ideation, which is encountered even in patients with untreated multiple sclerosis. Moreover, no raised incidence of these complications has been recorded in some studies (4,5). A critical review of the methodological limitations in studies that assessed mood disorders in patients on disease-modifying drugs for multiple sclerosis may help explain the widely divergent results from one study to another (22). Some results have argued against a specific role of interferon beta in the risk of depressive disorders.

A multicenter comparison of 44 and 22 micrograms of interferon beta-1a and placebo in 365 patients showed no significant differences in depression scores between the groups over a 3-year period of follow-up (23). In 106 patients with relapsing–remitting multiple sclerosis, depression status was evaluated before and after 12 months of interferon beta-1a treatment (24). According to the Beck Depression Inventory II scale, most of the patients had minimum (53%) or mild (32%) depression at baseline, and depression scores were not significantly increased after 1 year of treatment. There were no cases of suicidal ideation. In another study of 42 patients treated with interferon beta-1b, major depression at baseline was found in 21% of patients and was associated with a past history of psychiatric illness in most cases (25). Major depression was not considered as an exclusion criterion for interferon beta treatment when patients were on antidepressant therapy. There was a three-fold reduction in the prevalence of depression over the 1-year course of interferon treatment, suggesting a possible beneficial effect of treatment on mood. Finally, a single subcutaneous injection of interferon beta-1b did not alter cognitive performance and mood states in eight healthy volunteers (26).

The emotional state of 90 patients with relapsing–remitting multiple sclerosis has been carefully assessed with a battery of psychological tests at baseline and after 1 and 2 years of treatment with interferon beta-1b (27). In contrast to what was expected, and despite the lack of controls, there was significant improvement in emotional state, as shown by significant reductions in scores of anxiety and depression over time. In addition, there was no effect of low-dose oral glucocorticoids in a subgroup of 46 patients.

Depression has been quantified by telephone interview in 56 patients with relapsing multiple sclerosis 2 weeks before treatment, at the start of treatment, and after 8 weeks of treatment (28). Patients with a high depressive score 2 weeks before treatment significantly improved on starting treatment and returned to baseline within 8 weeks, whereas the depression score in non-depressed patients remained essentially unchanged. The investigators therefore suggested that patients' expectations had temporarily resulted in improvement of depression, and that increased depression during treatment is more likely to reflect pretreatment depression.

The clinical features, management, and prognosis of psychiatric symptoms in patients with chronic hepatitis C have been reviewed using data from 943 patients treated with interferon alfa (85%) or interferon beta (15%) for 24 weeks (29). Interferon-induced psychiatric symptoms were identified in 40 patients (4.2%) of those referred for psychiatric examination. They were classified in three groups according to the clinical profile: 13 cases of generalized anxiety disorder (group A), 21 cases of mood disorders with depressive features (group B), and six cases of other psychiatric disorders, including psychotic disorders with delusions/hallucinations ($n = 4$), mood disorders with manic features ($n = 1$), and delirium ($n = 1$) (group C). The time to onset of the symptoms differed significantly between the three groups: 2 weeks in group A, 5 weeks in group B, and 11 weeks in group C.

© 2006 Elsevier B.V. All rights reserved.

Women were more often affected than men. There was no difference in the incidence or nature of the disorder according to the type of interferon used. Whereas most patients who required psychotropic drugs were able to complete treatment, 10 had to discontinue interferon treatment because of severe psychiatric symptoms, five from group B and five from group C. Twelve patients still required psychiatric treatment for more than 6 months after interferon withdrawal. In addition, residual symptoms (anxiety, insomnia, and mild hypothymia) were still present at the end of the survey in seven patients. Delayed recovery was mostly observed in patients in group C and in patients treated with interferon beta.

One debatable case of visual pseudo-hallucinations occurred only, but not reproducibly, within 30–60 minutes after interferon beta-1a injection in a 37-year-old woman with disseminated encephalomyelitis (30).

Endocrine

While no evidence of thyroid dysfunction or antithyroid antibodies was found in 20 patients receiving interferon beta during 24 weeks for hematological malignancies (31), antithyroid antibodies were detected in 29% of patients with multiple sclerosis after a prospective follow-up performed at 6, 12, and 18 months of treatment (32). Biological thyroid abnormalities without antithyroid antibodies have also been found (SEDA-20, 332). Overall, thyroid disorders with antithyroid antibodies were reported in only three patients on long-term interferon beta treatment for multiple sclerosis (32,33).

Thyroid disorders before and during the first 9 months of interferon beta-1b treatment have been systematically investigated in eight patients with relapsing–remitting multiple sclerosis (34). Before treatment, one patient had positive thyroperoxidase antibodies and one was taking thyroxine for multinodular goiter. After 3 months three other patients developed sustained positive titers of thyroperoxidase antibodies, of whom one developed hypothyroidism after 9 months. These results are in accordance with a previous similar study and isolated case reports (SEDA-21, 374) (SEDA-22, 405), and suggest that interferon beta, like interferon alfa, can cause thyroid autoimmunity.

As suggested in a more comprehensive long-term follow-up study, interferon beta-induced thyroid dysfunction is often transient or has limited clinical consequences (35). Of 31 patients with multiple sclerosis regularly assessed for 30–42 months for thyroid function, 13 developed thyroid disorders during treatment with interferon beta-1b. None withdrew because of thyroid disorders. Of the eight patients with no previous thyroid disorders, one had a persistent but isolated increase in antithyroglobulin titer, six developed transient signs of hypothyroidism or hyperthyroidism during the first year of therapy, and only one had overt hypothyroidism after 12 months of treatment and required thyroxine replacement. Of the five patients with baseline signs of Hashimoto's thyroiditis, one had a transiently positive antithyroglobulin titer, one developed transient hyperthyroidism, and the three patients who had previously had or who newly developed subclinical hypothyroidism remained stable throughout the study. Overall, thyroid disorders occurred only during the first 12 months of treatment and no additional cases were detected after the first year of therapy. In the authors' opinion, pre-existing or new thyroiditis is not a contraindication to continuing interferon beta-1b treatment. Two patients took thyroxine replacement and continued to receive interferon beta-1b (36).

Metabolism

Severe hypertriglyceridemia, a well-known adverse effect of interferon beta, has been reported and fully investigated in a 39-year-old man receiving interferon beta for chronic hepatitis C (37).

Hematologic

Moderate reductions in white blood cell count (that is lymphopenia, leukopenia, and granulocytopenia) have been observed with recombinant interferon beta, and marked eosinophilia recorded in an atopic patient (SEDA-21, 374).

- A 42-year-old woman developed aplastic anemia after using interferon beta-1a for 1 year (38). There was hematological improvement after withdrawal and immunosuppressive therapy.

Reversible autoimmune hemolytic anemia (SEDA-20, 332) has also been reported.

Liver

Adverse hepatic effects of interferon beta were usually limited to a dose-dependent increase in transaminases, but transient autoimmune hepatitis has been described in one patient (39).

It has been suspected that interferon beta can accelerate hepatocellular carcinoma (40).

- A 62-year-old man with severe chronic hepatitis and positive serum anti-HCV, HBs, and HBc antibodies underwent unsuccessful treatment with interferon alfa for 3 months and then received interferon beta for 6 months with a partial response. During treatment, his alfa-fetoprotein (normal before treatment) progressively increased to seven-fold the upper limit of the reference range. There was also a slight increase in interleukin-6 serum concentration. A hepatocellular carcinoma was diagnosed 9 months later.

Liver carcinoma is an unexpected consequence of interferon beta in patients with chronic hepatitis C. However, the authors cited other published Japanese reports of hepatocellular carcinoma during or after interferon treatment. It is worth noting that interferon beta, but not interferon alfa, significantly increased serum interleukin-6 concentrations in patients with chronic hepatitis C (41), and that interleukin-6 has been suggested to promote the growth of hepatocellular carcinoma.

Fulminant liver failure has been attributed to interferon beta-1a (42), but it was subsequently confirmed that this case was confounded by concomitant exposure to nefazodone, which is hepatotoxic (43).

© 2006 Elsevier B.V. All rights reserved.

Urinary tract

Reversible hemolytic–uremic syndrome has been reported (SEDA-22, 405).

- Two women aged 24 and 44 years, whose primary diagnosis was relapsing multiple sclerosis, developed renal impairment and a thrombotic thrombocytopenic purpura-like syndrome within 2–4 weeks after starting interferon beta-1a (44). Thrombocytopenia and renal function normalized in the first patient, whereas the second patient had thrombotic angiopathy on renal biopsy and required dialysis while awaiting renal transplantation.

As interferon alfa has also been suggested to produce hemolytic–uremic syndrome with thrombotic thrombocytopenic purpura, it is tempting to speculate that either interferons or other cytokines may play a role in this syndrome.

Proteinuria, nephrotic syndrome, and various forms of renal lesions can be caused or exacerbated by interferon alfa (SED-14, 1252).

- Proteinuria with minimal–change nephrotic syndrome on renal biopsy has been attributed to interferon beta in a 64-year-old man with malignant melanoma (45). Although the proteinuria abated after withdrawal, the potential role of previous chemotherapy cannot be excluded.
- Nephrotic syndrome with segmental glomerulosclerosis has been reported in a 32-year-old woman with multiple sclerosis receiving interferon beta (46).

The clinicopathological features of proteinuria have been investigated in 23 patients with chronic hepatitis C who had new or worsened proteinuria during interferon treatment (interferon alfa 6–10 MU/day in three patients and interferon beta 6 MU/day in 20 patients (47)). Renal function and urinary findings were normal before treatment in 21 subjects. Proteinuria appeared after a mean of 12 (range 5–30) days after the start of treatment, and the mean value was 2.1 g/day. There was low selective proteinuria in 78% of the patients. Renal histopathology in 11 patients showed IgA glomerulonephritis in five, mesangial proliferative glomerulonephritis in four, membranoproliferative glomerulonephritis in one, and nephrosclerosis in one. There was only trace deposition of hepatitis C virus core antigen in three of nine patients, suggesting that hepatitis C was not the primary cause of these glomerulopathies.

Skin

Injection-site reactions are common after subcutaneous injection of interferon beta-1b, and are more frequent than with any other available interferons. In a multicenter placebo-controlled trial, 65% of patients receiving interferon beta-1b had reactions at the injection site compared with 6% in the placebo group (2). In contrast, only 5% of those who received interferon beta-1a had injection site reactions (3). The clinical features of injection site reactions to interferon beta-1b mostly consist of benign inflammatory reactions, but they can sometimes be more severe, with sclerotic dermal plaques, painful erythematous nodules, and deep cutaneous ulcers with skin necrosis (SEDA-21, 374) (48). Late severe reactions have included a case of squamous cell carcinoma at the injection site (SEDA-21, 375) and a case of panniculitis (49).

Since interferon beta-1b became available, 1443 instances of injection site reactions, 212 cases of injection site necrosis, and 10 cases of non-injection site necrosis were notified to the US Food and Drug Administration, and antibiotic therapy or surgery was required in 20–30% of patients (50). Severe necrotizing cutaneous lesions have also been attributed to subcutaneous interferon beta-1a (51).

In contrast to previous claims, even low-dose interferon beta-1b can produce severe local reactions and cutaneous necrosis, with no recurrence after interferon alfa injection and expected better tolerance to interferon beta-1a (52–55). The mechanisms of interferon beta-induced local skin reaction might involve a local vascular inflammatory process or platelet-dependent thrombosis, but positive intracutaneous tests to interferon beta have also been found (56).

There have been other isolated reports of skin lesions.

- Intravascular papillary endothelial hyperplasia with multiple lesions on both hands has been attributed to interferon beta-1b in a 50-year-old man with multiple sclerosis (57).
- Granulomatous dermatitis with disseminated pruritic papules and histological features resembling those of sarcoid granulomas has been described in a 57-year-old man who received interferon beta-1b (58). The first lesions were observed after 2 months of treatment, persisted for 2 years, and slowly improved after interferon beta withdrawal and treatment with hydroxychloroquine PUVA.
- Erythromelalgia has been attributed to interferon beta-1a in a 38-year-old woman (59). Complete recovery was obtained only after interferon withdrawal.
- In one patient, there was cutaneous mucinosis on skin biopsy, and skin lesions persisted for several months before healing spontaneously (60).

Other reports include exacerbation of quiescent psoriasis or induction of psoriatic lesions at the injection sites (SED-13, 1099) (SEDA-20, 332), and the development or exacerbation of lichen planus (SEDA-21, 375).

Musculoskeletal

Rhabdomyolysis associated with interferon beta has been reported (61).

- A 39-year-old man developed acute generalized myalgia and weakness in all four limbs 3 months after starting interferon beta-1a (22 micrograms three times a week) for relapsing–remitting multiple sclerosis. Serum creatine kinase activity peaked at about 95 times the upper limit of the reference range. Infectious and metabolic causes were ruled out and there was no argument in favor of an underlying metabolic muscle disorder. He recovered fully after interferon beta withdrawal and supportive treatment.

Although rhabdomyolysis has not been previously attributed to interferon beta, this case is in keeping with those described with interferon alfa.

- A 39-year-old man developed monoarthritis in his right elbow after receiving interferon beta for 16 days for chronic hepatitis C (62).

© 2006 Elsevier B.V. All rights reserved.

Although the arthritis resolved after withdrawal, this report casts doubt on the causal relation, as there was no recurrence on re-administration.

Reproductive system

Mild to moderate menstrual disorders were twice as frequent in patients receiving interferon beta compared with placebo (17 versus 8%). Severe persistent vaginal bleeding has been reported in a 19-year-old woman (SEDA-21, 375).

Immunologic

Hypersensitivity reactions

Hypersensitivity reactions to interferon beta are rare, with only two cases of immediate-type reactions (SEDA-20, 332) (63), and one case of urticaria associated with exacerbation of asthma (64).

- A 21-year-old woman had a severe anaphylactic-like reaction with laryngospasm and undetectable blood pressure within 10 minutes after interferon beta-1a injection (63). It is still uncertain that anaphylaxis was definitely attributable to interferon, because rechallenge and skin tests were not performed in this patient, who had tolerated the treatment for the 6 previous months.
- Urticaria developed after 9 months of treatment with interferon beta-1b in a 32-year-old woman with a previous history of penicillin allergy (64). She also had an exacerbation of asthma shortly after starting treatment. A positive intradermal test to interferon beta-1b, but not to interferon beta-1a or the diluents, suggested a specific IgE allergic reaction.

Another isolated case history has suggested that interferon beta-1b might have favored the development of a non-IgE-mediated anaphylactic reaction to previously well-tolerated injections of methylprednisolone (65).

Autoimmune disorders

In contrast to interferon alfa, the autoimmune consequences of interferon beta treatment have been poorly evaluated. Interferon beta does not appear to be associated with the appearance or increased titres of several auto-antibodies, and no clinical features of autoimmune disease were observed in patients receiving a 6-month course of interferon beta-1a or interferon beta-1b (66,67).

Subcutaneous lupus erythematosus reversible on withdrawal of treatment (SEDA-22, 405) and myasthenia gravis (SEDA-21, 375) have been described, but each only in a single patient receiving interferon beta.

The possible involvement of interferon beta in the occurrence of sarcoidosis has been noted in two patients (68,69).

Interferon beta antibodies

In multiple sclerosis, neutralizing antibodies to recombinant interferon beta occurred in 12–38% of patients treated for 2–3 years (3–5,70). There were no adverse consequences in patients who developed antibodies to interferon beta-1a (4), but there was reduced therapeutic efficacy in terms of clinical relapse rate or magnetic resonance imaging in several patients who had neutralizing antibodies to interferon beta-1b (SEDA-20, 332) (5,71).

The systemic availability of interferon beta-1b, measured by a myxovirus protein A assay, was completely inhibited in patients with neutralizing antibodies (72). The presence of increased titers of serum-binding antibodies increased the likelihood of neutralizing antibodies. From an in vitro study of nine patients who developed neutralizing antibodies against the available formulations of recombinant interferon beta (three on interferon beta-1a and six on interferon beta-1b), it appears that these antibodies systematically cross-react in both binding and biological assays (73). Although the sample size was small and lacked clinical confirmation, these results suggest that clinical benefit will not be obtained by switching to an alternative formulation when the absence of response or relapse during treatment is due to neutralizing antibodies.

The clinical significance of these antibodies is uncertain (74) and it has been proposed that decisions to discontinue treatment should be based on individual clinical responses and unequivocal demonstration of neutralizing antibodies with a reliable assay (70).

One study has shown that antibodies can spontaneously disappear in patients receiving long-term treatment. Of 24 of 51 patients who initially developed neutralizing antibodies, generally during the first year of treatment, only five still had antibodies after a mean treatment duration of 102 months (75). The mean time to antibody disappearance was 20 months.

A randomized study has been conducted in 161 patients to evaluate whether a monthly intravenous pulse of methylprednisolone reduces the frequency of neutralizing antibodies to interferon beta-1b (76). The patients who received both interferon beta and methylprednisolone had a 55% relative reduction in the development of neutralizing antibody and were significantly more likely to remain negative for neutralizing antibodies after 6 months of treatment compared with those who received interferon beta alone. The overall frequency of adverse effects and the number of withdrawals were similar between the groups, but headaches, fatigue, and myalgia were less frequent in the combination therapy group. A limitation of this study was that there was no difference in clinical outcome between the two groups.

Finally, possible differences in the immunogenic potential of recombinant and natural interferon beta preparations were found in a small study (77).

Second-Generation Effects

Teratogenicity

Data on outcomes in pregnancy after treatment with interferon beta-1a in patients with multiple sclerosis have been obtained from clinical trials (78). Of 29 pregnancies that occurred during or shortly after treatment withdrawal, 13 resulted in normal outcomes, two in premature births, one in fetal death, six in induced abortions, and seven in spontaneous abortions.

- A child whose mother had received interferon beta until 2.5 months before pregnancy had a right incomplete double renal pelvis and ureter (79). Although the authors discussed the possible role of interferon

© 2006 Elsevier B.V. All rights reserved.

therapy, the timing of exposure was obviously not suggestive of a causal relation.

Although the data are still very limited, it is advisable to reassure exposed patients and to withdraw interferon beta up to the time of delivery.

Drug Administration

Drug dosage regimens

In 188 patients with relapsing–remitting multiple sclerosis assigned to receive interferon beta-1a 30 micrograms intramuscularly once a week or interferon beta-1b 44 micrograms subcutaneously three times a week, only injection site reactions and neutralizing antibodies to interferon beta were significantly more frequent in the interferon beta-1b group (80). These differences were probably related to the subcutaneous route of administration of interferon beta-1b. In contrast, there were significant differences in favor of interferon beta-1b for clinical outcomes after 2 years of treatment.

In a comparison of two regimens of interferon beta-1a (44 micrograms Rebif subcutaneously three times a week versus 30 micrograms Avonex intramuscularly once a week) in 677 patients with relapsing–remitting multiple sclerosis, Rebif was more effective on primary clinical outcomes (patients remaining relapse-free at 24 weeks), but produced significantly more frequent injection site reactions (88 versus 28%), asymptomatic and mild liver enzyme abnormalities (18 versus 9%), mild white cell abnormalities (11 versus 5%), and neutralizing antibodies to interferon beta (25 versus 2%) (81). However, the severity of adverse events and withdrawal due to an adverse event were similar in both groups.

Drug–Drug Interactions

Theophylline

Interferon beta reduced theophylline clearance by 29% in seven patients (SED-13, 1099).

Interferon gamma

See also Interferons

General Information

Recombinant interferon gamma (interferon gamma-1b) is currently only approved as an adjunct to antibacterial therapy in chronic granulomatous disease (1), but its immunoregulatory potential has been investigated in other diseases. Clinical experience with interferon gamma is therefore limited and the most relevant information on long-term safety has been obtained from the ICGDSCG trial (2). In this study, adverse effects that were significantly more frequent with interferon gamma-1b (1.5 micrograms/kg or 50 micrograms/m^2) than with placebo included mild fever and flu-like symptoms, headache, and moderate injection site reactions. There were no adverse consequences on growth and development in children followed for a mean of 2.5 years (3,4). Several other adverse effects have been reported to the manufacturers, but causal evaluation is lacking (1).

© 2006 Elsevier B.V. All rights reserved.

Interferon gamma has been investigated in 27 patients with systemic sclerosis randomized to receive interferon gamma for 12 months. Most of them complained of symptoms consistent with a flu-like syndrome, namely headache (85%), fever (81%), and arthralgia and myalgia (70%) (5). There were adverse events (one or more per patient) leading to treatment withdrawal in four cases, including arthralgia, cardiac pain, atrioventricular block, reversible loss of hearing, and impotence; however, a causal relation with interferon gamma was not documented.

Organs and Systems

Cardiovascular

Heart rate, ventricular or supraventricular extra beats, and asymptomatic cardiac events were not significantly different during treatment compared with baseline in 20 patients receiving interferon gamma (6). Interferon gamma rarely produced cardiovascular adverse effects. Hypotension, dysrhythmias, and possible coronary spasm were sometimes observed, mostly in patients receiving high doses or with previous cardiovascular disorders (SEDA-20, 333) (SEDA-22, 405) (7,8).

Exacerbation of Raynaud's syndrome occurred in five of 20 patients with systemic sclerosis treated with interferon gamma (SEDA-20, 333).

Respiratory

Of 10 patients treated with interferon gamma-1b 200 micrograms three times a week for advanced idiopathic pulmonary fibrosis, four developed irreversible acute respiratory failure (9). All four patients had increasing dyspnea, fever, and rapidly progressive hypoxemia, and had new alveolar opacities on lung imaging. The symptoms occurred shortly after interferon gamma had been started in three patients, and after 35 injections in the fourth. Three patients died from refractory hypoxemia and the fourth underwent lung transplantation, but died a few weeks later. Pathological examination in two patients showed diffuse alveolar damage with pre-existing interstitial pneumonitis. Interferon gamma was suspected, as no other cause of abrupt pulmonary deterioration was found. Although the number of patients was small, the authors noted that before interferon beta pulmonary function tended to be worse in the four patients who developed acute respiratory failure than in the other six.

Psychological, psychiatric

Neuropsychiatric disturbances have not been consistently found in patients receiving interferon gamma, despite electroencephalographic monitoring and psychometric tests (10). However, careful examination led to the impression that interferon gamma can cause neurophysiological changes similar to those of interferon alfa (11), and data from the manufacturers also point to rare cases of nervous system adverse effects in patients treated with high-dose interferon gamma (1).

Endocrine

Interferon gamma can increase serum cortisol concentrations (12).

Metabolism

Reversible dose-dependent hypertriglyceridemia has been attributed to interferon gamma (13).

Hyperglycemia, reversible on interferon gamma withdrawal and a short course of insulin, has been reported in one patient (SEDA-22, 406).

Hematologic

Interferon gamma was supposedly the cause of asymptomatic non-immune hemolytic anemia in one patient receiving both interleukin-2 and interferon gamma (14).

Only minimal effects of interferon gamma on white blood cell counts have been observed (15).

Auto-immune thrombocytopenia occurred in a patient receiving interferon gamma (SEDA-22, 406).

Gastrointestinal

A convincing case of severe aphthous stomatitis has been reported in a patient receiving interferon gamma (SEDA-20, 333).

Urinary tract

Dose-related asymptomatic proteinuria was sometimes observed, and severe proteinuria with nephrotic syndrome has been reported once after low-dose interferon gamma (SED-13, 1100). Acute renal insufficiency is extremely rare (SEDA-20, 333) (16).

Skin

Induction of psoriatic lesions at the injection site has been observed in 10 of 42 patients treated with interferon gamma for psoriatic arthritis, while the joint symptoms were improved (17).

Single or multiple lesions of erythema nodosum leprosum occurred in 60% of patients given intradermal interferon gamma for lepromatous leprosy, and severe systemic symptoms required thalidomide treatment in two patients (18).

Severe erythroderma was observed in five of 10 patients after interferon gamma was added to ciclosporin for autologous bone marrow transplantation (19).

Immunologic

An anaphylactoid reaction and severe bronchospasm have been reported once after the first injection of interferon gamma (10).

Although interferon gamma is mainly used for its immunoregulatory properties, the possibility of clinical immune adverse consequences has been addressed in a limited number of prospective studies. In two studies involving patients with chronic hepatitis B treated for 4–6 months, most developed a new autoantibody (20,21), but none developed clinical evidence of autoimmune disease. However, other reports suggested that interferon gamma can either improve or aggravate immune or inflammatory conditions. Although no change in antinuclear antibodies

© 2006 Elsevier B.V. All rights reserved.

was reported in a trial of 54 patients with rheumatoid arthritis (22), increased or new antinuclear antibodies were observed in three of six patients with rheumatoid arthritis who received interferon gamma for 2–8 months, and two patients had clinical exacerbations of the disease (23). Isolated cases of systemic lupus erythematosus have been reported in patients receiving interferon gamma for rheumatoid arthritis (24,25). Rheumatoid or lupus-like symptoms associated with raised antinuclear antibodies titers were also noted in 17% of patients receiving interferon alfa and interferon gamma for myeloproliferative disorders, and in only 8.3% of patients treated with interferon alfa alone (26). Interferon gamma was also involved in the induction or reactivation of seronegative arthritis in patients with cutaneous psoriasis (27) and the unexpected exacerbation of multiple sclerosis in 39% of patients (28). Finally, neutralizing antibodies have exceptionally been found (SEDA-20, 333).

Interferons

See also Individual agents

General Information

The interferons, first described in 1957, include at least five natural human glycoproteins (alfa, beta, gamma, omega, and tau). Only the first three types are currently used, and they differ both structurally and antigenically. Interferon alfa is produced by macrophages, B cells, and null lymphocytes, interferon beta by fibroblasts, epithelial cells, and macrophages, and interferon gamma from T lymphocytes and macrophages after antigenic or mitogenic stimulation. The interferons share 30–40% of sequence homology and have antiviral and antiproliferative actions. Interferon gamma, produced by activated T cells and natural killer cells, is recognized by a different receptor and acts primarily as an immunoregulatory cytokine.

Uses

The uses of interferons are listed in Table 1.

Two authoritative reviews have outlined the therapeutic potential of interferons (1,2). A wide range of viral diseases or cancers are other candidates for interferon therapy (3–5).

Mechanisms of action

On binding to surface receptors, interferon alfa results in activation of cytoplasmic enzymes affecting messenger RNA translation and protein synthesis (6). The antiviral state takes hours to develop but can persist for days. Besides broad antiviral activity, interferons are of major importance in regulating immunological functions.

General adverse effects

The adverse effects of interferon are multifarious and the natural products seem to be less toxic than the pure synthetic compounds. Influenza-like symptoms with fever, chills, fatigue, myalgia, arthralgia, nausea, and lethargy, starting within 1 week after the start of treatment and lasting 1–7 days, seem to be very common (7,8). Adverse effects also include neurotoxicity (paresthesia, polyneuropathy), hepatic toxicity, renal toxicity, and an increase in eyelash growth (9–13). Neutralizing antibodies can lead to resistance in patients with hairy cell leukemia and chronic myeloid leukemia (14,15). The route of administration influences the provocation of an antibody response, and recombinant interferon beta is more likely to be immunogenic when given subcutaneously or intramuscularly than when given intravenously (16). Raynaud's phenomenon has been described after treatment with interferon alfa (17), and exacerbation of multiple sclerosis has been observed after treatment with interferon gamma.

The most common adverse effects reported in two large multicenter studies were fever (60%), leukopenia (43%), increased serum aspartate transaminase activity (30%), anorexia (30%), thrombocytopenia (25%), fatigue (21%), nausea, and vomiting (17%) (18,19). Compared with subcutaneous administration, intravenous interferon alfa is associated with similar adverse effects of greater severity and frequency (20,21).

Table 1 Names of different types of interferons and their indications

Generic name and trade name	Indications
Interferon alfa	Malignant diseases: hairy cell leukemia, chronic myelogenous leukemia, cutaneous T cell lymphoma, follicular lymphoma, multiple myeloma, Kaposi's sarcoma, diffuse melanoma, renal cell carcinoma, carcinoid tumors Viral diseases: condylomata acuminata, chronic active hepatitis B and C
Human natural leukocyte interferon alfa (IFN alfa-n3; Alferon)	
Lymphoblastoid interferon alfa (IFN alfa-n1; Welferon)	
Recombinant interferon alfa-2a (rIFN alfa-2a; Roferon)	
Recombinant interferon alfa-2b (rIFN alfa-2b; Intron A)	
Recombinant interferon alfa-2c (rIFN alfa,2c; Berofor)	
Interferon beta	Multiple sclerosis
Natural fibroblast (Fiblaferon)	
Recombinant interferon beta (rIFN beta; Avonex)	
Recombinant interferon beta-1b (rIFN beta-1b; Betaseron)	
Interferon gamma	Chronic granulomatous disease
Recombinant interferon gamma-1b (rIFN gamma-1b; Actimmune)

Interleukin-1

General Information

Interleukin-1-alfa and interleukin-1-beta are produced by two distinct genes with only 25% homology, but they act through the same receptor and share similar in vitro biological properties. Interleukin-1 on its own has modest antitumor activity and limited hemopoietic effects. It also acts synergistically with other colony-stimulating factors (for example GM-CSF, G-CSF, interleukin-3, or interleukin-6) to promote colony formation and stimulate hemopoietic recovery in patients undergoing autologous bone marrow transplantation or receiving cytotoxic anticancer treatment (1).

General adverse effects

Both forms of interleukin-1 have been investigated in humans, and they produce a wide and very similar spectrum of adverse effects (SED-13, 1101) (2). Whatever the dose, fever and chills are universal but only occasionally treatment-limiting. Tachyphylaxis can develop during prolonged administration. Other frequent but moderate adverse effects include transient fatigue, myalgia, arthralgia, dose-dependent headache, nausea, vomiting, diarrhea, and abdominal pain. Injection site reactions included local phlebitis, while subcutaneous injection of interleukin-1-beta can cause local pain and erythema. Interleukin-1-alfa can cause transient and moderate increases in bilirubin, aspartate transaminase, and serum creatinine concentrations.

Organs and Systems

Cardiovascular

The most significant adverse effect of both forms of interleukin-1 is dose-limiting hypotension resulting from a capillary leak phenomenon with clinical features of septic shock (2). Although mild weight gain, dyspnea, and pulmonary infiltrates can occur, severe capillary leak syndrome is usually not observed. Shortness of breath requiring oxygen and benign supraventricular dysrhythmias were sometimes noted. The maximum tolerated dose of interleukin-1 with pressors is therefore 0.3 micrograms/kg/day. The most probable mechanism underlying these complications is an interleukin-1-induced increase in nitric oxide production by vascular smooth muscle.

Nervous system

A few patients given interleukin-1 complain of somnolence, agitation, delusional ideation, photophobia or

© 2006 Elsevier B.V. All rights reserved.

subjective blurred vision, but at high doses some patients experienced a greater degree of central nervous system toxicity, with complaints of confusion, severe somnolence and seizures (3).

Endocrine

Various endocrinological effects have been observed, but without clinically apparent endocrinopathies (SEDA-20, 333).

Metabolism

Interleukin-1-beta has been associated with transient hypoglycemia (4).

Mouth and teeth

Interleukin-1-alfa can cause mucositis and xerostomia (3) and can increase the severity of chemotherapy-induced oral mucositis and erythema (5).

Interleukin-3

General Information

Interleukin-3 is produced by activated T lymphocytes and stimulates the proliferation and differentiation of the granulocyte, macrophage, eosinophil, basophil, erythroid, megakaryocyte, and mast cell lineages (1).

Observational studies

Subcutaneous recombinant interleukin-3 has been investigated in patients with chemotherapy-induced myelotoxicity, in the setting of autologous bone marrow transplantation or peripheral stem cell harvesting, or in patients with myelodysplastic syndrome, aplastic anemia, and Diamond–Blackfan anemia (1,2). Interleukin-3 given alone has limited clinical effects, but an enhanced hemopoietic response has been obtained with a genetically engineered GM-CSF/interleukin-3 fusion protein, PIXY321 (SEDA-21, 376) (3).

The specific toxicity of subcutaneous recombinant human interleukin-3 derived from *Escherichia coli* has been addressed in a 4-day study performed in healthy volunteers (4). All had mild-to-moderate dose-independent symptoms; flu-like symptoms, including fever, chills, headache, conjunctival congestion, myalgia, and diffuse aching, were the most frequent. Minor erythematous reactions at the injection site were also consistently described, and one patient had histological features of an allergic vasculitis resembling that reported with GM-CSF (SEDA-20, 335). Mild-to-severe skin rashes or urticaria were also sometimes observed, and there were bullae with hemorrhagic necrosis of the skin in one patient (5). In preliminary clinical trials, malaise, eye pain, nasal congestion, weakness or lethargy, tachycardia, and gastrointestinal disorders occurred in under 16% of patients (6). None of these effects was clearly related to dose, and withdrawal of treatment was not required. A similar safety profile was reported in patients who subsequently developed tachyphylaxis, and the adverse effect profile of yeast or interleukin-3 derived from *E. coli* did not appear to be different (6). Overall, the rate of withdrawal of treatment because of adverse effects was 17–50% in patients receiving 10 micrograms/kg/day. Constitutional symptoms, generalized skin reactions, and facial edema were the most frequent dose-limiting adverse events. In autologous bone marrow transplantation, the maximum tolerated dose was only 2 micrograms/kg/day. Interleukin-3-associated fever is supposedly the result of a dose-dependent increase in interleukin-6 and acute phase protein production.

Adverse effects related to interleukin-3 were observed in a comparison of G-CSF alone, GM-CSF alone, and sequential interleukin-3 and GM-CSF in 48 patients with cancer (16 in each group) receiving high-dose cyclophosphamide (7). In particular, fever above 38.5°C, skin rash, and headaches were more frequent during interleukin-3 administration. As a result, 90% of patients receiving interleukin-3 required pharmacological treatment for adverse effects.

Placebo-controlled studies

The potential hemopoietic benefits of postchemotherapy interleukin-3 are limited. In a phase III trial in 185 ovarian cancer patients treated with carboplatin and cyclophosphamide, premature withdrawal was significantly more frequent in patients randomized to received recombinant interleukin-3 (5 micrograms/kg from day 3 to day 12) than in the placebo group (8). The most frequent adverse effects were allergic reactions (50 versus 23%), which required interleukin-3 withdrawal in 21 patients compared with one in the placebo group, and headache (46 versus 19%). In this setting, interleukin-3 stimulated hemopoiesis, but did not reduce platelet transfusions or increase adherence to the chemotherapeutic regimen.

The benefit of interleukin-3 in promoting hemopoietic reconstitution after autologous bone marrow

© 2006 Elsevier B.V. All rights reserved.

transplantation has been investigated in 198 patients with malignant lymphoma who received either interleukin-3 (10 micrograms/kg for 4 weeks, 130 patients) or placebo (68 patients) (9). There was no significant advantage of interleukin-3 over placebo in regard to the number of platelet transfusions before engraftment, the time to platelet engraftment, or the incidence of hemorrhagic complications. This confirms that interleukin-3 alone has limited clinical effects. In contrast, significantly more patients who received interleukin-3 had to discontinue treatment because of adverse events (26 versus 7%). Adverse events that were significantly more frequent with interleukin-3 than with placebo included mucositis (69 versus 44%), headache (38 versus 13%), and rash (25 versus 12%). It is not yet known whether the initial route of administration (continuous intravenous infusion for 7 days followed by subcutaneous administration for 21 days) might account for these findings.

General adverse effects

Constitutional symptoms, generalized skin reactions, and facial edema are the most frequent. Although they are not easily attributable to interleukin-3, other significant adverse events noted during treatment have included exacerbation of arthralgia in a seronegative patient (5) and transient thrombocytopenia in patients with myelodysplastic syndrome or aplastic anemia (10). Signs of meningism with neck rigidity were sometimes found (10).

As with G-CSF and GM-CSF, the presence of interleukin-3 receptors on leukemia cells suggests a theoretical risk of disease aggravation. However, accelerated tumor growth has not been noted in patients with non-hemopoietic tumors or newly diagnosed non-Hodgkin's lymphoma (6). Overall, some types of disease progression were observed in 11 of 86 patients with myelodysplastic syndrome, but no clear relation between interleukin-3 and disease acceleration can be assessed at the moment.

PIXY321

The clinical and hematological effects of PIXY321, a genetically engineered GM-CSF/interleukin-3 fusion protein, have been evaluated in 71 women with breast cancer (11). In addition to chemotherapy (four cycles of fluorouracil, doxorubicin, and cyclophosphamide), the patients received either PIXY321 or placebo from days 3–15. Although the incidence and/or duration of chemotherapy-induced severe neutropenia was significantly reduced by PIXY321, there were more frequent systemic adverse effects (fever, chills, abdominal pain, arthralgia, and injection-site reactions) and more severe thrombocytopenia during cycles 3 and 4. Based on these results and the lack of a demonstrable advantage of PIXY321 over GM-CSF (12), the development of PIXY321 as an adjuvant treatment in cancer was halted. In one study only insomnia and rash were more common in patients treated with subcutaneous PIXY321 compared with intravenous GM-CSF alone after autologous bone marrow transplantation (13).

Organs and Systems

Cardiovascular

Hypotension, exacerbation or new onset of atrial fibrillation, and dyspnea were infrequently observed in clinical trials (6). Although weight gain and peripheral edema can develop, only one fatal case, compatible with a capillary vascular leak syndrome, has been reported (SEDA-20, 335).

Thrombophlebitis was recorded in 45% of patients treated for advanced ovarian cancer who also received intravenous interleukin-3 (14), and deep venous thromboses were reported in children treated with maintenance interleukin-3 for Diamond–Blackfan anemia (15). In addition, one smoking breast-cancer patient developed severe hypotension and cerebellar and superior mesenteric thrombosis after subcutaneous interleukin-3 administration (SEDA-19, 340). Collectively, these case reports suggest that interleukin-3 may contribute to the development of thrombosis, but a possible increased risk of thrombosis with interleukin-3 remains to be demonstrated.

Hematologic

Interleukin-3 caused a transient rise in circulating atypical B lymphocytes, with enlargement of the spleen and lymph nodes in two patients with large-cell lymphoma and the development of a clonally-related transient plasmocytosis in one patient with relapsing follicular non-Hodgkin's lymphoma (SED-13, 1109) (10,16).

There has been one case of bone marrow histiocytosis in a patient treated with interleukin-3 for refractory aplastic anemia (SED-13, 1109).

Immunologic

An anaphylactoid reaction to recombinant human interleukin-3 (rHuinterleukin-3) has been described (17).

- A 66-year-old man with radiation-induced aplastic anemia and myelodysplastic features failed to respond to multiple therapeutic regimens. A trial of recombinant human interleukin-3 was begun, but he had transient shortness of breath and hypotension after the first subcutaneous injection. On the next day, 2 hours after the second dose, he had restlessness, dyspnea, spasticity, wheezing, cyanosis, hyperthermia, tachycardia, and hypotension (70/50 mmHg). Full recovery was obtained with fluids, adrenaline, promethazine, and glucocorticoids.

Histamine release from circulating basophils was the suggested mechanism.

Drug–Drug Interactions

Angiotensin-converting enzyme (ACE) inhibitors

Severe hypotension within hours after interleukin-3 injection has been observed in three of 26 patients treated with angiotensin-converting enzyme inhibitors (SEDA-19, 340). Indirect synergy between ACE and interleukin-3 on nitric oxide production was suggested to be involved.

© 2006 Elsevier B.V. All rights reserved.

Carboplatin

In patients with ovarian cancer, the combination of interleukin-3 with high-dose carboplatin was poorly tolerated; severe fever, malaise, protracted nausea, vomiting, severe hypotension, and nephrotoxicity required withdrawal of interleukin-3 in 60% of patients when interleukin-3 was given only 24 hours after high-dose carboplatin (18).

GM-CSF

Combined sequential administration of interleukin-3 plus GM-CSF in patients treated for myelodysplastic syndrome suggested unacceptable toxicity (19).

Interleukin-4

General Information

Interleukin-4 is a pleiotropic cytokine, mostly produced by activated T cells, which acts on the proliferation and differentiation of B and T lymphocytes and enhances the function of natural killer cells, eosinophils, and mast cells (1). It is being investigated for potential antitumoral and hemopoietic actions.

General adverse effects

Moderate fever with flu-like symptoms, arthralgias, fatigue, anorexia, nausea, vomiting, headache, and transient hypotension were frequent at all doses and by all routes of administration, but were more severe and prolonged at high doses (2). Periorbital, facial, and peripheral edema were also noted. Frequent discomfort caused by severe and resistant nasal congestion, supposedly due to edema and vascular engorgement from histamine stimulation,

© 2006 Elsevier B.V. All rights reserved.

was sometimes dose-limiting. Mild asymptomatic increases in liver enzymes and minimal changes in serum creatinine concentrations can occur. No significant effects on serum hormone (ACTH, cortisol, thyrotropin, thyroxine, prolactin) or lipid concentrations have been noted (SEDA-20, 336). Other adverse events, as yet not clearly related to interleukin-4, included reversible Coomb's-positive hemolytic anemia, transient partial blindness, photophobia, and visual hallucinations. At the moment, only one report has suggested that long-term interleukin-4 may have stimulated the development of multiple myeloma (SEDA-21, 376).

Of 49 patients with advanced renal cell carcinoma treated with subcutaneous interleukin-4 (4 micrograms/kg/day for 28 days followed by a 7-day rest), nine had 13 episodes of grade 4 toxicity (3). Severe unexpected toxic effects included three cases of Bell's palsy and one episode of severe hypoglycemia in a previously well-controlled patient with diabetes mellitus.

Organs and Systems

Cardiovascular

The vascular leak syndrome was observed at a dose of 15 micrograms/kg by bolus or continuous intravenous administration, but a moderate capillary leak syndrome was also noted at lower subcutaneous doses (4).

Cardiac toxicity, consistent with myocardial infarction, was observed in three of seven patients with metastatic cancer receiving intravenous bolus interleukin-4 to a daily total of 800 micrograms/m^2 (5). A unique pattern of myocarditis with predominant polymorphonuclear, eosinophil, and mast cell infiltration was the possible cause of death in one case and suggested an allergic inflammatory myocardial process.

Endocrine

Permanent hypothyroidism associated with vitiligo was reported in a woman treated with interleukin-4 for metastatic malignant melanoma (SEDA-20, 336).

Hematologic

Unexpected severe neutropenia has been found in 33% of patients with AIDS-related Kaposi's sarcoma given interleukin-4 (SEDA-21, 376).

Isolated coagulation abnormalities with minor prolongation of prothrombin time were consistently observed, in patients given interleukin-4, particularly those with pre-existing liver disease (2).

Gastrointestinal

Significant gastrointestinal toxicity was described in patients who received interleukin-4 alone or in combination with interleukin-2 for advanced malignancy (6).

Antral or prepyloric ulcers and erosive gastritis were identified after 12 of 84 courses of interleukin-4 in 72 patients, of whom three suffered from life-threatening bleeding. There were no treatment-related deaths and no clear correlation with the dose of interleukin-4. A possible protective effect of interleukin-2 on the gastrointestinal mucosa was suggested. Although all but one of these patients also took indometacin, there was no recurrence of symptoms in several patients who developed ulcers during interleukin-4 treatment and further received interleukin-2 and indometacin. The ability of interleukin-4 to affect prostaglandin E_2 synthesis strongly suggests that interleukin-4 alone can contribute to the development of digestive mucosal injury.

Skin

Rare dermatological adverse effects have been noticed and consisted of a papular eruption. One patient had a pruritic papulovesicular eruption, which recurred after interleukin-4 re-administration and was compatible with transient acantholytic dermatosis (7).

Vitiligo associated with permanent hypothyroidism was reported in a woman treated with interleukin-4 for metastatic malignant melanoma (SEDA-20, 336).

Interleukin-6

General Information

Interleukin-6 is produced by T cells, monocytes, fibroblasts, endothelial cells, and keratinocytes, and regulates pleiotropic biological functions. Recombinant interleukin-6 is being evaluated for thrombopoietic and antitumoral properties (1).

General adverse effects

During clinical trials, intravenous and subcutaneous interleukin-6 produced universal moderate fever and flu-like symptoms (2). Mild nausea, weight loss, and taste

© 2006 Elsevier B.V. All rights reserved.

disorders sometimes occurred, and central nervous system symptoms (somnolence, restlessness, confusion, hallucinations) were dose-limiting in patients with advanced malignant cancer (SEDA-21, 376), but no clear dose-related effects have been demonstrated. Moderate injection site reactions usually followed subcutaneous interleukin-6 administration, and a diffuse maculopapular erythema occurred in one patient. In contrast to several other cytokines, interleukin-6 has not been associated with signs of vascular leak syndrome or hypotension. Neutralizing antibodies to interleukin-6 were rarely evidenced (SEDA-20, 336).

Whereas no major signs of toxicity appeared at doses up to 20 micrograms/kg/day in patients with malignant disease, the maximum tolerated dose of interleukin-6 was 5 micrograms/kg/day in patients with myelodysplasia or thrombocytopenia, and only 1 microgram/kg/day in autologous bone marrow transplant patients who developed hyperbilirubinemia and severe maculopapular rash with microvesicular steatosis as treatment-limiting adverse effects (2). Combination of interleukin-6 with G-CSF or GM-CSF was not associated with significant synergism or new forms of toxicity.

Biochemical effects of interleukin-6 included asymptomatic increases in liver function tests, transient proteinuria, and increased serum creatinine concentrations. Reductions in serum albumin and cholesterol concentrations, and increases in blood glucose concentrations were dose-related (SEDA-21, 376) (2).

Organs and Systems

Sensory systems

One isolated report documented reduced visual acuity and bilateral uveitis in a patient receiving a 2-week regimen of interleukin-3 and interleukin-6 for secondary myelodysplastic syndrome (SEDA-19, 341).

Endocrine

Interleukin-6 reduced serum thyrotropin and thyroid hormone concentrations and increased LH concentrations (SEDA-20, 336).

Hematologic

Dose-dependent and reversible normochromic normocytic anemia was consistently noted within several days after starting interleukin-6, and required blood transfusion at the highest dose (3). Hemodilution was considered as the primary mechanism.

Skin

Diffuse maculopapular erythema with histological features consisting of epidermal spongiosis and interstitial mixed inflammatory cell infiltrate was reported in one patient, and a causal role was suggested by the recurrence of symptoms after interleukin-6 re-administration (SEDA-19, 341).

Long-Term Effects

Tumorigenicity

The possibility of interleukin-6 might accelerate tumor growth was suggested by findings in two patients with solid tumors (SEDA-19, 341).

Interleukin-10

General Information

Interleukin-10 is a potent anti-inflammatory and immunosuppressive cytokine with beneficial effects expected in a wide range of diseases (1). In healthy volunteers, its adverse effect profile mostly consisted of flu-like symptoms at the highest dose (SEDA-20, 336). First-degree atrioventricular block was noted in a few patients. Due to immunomodulating properties, potential adverse immunological effects, namely an increased risk of infections, autoimmune disorders, or B cell lymphoproliferative disorders, can be anticipated.

Organs and Systems

Hematologic

The mechanisms of mild thrombocytopenia after multiple doses of interleukin-10 have been extensively explored in 12 healthy volunteers, of whom four received placebo and eight received subcutaneous interleukin-10 (8 micrograms/kg/day for 10 days) (2). Compared with placebo, there was a 40% fall in platelet count during interleukin-10 treatment and prompt normalization after interleukin-10 withdrawal. There were also moderate changes in hemoglobin concentration. Bone marrow function, platelet production, and serum thrombopoietin concentrations suggested that a reduction in bone marrow platelet production was the primary cause.

10-induced thrombocytopenia in normal healthy adult volunteers: evidence for decreased platelet production. Br J Haematol 2000;111(1):104–11.

Interleukin-12

General Information

Interleukin-12, an immunomodulatory cytokine, has potential effects in several cancer and infectious diseases. Although interleukin-12 was considered to be reasonably safe in early clinical trials, severe and sometimes fatal multiple organ adverse effects have been described in subsequent studies (SEDA-20, 336). This unexpected profile of toxicity was later shown to result from schedule-dependent toxicity, which occurred only in patients with cancer who received multiple high doses without an initial single dose of interleukin-12 (1). This severe toxicity has since been avoided.

Organs and Systems

Hematologic

Single cases of agranulocytosis and Coombs' negative hemolytic anemia have been attributed to twice-weekly interleukin-12 in 28 patients with renal cell cancer or melanoma (2). The patients responded only to cyclophosphamide and/or glucocorticoids, and the causative role of interleukin-12 was therefore inconclusive.

Immunologic

Interleukin-12 has been involved in the pathogenesis of several autoimmune disorders.

- A 53-year-old woman with previously mild and stable rheumatoid disease had an exacerbation of severe rheumatoid arthritis after each course of interleukin-12 for cervical carcinoma (3).

Iodinated contrast media

General Information

The radio-opacity of X-ray contrast media depends on the fact that they contain substances that have high atomic numbers, which absorb X-rays. Bismuth, now largely obsolete, has an atomic number of 83, barium 56. Since the soluble salts of barium are poisonous, the insoluble salt, barium sulfate, is used as a suspension. Soluble contrast media are based on iodine, which has an atomic number of 53. This means that in principle they can have the various adverse effects of other iodine-containing compounds.

Iodinated water-soluble contrast agents are of four types:

- High-osmolar ionic monomers (for example amidotrizoate (diatrizoate) iodamide, iotalamate, ioxitalamate, metrizoate)
- Low-osmolar ionic dimers (for example ioxaglate)
- Low-osmolar non-ionic monomers (for example iobitridol, iohexol, iomeprol, iopamidol, iopromide, ioversol)
- Iso-osmolar non-ionic dimer (for example iodixonal, iotrolan).

These are mainly used intravascularly, but can also be injected into body cavities, including the bile ducts and pancreatic ducts, which can be outlined during endoscopic retrograde cholangiopancreatography (ERCP), particularly the low-osmolar contrast agents. The high-osmolar water-soluble contrast agent Gastrografin (sodium amidotrizoate and meglumine amidotrizoate in a ratio of 10:66) is suitable only for oral or rectal administration. Oil-based iodinated contrast agents, such as Lipiodol, are also available and can be used to outline the ducts of the salivary glands and the lacrimal ducts. Currently, the low-osmolar contrast agents are routinely used for these applications.

The high-osmolar ionic monomers, which are sodium and meglumine salts of tri-iodinated benzoic acid, have been available since the 1950s. They are very hyperosmolar, having 5–8 times the osmolality of the blood. The hyperosmolality greatly increases the hemodynamic and toxic effects of these agents. In the 1970s, low-osmolar contrast media became available. This was achieved through converting tri-iodinated benzoic acid into a non-ionic molecule by replacing the COOH radical with an amide ($CONH_2$). This molecule in solution will not dissociate, allowing the availability of three atoms of iodine with only one active particle (a ratio of 3:1). Another development was the introduction of the monoacid dimer, in which two tri-iodinated benzoic rings are linked with a bridge and the COOH of one ring is converted into an amide. This gives the same iodine:particle ratio of 3:1 in solution, since there are six iodine atoms and two active particles in one molecule. The osmolality of the ionic dimeric contrast media is almost the same as that of the non-ionic monomeric agents and is about twice that of blood at iodine concentration of 300 mg/ml. In the late 1980s the non-ionic dimeric contrast media were synthesized by attaching two non-ionic, tri-iodinated benzoic rings. These dimers give iodine:particle ratio of 6:1, since

there are six iodine atoms and only one active particle in the molecule. The osmolality of the non-ionic dimers (iotrolan and iodixanol) at an iodine concentration of 300 mg/ml is equal to that of the blood. Iodixanol is the only non-ionic dimer currently in intravascular use (SEDA-21, 475) (SEDA-22, 502) (1–4).

Uses

For many types of investigation, contrast media have to be given intravascularly. Intravascular iodine-based contrast media are used for angiography and computed tomography, but since they are excreted mainly by the kidney, they are also used for excretory urography. Although the low-osmolar contrast media are safer than the high-osmolar contrast media, their use has not been universal because of high costs. However, the prices of low-osmolar contrast media are dropping, and in many countries high-osmolar ionic contrast media are no longer used intravascularly (SEDA-18, 441) (SEDA-22, 499). The media now used to outline cavities are mainly water-soluble and are preferred to water-insoluble or oily contrast agents.

- Cholecystography requires a contrast medium that is excreted primarily by the liver; iodipamide and ioglycamide have been long preferred, but the newer iodoxamate and iotroxate are more efficiently excreted by this route. However, cholecystography has become obsolete, with the availability of high quality real-time ultrasound scanning.
- In the gastrointestinal tract the insoluble barium sulfate is still most commonly used, but water-soluble iodinated media can be used in special circumstances.
- For retrograde urography, many different water-soluble iodinated media can be used, provided they are diluted sufficiently.
- For arthrography, ductography, and sinography, many different water-soluble iodinated media can be used, provided they are diluted sufficiently.
- For lymphography and ductography, iodinated oil is used. Iodinated water-soluble non-ionic dimeric media have also been used.
- Hysterosalpingography is now performed at most centers with low-osmolar water-soluble media.
- Bronchography was performed in the past with an aqueous or oily suspension, but these formulations have been withdrawn; the water-soluble non-ionic dimer iotrolan has been successfully used for fiberoptic bronchography.
- Myelography represents a special challenge, because of the sensitivity of nervous tissues to direct toxic effects; for this purpose the ionic media (which are neurotoxic) and the oily medium iophendylate have been superseded by non-ionic media, including the iso-osmolar non-ionic dimers (iotrolan and iodixanol), which are isotonic with cerebrospinal fluid and well tolerated by nervous tissues. However, myelography is rarely used in modern diagnostic imaging departments and has been widely replaced by magnetic resonance imaging (MRI).

Comparative studies

The authors of a large review of the comparative tolerability of contrast media used for coronary intervention recommended the use of ionic or non-ionic dimers over non-ionic low-osmolar monomeric agents, because of the antithrombotic advantage of the dimers (5). However, the recommendation to use ionic low-osmolar contrast media in preference to non-ionic contrast media is not widely endorsed, since the latter are less toxic than ionic media. In another study, there was no difference in the incidence of contrast media reactions between the non-ionic monomeric contrast agents iopamidol and iopromide, and both agents were well tolerated following left ventricle and coronary angiography (6). The authors concluded that both agents are perfectly acceptable for cardiac angiography.

Iodixanol 320 ($n = 307$) has been compared with the low-osmolar ionic dimer ioxaglate 320 ($n = 311$) in patients undergoing percutaneous coronary intervention (7). The two groups were well matched for basic demographic data and comparable in relation to cardiovascular state and other medical conditions. Fifteen patients (4.9%) in the iodixanol group and 27 patients (8.7%) in the ioxaglate group had reactions within 24 hours of the procedure; they were likely to have been due to the contrast medium, and included nausea, vomiting, flushing, facial edema, urticaria, and wheezing. There was no significant difference in the outcome of the procedure between the two groups. The authors suggested that in view of the higher incidence of adverse effects with ioxaglate, its automatic selection for percutaneous coronary intervention should be reviewed.

General adverse effects

The main types of collateral adverse effects of contrast media are listed in Table 1.

Low-osmolar contrast media are better tolerated than high-osmolar ionic media in cardiac and coronary angiography. However, it has been suggested that ionic contrast media may be advantageous during percutaneous transluminal coronary angioplasty, as they have some anticoagulant effect, which non-ionic media do not (SEDA-22, 501). The effects of the iso-osmolar non-ionic dimer iodixanol (iodine 320 mg/ml) and the low-osmolar ionic dimer ioxaglate (iodine 320 mg/ml) have been compared in 1411

Table 1 Adverse effects of soluble contrast media

Minor effects	Intermediate effects	Severe effects
Nausea, retching, and slight vomiting	Faintness	Collapse
Feeling of heat	Severe vomiting	Loss of consciousness
Limited urticaria	Extensive urticaria	Bronchospasm
Mild pallor or sweating	Edema of face or glottis	Edema of the glottis
Itchy rashes	Bronchospasm	Pulmonary edema
Arm pain	Dyspnea	Cardiac arrest
	Rigors	Myocardial infarction syndrome
	Chest pain	Cardiac dysrhythmias
	Abdominal pain	
	Headache	
	Tetany

patients, mean age 62 years, undergoing percutaneous transluminal coronary angioplasty in a multicenter, randomized, double-blind study (8). The groups were comparable in relation to the prevalence of cardiac and other medical conditions, including diabetes, obesity, and smoking habits. All the patients received heparin and all but four received an antiplatelet agent (100 mg or more of aspirin and/or ticlopidine). There was no significant difference between the two groups—the incidence of major adverse cardiac events was 4.7% (192 patients) after iodixanol and 3.9% (197 patients) after ioxaglate. However, hypersensitivity reactions and adverse drug reactions were significantly less common with iodixanol ($n = 5$) than with ioxaglate ($n = 18$). The reactions to iodixanol were mainly rashes and urticaria-like reactions. The reactions to ioxaglate were anaphylaxis ($n = 1$), urticaria ($n = 12$), coughing and throat tightness ($n = 12$), and in one patient rigors, fever, vomiting, and flushing.

The diagnostic accuracy of bronchography with iotrolan is similar to that reported with Dionosil (9). No serious complications or significant change in spirometry measurements and oxygen saturation are observed with bronchography using iotrolan. The main adverse effects are nausea and vomiting. Pyrexia, pulmonary infection, and urticaria-like reactions are rare (9,10).

Serious delayed reactions have been reported from Germany and Japan in 26 cases; the features included shock, hypotension, angioedema, and dyspnea (11).

Time-course

Most reactions occur within 5–10 minutes of injection, but they can be delayed for up to 7 days; it is advisable for patients to be under close observation for about 20 minutes after injection. In 449 fatal reactions to ionic media, deaths occurred in all age groups, but the incidence peaked in the age group of 50–70 years; 80% of the reactions began in the first 5 minutes after injection, and the other 20% began at 5–15 minutes after injection (12). Late but mild reactions can also occur, notably those that are due to "iodism" (SEDA-11, 411).

Delayed reactions to both ionic and non-ionic media have an incidence of 0.4–18%. Most reactions are not serious or life threatening; they include a flu-like illness, parotitis, nausea and vomiting, abdominal pain, headache, and allergy-like reactions with skin manifestations. The incidence of delayed skin reactions to iso-osmolar non-ionic dimers is twice as high as the incidence of delayed skin reactions to low-osmolar non-ionic monomers, and twice as high in Japan and USA as in Europe. The pathophysiology of these delayed reactions is unknown. In response to reports of delayed skin reactions to the non-ionic dimer iotrolan, particularly in Japan, the manufacturer (Schering, Berlin) decided to withdraw it from the market as an intravascular agent (SEDA-21, 482).

The incidence of delayed adverse reactions has been investigated in 2001 patients who underwent cardiac angiography with either iopamidol 340 (a non-ionic monomer; $n = 738$, ages 22–88 years, mean dose 1.79 ml/kg), ioxaglate 320 (an ionic dimer; $n = 644$, ages 28–86 years, mean dose 1.8 ml/kg) or iodixanol 320 (a non-ionic dimer; $n = 619$, ages 26–85 years, mean dose 1.74 ml/kg) (13). The authors considered reactions that occurred within 24 hours as early reactions and those that occurred after 24 hours but within 1 week of the cardiac catheterization as late reactions. The incidences of early reactions were 22% with ioxaglate, 8.8% with iopamidol, and 7.6% with iodixanol. The commonest early reactions were urticaria and nausea and vomiting, the respective incidences being 6.8 and 4.0% with ioxaglate, 0.8 and 1.0% with iopamidol, and 0.5 and 1.1% with iodixanol. A few patients developed sudden hypotension, 0.5% with iopamidol, 1.4% with ioxaglate, and 0.3% with iodixanol. Cardiac arrest occurred in two patients with iopamidol, three with ioxaglate, and one with iodixanol. The frequencies of delayed skin reactions, which were generally benign, were 12% with iodixanol, 4.3% with ioxaglate, and 4.2% with iopamidol. The authors concluded that selection of a contrast agent for diagnostic cardiac catheterization should take account of adverse effects. Iodixanol was the best-tolerated agent in the early phase of the study, but it was associated with a higher incidence of delayed skin reactions. The authors did not consider that the skin reactions represented a contraindication to iodixanol, although patients should be advised of this particular adverse effect. Furthermore, no contrast agent was free from these effects. Ioxaglate was the least well-tolerated agent in the early phase, with a much greater chance of causing nausea/vomiting and allergic reactions.

Incidence

In various earlier surveys of conventional ionic contrast media, the incidence of minor reactions was one in 13–30 cases, the incidence of intermediate reactions one in 57–130 cases, and the incidence of severe reactions one in 1000–4000 cases. The figures for the non-ionic media are much more favorable. In 1990, the Japanese Committee on the Safety of Contrast Media surveyed 169 284 patients who had received ionic media and 168 363 who had received non-ionic contrast media (14). In patients with a previous history of reactions to contrast media, the incidence of severe reactions was 0.73% with ionic media and only 0.18% with non-ionic media. Among patients with asthma, severe and very severe reactions occurred in 1.88% with ionic media and 0.23% with non-ionic media. In a Canadian survey of 1992, the overall incidence of adverse effects to contrast media was 3.9% for ionic media and only 0.9% for non-ionic media, despite the fact that the proportion of patients with heart disease as a pre-existing susceptibility factor was much higher in the non-ionic group (SEDA-22, 500).

In a study from France the incidence of adverse drug reactions after 1480 injections of low-osmolar iodinated contrast media was 0.34%; the frequency was higher in patients with a history of allergy (1.5%) (15). In a similar study of the prevalence of adverse drug reactions amongst in-patients in a North Indian referral hospital over 3 years, 317 adverse reactions were reported (0.3%) (16). Skin reactions (123 cases, 39%) and gastrointestinal disturbances (90 cases, 28%) made up a large proportion of the reported adverse reactions. Of all the adverse reactions, 15% (48 cases) were due to iodinated contrast media (details of the types of contrast media used were not provided in the report) and the common reactions were nausea/vomiting (24 cases, 7.5%) and rashes

© 2006 Elsevier B.V. All rights reserved.

(16 cases, 5%); however, there was serious life-threatening anaphylaxis in three cases (0.9%).

The incidence of adverse reactions has been investigated in Taiwan in 28 364 patients after intravenous injection of contrast agents during intravenous urography and CT scanning (17). There were adverse reactions in 495 patients (1.75%), including 467 patients (2.03%) of 20 260 examined with ionic contrast agents and 28 (0.34%) of 8076 patients examined with non-ionic contrast agents. The authors concluded that the risk of adverse reactions to non-ionic contrast agents is significantly lower than with ionic agents. Skin rashes, such as urticaria, were the most common adverse effects, followed by nausea and vomiting. Shock requiring cardiopulmonary resuscitation was rare and occurred in only six patients (0.02%); there were no deaths in this series.

Adverse reactions to intravascular iodinated agents are usually classified as minor, intermediate, or severe life-threatening. All types of reactions to low-osmolar contrast media are five times less common than reactions to high-osmolar contrast agents (SEDA-22, 489) (SEDA-23, 494) (SEDA-24, 519), and very severe adverse reactions to contrast media are rare, with a frequency of about 0.04% with high-osmolar agents and 0.004% with low-osmolar agents. However, there are no important differences in the safety profiles of the different low-osmolar non-ionic monomers (18).

In one US study of cardiac angiography, the incidence of adverse events was 32% with diatrizoate and 10% with iohexol; it should be noted however that the diatrizoate used in that study (Renografin 76^{TM}) causes calcium binding, which may have increased the rate of cardiac complications (19). The non-ionic agent iodixanol 320, which is virtually iso-osmolar, has been tested in cardiac angiography against iohexol and seemed to be better tolerated (20).

The safety of the non-ionic contrast agents has also been emphasized in a review from Germany, in which the authors documented a reduced risk of adverse drug reactions with non-ionic contrast agents during interventional cardiology (21). According to reports to the FDA, the incidence of lethal complications was 3.9% with ionic monomers, 6.39% with the ionic dimer ioxaglate, and 2.07% with non-ionic monomers. The authors also stated that non-ionic contrast agents do not have thrombogenic potential, a previous concern; currently, most authors would support this view (SEDA-22, 501) (SEDA-23, 497).

There was no difference in the incidence of adverse effects between iotrolan 320 and iohexol 350 in cardiac angiography for ischemic heart disease in 120 patients (22). There were no serious adverse events. One patient developed mild urticaria after iotrolan. Five patients in each group had mild unspecified delayed reactions.

An analysis of adverse reactions associated with drugs in Poland (1997–98) has shown that 11.5% of these reactions were due to radiographic contrast media. People aged 36–65 were the largest group to have adverse drug reactions (23).

According to a survey conducted by the Royal Australian College of Radiologists in 1986, the incidence of severe reactions with high-osmolar ionic contrast media was 0.36% in high-risk patients (patients with a strong history of allergy or bronchial asthma or a history of reactions to contrast media) and 0.09% in low-risk patients (24). The incidence of these reactions with low-osmolar non-ionic media was 0.03% in high-risk patients, and 0% in low-risk patients.

In another survey, the incidence of contrast media reactions after intravenous administration was evaluated over 14 years (25). The incidence of all reactions to contrast media was 6–8% with high-osmolar contrast media and only 0.2% with low-osmolar non-ionic agents. Most of the reactions (over 90%) were allergic-like, and severe reactions were rare (0.05%). One death was reported after the use of a low-osmolar agent. These data are compatible with previous reports, which showed that low-osmolar contrast media have a much better safety profile than high-osmolar media and that there is no significant difference in the incidence of acute adverse reactions between non-ionic dimeric and monomeric contrast media.

In another study there was no significant difference in the incidence of adverse effects associated with the use of the non-ionic dimer iodixanol or the non-ionic monomer iopromide in femoral angiography (26).

Delayed reactions

There are conflicting data on the risk of delayed reactions, comparing non-ionic monomers and iso-osmolar non-ionic dimers (iotrolan, iodixanol). European studies (27) have shown no significant difference (0.62% iotrolan, 0.82% non-ionic monomers), but studies from Japan and the USA have suggested that delayed reactions are 2–5 times more common with iotrolan.

The incidence of delayed adverse reactions to various non-ionic monomers in Japanese patients undergoing contrast-enhanced CT has been compared with the incidence in control patients who did not receive contrast. Delayed reactions occurred in 12% of patients who received contrast compared with 10% in the control group. The authors concluded that the frequency of delayed reactions that can be attributed to contrast media is 2.1%. The most common reactions were itching and limited urticaria (28). This report highlights the difficulty of verifying that adverse events that occur many hours after contrast administration are directly caused by the contrast agent.

The incidence of delayed reactions has been assessed in 403 Italian patients who received intravenous iopamidol during CT or urographic examination (29). A total of 50 patients (12%) developed delayed reactions. Allergy, previous exposure to a contrast agent, and being female were associated with a significantly higher incidence of delayed reactions. The most frequently reported delayed reactions were nausea and vomiting, drowsiness, rash, itching, and headache. All reported reactions were mild and resolved spontaneously.

In a questionnaire study of 11 121 Japanese patients, 216 (1.4%) developed immediate adverse reactions and 1058 (9.5%) reported having had delayed reactions after intravenous contrast administration during various CT examinations (30). Delayed reactions were reported by 18 patients (13%) of the 136 patients with immediate reactions who answered the questionnaire. All the patients, with the exception of 360 who received the non-ionic dimer iotrolan, were given non-ionic

© 2006 Elsevier B.V. All rights reserved.

monomeric contrast media. The dose was 60–200 ml. Delayed reactions were more frequent in patients with a history of allergy, past adverse reactions to contrast media or with a serum creatinine concentration over 180 μmol/l. Delayed reactions were also more frequent in women and in patients who had not previously received contrast media. There was no significant relation between the occurrence of immediate adverse reactions and the development of delayed reactions. The commonest delayed reactions were itching and skin reactions, which developed in 5.5% and 3.0% of the patients respectively. Skin reactions were observed twice as often in patients who were given iotrolan compared with those who were given monomeric agents. In the iotrolan group, 7.3% of the patients developed a skin reaction, 9.9% reported itching, and 60% of the reactions were severe or moderate. A quarter of the delayed reactions occurred within 6 hours after the examination and more than half occurred within 24 hours. Most of the reactions occurred within the first 3 days.

The incidence of delayed adverse reactions has been investigated in 2001 patients who underwent cardiac angiography with either iopamidol 340 ($n = 738$, aged 22–88 years, mean dose 1.79 ml/kg), ioxaglate 320 ($n = 644$, aged 28–86 years, mean dose 1.8 ml/kg) or iodixanol 320 ($n = 619$, aged 26–85 years, mean dose 1.74 ml/kg) (13). The authors considered reactions that occurred within 24 hours as early reactions and those that occurred after 24 hours but within 1 week as late reactions. The incidences of early reactions were 22% with ioxaglate, 8.8% with iopamidol, and 7.6% with iodixanol. The commonest early reactions were urticaria and nausea and vomiting, the respective incidences being 6.8 and 4.0% with ioxaglate, 0.8 and 1.0% with iopamidol, and 0.5 and 1.1% with iodixanol. A few patients developed sudden hypotension, 0.5% with iopamidol, 1.4% with ioxaglate, and 0.3% with iodixanol. Cardiac arrest occurred in two patients with iopamidol, three with ioxaglate, and one with iodixanol. The frequencies of delayed skin reactions, which were generally benign, were 12% with iodixanol, 4.3% with ioxaglate, and 4.2% with iopamidol. The authors concluded that selection of a contrast agent for diagnostic cardiac catheterization should take account of adverse effects. Iodixanol was the best-tolerated agent in the early phase of the study, but it was associated with a higher incidence of delayed skin reactions. The authors did not consider that the skin reactions represented a contraindication to iodixanol, although patients should be advised of this particular adverse effect. Furthermore, no contrast agent was free from these effects. Ioxaglate was the least well-tolerated agent in the early phase, with a much greater chance of causing nausea/vomiting and allergic reactions.

The Federal Institute of Drugs and Medical Devices in Germany has surveyed a total of 1135 adverse drug reactions (acute and late) associated with iotrolan 280 and 1354 reports associated with iodixanol at various iodine concentrations (31). There were late adverse reactions (observed later than 1 hour after injection) in 757 cases (67%) associated with iotrolan 280, and in 525 cases (39%) associated with iodixanol. Late reactions were observed mainly in the first 24 hours, with occasional reports at 24–72 hours after injection. Rarely, delayed contrast reactions have been reported more than 72 hours after injection, although they are difficult to substantiate. This study emphasizes the importance of extending the surveillance period for at least 72 hours after contrast administration. Most delayed reactions in this study were non-serious allergic-like reactions, with symptoms including itching, urticaria, erythema, edema, and bronchospasm. In a very few cases there were serious or life-threatening reactions, including Quincke's edema and hypotension.

The incidence of late adverse reactions to the iso-osmolar agent iodixanol has also been investigated in a retrospective comparison with the non-ionic monomer iohexol. Reactions after 3075 injections were reviewed. Patients were sent a written questionnaire to find out about the incidence of any acute or delayed reactions. Those who developed reactions were interviewed by telephone and specific second questionnaires were administered. The incidence of adverse reactions was low (2% for late adverse reactions and 2.3% for acute reactions). There was no significant difference in the incidence of acute or delayed adverse reactions to iohexol and iodixanol and there were no serious reactions (32).

Delayed reactions are generally benign, but not always. In a Japanese study, the incidence of delayed reactions was investigated in 6764 patients who received the low-osmolar non-ionic contrast medium iohexol intravenously (33). Delayed reactions (rash, pruritus, nausea, vomiting, fever, headache, and others) occurred in 192 patients (2.8%). There were no severe delayed reactions. A history of allergy and hay fever were risk factors for delayed adverse reactions.

Delayed adverse reactions to ioxaglate have been documented after coronary angiography with ioxaglate (34).

- A 63-year-old housewife had an acute myocardial infarction. Diagnostic coronary angiography was performed with ioxaglate and repeated 1 week later. On the morning after, she had intense shivering and generalized malaise, a temperature of 39.2°C, and hypotension. Several hours later she developed a non-pruritic maculopapular rash, starting on the face and extending within the next 48 hours to cover the entire body but sparing the mucous membranes. She had a mild eosinophilia (600×10^6/l) with a raised erythrocyte sedimentation rate (52 mm at 1 hour). Her IgE concentration was raised at 1593 kU/l. Blood cultures were negative. The initial clinical impression was that she had sepsis and she was therefore given vancomycin, netilmicin, and cefotaxime (dosages not stated). She improved rapidly and the fever and the rash resolved completely. She was discharged taking atenolol 100 mg/day and lysine acetylsalicylate 250 mg/day, but 3 days later she returned with a temperature of 39.8°C and recurrence of the skin rash. She had a marked eosinophilia (1.4×10^9/l) and raised liver enzymes, lactate dehydrogenase, and aldolase, but creatine kinase activity was in the reference range. She had a significantly raised concentration of circulating immune complexes. Atenolol and lysine acetylsalicylate were withdrawn and she was given acenocoumarol 2 mg/day and amlodipine 5 mg/day. The inflammatory syndrome rapidly disappeared and the enzymes and eosinophil count returned to normal. She had immunological investigations 2 months later. The total IgE was still raised. The leukocyte count and C-reactive protein concentration were within

© 2006 Elsevier B.V. All rights reserved.

the reference ranges. The serum antinuclear antibody titer was 1/256 and the antimitochondrial antibody titer was 1/128. Tests for antinative DNA, antihistone, and anti-smooth muscle antibodies were negative. Skin prick tests, intradermal tests, and patch tests with lysine acetylsalicylate, atenolol, heparins, vancomycin, netilmicin, cefotaxime, and the contrast agents ioxaglate, sodium ioxitalamate, iopamidol, and iohexol were negative at 15 minutes, but at 48 hours indurated erythematous papules were observed with ioxaglate, ioxitalamate, and iopamidol. A biopsy from the ioxaglate skin reaction showed discrete spongiosis of the epidermis associated with slight lymphocytic exocytosis. The basal layer contained numerous apoptotic keratinocytes. The superficial dermis was edematous and there was a perivascular inflammatory infiltrate composed mainly of T lymphocytes. There were no mast cells or eosinophils. Immunohistological examination showed no staining with anti IgE, IgG, IgM, C1q, C3, or C4. During follow-up she was completely normal at up to 1 year, with a normal eosinophil count and an IgE concentration of 440 kU/l.

This report documents a rare clinical reaction to ioxaglate, with a combination of a maculopapular rash, fever, hepatic and muscle involvement, eosinophilia, and a very high serum IgE concentration. The intradermal tests confirmed a delayed hypersensitivity reaction to ioxaglate. Histological examination of a skin biopsy identified the predominantly T lymphocyte nature of the infiltrate. A contributing role of the beta-blocker atenolol to the seriousness of the clinical syndrome must also be considered.

Mechanisms and susceptibility factors

The mechanisms underlying idiosyncratic adverse reactions are far from clear. Although many resemble allergic or anaphylactic events, the evidence does not suggest that they are as a whole induced immunologically, though some certainly are, and there is no doubt that in some cases contrast media act as antigens. Lalli believes that all contrast media reactions are explicable on a neurological basis; this hypothesis is not generally accepted, but most would agree that anxiety can be an important predisposing factor, for example to cardiac dysrhythmias. It has been suggested that contrast media act as histamine liberators, and there is evidence from animal experiments that this is the case, the methylglucamine media being more potent in this respect than the corresponding sodium salts (though ioxaglate may apparently also elicit histaminoid reactions (35); the antihistamine diphenhydramine has been recommended both for preventing and treating reactions (see below) and may have some efficacy. A further theory is that bradykinin is an essential mediator in systemic contrast media reactions (36). There is also older experimental evidence that contrast media can activate serum complement by the "alternative pathway," and it is postulated that this may be one of the factors in systemic adverse reactions, possibly by liberation of anaphylatoxin and with a risk of disseminated intravascular coagulation.

Adverse reactions to contrast agents have been linked to an in vivo interaction with enzymes involved in cholinergic activity. However, experimental results on this topic are conflicting. In a study of the in vivo effects of the non-ionic monomer iohexol and the high-osmolar ionic monomer diatrizoate on human plasma acetylcholinesterase and butyrylcholinesterase, both contrast agents significantly inhibited the enzymes (37). The effect was more pronounced with iohexol, which has a lower incidence of adverse effects than diatrizoate. The significance of this observation is not certain, but activation of these enzymes is not likely to be important in mediating the adverse effects of contrast agents. Other enzymes that are inhibited by iodinated contrast agents include hexokinase, glucose-6-phosphate dehydrogenase, and alcohol dehydrogenase (38).

More minor adverse reactions to the second-generation non-ionic water-soluble contrast media, such as headache, nausea, and vomiting, are more frequent in women than in men, particularly in women aged 26–50 years. Early ambulation increases the incidence of headaches. In one study, there was a higher incidence of delayed headaches after iopamidol in comparison with iohexol. Long-distance travel also appeared to increase the incidence of headaches after myelography (SEDA-15, 503). Dizziness was more frequent in patients over the age of 50 years. In a meta-analysis of 25 published studies, the incidence of symptoms after myelography was significantly higher when needles larger than 22G were used.

The risks (expressed as risk ratios) of adverse effects of contrast media after intravenous injection related to some susceptibility factors are listed in Table 2.

Prevention and management

Intravenous pre-testing is unreliable in determining susceptibility; in one survey of 33 400 patients, most of the reactions were not predicted by pretesting, although a positive pre-test did indicate an increased risk of a reaction (39). The value of the lymphoblast transformation test is very limited, although it certainly provides interesting evidence that contrast media can sometimes act as antigens (SEDA-16, 531) (40).

The value of prophylactic use of glucocorticoids to reduce the risk of contrast reactions is contentious. The Contrast Media Safety Committee (CMSC) of the European Society of Urogenital Radiology (ESUR) considered this issue and produced guidelines on how to reduce the risk of generalized reactions to intravascular use of contrast media (Table 3) (41).

In high-risk patients, and more particularly those with a history of poor tolerance of contrast media, measures will

Table 2 Risk ratios for adverse effects of contrast media after intravenous injection related to susceptibility factors

History	Minor reactions	Intermediate reactions	Severe reactions	Death
Allergy (all types)	1.6	2.6	3.9	
Hay fever	1.7	1.8	2.3	
Urticaria	1.5	4.8	2.0	
Asthma	1.2	2.7	5.1	
Heart disease	1.1	0.9	4.5	8.5

Table 3 European Society of Urogenital Radiology (ESUR) Guidelines on prevention of generalized contrast medium reactions in adults

A. Susceptibility factors for reactions
Previous generalized reaction to a contrast medium, either moderate (for example urticaria, bronchospasm, moderate hypotension) or severe (for example convulsions, severe bronchospasm, pulmonary edema, cardiovascular collapse)
Asthma
Allergy requiring medical treatment
B. To reduce the risk of generalized contrast medium reactions
Use non-ionic agents
C. Premedication is recommended in high-risk patients (defined in A)
When ionic agents are used
When non-ionic agents are used, opinion is divided about the value of premedication
D. Recommended premedication
Glucocorticoids
Prednisolone 30 mg orally or methylprednisolone 32 mg orally 12 and 2 hours before contrast medium
Glucocorticoids are not effective if given less than 6 hours before contrast medium
Histamine H_1 and H_2 receptor antagonists may be used in addition to corticosteroids, but opinion is divided
E. Remember for all patients
Have a trolley with resuscitation drugs in the examination room
Observe patients for 20–30 minutes after contrast medium injection
F. Extravascular administration
When absorption or leakage into the circulation is possible, take the same precautions as for intravascular administration

be necessary to contain risks of hypersensitivity reactions. Apart from using non-ionic and low-osmolar media, and diluting media for certain purposes, one can consider prophylactic premedication. Glucocorticoid premedication alone has often been advocated, particularly in patients with asthma; although it has been condemned as unnecessary with the current generation of contrast media (SEDA-18, 442) (SEDA-19, 426) it seems to be well founded in experience, reducing both the frequency and severity of reactions, but it certainly does not eliminate risk (42). A double regimen based on prednisolone and the antihistamine diphenhydramine has been advocated in various centers (SEDA-16, 531) (SEDA-18, 442) (43,44). To be effective, glucocorticoids should be given sufficiently far in advance; in some cases, an intravenous injection of dexamethasone given immediately before an infusion of contrast media failed to prevent an anaphylactic reaction (45).

H_1 and H_2 receptor antagonists, aminocaproic acid, or hyposensitization have all been proposed as means of reducing risk prophylactically. Aminocaproic acid was formerly used prophylactically in France, but was associated with a risk of massive intravascular coagulation (46).

In severe reactions, intravenous glucocorticoids are usually given on an empirical basis, with oxygen as required. Non-cardiogenic hypotensive shock usually responds best to fluid replacement, but vasopressors are occasionally required. Adrenaline is primarily indicated for bronchospasm and other allergic-type reactions, but caution is required to avoid cardiac dysrhythmias. Intravenous antihistamines are useful in angioedema, but can aggravate hypotensive reactions. Chemotoxic convulsions require intravenous diazepam and oxygenation.

Systemic adverse effects of enteral contrast agents

Oral radiographic contrast media can intravasate during gastrointestinal examination. Septicemia has been reported (47).

- A 46-year-old patient developed ischemic necrosis of the small bowel complicating mesenteric volvulus. Small bowel resection was carried out and ileal and jejunal stomas were established. Six weeks after the operation Gastrografin was given through the jejunal stoma. A mesenteric vein filled with Gastrografin and this was followed by rapid washout of the intravascular contrast medium. The examination was stopped immediately and 60 minutes later the patient developed chills and a high fever. Hemodynamic instability required the use of vasoactive drugs and infusion of isotonic solutions. Blood cultures grew *Escherichia coli*, *Pseudomonas aeruginosa*, and *Enterobacter* species. Treatment included imipenem and after 48 hours the patient was stable and the vasoactive agents were stopped. Endoscopy through the jejunal stoma showed multiple stenoses, which required surgical treatment, and the jejunum in the area of intravasation was resected.

Gram-negative septicemia possibly related to oral Gastrografin has also been reported in a premature neonate with necrotizing enterocolitis (48).

- A baby born after 26 weeks of gestation received oral Gastrografin (0.5 ml 8 hourly) for gut stimulation. Three days after the last dose of Gastrografin there was sudden clinical deterioration leading to shock. Blood cultures grew *Enterobacter*. Progressive deterioration continued to occur, with multisystem failure, leading to death. Autopsy was not performed.

The authors suggested that the high osmolality of Gastrografin may have aggravated the pre-existing mucosal injury in the gastrointestinal tract, leading to complete loss of mucosal integrity and an increase in gut permeability to micro-organisms and toxins. Oral Gastrografin and other hyperosmolar contrast media should not be used in patients, particularly neonates, with compromised bowel integrity, since the high osmolarity may aggravate the bowel injury. Low-osmolar contrast media should always be used in such patients.

Disseminated intravascular coagulation and severe hypotension have been documented after intravenous administration of Gastrografin, which is suitable only for oral or rectal administration (47).

Cost to benefit ratio

At a time when reductions in the costs of medical care are critical, decisions about which classes of contrast media to use are not determined purely on clinical grounds, but by a consideration of the cost to benefit ratio. Concern about

© 2006 Elsevier B.V. All rights reserved.

financial implications has been the major factor in preventing a universal conversion to non-ionic contrast agents, which are better tolerated but more expensive than high-osmolar ionic agents. In the USA, the Health Care Finance Administration (HCFA) has recommended that the use of the expensive non-ionic contrast media should be restricted only to patients with severe cardiac disease, a history of asthma, severe allergy, severe debility, sickle cell disease, or a previous severe adverse reaction to contrast media.

The results of a study in 1324 patients who underwent diagnostic arteriography have supported the selective use of non-ionic contrast agents following the HCFA guidelines. A cost saving of $41 per patient was possible without an increase in the incidence of complications (49).

Organs and Systems

Cardiovascular

Most severe reactions to contrast media are associated with cardiovascular manifestations, causing hypotensive shock and in some cases ventricular fibrillation and cardiac arrest; these events are reversible in most cases in which prompt treatment is given. In a case of hypotensive collapse reported in 1977, and followed by a small number of others, there was disseminated intravascular coagulation (50). In milder cases there is only hypotension, which can be transient and symptomless; in some cases there is bradycardia (due apparently to vagal overactivity) rather than tachycardia.

In more than 90 000 cardiac angiographies performed in US hospitals during 1991, the overall rate of complications with low-osmolar contrast media was 1.5%, including idiosyncratic reactions in 0.25%, vascular complications in 0.44%, neurological complications in 0.05%, dysrhythmias in 0.31%, and myocardial infarction in 0.06%; the death rate was 0.11%. In percutaneous coronary angioplasty major complications, generally of the same type, occurred in 5% of cases (51). In one large series of digital subtraction angiography examinations using iopamidol, the overall incidence of reactions was 2.5%; some occurred with a delay of 1 hour or more (52).

The safety of iodixanol 320 and iohexol 350 has been investigated in Swedish patients undergoing cardiac angiography for suspected coronary artery disease (53). Of 1020 patients, 502 aged 25–83 years received iohexol (median dose 105 ml, range 20–440) and 518 aged 18–85 years received iodixanol (median dose 115 ml, range 30–400). There were 134 patients with unstable angina in the iohexol group and 167 in the iodixanol group. Cardiac adverse events (angina pectoris, dysrhythmias, and dyspnea) within 24 hours of the examination were reported by 9% of the patients who received iohexol and 7% of patients who received iodixanol. There were two cases of ventricular fibrillation, both after iohexol. Cardiac adverse events in patients aged 65 years or more occurred in 11% with iohexol and 7% with iodixanol. The proportions of patients with unstable angina and cardiac adverse events were 18% with iohexol and 12% with iodixanol. The authors concluded that iodixanol could be advantageous in old patients and in those with unstable angina.

Iodixanol (a non-ionic dimer, 320 mg of iodine per ml) and ioxaglate 320 (a low-osmolar ionic dimer, 320 mg of iodine per ml) have been compared in a randomized study in 110 consecutive patients referred for coronary angiography and ventriculography (54). The incidence of adverse reactions was significantly higher with ioxaglate (28 versus 3%) but there was no difference in angiographic quality between the two agents. The increase in left ventricular end-diastolic pressure was significantly less with iodixanol than with ioxaglate. The QT interval was significantly prolonged by both agents, but the changes were less marked after iodixanol. The authors concluded that iodixanol and ioxaglate are of comparable diagnostic efficacy in coronary angiography and ventriculography but that iodixanol is better tolerated and has less marked hemodynamic and electrophysiological effects.

The hemodynamic effect of direct intra-arterial injection of contrast agents on capillary perfusion in man has been investigated (55). This was achieved through continuous recording of perfusion in the nail-fold capillaries of the right hand before and after a bolus injection of 20 ml of iodixanol 270 (a non-ionic dimer) or iopentol 150 (a non-ionic monomer) into the right axillary artery. The high-viscosity contrast agent iodixanol (5.8 mPa.s) caused a significant reduction in erythrocyte velocity, while iopentol, which has a much lower viscosity (1.7 mPa.s), had no effect. The authors concluded that high-viscosity contrast media can cause reduced organ perfusion. This effect could be significant in patients with atherosclerotic disease, as it might lead to reduced perfusion of the myocardium during coronary angiography.

Effects on blood pressure

Rapid peripheral intravenous injection of concentrated ionic contrast media produces a brief rise in systemic arterial pressure followed by a prolonged fall; the diastolic pressure decreases more than the systolic pressure and the heart slows; the pulse contour changes, and the venous pressure rises; the arterial hypotension is more marked if injection is rapid. The electrocardiogram can show flattening, splitting, or T-wave inversion; tachycardia is probably compensatory, as are the concomitant increases in venous pressure and pulmonary arterial pressure. Hypotension associated with a vasovagal reaction probably explained four deaths from acute coronary insufficiency (two each with iodoalphionic acid and iopanoic acid) in patients with ischemic heart disease.

- A 44-year-old man had a CT scan of the head with intravenous contrast enhancement (35 ml of ioversol 350) (56). He developed severe back pain 90 minutes later and then became acutely unwell, with nausea, vomiting, chills, tremor, and faintness. He rapidly became shocked (systolic blood pressure 80 mmHg, pulse 140/minute) and had a petechial rash over the trunk and upper limbs. He was given intravenous fluids (polygeline 2 liters and crystalloid 2 liters and adrenaline. Blood cultures were negative, and echocardiography, CT scan of the chest and abdomen, and abdominal ultrasound were normal. He continued to deteriorate, developed acute renal insufficiency with disseminated intravascular coagulation, and was given dopamine, aggressive fluid resuscitation, and antibiotics

© 2006 Elsevier B.V. All rights reserved.

(gentamicin, ceftriaxone, and erythromycin). His general condition gradually improved and he recovered fully.

The authors attributed these events to a severe delayed reaction to the contrast medium, manifesting as prolonged hypotension.

Injection of contrast media into the right side of the heart or pulmonary artery can be followed by transient pulmonary hypertension but systemic hypotension. The pulmonary hypertension is partially due to an increase in the pulmonary vascular resistance from capillary blockage by the altered erythrocytes, which have a reduced elasticity due to the effect of a hypertonic contrast medium. Reduced cardiac output accompanied by cardiac slowing and diminished force of contraction seem to explain the initial systemic hypotension; persistence of hypotension thereafter is probably due to the vasodilator effect of the contrast medium on the systemic vessels. Pulmonary angiography is particularly dangerous when the right ventricular end-diastolic pressure exceeds 20 mmHg. Iohexol appears to be a safer medium for pulmonary angiography (SEDA-14, 423).

Injection into the left ventricle or the proximal aorta is likely to produce more marked effects. Cardiac rate, stroke volume, and cardiac output increase. There is a rise in right and left atrial pressures and left ventricular end-diastolic pressure. The pulmonary arterial pressure is also increased. The blood volume expands and peripheral blood flow increases and then decreases as systemic resistance falls. The hematocrit falls and venous pressure gradually rises. As the systemic arterial pressure falls, the heart rate increases. These responses are largely due to the injection of strongly hypertonic solutions, which promote a rapid expansion of the plasma volume; water shifts from the extravascular fluid spaces to the blood and moves out of the erythrocytes, which shrink and become crenated. Blood viscosity rises, but plasma viscosity does not increase significantly. The erythrocytes give up potassium to the plasma and this might contribute to the observed reduction in peripheral vascular resistance.

In two cases of severe hypotensive collapse with generalized itching after left ventricular angiography with 76% sodium methylglucamine diatrizoate, the hypotension failed to respond to vasoconstrictors, and measurements of right atrial and right ventricular pressures showed marked reduction in filling pressures. Rapid intravenous infusion of isotonic saline caused prompt improvement in the blood pressure. A similar case of hypotension with a beneficial response to plasma expanders occurred in a case of prolonged shock after intravenous urography. Severe and prolonged hypotensive collapse has also been seen after antegrade pyelography through a nephrostomy tube under general anesthesia, but the patient in question had a previous history of an acute reaction (SEDA-18, 445). In two cases, injection of diatrizoate during arteriography under general anesthesia caused severe hypotensive collapse (SEDA-7, 452).

Acetrizoate has a more marked effect in this respect than an equiosmolar solution of diatrizoate. Methylglucamine salts appear to be relatively less vasoactive in the peripheral vessels. All these changes are considerably less marked with low-osmolar media such as ioxaglate, iopamidol, or iohexol, but not necessarily absent. Abdominal aortography with iohexol has been found to produce both a decrease in the systemic blood pressure and an increase in the plasma concentration of atrial natriuretic peptide; this may be due to increased intravascular volume (SEDA-16, 533).

Intra-arterial injection of conventional ionic contrast media results in vasodilatation. This is due mainly to hypertonicity of the medium, but toxicity is also a factor. The vasodilatation may in addition be partly due to an anti-cholinesterase action, since it is partially blocked by atropine. In clinical practice, aortography and peripheral arteriography are usually associated with a slight fall in blood pressure, tachycardia and discomfort in the limbs, such as heat or pain.

During cerebral angiography with either ionic or non-ionic agents, hypotension, bradycardia, and even transient asystole can occur, though there can also be reflex tachycardia (57), which can result in hypertension. These changes are more marked during vertebral angiography when the posterior cerebral arteries have been filled, suggesting that they are due to involvement of centers in the hypothalamus or brain stem. Visual disturbances can also occur, due to involvement of the occipital cortex (58). The reflex cardiovascular changes may be more serious in patients with coronary artery disease and can give rise to left ventricular failure. Both electrocardiographic and electroencephalographic changes are less common when methylglucamine salts are used. Premedication with atropine reduces the incidence of the cardiovascular changes, but not that of focal electroencephalographic effects. Their incidence has also been reduced by use of very small doses of contrast agents and by premedication with hypertonic mannitol in patients with raised intracranial pressure. One patient with metrizamide encephalopathy developed severe hypertension (SEDA-11, 415) (SED-12, 1182).

Electrocardiographic effects

In a comparison of the effects of iodixanol and ioxaglate during coronary angiography, 22 patients received ioxaglate for the first injection into the left coronary artery and iodixanol for the next injections, and 20 patients received the media in the reverse order (59). Those who received ioxaglate first received a mean of 102 ml of contrast medium and the iodixanol group 104 ml. The first three injections into the left coronary artery were subjected to electrocardiographic analysis. Deviation from baseline was greater in those who received ioxaglate first. The most pronounced effects of ioxaglate were on the ST segment and T wave: the T wave change vector magnitude increased 11-fold from baseline after ioxaglate and 5-fold after iodixanol; the increase in ST change vector magnitude was 4-fold with ioxaglate and 3-fold with iodixanol. The authors concluded that iodixanol caused less pronounced electrocardiographic changes than ioxaglate. These findings are in accord with experimental evidence that iodixanol is well tolerated by the myocardium.

Certain contrast media, notably the high-osmolar products based on sodium methylglucamine, Renografin-76 and MD-76, have calcium-binding properties and cause

© 2006 Elsevier B.V. All rights reserved.

more hemodynamic changes and a higher risk of ventricular fibrillation than the calcium-enriched media Angiovist and Hypaque-76 (60). In nine patients undergoing coronary arteriography, plasma measurements from the coronary sinus, there was a significant reduction in ionized calcium concentrations immediately after injection of Renografin 76 (sodium methylglucamine diatrizoate) into the coronary arteries. The effect was most marked and lasted longer in patients with vascular disease. The reduction in ionized calcium was attributed to the chelating agents (disodium EDTA and sodium citrate) present in some contrast media. This may have been a factor in causing electromechanical dissociation in cardiac muscle (SEDA-11, 412). The hypocalcemic effect of ionic contrast media can potentiate the effect of a calcium blocker such as verapamil (SEDA-8, 429) (SEDA-9, 410).

Non-ionic media cause fewer electrocardiographic changes than ionic media (SEDA-10, 424) (SEDA-11, 412). Non-ionic contrast media are almost sodium-free; they have little tendency to cause ventricular fibrillation or to depress cardiac contraction, and this small risk might (if in vitro animal studies are dependable) be further reduced by the addition of a very small amount of sodium (61). Following studies in dogs in which methylglucamine salts of diatrizoate or iotalamate produced only temporary T wave changes while sodium salts produced more marked changes with a fall in blood pressure and increase in coronary flow, the US manufacturers of a product containing sodium methylglucamine diatrizoate removed virtually all of its sodium content, but without announcing the change (62). Radiologists using the altered contrast medium noticed an unexpected increase in the incidence of ventricular fibrillation after coronary arteriography. Subsequent animal experiments confirmed that the new medium caused this effect, apparently by prolonging the time of depolarization. The addition of small quantities of sodium to the medium lessened this prolongation of the depolarization phase.

Prinzmetal angina with electrocardiographic changes has been seen 10 minutes after a dose of iodipamide (SEDA-2, 373). In another case an anaphylactoid reaction after left ventriculography was associated with electrocardiographic changes apparently due to coronary artery spasm (63).

In a comparison of the effects of ioxaglate (a low-osmolar ionic dimer) with iopamidol (a non-ionic monomer), iopamidol caused fewer electrocardiographic changes and a reduction in ventricular excitability compared with ioxaglate (64).

The electrocardiographic effects of different types of non-ionic low-osmolar contrast media have been investigated in 41 patients undergoing left ventricular angiography (65). There was transient prolongation of the QT interval in all of the patients. The effect did not cause important cardiac events and was less than 60 ms in most cases. The authors concluded that this effect was too brief to present any significant risk.

Left ventricular failure

Of 65 patients being investigated for intermittent claudication under general anesthesia, five developed pulmonary edema after retrograde aortic injection of sodium iotalamate (Conray 325 or 420). Three of the five had a history of myocardial disease and another had received 200 ml of Conray 420.

Although it is now widely acknowledged that low-osmolar non-ionic contrast media are better tolerated than high-osmolar ionic media, the choice of contrast agent does not affect the early results of percutaneous transluminal coronary angioplasty (66). However, the authors acknowledged that high-osmolar ionic agents carry higher risks of acute left ventricular failure. They retrospectively reviewed 401 patients who underwent percutaneous transluminal coronary angioplasty, 220 of whom received high-osmolar ionic media and 181 of whom received non-ionic contrast media. Acute left ventricular failure occurred more often in the high-osmolar group (1.4 versus 0%). There were no differences in the incidences of acute myocardial infarction (3.3% in each group) or urgent surgical intervention (0.5% with the high-osmolar agents and 0.6% with the low-osmolar non-ionic media). There were two cases of mild and transient central nervous system complications (loss of orientation and transient hemiparesis) with the high-osmolar contrast media. The authors concluded that in the majority of cases, the type of contrast medium used does not influence the early results of percutaneous transluminal coronary angioplasty in relation to its efficacy, the degree of revascularization, and residual narrowing. However, they acknowledged that the use of high-osmolar ionic media increases the risk of acute left ventricular failure after angioplasty. They attributed the finding that non-ionic contrast media increased the risk of abrupt vessel closure (4.5 versus 1.5%) to intravascular clotting. The suggestion that non-ionic agents are procoagulant is contentious, and there is no conclusive evidence to support this view (SEDA-22, 501).

Myocardial infarction

In spite of the safety of the non-ionic contrast media cardiac arrest can complicate the infusion of these agents.

- A 47-year-old man with chest pain and a myeloproliferative disorder had a CT scan of the abdomen with contrast enhancement (the type of contrast medium was not stated) (67). He had no significant past medical history or history of allergy. During a later CT scan of the abdomen infusion of 60 ml of the non-ionic monomer iohexol (iodine 300 mg/ml) caused a sudden cardiac arrest. Resuscitation was ineffective and post-mortem examination showed intramural acute and old organizing infarctions in the entire left ventricular wall.

Although the authors suggested that this event was an adverse effect of the contrast medium, it is possible that the cardiac arrest in this patient was secondary to an acute coronary event independent of the contrast agent.

Respiratory

Transitory changes in lung function can occur after bronchography due to retention of the contrast medium in the bronchi; normal diffusing capacity may not return for 3 days and it is better to avoid thoracic surgery during this period. When bronchography with propyliodone

© 2006 Elsevier B.V. All rights reserved.

preparations is performed during fiberoptic bronchoscopy, there may be marked arterial oxygen desaturation (SEDA-15, 504).

Some contrast medium inevitably reaches the lungs after injection, and tracer studies in the early 1960s showed that some degree of pulmonary oil embolism occurred in every patient (68). Pulmonary function studies have shown abnormalities, in particular a reduction in pulmonary diffusing capacity and pulmonary capillary blood volume, even in the absence of clinical signs or symptoms (69). Most cases are symptomless, although there can be mild pyrexia, while X-rays show stippling or an arborization pattern. If hypotension, cyanosis, dyspnea, and pleuritic pain occur, infarction should be suspected. The risk that blockage of lung capillaries by oil will endanger the patient is naturally greater if pulmonary function is already compromised, for example by neoplastic or fibrotic disease, or by radiotherapy.

In some patients, this phase of mechanical obstruction is followed after some days or 3–4 weeks by a chemical reaction, presumably as the oil breaks down to irritant fatty acids, which cause exudation and hemorrhage. Interference with the production of lung surfactant can also occur and a marked intravascular cellular reaction has been described (70). The chemical irritative phase is marked by fever, cough with sputum (often blood) and a variable degree of respiratory distress; there may even be tachycardia and hypotension.

Non-cardiogenic pulmonary edema has been seen several times after contrast media in patients with a prior history of myocardial infarct (SEDA-16, 531); it can also be a component of anaphylactic shock. Non-cardiogenic pulmonary edema has been reported as a complication of intravenous injection of iomeprol (71).

- A 68-year-old man with chronic obstructive pulmonary disease underwent CT examination of the abdomen with intravenous infusion of iomeprol for suspected hepatocellular carcinoma and 2 hours later developed severe dyspnea. A chest X-ray showed bilateral diffuse shadowing of the lungs and the heart shadow was not enlarged. A diagnosis of non-cardiogenic pulmonary edema was made and he improved with glucocorticoids.

Contrast media can cause severe bronchospasm, particularly in patients with asthma (72). Subclinical bronchospasm can occur after bolus injections of ionic contrast medium; the incidence is lower with non-ionic media (SEDA-8, 427).

Life-threatening adult respiratory distress syndrome after intravascular radiographic contrast injection is rare. It has been successfully managed by extracorporeal membrane oxygenation (73).

- A 62-year-old man developed adult respiratory distress syndrome 5 minutes after receiving a low-osmolar ionic contrast medium (140 ml of ioxaglate 200) during coronary angiography. His respiratory rate was 35/minute, blood pressure 60/40 mmHg, pulse rate 125/minute, PaO_2 49 mmHg, main pulmonary artery pressure 21 mmHg, central venous pressure 9 mmHg, and pulmonary capillary pressure 10 mmHg. A chest X-ray showed pulmonary edema. Laboratory investigations, electrocardiography, echocardiography, and coronary angiography were normal. In view of life-threatening hypoxia, extracorporeal membrane oxygenation was given for 50 hours, and 2 weeks later he was discharged without pulmonary symptoms.

In one case adult respiratory distress syndrome was accompanied by disseminated intravascular coagulation (SEDA-16, 531).

- Respiratory arrest occurred after aspiration of water-soluble contrast material in a 12-year-old girl who had been injured in a traffic accident. Gastrografin diluted with tap water (540 ml) was given into the stomach via a nasogastric tube as part of CT-enhanced contrast examination of the abdomen. She also received 150 ml of non-ionic contrast media (iopamidol, iodine 300 mg/ml) intravenously, which was followed by vomiting attacks. She became irritable and had an acute fall in oxygen saturation and progressive respiratory distress, which required endotracheal intubation. The CT scan that was performed after she became stable showed contrast material in the lungs.

The authors concluded that aspiration of contrast material can be life-threatening and that administration of oral contrast media after trauma can increase the risk of aspiration of gastric contents (74).

Accidental inhalation of hypertonic contrast media during oral administration can cause fatal non-cardiogenic pulmonary edema (75).

In pediatric bronchography, segmental collapse occurs in half the cases, but is particularly common with the aqueous media. Collapse also seems to be more common when halothane and oxygen are used as the anesthetic agents (SEDA-15, 504); this has been attributed to the rapid absorption of the anesthetic gases combined with the partial bronchial block caused by the contrast medium.

Pulmonary fibrosis and microlithiasis has been reported as a late complication of lymphography with iodized oil, but a causative relation was uncertain (SEDA-12, 397).

Nervous system

Animal experiments with the ionic media have shown that these damage the blood–brain barrier, thereby creating a degree of risk to brain tissue when they are used in cerebral angiography, although they have often been used safely. Other evidence suggests that sodium increases the neurotoxicity of the contrast medium, possibly by increasing its diffusibility into the brain. Methylglucamine, on the other hand, reduces neurotoxicity. The addition of a small quantity of calcium also appears to reduce toxicity, at least when added to sodium. There are only marginal differences in neurotoxicity as measured in animal experiments between the diatrizoate, iotalamate, and metrizoate anions. Calcium methylglucamine metrizoate probably has the lowest neurotoxicity of the ionic media, followed closely by methylglucamine iotalamate. In clinical use, however, the calcium-containing formulations appear to cause a greater degree of discomfort because they cause a sensation of heat.

Although the non-ionic media produced less injury to the blood–brain barrier in animals, clinical studies have not generally shown them to be better tolerated when

© 2006 Elsevier B.V. All rights reserved.

used for cerebral angiography, and it has been argued that these expensive media should now only be used where the blood–brain barrier is thought to be defective (76).

Transient neurological changes after myelography include asterixis, aphasia, and reversible visual defects. In one patient, asterixis and head bobbing were still present 3 months after myelography with metrizamide (SEDA-7, 453). An isolated case of persistent cervical myelopathy has also been reported after lumbar myelography with metrizamide.

A variety of other neurological complications have also been recorded. These include Guillain–Barré syndrome, auditory or visual disturbances, motor aphasia, sixth nerve palsy (SEDA-8, 431), mania, organic brain syndrome (SEDA-10, 425), confusional changes, and absence status. Absence status responds rapidly to intravenous diazepam (SEDA-14, 415).

Death has occurred following deterioration of neurological status. There has been a higher incidence of such complications in diabetics (SEDA-11, 415). Aspiration of 20–25 ml of cerebrospinal fluid after metrizamide myelography appears to reduce the incidence of neurological adverse effects (77).

All ionic contrast media are neurotoxic and they should not be injected into the subarachnoid space or intrathecally, and stern warnings against such use have been issued, for example by the American FDA (SEDA-18, 445). When they have accidentally been used, deaths have resulted (SEDA-18, 445) (78). Accidental misuse of diatrizoate for myelography, with fatal consequences, has been a serious problem (SEDA-22, 500). Lavage of the subarachnoid space with saline in such cases has been effective in reducing toxicity (SEDA-15, 504).

Accidental injection of diatrizoate into the subarachnoid space has occurred as a result of misplacement of the needle in arteriography, in discography, from inadvertent use in myelography, or during injection of a myelocele. Severe convulsions with extensor spasms occur and can result in death, particularly if the agent comes into contact with the brain; the onset of convulsions can be rapid, but they can also be delayed for several hours. Two patients developed renal insufficiency as an additional complication (SEDA-8, 1046).

The earliest water-soluble medium used for lumbar myelography or radiculography, sodium methiodal, had an irritant effect and required spinal anesthesia, which sometimes caused hypotension. Methylglucamine iotalamate was less irritant, while methylglucamine iocarmate had still lower neurotoxicity. However, even these two media could cause convulsions or muscle spasms if the contrast agent came into contact with the conus medullaris. For this reason the patient was postured with the head raised for several hours after the examination to prevent the contrast medium passing above the L-l vertebral level. Diazepam might also be given prophylactically. When convulsions did occur they could be severe, even resulting in fractures or dislocation of a hip. A convulsive pattern without actual convulsions has also been seen on the electroencephalogram in some patients.

Metrizamide was the first non-ionic contrast medium and became widely used for myelography and ventriculography. It was much less neurotoxic than iocarmate, although electroencephalographic changes lasting up to 3 days were found in some 16% of cases in early studies. Today, metrizamide is no longer used and has been succeeded by new generations of non-ionic monomers (iopamidol, iohexol) and dimers (iotrolan, iodixanol) which are well tolerated with low neurotoxicity (SEDA-22, 501). The need for intrathecal injection of contrast media in the developed world has dramatically fallen with the wide availability of MRI.

Visual evoked responses 20 hours after myelography can be delayed, with a correlation with the severity of headache after myelography; the delay in visual-evoked response is less marked with iopamidol than with metrizamide. It has been suggested that this technique may be useful in the assessment of myelographic contrast media toxicity (79).

In 439 myelographic procedures with metrizamide the most frequent adverse effect was headache, which could be differentiated into early-onset headache (related to hydrodynamic modifications in the spinal fluid following lumbar puncture) and late-onset headache (reflecting a specific metrizamide effect) (80). The frequency of late-onset headache was at least 27%, but altogether 46% of the patients had headache at one time or another. In this series, meningeal irritation was seen in 5%, sometimes in a severe form, mimicking a septic complication. There was spinal irritation in two cases and epileptic fits in one. An acute psychotic organic syndrome was common after cervical myelography with high doses of metrizamide. There was a severe anaphylactic reaction in one patient. The results of this study have generally been confirmed by others; seizures are clearly very rare with these non-ionic media, though they have occurred, even with iohexol (81), as have involuntary movements and facial twitching (82) and nystagmus (83). Meningeal irritation and paraplegia have both been seen with iohexol (SEDA-16, 536) and a case of aseptic meningitis with iotrolan (SEDA-16, 536).

In comparative trials, iopamidol and iohexol produced fewer adverse effects than metrizamide and they do not so far appear to have given rise to the psychosyndrome, but slight electroencephalographic changes can occur even with the newer media. Seizures and clonic jerks have been reported when relatively large doses of iopamidol have been used in myelography (SEDA-7, 455) (SEDA-13, 436).

Four cases of cauda equina syndrome have been described with methylglucamine iocarmate used for radiculography, although in two cases faulty technique was perhaps contributory.

Loss of consciousness can occur if there is hypotensive collapse; rarely there can be prolonged coma.

Convulsions, seen as part of an idiosyncratic reaction, tend to occur in patients with an existing tendency to epilepsy, or to occur as consequences of hypotensive collapse, cardiac arrest, or overdose.

Intraventricular metrizamide can cause perivascular mononuclear infiltration in the walls of the ventricles. This histological appearance may be mistaken for encephalitis if previous exposure to metrizamide is not considered (SEDA-7, 454).

A few cases of severe purulent meningeal reactions to iopamidol have been briefly described (84). In one exceptional report, a hemorrhagic meningeal reaction and

© 2006 Elsevier B.V. All rights reserved.

thrombosis of the superior longitudinal sinus followed sacroradiculography with iopamidol (85). A case of transitory abducent nerve palsy has been reported after myelography with iopamidol (SED-12, 1183) (86).

Electroencephalographic changes

In 292 patients undergoing examinations with metrizamide, electroencephalography showed minor non-specific changes in 13% 24 hours after the injection. In 4% there were more marked abnormalities, such as spikes, spikes and waves, or paroxysms of bilateral synchronous high voltage rhythmic delta waves, apparently due to a direct toxic action of metrizamide on the cerebral cortex. They occurred shortly after the injection, and in the patients involved, a large amount of the contrast medium had flowed intracranially. Diazepam did not appear to have any significant effect on the electroencephalographic changes (SEDA-15, 504).

In a series of 308 cerebral angiograms in which metrizamide and meglumine metrizoate were compared on a randomized, double-blind basis, metrizamide caused a lower incidence of electroencephalographic changes, but the incidence of clinical complications showed no significant difference in the two groups, suggesting that the problems were mainly caused by other factors, such as thromboembolism; thromboembolism has indeed been suspected after cerebral angiography, even with iohexol (SEDA-13, 435).

Acute encephalopathy

Acute encephalopathy has been reported after intrathecal administration of non-ionic media (87).

- Six hours after 10 ml of iohexol (Omnipaque, iodine 240 mg/ml) had been injected into the left lateral ventricle during an operation on the thalamus of a 63-year-old man with Parkinson's disease, his level of alertness deteriorated and he became disorientated and confused. A CT scan of the head showed the surgical lesion and artefacts due to contrast medium, but no other abnormalities. After 24 hours, he became more alert, with coherent speech, but there was still mild disorientation. These symptoms resolved within the next 2 days.

According to the authors, this was the first case of encephalopathy after iohexol ventriculography, with the onset of symptoms several hours earlier than in myelography cases, probably owing to direct administration into the ventricular system. Awareness of this complication can be helpful in patient management after procedures in which iohexol is given intrathecally.

Transient contrast encephalopathy has been reported after carotid artery stenting (88).

- An 82-year-old right-handed man was given 50 ml of the ionic low-osmolar contrast agent ioxaglate 320 for carotid angiography. The next day his right internal carotid artery was stented and a total of 180 ml of ioxaglate was used. Aspirin, ticlopidine, and heparin 5000 units were given during the procedure. While he was still on the table he developed rapidly worsening confusion and a left hemiparesis. A CT scan without contrast 4 hours later showed marked cortical enhancement and cerebral edema in the distribution of the right anterior and middle cerebral arteries. He rapidly improved and had complete neurological recovery after 48 hours; 1 month later he was asymptomatic.

The cerebral contrast enhancement on the CT scan suggested disruption of the blood–brain barrier. This could have been due to the large volume of contrast medium used during the stenting procedure. This complication must be differentiated from massive cerebral infarction and hyperperfusion syndrome: the rapid radiological resolution and clinical recovery excluded cerebral infarction; hyperperfusion syndrome would have involved the carotid distribution exclusively, rather than both the ipsilateral carotid and posterior circulations. The authors recommended close follow-up of patients after such procedures. The safety of subsequent cerebral angiography in a patient with a history of such a reaction has not been studied extensively, and extreme caution must be exercised should the need for repeat angiography arise later.

Adhesive arachnoiditis

Methylglucamine iocarmate and methylglucamine iotalamate have both caused persistent arachnoiditis, leading to obliteration of nerve roots and constriction of the dural sac; operative treatment after myelography increases the risk of arachnoiditis, which is dose-dependent and varies with the contrast medium used (89,90).

Aseptic meningitis

Aseptic meningitis has been reported after iohexol myelography (91).

- A 74-year-old woman underwent lumbar myelography with iohexol (12 ml, iodine 240 mg/ml) for low back pain, having had iohexol myelography 2 years before with no complications, and 18 hours later developed headache, pyrexia (39°C), shivering, sweating, neck stiffness, nausea, and mild confusion. She had a leukocytosis (16.4×10^9/l) and a high C-reactive protein (145 micrograms/ml). There were leukocytes in the cerebral spinal fluid (11.5×10^9/l, 98% polymorphonuclear leukocytes), with protein 6.6 g/l and glucose 3 mmol/l, but a Gram stain was negative and no microorganisms were grown. She recovered spontaneously.

The authors suggested that this was a meningeal reaction to iohexol, since the interval between the injection of iohexol and the onset of symptoms was short, the symptoms resolved quickly, and there was no evidence of infection.

In the Netherlands, around 1979 there were several reports of aseptic meningitis after the use of metrizamide (SED-12, 1183) (92), and the complication has been reported since with iopamidol (93). Streptococcal meningitis has also been reported (94).

Convulsions

Up to 1979 it was estimated that some 360 000 cases of myelographies had been performed with metrizamide and that there had been 40 cases of epileptic attacks after its use (95); although they tended to relate to investigations in the upper part of the spine, three related to cases of lumbar myelography; a further case was later described. In some of these instances the use of other drugs may

© 2006 Elsevier B.V. All rights reserved.

have played a role, including chlorpromazine, antihypertensive drugs, diphenhydramine, and pethidine (SED-12, 1182). The role of chlorpromazine in facilitating metrizamide-induced convulsions has been confirmed in animal studies; it was formerly recommended that phenothiazines should be withdrawn at least 48 hours before intrathecal use of metrizamide. Some, but by no means all, of the patients experiencing convulsions with metrizamide have a history of epilepsy.

- A 69-year-old man with idiopathic nasal bleeding underwent contrast-enhanced CT examination of the head with an intravenous non-ionic low-osmolar contrast medium (96). Convulsions and tremor developed 1 hour after the examination and lasted for 50 minutes.

There was an increased risk of seizures in patients with a previous history of seizures and in association with antineoplastic therapy (97). Patients with thrombotic thrombocytopenic purpura also appear to be at greater risk of seizures during contrast examination. Fatal status epilepticus can occur during CT (98). The non-ionic agent iopamidol appears to be less likely to cause seizures (76).

Cortical blindness

Cortical blindness after exposure to contrast agents has been reported to be as high as 1–4% in patients undergoing vertebral angiography, even with modern non-ionic low-osmolality contrast agents. It has been thought to be due to breakdown of the blood–brain barrier of the occipital cortex with subsequent direct neurotoxicity of the contrast medium. Repeated exposure to contrast agents did not cause recurrent episodes of cortical blindness. The outcome seems to be favorable, with return of vision within 24–48 hours and probably no increased risk on re-exposure. Occasionally cortical blindness can be caused by other procedures, for example coronary angiography (99).

- During coronary angiography, a 55-year-old man was given 280 ml of non-ionic contrast media iomeprol (iodine 350 mg/ml). Ten minutes later he became progressively confused and developed complete loss of vision. A CT scan of the head showed pronounced intracerebral enhancement of contrast media in the posterior third of the brain without evident relation to a vascular territory and a straight border towards normal brain tissue. Angiography of the right vertebral artery showed normal patency of the vertebrobasilar and venous systems, excluding thromboembolic events in the posterior cerebral circulation. Another CT scan of the head 1 day later showed clearing of the contrast medium. The neurological deficit resolved more slowly, but there was normal vision and minimal amnestic deficit after 5 days.

These findings were compatible with leakage of contrast medium through the blood–brain barrier, direct or indirect neurotoxicity of the contrast media being the most likely explanation for the neurological symptoms.

- A 64-year-old man developed transient cortical blindness after right subclavian, aortic, and femoral arteriography for ischemic pain in his left leg (100). Iopromide 250 ml (iodine 300 mg/ml) was used. The patient was hemodynamically stable throughout the procedure, at the end of which he had blurred vision and a slight headache. He could see shapes and colors but could not focus. There were no field defects. His pupillary reflexes and eye movements were normal. His vision improved 3 hours later and fully recovered after 48 hours.
- A 29-year-old man had a subarachnoid hemorrhage due to an arteriovenous malformation, which was embolized (101). During the procedure he suddenly lost consciousness, regained it 15 minutes later, but complained of total blindness. Cerebral angiography showed no arteriovenous malformation and no abnormality in the vertebrobasilar system. A CT scan of the head showed considerable contrast enhancement of the occipital lobes and 2 hours later the contrast had cleared. An MRI scan 12 hours later showed no evidence of infarction in the occipital lobes. Two days later his sight gradually returned and 7 days later he had completely recovered.

The authors of the second report thought that these adverse effects were probably due to the low-osmolar non-ionic contrast agent. Disruption of the blood–brain barrier is a factor in the pathophysiology of this complication.

- After difficult cardiac angiography in the supine position, an elderly man with arteriosclerosis developed transient cortical blindness (102). On CT scan there was contrast enhancement of the occipital lobes.

The best explanation of this observation is that a large amount of contrast medium entered the vertebral artery and passed upwards, passing a defective blood–brain barrier. Similar complications have been described in other patients, sometimes with amnesia, after cardiac catheterization and angiography (SEDA-18, 444).

- A 63-year-old woman with a left-sided spastic hemiparesis underwent cardiac and coronary angiography with a large volume (300 ml) of the non-ionic contrast medium iomeprole (iodine 350 mg/ml) (103). After the procedure her hemiparesis dramatically worsened, prompting emergency CT scanning of the head, which showed a marked hyperdensity in the right cerebral hemisphere. She recovered from this acute event, and follow-up CT of the brain showed complete resolution of the hyperdensity.

The right hemisphere was more affected in this case, because the contrast medium injected into the left ventricle or ascending aorta during angiography is likely to reach the right brachiocephalic artery first. The hyperdensity of the affected cerebral hemisphere seen on CT scanning was due to leakage of the iodinated contrast medium into the extracellular space, because of an increase in the permeability of the blood–brain barrier.

Paraplegia

Paraplegia can occur after angiography (104). In one series of five patients, four had tetraplegia (three being due to parathyroid arteriography and one after angiography of the posterior fossa), and in the fifth, paraplegia followed attempted renal angiography. When these

© 2006 Elsevier B.V. All rights reserved.

neurological complications occur after angiography, the iodine content of the cerebrospinal fluid is raised.

There are various explanations, backed by animal studies, for this complication. When there is obstruction to the normal outflow of blood from the aorta, there is an increased risk that the contrast agent will be diverted into the spinal circulation. This effect can be aided by a gravitational factor if the examination is performed with the patient in the supine position.

The risk may not be the same for all contrast agents; the relation between the compound used and the neurotoxic effects is discussed below in connection with cerebral angiography.

Stroke

Cerebral effects can complicate thoracic aortography when excessive doses of concentrated agent are injected, particularly if the catheter is sited so that the major dose of contrast agent is directed into the cerebral circulation. In one case, 10 ml of sodium iotalamate 70% was injected into the carotid artery, being mistaken for methylglucamine iotalamate 60%; this was followed by an immediate convulsion, with loss of consciousness for 2 minutes. The patient at first appeared to have recovered completely, but hemiparesis followed and persisted for some 24 hours. Such changes are presumably due to cerebral edema after transient damage to the blood–brain barrier.

Cerebral oil embolism has been described in nine patients in one series of 3500 lymphograms (105) and in eight patients in another series of 16 501 investigations (106). All nine patients in the former series developed neurological signs, usually within 48 hours, reaching a peak in 4–7 days; the symptoms included motor dysfunction, paraplegia, and deep coma lasting for some weeks; three of the nine died. The electroencephalographic findings in these patients pointed to diffuse brain emboli. Evidence of retinal fat embolism can be useful in confirming the diagnosis and computed tomography can show collections of ethiodol in the brain. In the early phase after radiotherapy to the lungs, the vasculature is damaged, so that contrast agent is less effectively retained in the lungs. If lymphography is performed at this stage, there is an increased risk of cerebral embolism.

Sensory systems

Hearing impairment has been attributed to contrast agents.

- A 37-year-old man with recurrent attacks of low back pain underwent drip intravenous pyelography to exclude the possibility of stones of the urinary tract (8). Iohexol 300 was used, but the total volume was not documented. He had had drip intravenous pyelography for suspected urinary calculi 5 years before. A few hours after the procedure he suddenly had bilateral hearing loss and tinnitus in the right ear. He complained of dizziness and nausea but had no rotatory vertigo or skin rash. A pure-tone audiogram 2 days later showed complete right-sided and partial left-sided deafness. CT and MRI scans showed no abnormalities in the inner ear, internal auditory canal, or posterior fossa. He was given intravenous high-dose hydrocortisone sodium succinate, 10% dextran, and batroxobin, but there was no improvement in hearing. The dizziness and tinnitus in the right ear persisted, as did the deafness, for a further 2 months.

Hearing disturbances attributable to contrast agents are extremely rare. The hearing loss in this patient developed more than 1 hour after the injection of iohexol, without any evidence of other causes. The authors suggested that the hearing disturbance might have been attributable to cochlear impairment caused by a delayed allergic reaction or chemical toxicity of the contrast medium.

Psychological, psychiatric

To reduce the incidence of generalized reactions to contrast media in high-risk patients some authors have advocated the prophylactic administration of glucocorticoids (prednisolone 30 mg orally or methylprednisolone 32 mg orally, 12 and 2 hours before contrast injections). In one case an acute psychosis complicated glucocorticoid premedication to reduce the risk of contrast reactions (107).

- A 13-year-old girl with bipolar disorder and a history of adverse reactions to contrast media was given methylprednisolone (32 mg/day) and ranitidine (300 mg/day) before a CT scan of the head with intravenous contrast enhancement. One day after, she developed psychiatric symptoms, which were more severe than her initial symptoms, including extreme agitation and mental confusion. All medications were withdrawn and her symptoms resolved within 2 weeks.

The authors suggested that the recurrence of the manic symptoms could have been due to premedication with prednisolone. Exacerbation of manic symptoms after the use of glucocorticoids has been documented before, but never in a case of short-term premedication before contrast-enhanced radiographic examination. This report shows that even a short-term course of glucocorticoids can have significant adverse effects in patients with a history of mood disorders.

In 2500 cases of cervical myelography with metrizamide, there were transient mental reactions in 25, including 13 cases of confusion or disorientation, four of depression, two of hallucinations, two of psychosis, and one each of anxiety, drowsiness, dysphasia, and nightmares (108).

Of 18 German patients undergoing lumbar myelography with metrizamide, six had an organic psychosis, characterized by impaired memory and depression, but it was demonstrable only by psychometric tests and disappeared within 5 days (109). In four of the 18 patients there was hyporeflexia or areflexia and in three there were electroencephalographic changes; there was no correlation between these various types of effect.

Visual hallucinations are very rare adverse effects of contrast media, with isolated reports after vertebral angiography or myelography. The mechanism of this adverse reaction could be similar to that reported in transient cortical blindness after infusion of contrast agents. However, other possibilities include a toxic effect of contrast media on the optic nerve, transient impairment of cerebral blood flow, which could be mediated through the release of the potent vasoconstrictor endothelin, or the formation of microclots. Two cases of

© 2006 Elsevier B.V. All rights reserved.

visual hallucinations after coronary angiography have been reported (110).

- A 70-year-old woman with a history of mastectomy developed syncope which lasted a few seconds. She had taken tamoxifen 10 mg bd for 10 years and had no history of allergic reactions. Doppler ultrasound showed aortic stenosis and coronary angiography was performed using 150 ml of iopromide (a non-ionic contrast medium, iodine 370 mg/ml). She had visual hallucinations (spiders on the wall, moving curtains) 30 minutes after the injection of iopromide. The symptoms resolved 72 hours later without any specific treatment. Neurological and psychiatric examinations were normal, as were brain MRI and Doppler ultrasound of the carotid and vertebral arteries.
- A 64-year-old man with a history of ischemic heart disease underwent coronary angiography with 150 ml of iopromide (iodine 370 mg/ml). One hour later he had visual hallucinations (moving objects, pictures of familiar persons), which resolved about 40 hours later without any treatment. He had taken the following drugs for a year: nifedipine 10 mg tds, metoprolol 50 mg bd, and aspirin 325 mg/day. His serum creatinine concentration was in the reference range and there was no history of allergies or previous exposure to contrast media.

Myelography with either iopamidol or metrizamide can cause transitory deterioration in memory as determined by psychological tests, but the effect is less with iopamidol (111).

Many of the psychiatric complications of cerebral angiography may be due to arterial trauma rather than to the toxic effect of the contrast agent. If the investigation is undertaken under general anesthesia, the use of a volatile anesthetic can in itself cause an increase in intracranial pressure and thereby constitute an aggravating factor (112). Focal electroencephalographic changes can occur on the side of the injection, and if these are prolonged they can be followed by evidence of neurological involvement. Transient global amnesia and confusional states have been reported after cerebral angiography, even with non-ionic media (SEDA-9, 410) (113).

Endocrine

Contrast agents contain very large amounts of iodine, though it is in a bound form. Liberation of iodine (114) from these agents can produce some inhibition of thyroid function in healthy subjects for up to 3 months, but can also increase hormonal synthesis in a thyroid adenoma, and cases of frank thyrotoxicosis have been attributed to these agents, the effect starting within a few days (115). Hypothyroidism has also been reported, particularly in neonates. Contrast medium-induced hyperthyroidism is rare and usually occurs in patients with autonomous thyroid function. Treatment is exclusively symptomatic. Prophylaxis with sodium perchlorate should be considered in cardiac patients with a goiter and a subnormal concentration of thyroid stimulating hormone (TSH) (SEDA-21, 478) (116). In premature babies and neonates thyroid complications can develop after intravascular administration of iodinated contrast media and great caution should be exercised during radiological examinations in infants (SEDA-20, 420).

Thyroid metabolism has been prospectively investigated in 102 patients undergoing diagnostic coronary angiography (117). Thyroid function tests (T3, rT3, T4, free T4, and TSH) and urinary iodine excretion were measured before and 3 weeks after diagnostic intra-arterial administration of iodinated contrast agents. Only euthyroid patients were included, in order to determine whether the administration of non-ionic iodine-containing contrast agents causes significant thyroid function changes in euthyroid patients and whether thyroid morphology is a prognostic factor for the risk of hyperthyroidism. Serum concentrations of thyroid autoantibodies (TPO-Ab, Tg-Ab, TSH-receptor-Ab) were measured. Thyroid ultrasound showed that 37 patients had normal thyroid glands. The gland was of normal size but nodular in 16 patients, there was a diffuse goiter in 15 patients, and a nodular goiter in 34 patients. In 25 patients Tg-Ab was positive and in 13 patients TPO-Ab was positive; TSH-receptor-Ab was not detected in any patient. T3 concentrations did not change significantly after the administration of iodine. T4 and free T4 concentrations underwent significantly different changes in the four groups. The amount of iodine given did not affect the changes in the serum concentrations of TSH, T3, T4, free T4, or rT3. Raised concentrations of urinary iodine correlated with the amount of contrast medium given. There were no cases of hyperthyroidism. The study showed that thyroid function was significantly altered after coronary angiography, independent of antibody status and the amount of contrast agent given, but dependent on thyroid morphology.

The effects of iopromide on thyroid function have been investigated in 20 pre-term infants with very low birth weights and 26 matched premature infants who did not receive contrast medium (118). The dose of iopromide (iodine 300 mg/ml) was 0.3–1.0 ml. Iopromide did not affect the concentrations of free thyroxine and thyroid stimulating hormone. This was attributed to the small amount of free iodide that iopromide contains (0.6 microgram/ml) compared with other contrast media, in which the free iodide concentration ranges from 1.8 micrograms/ml (iohexol) to 4 micrograms/ml (ioxaglate). Furthermore, hypothyroidism has previously been described after the injection of less than 1 ml of ioxaglate 320 in 13 premature infants of less than 34 weeks gestational age and in other children after the injection of iopamidol. The authors concluded that iopromide may be superior to other contrast media in protecting infants of very low birth weight from thyroid dysfunction. It is advisable to monitor thyroid function when contrast media are given to such infants.

- A 54-year-old man developed Graves' disease and hypoadrenalism secondary to adrenocorticotropin deficiency soon after a cranial CT scan with an iodine-containing contrast agent (119).

It was presumed that the iodine load (about 30 g) had precipitated thyrotoxicosis in this patient, who had antibodies to the thyrotropin receptor, which in turn precipitated collapse due to adrenal insufficiency.

© 2006 Elsevier B.V. All rights reserved.

In three women (aged 63, 72, and 75 years) with subclinical goiters, hyperthyroidism developed after the intravenous administration of iodinated contrast medium (120). There was a marked rise in the concentration of free T4. The hyperthyroidism improved spontaneously in all three.

In 51 sick neonates given two different non-ionic, iodine-containing contrast agents, metrizamide and iohexol, urinary iodine excretion was increased on day 5 after iodine exposure (121). In 17 term neonates given Amipaque, the median TSH concentration was normal after 5 days and 2 weeks, and there was only one case of transient hypothyrotropinemia; median concentrations of T3 and T4 were in the lower reference ranges. However, in 15 neonates given Omnipaque the median TSH was raised and T3 and T4 concentrations were very low. There was hypothyroidism in six of the eight preterm and one of the seven term neonates.

- Mild hypothyroidism with a goiter developed in a 15-year-old boy 6 weeks after lymphangiography with Lipiodol ultrafluid; the goiter disappeared after 3 months treatment with levothyroxine (SEDA-7, 454).

Metabolism

Iopanoic acid is as potent a uricosuric agent as probenecid and this effect might explain some renal complications; aspirin reduces the uricosuric effect but can also impair X-ray visualization because of competition at plasma protein-binding sites. Fluctuations of serum urate after oral cholecystography can interfere with diagnostic tests and even precipitate an attack of gout (122).

Electrolyte balance

Iodinated contrast media can cause increased release of potassium from blood cells and vascular endothelial cells, as has been investigated in vitro using blood, collected from 52 patients, mixed with iodinated contrast media for 30 minutes (123). The following contrast media were used: iopamidol (iodine 370 mg/ml), ioxaglate (iodine 320 mg/ml) and diatrizoate (iodine 370 mg/ml). Potassium release increased after exposure to the contrast media and the high-osmolar diatrizoate caused the greatest release, followed by iopamidol and then ioxaglate. The osmolality of contrast media may play an important role in the mechanism responsible for the release of potassium from blood cells. Chemotoxicity may also play a role. There are no data to suggest that the release of potassium is due to hemolysis, and it is most likely due to increased membrane permeability.

Mineral balance

Contrast agents can lower serum calcium and magnesium concentrations (124), which may be relevant to the occasional occurrence of tetany (SEDA-7, 452).

Hematologic

A single case of severe but reversible hypoplastic anemia has been attributed to sodium diatrizoate (125). Ionic contrast media have a disaggregating effect on erythrocytes, and hyperosmolar agents reduce their elasticity (SEDA-22, 501). When blood is diluted with 90% sodium diatrizoate in vitro, there is initially a reduction in erythrocyte diameter, due to the hypertonic environment, but as more contrast medium is added, the erythrocytes increase in diameter because of damage to the cell wall; this tallies with the fact that cases of hemolysis and hemoglobinuria have been reported with amidotrizoate (126).

Iodinated water-soluble contrast agents have traditionally been contraindicated in patients with sickle cell disease, because of possible shrinkage of erythrocytes secondary to the high osmolality of these agents, which can lead to impaired blood flow through the microcirculation and can precipitate or exacerbate a sickle cell crisis. The hematological and rheological effects in vitro of four contrast agents of different osmolalities (iodixanol 290 mmol/kg, ioxaglate 600 mmol/kg, iohexol 844 mmol/kg, and diatrizoate 1940 mmol/kg) have been compared (127). Blood was tested from 10 healthy and 10 sickle cell donors at drug concentrations of 0, 1, 10, and 30% w/v in an attempt to approximate the circulating concentrations of contrast medium that might occur during bolus injection. There were significant hematological effects in the blood of both the healthy and sickle cell donors: there was a concentration-related reduction in hematocrit and MCV and an increase in MCHC, all of which varied directly with the osmolality of the contrast medium (amidotrizoate > iohexol > ioxaglate > iodixanol). Only with amidotrizoate at concentrations of 10–30% was there marked echinocytosis. There was no significant increase in the number of irreversibly sickled cells in donors with hemoglobin S. The filterability of erythrocyte suspensions through capillary-sized pores was impaired in both healthy and sickle cell samples in direct proportion to the osmolality of the contrast medium. Filterability effects were greater with sickle cells than healthy erythrocytes. Iodixanol, which is iso-osmolar with blood, had little effect on erythrocyte volume and had no significant effect on the filterability of healthy or sickle cells. These results suggest that microcirculatory impairment after infusion of contrast agents can occur in sickle cell disease because of the unusual rheological sensitivity of HbSS erythrocytes and may be avoided by using low-osmolar or iso-osmolar contrast agents.

Acute thrombocytopenic purpura has been reported in three patients given contrast agents (SEDA-11, 413). Severe thrombocytopenia has rarely been reported after iopanoic acid (128), iocetamic acid (129), and sodium iopodate; in the last case there was evidence that the patient had developed platelet antibodies of the type associated with other drug-induced thrombocytopenias (130).

- Thrombocytopenia occurred 24 hours after 100 ml of iopamidol was given intravenously during cranial CT scanning to investigate a 9-month history of headache (131). The patient reported purpuric lesions on her legs, abdomen, and gingival bleeding within 24 hours of the scan, and examination of the peripheral blood at 48 hours confirmed severe thrombocytopenia. A bone marrow smear showed a prominent increase in megakaryocytes and dysmegakaryopoiesis. The bleeding time was longer than 15 minutes. Other laboratory values were within normal limits. Within 10 days, all the lesions disappeared spontaneously and the platelet count improved gradually and returned to normal within 2 months.

© 2006 Elsevier B.V. All rights reserved.

The pathogenesis of this complication is not understood but is most likely an immunological response to the contrast agent.

Clotting time is longer shortly after administration of ionic contrast agents (132). Non-ionic contrast agents do not have a similar anticoagulant action. In contrast, if blood is allowed to mix with a non-ionic medium in a syringe or catheter, thrombus formation can occur and this could be a cause of thromboembolism (SEDA-15, 502) (133). The non-ionic agents are not so much thrombogenic as less anticoagulant than their ionic predecessors (SEDA-19, 429). The risk of thromboembolism with ionic agents has been described in some contested studies as being 4–10 times higher (SEDA-17, 537) (SEDA-18, 444) (134). The non-ionic agents produce profound degranulation of platelets in vitro, but this is unrelated to thrombin generation (135). However, some prefer to heparinize when giving the non-ionic media. This issue is contentious, and although non-ionic agents are viewed as being less anticoagulant than ionic agents, they are not considered to be procoagulant (SEDA-22, 501). Adherence to a high standard of angiographic technique, with regular flushing of the catheter with isotonic saline is crucial to avoid thromboembolic complications during angiography.

The effects of contrast agents on leukocytes, platelets, and endothelium have been investigated in 19 subjects (mean age 63 years) undergoing angiography with the non-ionic contrast medium iohexol 350 (median volume 40–160 ml) for leg ischemia (136). Blood was obtained from the external iliac vein before and at several intervals after the injection of the contrast agent into the ipsilateral femoral artery. Markers of endothelial cell injury (von Willebrand factor), platelet activation (soluble P selectin), and leukocyte activation (neutrophil elastase and soluble L selectin) were measured in citrated plasma. Soluble intracellular adhesion molecule-1 and thromboxane B_2, which are non-specific markers of inflammation, were also measured. Compared with the sample before angiography, concentrations of soluble L selectin and soluble intracellular adhesion molecule-1 were reduced immediately after passage of the last bolus of contrast medium; 15 minutes later the concentrations returned to normal, but the concentration of von Willebrand factor had increased. After 30 minutes, only thromboxane B_2 concentrations were increased. On the next day both von Willebrand factor and soluble P selectin were increased. These data point to both early and late effects of contrast agents on markers of endothelial, platelet, and leukocyte function. The authors suggested that these adverse changes may increase the risk of coagulopathy and thrombosis after contrast examination and increase the risk of re-stenosis after angioplasty.

The hematological effects of ioxaglate (a low-osmolar ionic dimer) 105 (range 95–114) ml ($n = 15$) and iopromide (a low-osmolar non-ionic monomer) 102 (range 90–108) ml ($n = 16$) have been investigated in patients undergoing abdominal and femoral angiography (137). The aim was to investigate in vivo whether non-ionic contrast media are less anticoagulant or more prothrombotic than ionic agents. Activation of coagulation and platelets were found in almost 50% of patients before any contrast medium was given. Both iopromide and ioxaglate caused further increases in thrombin-antithrombin complex, prothrombin fragments $1 + 2$, and beta-thromboglobulin; the degree of activation was similar with both agents. In contrast to the findings in in vitro studies, there were no significant differences between the effects of the non-ionic agent iopromide and the ionic agent ioxaglate. The results supported the notion that the catheterization procedure per se may represent a source of hemostatic activation and that ionic contrast agents have insufficient anticoagulant effect to prevent clotting activation being induced by the procedure. The study also yielded no support for the concept that non-ionic contrast media are less anticoagulant or more prothrombotic than ionic agents.

However, it has been suggested that anticoagulant effects are high with ionic media and low with non-ionic media (138). The authors also suggested that there is no direct activation of platelets with low-osmolar ionic and non-ionic dimeric contrast agents but a high degree of activation with non-ionic monomeric contrast media. They concluded that although the interaction between contrast media and coagulation has been widely studied in vitro and in vivo, this issue is contentious and further studies are required for better understanding.

Within a few hours after lymphography, the lymph nodes show dilatation of the marginal and intermediate sinuses and a giant-cell reaction, with diffuse reticulocytosis and sinus histiocytosis. Diffuse plasmacytosis and an increase in the eosinophil count can also occur. The response is maximal after 10–14 days, but the changes in the lymph nodes may not be eliminated for as long as 15 months (SED-12, 1184) (139).

The thrombotic complications after angioplasty have been investigated in patients with unstable angina (140). There was no significant difference in the incidence of thrombotic complications between patients who received the low-osmolar ionic dimer ioxaglate ($n = 103$) and those who received the non-ionic agent iopamidol ($n = 102$), although there was a non-significant trend towards more thrombus formation in the non-ionic group (21 of 129 patients) compared with the ionic group (15 of 141 patients). The two groups were well matched with respect to age, sex, class of unstable angina, and susceptibility factors. There was no significant difference between the two groups with respect to clinical outcome in the first 24 hours after percutaneous coronary angioplasty.

- Disseminated intravascular coagulation has been described in a 63-year-old man who received 50 ml of the non-ionic monomer iobitridol (iodine 300 mg/ml) for arteriography (141).

Mouth and teeth

Swelling of the parotid glands has been recognized as an occasional effect of contrast agents for very many years (142). It occurs particularly when there is renal insufficiency; the swelling usually occurs 2–4 days after the procedure and can last for several days, but evanescent salivary gland enlargement can also occur within a few minutes of injection and last for a number of hours. In one case the complication was associated with paralysis of the facial nerve, which largely subsided over the next 9 weeks.

Gastrointestinal

Nausea and vomiting can occur in reaction to contrast agents. Diarrhea is less common but has been repeatedly reported, sometimes with angioedema of the bowel (143).

Infarction of the bowel was formerly a very occasional complication of abdominal aortography and was due to injection of contrast medium into the mesenteric arteries. Most of these cases were due to the older media, such as acetrizoate; however, small bowel injury has occurred after injection of a concentrated bolus of sodium iotalamate (144). Ileus has been reported after mesenteric angiography in a patient with renal insufficiency (SED-12, 1177) (145).

Intra-arterial injection of lipiodol (iodized oil) has been used to enhance the accuracy of computed tomography in hepatic tumors. This can cause transient bowel ischemia with nausea, vomiting and diarrhea.

The use of Gastrografin for pre-operative mechanical bowel preparation has been investigated in 58 patients (aged 45–80 years) listed for elective colorectal operations (146). One group (30 patients, mean age 67 years) was given oral Gastrografin 200 ml and 3 liters of water for 2 days before the operation. The rest (28 patients, mean age 65 years) were given Ringer's solution 5–20 liters, warmed to body temperature, through a nasogastric tube; preparation was considered complete when the patient excreted clear fluid. All were given metronidazole and cefuroxime as antibiotic prophylaxis during the perioperative period. There were no significant adverse effects in the Gastrografin group, apart from nausea in six patients. In the Ringer's solution group there was nausea in 15 patients and vomiting in eight. A clean colon was found at operation in 93% of patients in both groups. The authors concluded that Gastrografin is well tolerated and can be used successfully for mechanical bowel preparation before elective colorectal surgery.

The rectal administration of Gastrografin 400–1000 ml in patients with suspected diverticular disease before CT examination of the abdomen has been investigated in 308 patients (aged 19–97 years) (147). None of the CT scans showed extravasated contrast material in the peritoneal cavity as a sign of bowel perforation. No patient had sudden clinical deterioration after the examination. All tolerated the contrast medium well and there were no allergic reactions. High-quality diagnostic examinations were obtained in all patients.

Contrast agents caused release of vasoactive intestinal polypeptide in a patient with a vipoma of the pancreas and hepatic secondaries (SEDA-11, 411) (148).

The high-osmolar agents amidotrizoate and iotalamate were formerly recommended for oral use in preference to barium where there was a risk of perforation, but the osmotic effect of such material can lead to diarrhea and fluid loss, which can be dangerous in weak patients. Amidotrizoate, despite its cathartic action, can occasionally cause ileus when given postoperatively (149); it can also be precipitated as a solid mass in the stomach when gastric acidity is high, but also in an achlorhydric gastric stump following partial gastrectomy if there is stomal obstruction. On one occasion, when diatrizoate was used to fill the gastric balloon of a Sengstaken–Blakemore tube, hydrogen ions from the gastric content apparently penetrated the balloon, precipitated the contrast medium, and thus prevented the balloon's removal.

Low-osmolar media such as iohexol are now preferred for oral use; they can still cause some diarrhea, for example in 18 out of 40 cases in one series (SEDA-16, 529). Absorption can be increased if there is mucosal damage in the bowel, such as in Crohn's disease, resulting in delayed excretion but not apparently involving risk (SEDA-18, 441).

Amidotrizoate enemas are still sometimes used to treat meconium ileus or constipation, and it is important to give intravenous fluids so as to avoid dehydration. Hypomagnesemia can also occur (150). Osmotic effects lower in the gastrointestinal tract have even led to distention and cecal perforation (151). Stasis of amidotrizoate in dilated loops of bowel can cause inflammatory changes or necrosis (152,153).

Liver

Sulfobromphthalein retention is increased by sodium iopodate or iopanoic acid, probably by competition in the hepatic excretory pathway. The mechanism is not clear. Serum bilirubin concentration can rise, and there can be a slight increase in serum enzymes, persisting for a few days.

There have been several reports of hepatotoxicity of iodipamide, variously characterized by epigastric pain, nausea and vomiting, jaundice, pyrexia, and tenderness over the liver, with abnormal liver function tests. Biopsy has shown centrilobular necrosis (154). The incidence of abnormal liver function tests may be as high as 18% after a dose of 40 ml, and the quantity given should be as small as possible. Prior administration of glucocorticoids or sulfonylureas impairs hepatic excretion of ioglycamide. Both iodoxamate and iotroxate can affect liver function tests; in a small series of cases, the degree of intrahepatic cholestasis appeared to be relatively more marked after iodoxamate than after iotroxate (SED-12, 1168) (155).

- A 19-year-old woman without previous hepatic impairment developed abdominal pain and an acute rise in liver enzymes after an injection of iopromide (156). During intravenous infusion of iopromide she developed vomiting and hypotension, which resolved within a few hours. Repeat laboratory tests showed a rise in serum transaminases, which peaked on the second day and then rapidly fell. There was a slight prolongation of the prothrombin time and a moderate increase in total serum bilirubin. Serum gamma-glutamyl transpeptidase activity was normal. Ultrasonography of the liver and biliary tree was normal and serological markers for viral hepatitis were negative. Two weeks later, liver function tests were all in the normal range.

An acute rise in liver enzymes after intravascular iopromide is uncommon and has been previously reported only in some patients with concomitant hepatic impairment. In this case, the temporal association (rapid clinical onset and raised serum transaminases after the injection of iopromide) suggested that iopromide may have played a role in the occurrence of the hepatitis-like picture.

Biliary tract

Embolization of the cystic artery can cause acute acalculous cholecystitis (SEDA-15, 505).

Water-soluble contrast media are used to examine the pancreas and bile ducts during ERCP. Contrast media can affect the examination of bile for microlithiasis (157). Bile contaminated with contrast media during ERCP had pseudo-microlithiasis, mimicking calcium bilirubinate granules. This effect was observed with both the high-osmolar contrast medium sodium amidotrizoate and the low-osmolar medium iohexol. The authors concluded that bile collected during ERCP to be examined for microlithiasis should be collected without contamination by contrast agents. If this is not possible, pathologists should be aware that contrast media can cause pseudo-microlithiasis. Awareness of this effect may prevent unnecessary cholecystectomy.

Pancreas

Contrast agents can cause transitory enlargement of the pancreas (SEDA-11, 411). Oral and intravenous cholangiography have very rarely been reported to precipitate acute pancreatitis (158).

An experimental study has suggested that intravenous injection of contrast media can cause increased mortality associated with severe pancreatitis (SEDA-19, 425). There was little difference between ionic and non-ionic agents. The authors argue that contrast-enhanced CT should be avoided in patients with severe pancreatitis as it can exacerbate it.

Acute pancreatitis is a well-recognized complication of ERCP, and contrast media have been incriminated in its pathogenesis. It has been suggested that the use of low-osmolar non-ionic contrast media may minimize the risk. However, this has not been proven conclusively.

The iso-osmolar non-ionic dimer iotrolan and the low-osmolar ionic monomer iopromide (osmolarity about twice that of the blood) have been compared in 40 patients who underwent ERCP (159). They were randomized to receive either iopromide (iodine 300 mg/ml, 770 mosmol/kg, mean dose 15 ml) or iotrolan (iodine 300 mg/ml, 320 mosmol/kg, mean dose 12 ml). Pancreatitis after ERCP occurred in two patients given iopromide and in five given iotrolan. There were no significant differences between the groups in the time-course of changes in serum pancreatic enzyme activities, changes in acute-phase proteins, or the incidence of abdominal pain.

Experimental data suggest that high-osmolar ionic contrast media are more likely to cause chemical irritation of the pancreas, precipitating pancreatitis (159). However, clinical trials have not shown a clear advantage in using non-ionic media in ERCP. For example, in the above-mentioned study, iotrolan did not offer an advantage compared with iopromide (159). The authors suggested that overfilling of the pancreatic duct with contrast medium could be an important factor in the pathogenesis of ERCP-induced pancreatitis and that careful technique is important to avoid this complication.

Urinary tract

The kidney is the main route of elimination of water-soluble contrast agents. Ideally, the agents should be filtered without causing functional or structural changes in the kidney. Unfortunately, this is far from attainable and these agents cause altered renal function and structural changes in the renal tubules. These effects are usually of no clinical significance in patients with normal kidneys. However, in the presence of renal impairment, further significant deterioration in renal function can occur and can lead to significant morbidity and even mortality in some cases (4). Clinical experience has shown that non-ionic low-osmolar contrast media are less nephrotoxic than high-osmolar agents, particularly in patients with pre-existing renal impairment (SEDA-19, 428). However, renal tolerance of the different commercial formulations of non-ionic agents seems to be comparable.

Contrast medium-induced renal damage is associated with impaired renal function (an increase in serum creatinine by more than 25% or 44 μmol/l) within 3 days after the intravascular administration of a contrast medium in the absence of an alternative cause.

Presentation

A slight transitory increase in serum creatinine commonly occurs after the administration of contrast agents, and dysuria can occur. Acute renal insufficiency is uncommon with the agents currently in use, but some 100 fatalities were reported with bunamiodyl sodium. The mechanism is not clear; diffuse acute tubular necrosis, sometimes with crystals of calcium salts, has been found at biopsy or autopsy (160). A reduction in creatinine clearance within the reference range is common. The possibility that these agents might simply block the renal tubules has been advanced, but they are only present in the urine in small amounts in their non-conjugated, that is relatively insoluble, form. An effect on uric acid excretion might be involved. In any event, sufficient fluid should be given to ensure an adequate flow of urine.

The term "contrast nephrotoxicity" implies that impairment in renal function (an increase in serum creatinine by more than 25% or 44 μmol/l) has occurred within 3 days after the intravascular administration of contrast agents and the absence of an alternative cause (161). The increase in serum creatinine, which reflects a reduction in glomerular filtration rate, often peaks within 3–4 days after the administration of contrast agents. Mild proteinuria and oliguria can also occur. However, most patients with contrast nephrotoxicity tend to be non-oliguric, except those with pre-existing advanced chronic renal insufficiency. Heavy proteinuria is an unusual feature of contrast medium nephrotoxicity (162). Urinary enzymes are often increased after the administration of contrast agents. However, no relation has been established between a reduced glomerular filtration rate, a raised serum creatinine (the characteristic features of contrast nephrotoxicity), and the presence of enzymuria after the administration of contrast agents. It is therefore argued that the detection of urinary enzymes is of little importance to the clinical assessment and management of contrast medium nephrotoxicity (163). A persistent nephrogram on plain radiography or CT of the abdomen for 24–48 hours after the injection of a contrast agent has also been described as a feature of contrast nephrotoxicity

© 2006 Elsevier B.V. All rights reserved.

(162,164). This sign is now considered to be non-specific and can be observed in a number of cases without nephrotoxicity (165). However, the presence of this sign may discourage the administration of further doses of contrast agents (161). Fortunately, most episodes of contrast medium nephrotoxicity are self-limiting and resolve within 1–2 weeks. Permanent renal damage is rare and occurs only in a very few instances. However, contrast medium nephrotoxicity can increase the risk of severe non-renal complications and prolong hospital stay (4,161).

Contrast nephrotoxicity can be confused with the syndrome of atheroembolism that can occur after angiography. This condition is not caused by contrast agents, but results from trauma to atherosclerotic blood vessels, precipitating cholesterol microemboli. The clinical picture is characterized by acute renal insufficiency associated with distal digital infarction and skin mottling. Renal histology shows the pathognomonic microvascular cholesterol emboli (4).

Incidence

There are wide variations in the reported incidence of contrast nephrotoxicity because of differences in patient selection, the type of radiological procedure, and the definition of renal impairment. Contrast nephrotoxicity is relatively uncommon in people with normal renal function, in whom it is 0–10%. Pre-existing renal impairment increases the frequency, with a reported incidence of 12–27% in several prospective controlled studies. In some studies the incidence was as high as 50%, in spite of the use of low-osmolar contrast agents and adequate hydration. Dialysis may be required in some of these patients (SEDA-22, 502).

The causes of acute renal insufficiency have been surveyed in elderly patients (over 60 years) admitted to a hospital in India over 12 months (166). Of 4176 patients 59 (1.4%) developed acute renal insufficiency during hospitalization. Contrast medium injection was the culprit in 10 patients.

The incidence of contrast-induced renal damage has been investigated in 100 consecutive trauma patients (mean age 37 years) who underwent angiographic embolization (mean dose of contrast agent "non-ionic low osmolar" 248 ml) for bleeding in the abdomen or pelvis (167). None had diabetes or renal impairment before the injury (mean baseline serum creatinine 88 μmol/l). The serum creatinine increased by more than 25% of baseline in five patients, and returned to baseline within 5 days.

Comparative studies

The renal effects of iodixanol 40–100 ml and iohexol 42–102 ml have been compared in 116 patients undergoing renal and/or peripheral angiography (168). The two groups had the same baseline renal function and prevalence of diabetes. The serum creatinine rose by more than 10% in 15% of the patients given iodixanol and in 31% of the patients given iohexol and by more than 25% in 3.7% of the patients given iodixanol and in 10% of the patients given iohexol during the week after angiography. There was a correlation between the dose of contrast medium and the change in serum creatinine in both groups. These results suggest that iodixanol may be slightly less nephrotoxic than iohexol. However, previous reports have failed to show a significant difference between the non-ionic dimers and non-ionic monomers in relation to renal tolerance. The authors suggested that factors other than contrast media may have contributed to the rise in serum creatinine in some of their patients.

The renal effects of low-osmolar contrast agents (iopromide, ioversole, and ioxaglate) have been evaluated in 45 patients who underwent cardiac angiography (169). Iopromide (iodine 370 mg/ml, mean dose 1.9 g/kg) was used in 15 patients (mean age 62 years, mean serum creatinine 107 μmol/l, mean creatinine clearance 67 ml/minute), ioversole (iodine 320 mg/ml, mean dose 1.8 g/kg) in 15 patients (mean age 62 years, mean serum creatinine 103 μmol/l, mean creatinine clearance 71 ml/minute), and ioxaglate (iodine 320 mg/ml, mean dose 1.8 g/kg) in 15 patients (mean age 63 years, mean serum creatinine 100 μmol/l, mean creatinine clearance 71 ml/minute). All were normally hydrated and none had been examined with contrast agents in the months before the study or had been treated with nephrotoxic drugs. There were minor increases in serum creatinine 24 hours after ioversole (from 103 to 107 μmol/l) and ioxaglate (from 100 to 106 μmol/l) and at 48 hours after iopromide (from 107 to 115 μmol/l). Plasma concentrations of $beta_2$-microglobulin increased only with ioxaglate (from 1.9 to 2.0 micrograms/ml at 24 hours). There was a reduction in creatinine clearance from 71 to 55 ml/minute only with ioxaglate 6 hours after the administration, but it returned to baseline 24 hours later. There were no significant variations in creatinine clearance at 48 hours after angiography. There were increases in the activities of different tubular enzymes in the urine after angiography with all the contrast agents, but the changes were larger after ioxaglate. The tubular effects were maximum at 6–24 hours and returned to baseline within 72 hours after angiography. In summary, all three low-osmolar contrast agents caused reversible tubular damage, indicated by increased enzymuria, which was higher after ioxaglate. In addition, ioxaglate slightly impaired glomerular function. None of the observed changes in renal function were clinically relevant and they were not statistically significant. In summary, none of the three low-osmolar contrast agents caused significant changes in renal function. However, the authors suggested that ioxaglate is probably more nephrotoxic than non-ionic monomeric agents, and that other physicochemical properties beside osmolality play a role in nephrotoxicity due to contrast agents.

Placebo-controlled studies

The clinical and biological tolerance of iobitridol (Xenetix, a non-ionic medium, osmolality 915 mosmol/kg at an iodine concentration of 350 mg/ml) has been assessed in a placebo-controlled study in 21 patients with chronic renal insufficiency (glomerular filtration rate less than 60 ml/minute) (170). Serum creatinine and creatinine clearance remained stable 24 and 48 hours after the procedure. No patient had a nephrotoxic reaction or acute oliguria. Only one patient given iobitridol had an increase in serum creatinine of more than 15% from baseline; the serum creatinine normalized within 4 days of contrast administration. One patient given placebo had

© 2006 Elsevier B.V. All rights reserved.

a similar increase in serum creatinine, which recovered within 48 hours. The author suggested that the use of non-ionic media such as iobitridol should result in a substantial reduction in the incidence of contrast nephropathy.

Susceptibility factors

There are several susceptibility factors for the development of contrast agent-induced renal damage, including pre-existing renal insufficiency, particularly if it is secondary to diabetes mellitus, dehydration, multiple repeat exposure to contrast media within a short period of time (72 hours), congestive heart failure, or concurrent administration of nephrotoxic drugs, such as non-steroidal anti-inflammatory drugs (171).

- A 45-year-old man with aggressive hypertension underwent abdominal aortography to assess the possibility of renal artery stenosis (172). His baseline renal function was reduced and the serum creatinine was 210 μmol/l. He received 1000 ml of saline solution intravenously as prophylaxis against contrast nephropathy. An unidentified high-osmolar contrast medium was injected into the abdominal aorta above the level of the renal arteries. There were atherosclerotic changes in the abdominal aorta and a discrete stenosis of left renal artery. Oliguria developed 24 hours later and the serum creatinine rose to 350 μmol/l. He was given isotonic saline (2 l/day) with 100 mg of furosemide. After 2 days the serum creatinine concentration fell to 190 μmol/l and his daily urine volume increased to 1.6 l/day.

The risk of contrast-induced acute renal insufficiency is particularly high in patients with diabetic nephropathy. Diabetes mellitus per se without renal impairment is not a susceptibility factor. The degree of renal insufficiency before the administration of contrast agents largely determines the severity of the nephrotoxicity. Old age (over 60 years), dehydration, and congestive cardiac failure are also risk factors. Multiple myeloma has been considered in the past as a risk factor for contrast nephrotoxicity. However, if dehydration is avoided, low-osmolar contrast agents rarely cause acute renal insufficiency in patients with myeloma. The concurrent use of nephrotoxic drugs, such as non-steroidal anti-inflammatory drugs (NSAIDs) and aminoglycosides, potentiates the nephrotoxic effects of contrast media. The importance of hypertension, hyperuricemia, or proteinuria per se as susceptibility factors for contrast nephrotoxicity is not clear (161,162). Large doses of contrast agents and multiple injections within 72 hours increase the risk of contrast nephrotoxicity. However, it has been reported that the intravenous administration of high doses of low-osmolality non-ionic iodinated contrast agent is safe in patients who have no pre-existing renal dysfunction or other underlying risk factors, even if doses as high as 800 ml are used (SEDA-21, 479). The route of administration is also important, and contrast agents are less nephrotoxic when administered intravenously than when given intra-arterially into the renal arteries or the aorta proximal to the origin of the renal blood vessels. The acute intrarenal concentration of contrast agent is much higher after intra-arterial injection than after intravenous administration. The type of contrast agent is also an important predisposing factor for contrast nephrotoxicity. High-osmolar contrast media are more nephrotoxic than low-osmolar contrast media, particularly in patients with pre-existing renal impairment. Whether the non-ionic dimers, which are iso-osmolar and highly hydrophilic, are less nephrotoxic is not yet clear. Clinical experience has so far shown no difference in the renal tolerance of non-ionic monomers and the iso-osmolar dimers (161).

The pharmacokinetics and safety of the low-osmolar non-ionic contrast agent iomeprole have been investigated in healthy volunteers and patients with various degrees of renal impairment (173). Six patients had normal renal function (glomerular filtration rate over 100 ml/minute, aged 22–58 years), six had mild renal impairment (glomerular filtration rate 51–75 ml/minute, aged 36–74 years), six had moderate renal insufficiency (glomerular filtration rate 26–50 ml/minute, aged 58–79 years), and four had severe renal impairment (glomerular filtration rate below 25 ml/minute; aged 34–73 years). Eight patients (aged 24–62 years) with end-stage renal disease who were receiving chronic hemodialysis were also studied. All received a single intravenous 50 ml bolus injection of iomeprole (iodine 400 mg/ml) and dialysis was performed about 2 hours later. The half-life of iomeprol increased progressively with increasing renal impairment. The half-life was 2 hours in patients with normal renal function, 4–6 hours in those with mild renal impairment, and 16–48 hours in those with severe renal impairment. Fecal excretion over 120 hours ranged from 1.6% of the total dose in healthy subjects to 7.2% in those with severe renal impairment. Thus, the pharmacokinetics of iomeprole are similar to those of other water-soluble contrast agents.

Hepatic cirrhosis is not a susceptibility factor, according to the results of a study in 72 patients with hepatic cirrhosis and 72 controls, who received 100–150 ml of low-osmolar contrast media intravenously for abdominal or chest CT scans (174). Serum creatinine was measured before and 48–72 hours after the administration of the contrast agent. The incidence of contrast nephrotoxicity was comparable in the two groups (two patients in the cirrhosis group and one control).

The type and dose of contrast media are important factors in the development of contrast nephrotoxicity. In patients with pre-existing renal impairment, low-osmolar non-ionic contrast agents are less nephrotoxic than high-osmolar agents and the iso-osmolar non-ionic dimers are less nephrotoxic than the low-osmolar non-ionic monomers. In 129 diabetic patients (mean age 71 years) with renal impairment (baseline serum creatinine 133–309 μmol/l) requiring angiographic examinations, the iso-osmolar dimer iodixanol ($n = 64$) was significantly less nephrotoxic than the low-osmolar non-ionic monomer iohexol ($n = 65$) (175). The incidence of contrast nephrotoxicity was 3% in the iodixanol group and 26% in the iohexol group. The authors concluded that iodixanol has low nephrotoxicity and should be the contrast agent of choice in patients at high risk of this complication.

Pathophysiology

The pathophysiology of contrast nephrotoxicity involves a reduction in renal perfusion caused by a direct effect of

© 2006 Elsevier B.V. All rights reserved.

contrast agents on the kidney and toxic effects on the tubular cells. The mechanisms responsible for the reduction in renal perfusion involve tubular and vascular events. The endogenous vasoactive peptide endothelin seems to play an important role in mediating the nephrotoxic effects (SEDA-20, 421) (161).

Renal damage can occur in infants who receive large doses of ionic contrast agents during cardioangiography. Fatal cases after doses of more than 3 ml/kg had renal medullary necrosis or severe proximal tubular vacuolation. In other infants, such doses have produced microscopic hematuria. Renal necrosis has occurred in infants after intravenous administration of sodium diatrizoate 1–3 ml/kg, but these children were in very poor general condition. In high-risk adults, cardioangiography can similarly cause contrast nephropathy (SEDA-15, 501).

In abdominal aortography, the contrast agent reaching the renal parenchyma is relatively undiluted, so that factors of concentration and volume are more important, particularly if a bolus of high concentration is accidentally injected directly into the renal artery. In the early days of abdominal aortography, renal damage was a significant hazard, mainly because the agents then in use were relatively toxic, but at high doses or high concentrations the agents now used can also cause renal damage. In 400 patients undergoing angiography with high doses of an ionic contrast agent, the overall incidence of acute renal dysfunction was 11%, but in patients with pre-existing renal disease the incidence was 42%. Injections close to the renal arteries are more likely to cause renal damage than a similar dose of contrast agent injected intravenously for digital vascular imaging (SEDA-9, 408). In a patient with renal artery stenosis an intra-aortic injection of 30 ml of 50% methylglucamine diatrizoate at the level of the renal arteries resulted in oliguria with pyrexia within a few hours, and the urine output only gradually recovered over about 2 months (176). Diabetes was a predisposing factor in another case (SED-12, 1177) (177). In two other cases, renal insufficiency was followed by nephrogenic diabetes insipidus and nephrotic syndrome (SED-8, 1042) (178).

Contrast media, particularly high-osmolar agents, can cause a significant natriuresis and diuresis. In 42 patients who underwent cardiac angiography, the fractional excretion of sodium, the urinary excretion of the renal natriuretic peptide urodilatin, and the plasma concentration of atrial natriuretic peptide were measured before and after intravascular diatrizoate (an ionic high-osmolar contrast agent) 55 ml, or the non-ionic agent iopamidol 200 ml (179). None of the patients had diabetic nephropathy or multiple myeloma. Diuretics, angiotensin converting enzyme inhibitors, and non-steroidal anti-inflammatory drugs were withheld for at least 12 hours before the examination, and 11 patients received a mean of 600 ml of isotonic saline intravenously before and during angiography, because of mild chronic renal insufficiency. The other 31 received no volume expansion. Both groups received a similar volume of radiocontrast agent. After angiography the plasma concentration of atrial natriuretic peptide and the urinary excretion of urodilatin both increased. Urinary urodilatin excretion correlated with an increase in the fractional excretion of sodium. There was no correlation between the serum concentration of atrial natriuretic peptide and urinary sodium excretion. This study suggests that the intravascular administration of contrast agents causes a natriuresis associated with the urinary excretion of urodilatin. This is consistent with the hypothesis that urodilatin may contribute to sodium excretion after radiocontrast administration in a paracrine manner.

Transient proteinuria is common after aortography and selective nephroangiography, because of an increase in glomerular permeability. Ioxaglate, iopamidol, and iohexol cause only negligible proteinuria (SEDA-8, 428) (SEDA-11, 413).

Enzymuria has been reported after the intravascular administration of high-osmolar or low-osmolar contrast media (180). The study suggested that the brush-border enzyme gamma-glutamyl transpeptidase is a better marker for tubular toxicity due to contrast media than alanine aminopeptidase. However, no relation has been established between a reduction in glomerular filtration rate, a rise in serum creatinine (the characteristic features of contrast nephrotoxicity), and the presence of enzymuria. It has been argued that the detection of urinary enzymes is of little importance to the clinical assessment and management of contrast medium nephrotoxicity (161).

In patients who have received iodinated contrast media, urinary beta$_2$-microglobulin, albumin, epidermal growth factor, and gamma-glutamyl transpeptidase, *N*-acetyl-beta-D-glucosaminidase, and serum angiotensin-converting enzyme (ACE) activities are sensitive markers for the early detection of subclinical contrast medium-induced nephrotoxicity (181). At 24 hours after injection of contrast agents in 16 patients (aged 18–62 years, nine men), serum ACE and urinary beta$_2$-microglobulin, albumin, and enzymes were significantly raised. At 48 hours, serum creatinine concentrations increased significantly and urinary excretion of albumin remained significantly increased, but urinary enzyme excretion began to recover. Urinary excretion of epidermal growth factor was significantly reduced, due to tubular injury; healthy tubular cells release this factor into the urine and it is not filtered at the glomeruli. The observation that urinary albumin excretion continued to increase after the urinary enzymes started to recover suggests that the albuminuria induced by contrast media is probably due to glomerular and not tubular dysfunction. The mechanism of the rise in serum ACE activity is not known, but it may be due to damage to the vascular endothelial cells of glomeruli, ACE release from the brush borders of the epithelial cells of the proximal tubules, or an increase in vascular permeability and leakage of the enzyme into the blood.

Acute reduction in renal perfusion is considered important in the pathophysiology of contrast agent-induced nephrotoxicity. Color-coded duplex sonography has been used in assessing intrarenal vascular resistance in 10 patients (mean age 51 years) after intravenous injection of 100 ml of the low-osmolar contrast medium iopamidol (iodine 300 mg/ml) (182). The resistive index was measured at 1-minute intervals over 10 minutes after injection in each patient. There was a statistically significant rise in resistive index at 2, 3, 4, and 5 minutes after injection, mean values 0.74, 0.75, 0.72, and 0.75

© 2006 Elsevier B.V. All rights reserved.

respectively. The resistive index then fell progressively to baseline values (mean 0.70) within 10 minutes. The authors concluded that color-coded duplex sonography is a simple method for checking changes in renal flow resistance after intravascular contrast agents. They suggested that arterial Doppler flow measurement is ideal for investigating the pathophysiological mechanism of contrast agent-induced nephrotoxicity.

Prevention

Prevention of contrast nephropathy rests largely on the exclusion of high-risk cases, such as very ill patients with diabetic renal insufficiency, severe cardiovascular disease with reduced renal blood flow, jaundice, pre-existing uremia, and multiple myeloma. When the investigation is nevertheless needed in these conditions, the lowest possible dose of a low-osmolar non-ionic contrast medium should be used in patients at high risk of this complication. High-osmolar contrast media and large doses should be avoided. In addition, intravenous hydration with saline (1 ml/kg /hour for 4–6 hours before contrast injection to be continued for 12 hours afterwards) should be given. The concomitant use of other potentially nephrotoxic agents should be avoided. Finally, since the small amounts of contrast agent that remain in the body after a radiographic examination can potentiate renal damage resulting from subsequent events, there should be a delay of at least 12 hours after the examination before undertaking any surgery that could adversely effect the kidney, for example, procedures requiring temporary renal clamping or percutaneous balloon dilatation of the renal artery. A similar delay is advised between cerebral angiography and renal harvesting for transplantation. If renal glomerular filtration is reduced by 50% or more, a delay of 24 hours or more may be advisable after aortofemoral angiography (SEDA-15, 502).

Saline

Whether half-strength or isotonic saline should be used has been investigated in 809 patients who received half-strength saline and 811 patients who received isotonic saline (183). The two groups were matched in relation to baseline characteristics, and the mean serum creatinine before contrast injection was 80 μmol/l. All underwent coronary angioplasty using the low-osmolar non-ionic contrast medium iopromide (mean volume 234 ml). The incidence of contrast nephrotoxicity in those who received isotonic saline was 0.7% and in those who received half-isotonic saline it was 2%. The authors concluded that isotonic saline is superior to half-strength solution in reducing the incidence of contrast media nephrotoxicity.

Hemodialysis

Although hemodialysis is effective in removing contrast media from the body, its ability to prevent contrast nephrotoxicity has been disappointing. Hemodialysis after contrast administration in patients with pre-existing renal impairment does not prevent contrast nephropathy (SEDA-22, 502) because of the very rapid onset of renal damage (SEDA-21, 481) (SEDA-22, 501), since the effect of contrast media on the kidney after intravascular administration is almost instant and hemodialysis is usually offered at best 30–60 minutes after the procedure, which is too late to prevent the effects of contrast media on the kidney.

In patients with pre-existing renal impairment, hemodialysis did not influence the incidence or outcome of contrast-induced nephropathy, in spite of eliminating contrast agents effectively from the circulation. The same group has now confirmed their previous observation in a bigger study in 30 patients with pre-existing renal impairment (184). Hemodialysis did not influence the incidence or outcome of contrast-induced nephropathy, in spite of effective elimination of contrast medium from the circulation. The failure of hemodialysis to protect against the development of contrast nephropathy is due to the very rapid onset of renal injury after the administration of contrast medium.

The use of hemodialysis immediately after intravascular administration of contrast agents to prevent the development of nephrotoxicity in patients with renal impairment has been investigated in 15 patients with a mean serum creatinine of 234 μmol/l before contrast injection (185). The patients were randomized to receive either conservative treatment or hemodialysis for 2–3 hours, starting as early as possible (mean 106 minutes) after administration of the contrast agent. The increase in serum creatinine on days 2 and 3 after contrast injection was higher in the dialysed group. The incidence of nephrotoxicity, defined as an increase in serum creatinine by more than 44 μmol/l within 48 hours after administration of the contrast agent, was significantly higher in the dialysed group (43 versus 13%). The authors concluded that hemodialysis performed within 2 hours after contrast injection did not prevent the development of nephrotoxicity in patients with reduced renal function; indeed, it seems to have made things worse.

The use of prophylactic hemodialysis, in most cases starting more than 20 minutes after injection of a contrast agent, has been investigated in 113 patients with renal insufficiency (serum creatinine concentration over 200 μmol/l) (186). Hemodialysis did not reduce the incidence of contrast nephrotoxicity. This failure could have been related to the rapid onset of renal injury after the administration of the contrast agent.

The Contrast Media Safety Committee of the European Society of Urogenital Radiology (ESUR) has produced useful guidelines on dialysis and the intravascular use of contrast media (Table 4) and has reviewed the literature on this subject (187). In addition, they have produced guidelines on the prevention of contrast medium-induced renal damage (Table 5) following a consensus of experts in this field and of members and fellows of the society (188).

Acetylcysteine

The antioxidant *N*-acetylcysteine has also been recommended to reduce the risk of contrast nephrotoxicity. *N*-acetylcysteine 600 mg bd for 2 days, starting the day before the examination, in addition to hydration, reduced the incidence of contrast nephrotoxicity in 41 patients (189). The incidence of contrast nephrotoxicity was 2%

Table 4 European Society of Urogenital Radiology (ESUR) simple guidelines on dialysis and contrast media administration (188)

Patients on dialysis	Recommendations
Hemodialysis (all contrast media can be removed by hemodialysis)	Avoid osmotic and fluid overload Correlation of the time of contrast media injection with the hemodialysis session is unnecessary Extra hemodialysis session for removal of contrast media is unnecessary
Continuous ambulatory peritoneal dialysis (CAPD) (all contrast media can be removed by peritoneal dialysis)	X-ray examinations To protect residual renal function, refer to ESUR guidelines to avoid contrast medium-induced renal damage Hydration should be considered only after careful evaluation of fluid balance state of the patient Hemodialysis is unnecessary MRI scans To protect residual renal function, use doses under 0.3 mmol/kg of gadolinium-based contrast agents
Patients with severely reduced renal function	Refer to ESUR guidelines to avoid contrast medium-induced renal damage (hydration, use small doses of low-osmolar contrast media) Hemodialysis is unnecessary In MRI avoid doses over 0.3 mmol/kg of gadolinium-based contrast agents

Table 5 European Society of Urogenital Radiology (ESUR) simple guidelines to avoid Contrast Medium Nephrotoxicity (227)

Definition	Contrast medium nephrotoxicity is a condition in which an impairment in renal function (an increase in serum creatinine by more than 25% or 44 μmol/l) occurs within 3 days after the intravascular administration of a contrast medium in the absence of an alternative cause
Susceptibility factors	Raised serum creatinine concentration, particularly secondary to diabetic nephropathy Dehydration Congestive heart failure Age over 70 years Concurrent administration of nephrotoxic drugs, for example NSAIDs
In patients with susceptibility factors	*Do* Make sure that the patient is well-hydrated; give at least 100 ml/hour orally (for example soft drinks) or intravenously (isotonic saline) depending on the clinical situation, starting from 4 hours before to 24 hours after contrast administration; in hot climates increase the fluid volume Use low-osmolar or iso-osmolar contrast media Stop administration of nephrotoxic drugs for at least 24 hours Consider alternative imaging techniques that do not require the administration of iodinated contrast media *Do not* Give high-osmolar contrast media Administer large doses of contrast media Administer mannitol or diuretics, particularly loop-diuretics Perform multiple studies with contrast media within a short space of time

in patients who received acetylcysteine (baseline serum creatinine 220 μmol/l) following intravenous injection of 75 ml of low-osmolar non-ionic contrast media, and 21% in controls (baseline serum creatinine 211 μmol/l). However, the dose of contrast medium used was rather small and the patients did not have advanced renal impairment before contrast injection.

A study from Germany has shown that the antioxidant acetylcysteine plus intravenous saline 0.45% prevented the reduction in renal function induced by contrast agents (190). The authors prospectively studied 83 patients with chronic renal impairment (creatinine clearance under 50 ml/minute). The patients took oral acetylcysteine 600 mg bd for 1 day before and 1 day after the contrast medium. Saline 0.45% was given intravenously at a rate of 1 ml/kg/hour for 12 hours before and 12 hours after 75 ml of iopromide (iodine 300 mg/ml) intravenously. All the patients were encouraged to drink if they were thirsty. A matched control group received placebo and saline. The mean serum creatinine in the control group (42 patients, mean age 65 years) rose from a mean of 212–226 μmol/l 48 hours after contrast injection. In those given acetylcysteine (41 patients, mean age 66 years) the serum creatinine was 220 μmol/l before contrast injection and 186 μmol/l 48 hours after. One patient given acetylcysteine and nine controls developed contrast-induced nephrotoxicity. This suggests that the prophylactic oral administration of the antioxidant acetylcysteine in patients who are adequately hydrated with saline prevents contrast-induced nephrotoxicity in patients with chronic renal insufficiency. The main limitation of this study was the relatively small dose of intravenous contrast medium used (75 ml). It is important to determine whether acetylcysteine plus saline would still offer the same protection if higher doses of contrast media were used or if the agent was given intra-arterially.

Calcium channel blockers

In addition to using a small dose of low-osmolar non-ionic contrast medium and offering hydration, some authors have recommended the use of calcium channel blockers in patients at high risk of contrast nephrotoxicity. However, the effectiveness of this class of drugs in preventing contrast nephrotoxicity has not been consistently

© 2006 Elsevier B.V. All rights reserved.

proven, particularly in patients with pre-existing advanced renal disease (191). Furthermore, some studies have suggested that the prophylactic administration of renal vasodilators, such as dopamine or calcium channel blockers, could have a deleterious effect, particularly in patients with diabetic nephropathy (SEDA-18, 444) (161). There is no conclusive evidence that these drugs are effective, particularly in patients with diabetic nephropathy who are at high risk of this complication (SEDA-19, 428).

Dopamine receptor agonists

In a study from the USA, dopamine was effective in preventing further deterioration in renal function in patients with a raised serum creatinine undergoing angiography for lower limb ischemia (192). Dopamine (2.5 mg/kg) was given to 28 patients beginning 1 hour before injection of contrast medium (Omnipaque 300, mean volume about 140 ml) and continuing for a total of 12 hours. Patients in the control group received an equal volume of isotonic saline. Serum creatinine was measured daily for 4 days after arteriography. Dopamine reduced the incidence of contrast nephrotoxicity (defined as an increase in the baseline serum creatinine concentration over 44 μmol/l) from 44 to 18%. Previous studies have not shown any protective effect of dopamine against contrast-induced nephropathy, in spite of marked increase in renal blood flow shown in a study of patients undergoing cardiac catheterization (161).

A report from Italy has suggested that intravenous saline 0.4% before and after administration of the contrast medium, an infusion of dopamine 3 micrograms/kg/minute for 24 hours after the contrast medium, intravenous furosemide 80 mg 30 minutes before the contrast medium, or intravenous mannitol (20%) 250 ml 1 hour before and 1 hour after the contrast medium each prevented the reduction in renal function caused by the non-ionic agents iobitridol, ioversol, or iodixanol (193). However, the protocol of the study was not described, and previous studies have shown that dopamine, furosemide, and mannitol do not offer good protection against contrast media-induced nephrotoxicity. On the other hand, volume expansion with intravenous saline has been found to offer some protection (190).

Fenoldopam, a selective dopamine D_1 receptor agonist, has also been advocated to reduce the risk of contrast nephrotoxicity. It is a renal vasodilator and increases glomerular infiltration rate. The authors of a review of studies that used fenoldopam to prevent contrast nephrotoxicity concluded that it offers good protection (194). In another study, the incidence of contrast nephrotoxicity was 4.7% in patients who received intravenous fenoldopam 0.1 micrograms/kg/minute starting 15–20 minutes before contrast injection and continued for 6 hours after and 19% in controls (195). However, fenoldopam has not been consistent in offering good protection against contrast nephrotoxicity, it has to be given by intravenous infusion, and it requires careful monitoring of blood pressure and dosage adjustment if hypotension develops.

Endothelin receptor antagonists

Although endothelin is considered to be an important mediator of the renal effects of contrast media, a report from the USA has shown that prophylactic administration of a non-selective endothelin receptor antagonist not only did not protect against contrast nephrotoxicity but exacerbated it (196). In this study, 158 patients with chronic renal insufficiency (mean serum creatinine 242 μmol/l) undergoing cardiac angiography were randomized to receive either the non-selective endothelin antagonist SB290670 (mean age 65 years, 51 men, 26 women) or placebo (mean age 67 years, 59 men, 22 women). The mean doses of contrast medium were 104 ml in the SB290670 group and 122 ml in the placebo group. Only low-osmolar radiographic contrast media were used. The dose of SB290670 was 100 micrograms/kg over 10 minutes followed by an infusion of 1 microgram/kg/minute starting 30–150 minutes before administration of contrast medium and continuing for 12 hours after. All the patients received intravenous hydration with saline 0.45% (1 ml/kg/hour) beginning 2–12 hours before contrast medium and continuing for at least 12 hours after. The mean increase in serum creatinine 48 hours after angiography was higher with SB290670 than placebo (64 versus 34 μmol/l). The incidence of radiocontrast nephrotoxicity was significantly higher with SB290670 than placebo (56 versus 29%). The authors concluded that a non-selective endothelin receptor antagonist may increase the incidence of contrast media nephrotoxicity and they questioned the role of endothelin in mediating the renal effects of contrast media. However, there were flaws in the design of this study. First, the endothelin receptor antagonist was administered only for a maximum of 12 hours after contrast examination—a longer period (2–3 days) should have been considered, since the reduction in renal function after contrast examination peaks at 48–78 hours, and in previous studies a single dose of nitrendipine 20 mg did not prevent contrast nephrotoxicity, whereas 20 mg/day for 3 days offered good protection. Secondly, a non-selective endothelin receptor antagonist is probably not suitable for the prevention of contrast nephrotoxicity. Blocking endothelin B receptors does not offer an advantage, since these receptors mediate renal vasodilatation and they also act as clearance receptors for endothelin. B receptor blockade could have caused the raised plasma endothelin concentrations that were observed in the treated group and may explain why the non-selective endothelin antagonist exacerbated contrast medium nephropathy. A selective endothelin A receptor antagonist should be studied before a role for this class of drugs in preventing contrast nephrotoxicity is excluded.

Theophylline

Theophylline, a non-selective adenosine receptor antagonist, has also been recommended, since adenosine has been suggested to be an important mediator of contrast-induced nephrotoxicity. Patients undergoing coronary angiography with the high-osmolar contrast medium diatrizoate (iodine 370 mg/ml) were randomized to receive either theophylline (200 mg bd orally 24 hours before and for 48 hours after coronary angiography, $n = 35$, mean age 54 years, mean dose of contrast medium 78 ml) or placebo ($n = 35$, mean age 52 years, mean dose of contrast medium 80 ml) (197). The glomerular filtration rate

© 2006 Elsevier B.V. All rights reserved.

at 48 hours was reduced by 36% (from a mean of 85 ml/minute to a mean of 67 ml/minute) in the placebo group and by 9% in the theophylline group. Contrast nephrotoxicity, defined as a fall in glomerular filtration rate by 25% or more from baseline at 48 hours developed in 11 patients in the control group and only in one patient in the theophylline group. The authors concluded that nephrotoxicity induced by high-osmolar contrast media can be reduced by prophylactic administration of theophylline.

The protective effect of theophylline against contrast media nephrotoxicity has also been shown in another study (198). Intravenous theophylline 100 mg 30 minutes before intravascular administration of 100 ml of low-osmolar contrast medium offered good protection against contrast nephrotoxicity in patients with chronic renal insufficiency (mean serum creatinine 183 μmol/l). The incidence of contrast nephrotoxicity was 4% in the theophylline group and 16% in the placebo group (base line serum creatinine 110 μmol/l). The authors concluded that theophylline offers good protection against contrast nephrotoxicity in patients with pre-existing renal impairment. However, the dose of contrast medium was relatively small (100 ml) and the pre-existing renal impairment was not advanced. The consistency of theophylline in offering good protection against contrast nephrotoxicity has not been confirmed at higher doses of contrast media and in patients with more advanced renal disease.

Comparative studies

The protective effects of intravenous hydration alone (0.45% isotonic saline, 1 ml/kg/hour for 12 hours before and 12 hours after contrast administration), fenoldopam (0.1 microgram/kg/minute for 4 hours before and 4 hours after the procedure), and acetylcysteine (600 mg bd 24 for hours before and 24 hours after the procedure) have been compared in preventing contrast nephrotoxicity after intravascular administration of low-osmolar non-ionic contrast medium (199). The incidence of nephrotoxicity was 15% in the hydration group, 16% in the fenoldopam group, and 18% in the acetylcysteine group. All the groups were comparable and baseline creatinine clearance was about 60 ml/minute in all the patients who received a similar dose of the contrast medium (1.5 ml/kg). The authors concluded that fenoldopam and acetylcysteine do not offer extra protection against contrast nephrotoxicity over hydration alone.

Skin

The incidence of skin reactions to drugs has been analysed from spontaneous reports in Italy (200). Antibiotics most commonly caused skin reactions, followed by NSAIDs, analgesics, and radiocontrast agents, which were responsible for 2.7% of the reactions (71 cases); these included nine cases of exanthemas and 36 cases of urticaria.

Fixed drug eruption caused by non-ionic contrast media is rare (SEDA-22, 502), but has been attributed to the non-ionic contrast medium iomeprol (Iomerone, Bracco) (201).

- A 67-year-old Japanese woman developed multiple pea-sized erythematous plaques on the trunk and extremities 4 days after receiving 100 ml of iomeprol intravenously for a CT scan. She was treated with oral betamethasone 1.5 mg/day and glutathione 300 mg/day for 3 days. She then used topical betamethasone valerate ointment for a month until the erythematous plaques completely disappeared, leaving pigmentation. Six months later she was erroneously given 100 ml of iomeprol intravenously during a CT scan and the next morning developed erythematous plaques mixed with vesicles at the same sites as before. Biopsy showed histological changes compatible with a fixed drug eruption. In addition, both patch testing and intradermal testing were positive to iomeprol.

This report shows that non-ionic contrast media can cause multiple fixed eruptions and that repeated administration of the causative agent can be associated with a more severe eruption.

Rarely typical iododerma, sometimes with other skin and systemic complications, can occur (202) and causes a papulopustular eruption. Vegetating iododerma, in which pustules and vesicles coalesce to form large vegetating masses that later ulcerate, is very rare and its pathogenesis is unclear. A cell-mediated immune reaction, an inflammatory mechanism, and an idiosyncratic reaction in patients with other underlying diseases have been suggested. Iododerma occurs more often in patients with renal insufficiency, because of impaired clearance of contrast media. Oral or topical glucocorticoids have been of some benefit in treating this condition. Vegetating iododerma with a fatal outcome has been reported (203).

- A 65-year-old woman with a history of allergy to penicillin and abnormal renal function had cardiac angiography and a week later became breathless and slightly febrile and developed pustulovesicular lesions on the face, elbows, and legs. The lesions on the face coalesced into vegetating masses. Cultures from the skin lesions did not yield bacteria, fungi, or mycobacteria. Histological examination of the vegetating mass showed an inflammatory exophytic lesion with an ulcerated surface and an inflammatory infiltrate consisting mainly of neutrophils and eosinophils in the dermis. The lesions responded to 1:1000 copper sulfate solution. However, she continued to deteriorate despite hemodialysis and died 6 days later.

In this patient, renal insufficiency contributed to the development of iododerma and her death was due to poor cardiorespiratory function.

Delayed skin rashes have been noted in 5% of patients undergoing urography. Allergic-like skin reactions to intravascular contrast media can develop 24–96 hours after administration (204).

- A 73-year-old woman underwent CT scanning with contrast enhancement (250 ml of intravenous iopentol, a non-ionic contrast medium, iodine 300 mg/ml) for staging a malignant melanoma. Four days later she developed progressive pruritus beginning on the back and neck. On the sixth day she had a disseminated pruriginous papular partially confluent exanthema involving the trunk, neck, and proximal extremities. The eruption became generalized while she was receiving local corticosteroids and oral clemastine. Remission

© 2006 Elsevier B.V. All rights reserved.

of the eruption was achieved with intravenous prednisolone 64 mg and dimethindene maleate 12 mg. Patch and intracutaneous tests to iopentol, but not to other contrast media, evoked a red indurated skin reaction after 48 and 72 hours. Histology and immunocytochemistry of the skin test site to iopentol showed an infiltrate consisting mainly of CD45RO+ and CD4+ lymphocytes together with eosinophils.

This reaction shared the features of a delayed hypersensitivity reaction (exanthematous rash, positive patch test) and of a late phase reaction (CD4+ lymphocytic infiltrate together with eosinophils). The authors emphasized the importance of skin testing in the diagnosis of delayed skin reactions to contrast media.

Other cases of delayed skin reactions have been reported.

- A 64-year-old woman with a history of an exanthematous skin eruption to an antibiotic and allopurinol had had a previous adverse reaction after angiography with radiographic contrast media. Her symptoms had included shivering and a generalized pruritic exanthema. Then, 30 minutes after intravenous angiography with iopromide (a non-ionic contrast medium), she developed shivering and dyspnea immediately followed by loss of consciousness; 3 hours later a generalized pruritic maculopapular rash developed.
- A 63-year-old woman with glomerulonephritis underwent angiography. She had a history of an immediate adverse reaction to lidocaine and of dyspnea, wheeze, and paresthesia of the fingers to repeated infusion of contrast media. Several hours after the last procedure she developed a generalized pruriginous maculopapular rash.
- A 60-year-old man underwent coronary angiography with iopamidol 200 ml. One day later he developed infiltrated erythema of the face with a generalized maculopapular rash. The skin symptoms receded within 1 week after treatment with a corticosteroid ointment. Coronary angiography with iopamidol was repeated 3 years later and again within 1 day a maculopapular rash developed and regressed within a few days with intravenous dimethindene and prednisolone-21-hydrogen succinate.
- A 54-year-old woman and a 68-year-old man developed rashes 24 hours after intravascular injection of iohexol (a non-ionic monomer) (205). The woman developed widespread pruritic erythema and eyelid edema. The man developed a maculopapular rash involving the trunk and legs. Both patients were treated with antihistamines, which resulted in complete recovery within 1 week. The man had slight desquamation of the affected area after his rash resolved. Patch tests were positive to iohexol in both patients. The man also had a positive patch test to iodixanol and the woman was positive to the non-ionic monomer ioversol.

Intracutaneous and patch tests were performed in the first two patients (206) with a series of ionic and non-ionic contrast media in concentrations of 1% according to international guidelines. In the first patient there were late positive intracutaneous and patch tests after 24–48 hours only to some of the tested contrast agents. In the second patient intracutaneous and patch tests showed late reactions to nearly the same contrast media. More than 20 patients with only immediate anaphylactoid reactions to contrast media gave negative results to these tests. The authors concluded that positive skin tests suggest an immunological basis for late reactions to contrast media. In the third case (207) patch and prick skin tests were performed using several iodinated contrast media. Intravenous provocation tests were also performed with several water-soluble contrast media using 5 ml in each case at strengths of 1:1000, 1:100, 1:10, and undiluted. Positive skin tests were observed with iopamidol, and the intravenous provocation test caused infiltrated erythema of the face and generalized maculopapular rashes. Skin biopsies showed heavy lymphohistiocytic infiltration at the site of positive skin tests. The authors concluded that the rashes represented delayed allergy to iopamidol.

Delayed skin reactions after contrast media have the features of true delayed hypersensitivity reactions, including positive skin tests (SEDA-24, 523). A generalized macular rash 24 hours after injection of ioversol with positive skin tests has been reported (208).

- A 61-year-old man received ioversol during a CT examination and 1 day later developed a generalized macular rash, which lasted for 2 weeks. Prick, intradermal, and patch tests with different types of non-ionic contrast media showed a delayed hypersensitivity reaction to ioversol, which lasted for 7 days.

Urticarial or erythematous rashes can occur and persist for a few days. Rarely acute vasculitis, Stevens–Johnson syndrome, and bullous lichen planus have been reported (SEDA-11, 411) (SEDA-14, 422).

- A 33-year-old man had three contrast-enhanced CT scans with iohexol over about 2 weeks, and developed a disseminated erythematous skin rash. Because drug allergy was suspected, all drugs were withdrawn (209). Because of a persistent fever a fourth CT scan was performed with iohexol, and 2 hours later he developed malaise, pruritic erythema, hypotension, and cutaneous bullae affecting 50% of his body surface and his oral mucosa. He was treated for toxic epidermal necrolysis and his skin healed without scarring or altered pigmentation. Skin patch tests, prick tests, intradermal tests, and intravenous and oral single-blind challenges with the antibiotics he had received were negative. However, a patch test with iohexol (iodine 300 mg/ml) was positive at 48 hours: erythema and multiple small flaking blisters appeared in the patch area. Identical patch tests in healthy controls were negative.

Other rarities reported sporadically (but all in more than one case) include the Koebner phenomenon (210), fixed drug eruptions (for example with iotalamate (211)), and delayed reactions of various types. Reports of severe drug eruptions have become more frequent since the introduction of the non-ionic contrast media, but this may simply be due to the fact that in recent years there has been greater awareness of such reactions (SEDA-16, 538) (SEDA-19, 427) (SEDA-22, 502).

Iocetamic acid seems more likely than other agents to cause skin reactions. Persistent urticaria has been seen in cases where iophendylate was used in myelography and the residue remained in situ (SED-12, 1180) (SEDA-16, 536).

© 2006 Elsevier B.V. All rights reserved.

Exacerbation of a lupus-like illness after injection of iodinated contrast agents has been reported (SEDA-9, 411) (SEDA-19, 427). All iodinated contrast agents should be used with caution in patients with systemic lupus erythematosus and perhaps in other types of vasculitis.

Reticulated purpura has been reported after the use of diatrizoate meglumine, a high-osmolar water-soluble contrast agent, for hysterosalpingography (212).

- Within 48 hours of a hysterosalpingogram using diatrizoate meglumine, a 34-year-old woman developed a burning sensation in her left leg, 4 days later developed tenderness and redness on the left posterior thigh and calf, and 4 days after that mottling of the skin of the thigh. Two weeks later she had marked tenderness and purpuric macules in a reticulated pattern on both legs. A skin biopsy showed changes suggestive of erythema multiforme. There was no evidence of vasculitis. The skin lesions persisted unchanged for about 1 week, after which they resolved without treatment.

This clinical picture of reticulated purpura with the formulation of a few bullae has not been previously reported after injection of contrast agents. The histological changes supported the diagnosis of a drug reaction. Although some of the histological findings are seen in erythema multiforme the patient's clinical presentation did not support that diagnosis.

The skin can be involved in allergic reactions after lymphography. Dermatitis has also been described some days after lymphography and apparently due to extravasation of the iodized oil into the tissues (SED-12, 1184) (213). Since lymphography requires an incision, wound infections can occur and rarely lymphangitis.

In 17 of 53 cases with obstructive lymphedema there was an increase in limb volume after lymphangiography with Lipiodol ultrafluid (iodinated poppy seed oil), and 10 cases had features resembling lymphangitis. In one patient there was an allergic reaction, with rapid development of edema and an increase in limb volume by 2 liters. Whereas contrast medium virtually disappears from normal lymphatics within 8 hours, in cases of obstructive lymphedema Lipiodol remains in the lymphatics for several days and it appears to cause a low grade chemical inflammation with obliteration of the lymphatics (SEDA-7, 454).

- A woman with an inoperable carcinoma of the cervix developed reticulohistiocytosis with arthritis and skin papules after lymphography with Lipiodol ultrafluid (214). Two later examinations with diatrizoate caused exacerbation of the disease within 24 hours. The condition receded spontaneously after 12 months, and subsequent examinations with metrizamide and iodamide were symptom-free.

Lymphatic obstruction is also an important factor in the etiology of oil embolism during lymphography causing shunting via distal lymphovenous communications.

Musculoskeletal

A transitory myopathy has been reported after iopamidol (215).

Immunologic

French workers investigating the causes of severe reactions to iodinated contrast agents suggested that any patient who has had a severe anaphylactoid or anaphylactic reaction after the injection of a contrast agent should undergo immunological assessment (216). The diagnosis of drug anaphylaxis is usually based on the history, proof of mediator release, and the presence of drug-specific IgE antibodies or positive skin tests. In five patients with severe anaphylactoid reactions after the intravascular injection of an iodinated contrast agent, the clinical symptoms, biology, and skin tests were consistent with anaphylaxis. The authors also reported that no premedication has proved effective in preventing subsequent allergic reactions to contrast agents.

In one study iodinated contrast agents were among the top 10 drugs responsible for anaphylaxis (161 cases due to contrast media out of 1338 reports of anaphylaxis) (217). Dextran was the most common cause of anaphylaxis (418 cases). The overall death rate was significantly higher in men than in women and increased with age. The report also suggested that since the introduction of low molecular weight dextran 1 the incidence of severe anaphylaxis to dextran has fallen markedly and that radiographic contrast agents may now be the most common agents causing anaphylaxis. Most of the anaphylactic reactions and all the fatal cases were due to ionic agents.

Patients allergic to additives, such as parabens in sodium iopodate, can react to them, for example with rash (218).

Hypersensitivity reactions seem to be less common after arteriography than after urography, perhaps because the agent does not pass directly through the lungs, although the data are limited. There were mild allergic reactions in six of 167 patients who underwent arteriography with iodamide (SED-12, 1175) (219). Two severe delayed generalized cutaneous reactions with blistering occurred after lumbar aortography with iopamidol and iohexol (SED-12, 1175) (220).

Three cases of mild allergic-like reactions to oral water-soluble iodinated contrast media during CT examinations of the abdomen have been documented (221). Two patients received Gastrografin and the third received the same agents under the brand name Gastroview. The main reaction was a skin rash that resolved within 2 days. The author advised that clinicians and radiologists should be aware of the potential for adverse reactions to oral iodinated contrast agents. In another case, a severe systemic allergic reaction occurred in a patient who was given oral iohexol (222). In a patient with known allergy to iodinated contrast media it would be prudent to consider barium suspension in preference to an iodinated agent to outline the bowel.

Allergic or even anaphylactic reactions can occur after lymphography, either to the contrast agent or to the dye; in hypersensitive patients, prior use of glucocorticoids and antihistamines may fail to prevent a severe reaction (223).

Non-IgE-mediated anaphylactic (anaphylactoid) reactions

A life-threatening anaphylactoid reaction occurred in a child after intravenous administration of a non-ionic contrast medium (ioversol) (224).

© 2006 Elsevier B.V. All rights reserved.

- A 3-year-old girl was investigated for hypertension and a renal arteriogram was performed. Her blood pressure before the study was 125/60 mmHg. She received 30 ml of ioversol (iodine 320 mg/ml). Within 30 seconds she developed tachycardia (200/minute) and hypotension (60/20 mmHg). She developed diffuse urticaria over her entire body and there was wheezing on auscultation. Cardiopulmonary resuscitation was begun and she received a saline infusion and adrenaline 1:1000 subcutaneously, 0.01 ml/kg, intravenous diphenhydramine 1 mg/kg, and intravenous hydrocortisone 5 mg/kg. She responded rapidly. Surprisingly, the authors thought that the contrast medium had not caused this response, and the patient was subsequently given a second injection of ioversol 320 in a dose of 1 ml/kg. Within 60 seconds she again became tachycardic and hypotensive and urticaria reappeared over the whole body with wheezing. Similar treatment was offered and she responded rapidly.

The authors claimed that this was the first case report of anaphylactoid shock after the administration of ioversol in a child.

A fatal anaphylactoid reaction to an intravenous non-ionic contrast medium occurred during a CT scan (225). The authors highlighted the value of measuring serum tryptase in the diagnosis of anaphylactoid reactions.

- An 81-year-old man underwent CT scanning of the head with intravenous contrast enhancement (100 ml of the non-ionic contrast medium iopamidol). After the injection he complained of sweating and nausea and had a cardiorespiratory arrest. Immediate resuscitation and intravenous dexamethasone and adrenaline were not successful. Mast cell tryptase activity in a sample taken 4 hours after death was high. At autopsy, the coronary and pulmonary arteries were patent. The right heart chambers were moderately enlarged. The lungs were hyperemic and edematous and there was obstructive edema of the larynx.

This patient had all the features of anaphylactoid reactions, which include pulmonary and laryngeal edema and a massive rise in serum tryptase. The half-life of tryptase is about 2 hours. Moderately raised post-mortem tryptase activity in the absence of anaphylaxis has been described. Therefore, only very high serum tryptase activity, as seen in this case, should be regarded as specific for fatal anaphylactoid reactions.

Graft-versus-host disease

Three cases of cutaneous graft-versus-host disease triggered by contrast agents have been reported (226).

- A 49-year-old man with acute myeloid leukemia underwent allogeneic bone marrow transplantation from his brother. Pre-existing pulmonary aspergillosis was treated with intravenous amphotericin. ACT scan of the chest and abdomen 120 ml of the non-ionic dimer iodixanol was performed and 6 hours after the injection he developed generalized erythema with a pruritic painful skin rash. Skin biopsies showed changes typical of chronic graft-versus-host disease. He received prednisolone 50 mg orally and the rash resolved within a few weeks.
- A 30-year-old woman with acute myeloid leukemia received an allogeneic bone marrow transplant from her brother. A CT scan of the abdomen was performed a few weeks after transplantation using 150 ml of iodixanol. Two days later she developed acute cutaneous graft-versus-host disease, which was treated with intravenous methylprednisolone 1 g/day for 4 days. Four months later, another CT was performed with 150 ml of iodixanol and 2 hours later she developed a generalized maculopapular rash over the whole body, which was diagnosed as grade-2 graft-versus-host disease. Intravenous methylprednisolone 1 g and clemastine 2 mg did not control the rash, which worsened. She was given daclizumab 50 mg/day for 2 days, prednisolone 100 mg/day, and mycophenolate mofetil 2 g/day. The rash resolved completely within 10 weeks.
- A 38-year-old man with acute myeloid leukemia underwent allogeneic bone marrow transplantation from his brother. He received iopromide 120 ml during CT scanning of the chest 15 months after the transplantation and 6 hours later developed generalized erythroderma, which was treated with oral prednisolone 50 mg. The lesion persisted and cholestatic jaundice developed. Graft-versus-host disease of the skin and liver was diagnosed. The patient still required immunosuppressive therapy and prednisolone 18 months after the event.

The authors suggested that the skin manifestations had been due to graft-versus-host disease triggered by the contrast medium and not a type-IV immunological reaction. Skin biopsy in one of the patients showed typical features of graft-versus-host disease. In addition, the reactions in these patients lasted for longer than one would expect in simple delayed reactions with skin manifestations, which usually resolve within 7–10 days.

Prevention

Prophylactic use of immunosuppression has been described to prevent delayed hypersensitivity reactions to contrast media (227).

- A 19-year-old man developed delayed hypersensitivity skin reactions to iopamidol (a low-osmolar contrast medium) after cerebral angiography for an arteriovenous malformation. Three months later he required embolization of the malformation. He was given prophylactic betamethasone (4 mg/day) for 2 days before the procedure in which iopamidol was used again. Three days after the embolization he developed a generalized maculopapular rash with severe itching. The rash resolved completely after intramuscular chlorphenamine 10 mg bd for 10 days and oral prednisone 25 mg bd. Skin tests confirmed a delayed hypersensitivity reaction to iopamidol and other types of contrast media. One month later he required further embolization and underwent immunosuppression with oral ciclosporin 100 mg bd and intramuscular methylprednisolone 40 mg/day for 1 week before and 2 weeks after the embolization. The contrast medium iobitridol, which gave negative results in skin tests, was used. The patient tolerated the procedure and did not develop further reactions.

Infection risk

Malarial relapse followed administration of iodipamide in two cases (228).

Body temperature

Several patients have developed hyperthermia after receiving metrizamide (SEDA-10, 425). A fatal case of malignant hyperthermia occurred after 100 ml of diatrizoate (229).

Death

There has been a review of 449 fatal reactions to ionic media (12). Deaths occurred in all age groups, but the incidence peaked in the 50–70 year age group; in this older group, cardiovascular collapse, cardiac arrest, and pulmonary edema were the most common features, but pulmonary edema appeared to be the commonest autopsy finding in all age groups (230). Of 53 deaths due to urography or computed tomography; 35 were of cardiac origin and eight were attributed to pulmonary edema. The presenting features in eight cases were nausea and vomiting, while seven patients developed shock or hypotension.

A fatal reaction has been reported in a case of Waldenström's IgM paraproteinemia (231). Ioglycamide produced fatal gel precipitation of the plasma in a case of Waldenström's IgM monoclonal paraproteinemia (232).

Long-Term Effects

Mutagenicity

An increased frequency of chromosomal aberrations and sister chromatid exchanges has been found in lymphocytes up to 1 week after intravenous urography; diatrizoate produced more changes than ioxaglate (SEDA-19, 430) (233). Earlier it was reported that the incidence of chromosomal aberrations in the lymphocytes of seven infants who underwent angiocardiography was higher than expected. Whether this means that contrast media produce significant cytogenetic damage is not at all clear.

Tumorigenicity

Some have suggested that the passage of contrast agents through malignant lymph nodes may facilitate metastases; one relevant case relates to Hodgkin's disease (234) and another to melanoma (235). There is also some animal evidence of this. However, it has generally been considered that lymphography is unlikely to be a significant factor in malignant dissemination and that its diagnostic value in planning treatment far outweighs any theoretical risk. Computed tomography and magnetic resonance imaging have now largely replaced lymphography for the demonstration of malignant lymph nodes.

Second-Generation Effects

Fetotoxicity

The main adverse effect of iodine-containing contrast agents after amniofetography is transient hypothyroidism, which has often been reported (236–246).

Iophenoxic acid, now obsolete, passes the placental barrier and can alter thyroid function in mothers and fetuses (247). In one case, a child was born with congenital hypothyroidism 5 years after the mother had undergone cholecystography (248); in a similar case the mother had been given iophenoxic acid 8 years before pregnancy (SED-12, 1167) (249).

Lactation

Contrast agents are excreted into breast milk, and they should not be used in breastfeeding women (SEDA-6, 404).

Susceptibility Factors

Genetic factors

Racial differences could be a factor in the high incidence of delayed skin reactions to contrast media in Japan, as 43% of Japanese are deficient in acetaldehyde dehydrogenase. This deficiency results in the accumulation of acetaldehyde, which potentiates the ability of contrast agents (especially dimers), to bridge proteins, which is a probable causative factor in many of their adverse effects (11).

In 1798 Indian patients the prevalence of adverse reactions to high-osmolar ionic iodinated contrast media was 21% (mild 19%, moderate 1.3%, and severe 0.3%) and there was only one death. The incidence of adverse effects was significantly higher in patients with risk factors, such as a history of previous contrast reactions (46%), bronchial asthma (69%), and diabetes mellitus (60%), compared with patients with no risk factors (21%). The authors tried to throw some light on the relation between race and incidence of contrast reactions. They showed that the incidence of mild reactions in the Indian patients (19%) was significantly higher than reported in white patients (5–15%) but that there was no difference in the incidence of moderate or severe reactions between the two populations (250).

The incidence of contrast reactions amongst patients of Indian origin in the UK was significantly higher than in the endogenous white population, with an eight-fold increase in severe reactions (251). There was also a significant increase in the incidence of reactions amongst patients of Mediterranean origin, but to a lesser degree.

There is no clear explanation for racial differences in the incidences of contrast agent reactions.

Age

Neonates are particularly sensitive to the effects of iodine, and transient hypothyroidism has often been reported, particularly in pre-term infants (237,252,253). The low glomerular filtration rate in infants can also result in delayed excretion of contrast agents.

The efficacy and safety of iodixanol has been documented in children. Iodixanol was well tolerated without any important adverse events in 25 children under 4-years-old undergoing excretory urography (254).

The use of low-osmolar contrast media in gastrointestinal imaging has been investigated in children under 16 years. One group received the iso-osmolar dimer

© 2006 Elsevier B.V. All rights reserved.

iodixanol (74 patients, mean age 5.8 years, range 0–15, mean volume of contrast medium 87 ml) and the other group received the low-osmolar non-ionic monomer iohexol (78 patients, mean age 6.4 years, range 0–15, mean volume of contrast medium 93 ml) (255). There was a lower frequency of adverse events with iodixanol than with iohexol. Diarrhea developed in 16% of the patients given iodixanol and in 36% of those given iohexol.

The safety of the iso-osmolar dimer iotrolan in imaging the upper gastrointestinal tract has been investigated in neonates and young children (81 patients, age range 2 days to 14 years), 21 of whom were under 1 month old (256). The dose of contrast medium was 15–30 ml. There were no significant adverse effects and the authors concluded that iotrolan is a safe contrast agent for imaging the gastrointestinal tract in children.

Renal disease

In patients receiving hemodialysis, the mean plasma iomeprole concentration fell by 36% at 2 hours after administration when hemodialysis was started. The mean half-life on dialysis was 4.4 hours. The effective fall in plasma iomeprole concentration after a single dialysis was about 70%. The mean fraction of the dose recovered in the dialysate was 58%. The mean dialysis clearance was 81 ml/minute. The extraction efficiency of the dialyser was about 40%. The only adverse effect was infection of an arteriovenous fistula in a patient with end-stage renal disease, which was unrelated to the contrast agent. There were also mild to moderate adverse effects, but all resolved without sequelae. The most common adverse effects were headaches and sensations of warmth. Others were paresthesia, abdominal pain, taste disturbance, and nausea. None of the events was considered to be clinically important. There were no clinically important changes in vital signs, physical examination, electrocardiography, or clinical laboratory evaluations. The authors concluded that iomeprole is safe and well tolerated and can be almost completely eliminated both in patients with renal impairment and in patients receiving dialysis.

Hepatic disease

The risk of renal insufficiency after contrast agents is greater in the presence of hepatic insufficiency, apparently because in such cases both blood concentrations and renal excretion of the contrast medium are greater (SEDA-10, 422).

Other features of the patient

A high incidence of histamine release and anaphylactoid reactions to contrast media has been reported in patients with malignant tumors (257). Patients with malignant tumors were randomized into two groups. One group ($n = 66$) received non-ionic low-osmolar contrast media (iopamidol) and the other ($n = 64$) received high-osmolar ionic contrast media (ioxitalamate). An average of 100 ml of contrast medium (range 60–140 ml) was given before CT scanning in both groups. The incidence of reactions (tachycardia, bradycardia, hypertension and hypotension, a fall in oxygen saturation, nausea, vomiting, headache, and skin reactions) was similarly high in both groups (58% with iopamidol and 42% with ioxitalamate). The increases in plasma histamine concentrations were also similar: median 0.43 (range 0–13) ng/ml with iopamidol and 0.15 (0–12) ng/ml with ioxitalamate. The authors concluded that patients with malignancies are at risk of histamine-associated contrast reactions and suggested that antihistamine prophylaxis with histamine H_1 and H_2 receptor antagonists should be considered in these patients. However, there is no conclusive evidence that antihistamines offer effective prophylaxis against reactions to contrast media.

Routine electrocardiographic monitoring during intravenous urography shows that there are significant abnormalities in patients with heart disease and that the incidence of these abnormalities appears to be related to the dose of contrast agent and the speed of injection (258). Patients with a history of angina can develop ischemic electrocardiographic changes with or without chest pain after the injection of a contrast agent into the superior vena cava; one such patient developed ventricular fibrillation (259).

In patients with myasthenia gravis, crises may be precipitated by contrast agents (260). An acute myasthenic crisis with apnea was induced by contrast CT with diatrizoate in two patients with myasthenia gravis and this was followed by prolonged aggravation of the myasthenia (261). This has also occurred with iopamidol (SEDA-12, 396).

Patients with pre-existent thyrotoxicosis present a problem, since the condition may be aggravated by contrast agents, even to the point of precipitating a thyroid storm (262).

Patients with a history of previous reactions to contrast media have a 35–40% chance of reacting again if re-examined.

In patients with sickle-cell disease, a high local concentration of contrast medium in the blood during arteriography can cause sickling, with resulting thrombosis. One patient with sickle cell disease developed severe intravascular hemolysis, thrombocytopenia, leukocytosis, and pulmonary infiltrates after left ventriculography and coronary angiography with meglumine diatrizoate (263). In vitro studies suggest that the non-ionic agent iopamidol causes significantly less sickling than conventional ionic contrast agents, and iopamidol would therefore be preferable for arteriography in patients with this disorder (SEDA-7, 453).

There appears to be an increased risk of seizures due to vasospasm if cerebral angiography is performed during or shortly after an attack of migraine (SEDA-11, 412).

Drug Administration

Drug formulations

BR21 is a sterile pyrogen-free suspension containing iomeprol, both free in solution and entrapped in liposomal vesicles. The suspension ideally contains iodine 320 mg/ml with an osmolality of 560 mosmol/kg. The liposomes are 0.4 μm unilamellar vesicles in which the membrane is made of phospholipid. The total lipid concentration of the suspension is about 20 mg/ml. About

© 2006 Elsevier B.V. All rights reserved.

40 mg/ml of iodine are trapped within the liposomal vesicles and there is 280 mg/ml in the external phase. BR21 is taken up by the reticuloendothelial system and can enhance normal liver tissue, whereas neoplastic lesions, which lack reticuloendothelial cells, are not enhanced.

The safety and pharmacokinetics of intravenous BR21 have been evaluated in 30 healthy adult men in a phase I, single-blind, placebo-controlled, ascending-dose study (264). Four volunteers each received a single intravenous dose of BR21 (0.5, 1.0, 1.5, 2.0, or 2.5 ml/kg), and for each dose of BR21 two volunteers received saline 0.9%. All adverse events (headache, metallic taste, nausea, back pain, dizziness, tremors, sweating) were minor or mild and resolved rapidly without treatment. There was no difference in the incidence of adverse events from dose to dose of BR21 or between BR21 and saline. There were no significant changes in vital signs, electrocardiography, or laboratory findings.

A formulation of liposome-encapsulated iodixanol has been evaluated as part of a phase 1 assessment of diagnostic efficacy and safety (265). The formulation is a ready-to-use suspension of multilamellar liposomes with a mean size of 340 nm. The main constituents of the liposome wall are phosphatidylcholine and phosphatidylserine. The concentration of iodine in the formulation is 200 mg/ml (encapsulated iodine 80 mg/ml). The encapsulated iodine-to-lipid ratio is 1.5. This new formulation was injected in doses of 10, 30, 70, and 100 mg of encapsulated iodine per kg in 5, 8, 8, and 8 healthy volunteers (mean age 30 years). Saline was given to two volunteers in each dose group, in a volume matching that of iodixanol at the 70 mg dose. The intravenous injection was carried out using a power injector at a rate of 2 ml/second. There were dose-dependent changes in leukocyte count. During the first 2 hours the leukocyte count fell and then rose. At 10 and 30 mg doses the changes were small and in most of the volunteers did not exceed the reference range. At higher doses there was a prominent increase in neutrophils with rod-shaped nuclei, suggesting increased release from the bone marrow. C-reactive protein also rose dose-dependently, suggesting a cytokine-mediated reaction. Leukocyte count and C-reactive protein normalized spontaneously after 24 hours. The volunteers had subjective adverse events at doses of 70 and 100 mg; these included chills (88%), back pain (25%), flu-like symptoms (13%), and nausea and vomiting (38%); they started within 1 hour and recovered spontaneously within 3 hours. No adverse events were interpreted as severe, but they were judged to be too pronounced to be clinically acceptable. Research is needed to find a formulation that causes fewer adverse events without compromising diagnostic quality.

Another hepatocyte-specific contrast formulation, dysprosium ethoxybenzyltris(carboxylatomethyl)triazaundecanedioic acid diethylenetriaminepenta-acetic acid (Dy-EOB-DTPA), has been used for liver CT imaging (266). It contains calcium-EOB-DTPA (0.5 mg/ml), trometamol (1.2 mg/ml), and hydrochloric acid (final pH 7.4). It has been described as a stable metal chelate with high tolerability in vitro and in animal studies, in which a long-lasting increase in CT density of about 30 Hounsfield units has been reported. A total of 40 healthy male volunteers (mean age 33 years) received intravenous infusions of Dy-EOB-DTPA, 0.05, 0.1, 0.25, 0.375, or 0.5 mmol/kg over 10 minutes ($n = 6$ in each group), or placebo ($n = 2$ in each group). There were adverse effects in four of the 10 patients who were given placebo and 22 of the 30 who were given Dy-EOB-DTPA. The most common adverse events were nausea (25%), headache (18%), paresthesia (15%), loss of appetite, allergic reactions, back pain, and injection site hemorrhage (7.5%). The adverse effects were generally mild or moderate, but there was a slight increase in intensity at the higher doses. There were gastrointestinal adverse events in all six of the volunteers who received 0.5 mmol/kg. Nausea was the longest lasting and in one case it was severe. The results of laboratory tests did not exceed the reference ranges. Vital signs, hemodynamic parameters, and electrocardiography were not affected by the contrast agent. Over 50% of the adverse events were considered to be unrelated to the drug. The authors concluded that this liver-specific contrast formulation has a good safety profile.

Drug contamination

Contrast media used for arteriography contain a variety of microscopic particles. When glass ampoules are opened, they contain a larger number of particles than rubber-capped vials because of the vacuum effect on glass particles during the opening of the ampoule (267). This can theoretically cause microembolism. Angiographic catheters and guide wires also contain a very large number of particles derived from the manufacturing process, and the release of these particles is increased some sixfold after the insertion of the guide-wire into the catheter (SED-12, 1179) (268). Vials should be opened by removing the cap and not by puncture of the membrane, since the needle usually pushes large rubber particles into the solution. Ideally, contrast media should be filtered before injection, but this will often not be practicable.

In the case of glass ampoules, if the ampoule is allowed to stand for 30–60 seconds after opening, most of the larger particles will have sedimented to the bottom of the ampoule. These can then be avoided by leaving the lower 2–3 mm of contrast medium in the ampoule.

Drug administration route

Oral and rectal

The high-osmolar contrast agents diatrizoate and iotalamate were formerly recommended for oral use in preference to barium when there was a risk of perforation, but the osmotic effect of such material can lead to diarrhea and fluid loss, which may be dangerous in weak patients. Diatrizoate, which has a cathartic action, can occasionally cause ileus when given postoperatively (149); it can also be precipitated as a solid mass in the stomach when gastric acidity is high, but also in an achlorhydric gastric stump after partial gastrectomy if stomal obstruction is present. On one occasion when diatrizoate was used to fill the gastric balloon of a Sengstaken–Blakemore tube, hydrogen ions from the gastric content apparently penetrated into the balloon, precipitating the contrast medium and preventing the balloon's removal. Accidental inhalation of hypertonic contrast media during oral administration can cause fatal pulmonary edema (75).

© 2006 Elsevier B.V. All rights reserved.

Low-osmolar agents such as iohexol are preferred for oral use; however, they can still cause some diarrhea, for example in 18 out of 40 cases in one series (SEDA-16, 529). Absorption can be increased if there is mucosal damage in the bowel, such as in Crohn's disease, resulting in delayed excretion but not apparently involving risk (SEDA-18, 441).

Diatrizoate enemas are still sometimes used to treat meconium ileus or constipation and it is important to give intravenous fluids so as to avoid dehydration. Hypomagnesemia can also occur (150). Osmotic effects lower in the gastrointestinal tract have even led to distention and cecal perforation (151). Stasis of diatrizoate in dilated loops of bowel can cause inflammatory changes or necrosis (152,153).

Severe systemic reactions to enterally administered water-soluble contrast media are rare but they do occur, for example with oral iohexol (222).

Intra-arterial injection

Local vascular complications associated with angiography include intramural injection of contrast medium (leading to dissection of the arterial wall), arterial thrombosis, phlebitis, venous thrombosis, embolic phenomena, and damage to atheromatous plaques in the aorta leading to cholesterol embolism (SEDA-14, 423) (269). Injection of contrast material into an intervertebral disc during angiography can cause lumbar pain associated with disc necrosis. Acute pancreatitis has been reported after aortography with sodium acetrizoate 70% w/v accidentally injected into the celiac axis. A report from 1958 described a fatal case of bilateral adrenal necrosis following lumbar aortography (SED-12, 1178) (270). Aortography in patients with pheochromocytoma can produce hemorrhage into and around the adrenal tumor; in one case adrenal insufficiency followed bilateral adrenal venography (271).

Cerebral angiography

The risk of neurological complications after cerebral angiography is 0.55–3.2% but increases to 10% in patients with symptomatic carotid stenosis; the incidence of clinically silent cerebral embolism is unknown. Diffusion-weighted magnetic resonance imaging before and after cerebral angiography has been carried out to assess the prevalence of embolic events in 100 consecutive angiographies in 91 patients (272). The patients underwent neurological assessment before, immediately after, and 1 day after angiography. There were 42 bright lesions in 23 patients after 23 procedures in a pattern consistent with embolic events. There were no new neurological deficits after any angiographic procedure. The frequency of lesions correlated significantly with a history of atherosclerotic arterial disease, the complexity of the angiographic procedure, and the amount of contrast medium used. The authors concluded that after diagnostic and interventional cerebral angiography embolic events are more frequent than the neurological complication rate. The incidence of embolism is closely related to the vascular risk profile.

Intravenous injection

Subcutaneous extravasation of contrast media during rapid intravascular injection can cause local irritation and inflammatory responses. The severity of these effects depends on the volume and osmolality of the extravasated contrast medium. High-osmolality contrast media can cause skin ulceration and necrosis. Subcutaneous hyaluronidase, aspiration of fluid, elevation of the limb, and topical application of cold compresses are some of the measures used to treat this complication.

The frequency of extravasation of ionic and non-ionic contrast media during rapid bolus injection in 5106 CT contrast-enhanced scans was 0.9% (31 patients had extravasation of ionic media and 17 patients had extravasation of non-ionic media) (273). There was no correlation between the injection rate and the frequency of extravasation. None of the patients who had extravasation had permanent damage.

With highly concentrated sodium-containing media, such as sodium iotalamate 420, severe arm pain and late thrombosis can occur (274). In a comparison of the sodium and methylglucamine salts of diatrizoate, even with lower concentrations, the incidence of arm pain was higher with the sodium salt. Extravasation of ionic contrast medium in the soft tissues can cause a chemical cellulitis, leading to skin necrosis, particularly if the circulation is compromised (SEDA-10, 424); tissue damage is less severe with the non-ionic media. The risk of extravasation is greatest with the rapid injection of large doses needed in computed tomography. In rare cases, this has resulted in gangrene, particularly in venography. Arterial insufficiency probably results in slower removal of the agent and hence more prolonged exposure to it.

As in many other areas, the non-ionic media are less noxious in this respect; this has been shown in animal studies (SEDA-16, 530) and in a number of clinical cases in which extravasation of large volumes of iopamidol responded to palliative measures and had no lasting ill-effects (275). Among the ionic media, the methylglucamine media seem to have more local toxicity than their sodium equivalents.

Extravasation of ionic and non-ionic contrast media after rapid bolus infusion has been studied in 5106 CT studies in adults (276). The mean infusion rate was 2.8 ml/second and extravasation occurred in 48 patients (0.9%). Injection rate did not correlate with the frequency or amount of extravasation. Average age and use of ionic versus non-ionic contrast medium were identical in patients with and without extravasation. There was no sex difference. There was extravasation of ionic contrast medium in 31 patients, nine of whom had extravasation of at least 50 ml. There was extravasation of non-ionic contrast medium in 17 patients, of whom seven had extravasation of at least 50 ml. Hyaluronidase infiltration was often used to treat more extensive extravasation in 10 patients each with extravasation of ionic or non-ionic media. No patient required surgical intervention and none had severe or long-term effects.

The adverse effects of contrast agents during computed tomography (CT) are broadly similar to those during excretion urography, but the incidence of serious reactions and deaths may be higher, because reactions are harder to treat when the patient is in a scanner (SEDA-7, 451). Renal insufficiency can occur in patients with diabetes and pre-existing renal disease or as a result of multiple examinations. In *Herpes simplex* encephalitis,

© 2006 Elsevier B.V. All rights reserved.

there can be prolonged retention of contrast medium in the brain. In patients with spinal tumors, stimulus-sensitive extensor spasms can occur in the trunk and limbs (SEDA-7, 453).

For computed tomography, large volumes of contrast medium have to be injected under pressure and this can lead to problems such as subclinical air embolism (SEDA-14, 422) and extravasation. In one series of 20 950 CT scans using non-ionic media, there was extravasation of 3–100 ml in 28 cases; the degree of extravasation depended on the pressure applied. When extravasation occurs, the extent of tissue damage depends primarily on the osmolarity of the contrast medium, but it is clear that of the ionic agents, the methylglucamine salts cause more damage than the sodium salts do (277).

Phlebography sometimes causes superficial thrombophlebitis in the injected vein. Of 61 previously healthy patients who had undergone phlebography, four had clear evidence of subsequent deep vein thrombosis and in two of these there were signs of non-fatal pulmonary embolism. The incidence of thrombosis may indeed have been higher, because there was abnormal fibrinogen uptake in 20 individuals, although the result could have been non-specific (278). The risk of thrombophlebitis is significantly less when low-osmolar media are used (SEDA-9, 410) (SEDA-11, 414).

Necrosis of the skin can follow peripheral venography (279); in these cases there had been some extravenous injection, and impaired circulation probably resulted in slower removal of the agent and hence more prolonged exposure to it. Gangrene of the toes has also occurred.

Polyarthropathy, in a severe and acute form, has been described as a rare complication of venography in patients with end-stage renal insufficiency (SEDA-18, 445).

Fat embolism is a rare complication of intra-osseous phlebography (280,281).

Orbital venography has been largely superseded by computed tomography and magnetic resonance imaging. This technique has usually been safe, but there have been reports of hemorrhage in a lymphangioma of the orbit and of transitory retinal artery spasm or retinal hemorrhage, the last two involving subjects with diabetes (SED-12, 1179) (282).

Priapism due to venous thrombosis has been reported after penile cavernosography with ioxaglate and diluted iotalamate (283). Contrast agents can cause endothelial damage in the corpus cavernosum. Prior injection of 1000–2000 units of heparin into the corpus cavernosum and the use of diluted non-ionic media have therefore been advocated for this procedure (284).

Subcutaneous or intramuscular injection

In the past, when intravascular injection proved difficult, contrast media were sometimes given by the subcutaneous or intramuscular routes. On occasion, severe sloughing of tissue resulted. Addition of hyaluronidase in order to alleviate this problem only aggravated it, and dilution with water, saline, or procaine solution also proved useless. If, in exceptional circumstances, these routes have to be used, the medium should be injected in small quantities at multiple sites.

Intra-articular injection

Minor reversible edematous changes have been noted in the synovial membrane after arthrography, and a chemical synovitis can occur (SEDA-10, 425).

Amniofetography

Ultrasound has superseded amniofetography, a procedure in which contrast media are injected into the amniotic sac during pregnancy to delineate fetal abnormalities. Diatrizoate, iotalamate, and, earlier, iodized oil were used. There is a theoretical risk of premature labor. Accidental injection of contrast medium into the fetal subcutaneous tissues could cause sloughing of the skin or subcutaneous necrosis. Cases of thyroid hyperplasia or hypothyroidism were also commonly described.

Arthrography

After injection of a contrast agent into a joint, the synovium becomes edematous and hemorrhagic within 2 hours. At 24 hours, there is tissue eosinophilia and vascular congestion. Eosinophilia of the synovial fluid can also occur. The complications reported in a survey of 126 000 examinations (285) are shown in Table 6.

Bronchography

Computed tomography of the lungs has reduced the requirement for bronchography, but it is still of value in selected cases. Iotrolan is most commonly used and is well tolerated. Adverse effects resulted from earlier products used in the field.

Hytrast (a mixture of iopydol and iopydone in aqueous suspension with carboxymethylcellulose) was generally withdrawn because it gave rise to a foreign body reaction. Iodized oil was formerly popular, but iodism was not uncommon and sometimes even fatal; sulfanilamide was added to one particular formulation of iodized oil to increase its viscosity and on occasion produced methemoglobinemia and cyanosis. Late granulomatous reactions in the lungs, followed by long-term fibrosis were also described with iodized oil, as were early allergic granulomatous reactions and other types of allergic reaction, such as pneumonitis and urticaria.

About one-third of patients undergoing bronchography have some type of reaction. The most common symptoms

are headache, nausea and vomiting, fever, iodism, and dyspnea. Less frequent reactions include wheezing, diarrhea, dizziness, cyanosis, chest pain, and pneumonia. Aqueous propyliodone produces more reactions than the oily form, but as a rule the product that produces most reactions also produces the best visualization. Symptoms are also related to the volume of agent used and the degree of alveolarization.

In a survey of 100 000 bronchograms published in 1967, 18 deaths were attributed to the technique. However, half of the deaths were due to the local anesthetic, generally used in excessive amounts. Fatalities tended to occur in children, patients with limited respiratory reserves, or subjects with severe hypersensitivity reactions (SED-12, 1185) (286).

If the cricothyroid route is used for bronchography, contrast medium may be accidentally injected into the soft tissues of the neck; propyliodone has under these conditions produced an inflammatory reaction leading to dysphagia, pain on movement of the neck, and mediastinal spread, rarely with electrocardiographic changes suggesting pericarditis. Oral glucocorticoids with antibiotic cover usually produce dramatic relief of symptoms.

Heating lowers the viscosity of propyliodone and should be avoided. Death from progressive acute respiratory failure resulted from bilateral bronchography under general anesthesia using propyliodone which had been heated in an autoclave.

Cholecystography and cholangiography

Ultrasonography is now the primary imaging technique for the assessment of the gall bladder and bile ducts, and oral cholecystography is obsolete. Contrast agents that have been used for oral cholecystography are weak iodinated organic acids that are absorbed and then largely conjugated with glucuronic acid. The most widely used agents have been iopanoic acid and sodium or calcium iopodate; tyropanoate and iocetamic acid have also been used. Bunamiodyl sodium, which was nephrotoxic, has been withdrawn.

The use of intravenous cholangiography has fallen dramatically in recent years, largely because of the advent of new and safer techniques for imaging the biliary tree, including high-quality ultrasound. However, with the introduction of laparoscopic cholecystectomy, the technique is occasionally used to assess bile duct anatomy before surgery (SEDA-19, 426). Intravenous cholangiography with meglumine iotroxate was reported to be acceptably safe. Contrary to popular opinion, reactions are apparently no more frequent with modern agents for intravenous cholangiography than with angiographic agents (SEDA-20, 416).

In a national survey in Britain in 1970, when drugs were generally given for this purpose in a single injected dose, intermediate reactions to iodipamide occurred once in every 700 cases, severe reactions once in every 1600, and deaths once in every 5000 (SED-12, 1168) (72). The introduction of infusion cholangiography (in which the contrast medium is given over 15–30 minutes) reduced the incidence of minor reactions, allowing the liver to excrete the contrast medium more efficiently, so that doses as low as 3–5 ml of ioglycamide or 10 ml of 50% iodipamide can be used. According to a 1975 report from France, serious reactions nevertheless occurred once in every 310 infusion cholangiographies (SEDA-10, 422) (287).

Pyrexial reactions occurred in 5.3% of cases after postoperative cholangiography through a T-tube; in two patients there was endotoxic shock (SEDA-5, 420).

A fatal reaction occurred when diatrizoate was used for operative cholangiography and contrast medium entered the bloodstream (288).

Using a fine needle, with sodium diatrizoate as the contrast medium, percutaneous hepatic cholangiography is a relatively safe technique for use in cases of obstructive jaundice in which the high serum bilirubin precludes oral or intravenous techniques. The complications of bile peritonitis and internal hemorrhage are best avoided by decompression of dilated ducts. Bile blood fistula can lead to fatal endotoxic shock due to bacteria escaping from the obstructed biliary tract (289). The rapid appearance of a pyelographic shadow can be a useful diagnostic sign, calling for immediate antibiotic therapy. However, it is now usual to give a broad-spectrum antibiotic immediately before the examination. Acute renal insufficiency has been reported after transhepatic cholangiography (SEDA-10, 423).

Cholangiopancreatography

Although a severe contrast medium reaction with shock has been observed, this was the only contrast medium reaction in a series of 2000 cases of ERCP reported in 1977 (290). In some other reports, there were milder degrees of allergic reactions (291). In a series of 10 000 cases reported in the USA in 1976 (292), the most serious adverse effects were cholangitic sepsis (0.8%, fatal in 0.08%) and pancreatic sepsis (0.3%, fatal in 0.06%), but there was a 1% incidence of injection pancreatitis and other cases of drug interactions (diazepam, spasmolytic agents), instrumental injury, and aspiration pneumonia. Pancreatitis can result from over-filling of the pancreatic duct. To minimize the risk of pancreatitis after ERCP the examination should be performed with care. High-pressure injection of the contrast medium should be avoided to reduce the risk of overfilling and extraductile extravasation. In addition, low-osmolar non-ionic contrast agents should be used (SEDA-19, 425) (SEDA-20, 417). Significant quantities of contrast agent can be absorbed after ERCP. Transient asymptomatic hyperamylasemia can occur (SEDA-14, 422), and in one series there was a 15% incidence of mild renal dysfunction (293).

Discography

Subdural empyema with residual quadriparesis has been reported as a rare complication of discography (294).

Hysterosalpingography

Water-soluble agents are generally preferred for hysterosalpingography, agents such as diatrizoate or iotalamate being most commonly selected. It has sometimes been suggested that low-osmolar contrast media should be preferred; however, a double-blind comparison of the low-osmolar medium ioxaglate (Hexabrix 320) with methylglucamine diatrizoate (Conray 280) in 100 patients showed no difference in the incidence of early or late adverse effects between the two agents (295).

There is no justification for using specialized formulations based on the more toxic molecules acetrizoate or

© 2006 Elsevier B.V. All rights reserved.

iodipamide; these cause more severe pain and can also cause hypotension and shock.

Iodized oil, at one time widely used, caused less pain but was suspected of causing adhesions and there was certainly some risk of oil embolism after intravasation, for example retinal embolism with visual impairment lasting for some months and several cases of pulmonary oil embolism (SEDA-16, 537). Skin testing with iodized oil on occasion resulted in both local and generalized reactions. Like later agents, lipiodol could also cause salpingitis.

The main remaining disadvantage of the currently used water-soluble media is their tendency to cause lower abdominal pain, which can be severe, during or shortly after the injection; it can last for 24 hours or longer. These adverse effects are likely to be less severe with low-osmolar non-ionic media. Vaginal bleeding can occur and the following menstrual period can be deranged. With all contrast media there is a possibility of hypersensitivity reactions, and dextran as an additive has on occasion produced anaphylactic symptoms (SEDA-15, 505). Salpingitis can occur with any contrast agent.

Lymphography

Lymphography is rarely required with the availability of modern CT and MRI scanners. However, intradermal injection of 2–4 ml (iodine 300 mg/ml) of iso-osmolar non-ionic dimers (iotrolan and iodixanol) at a rate of 0.1 ml/minute can be used to assess the lymphatics in limbs with lymphedema. The procedure is safe with no serious adverse effects, but idiosyncratic and allergic like reactions can occur.

Iodized oils are usually used as contrast media for lymphography and can cause iodism. Reactions can also occur to the dye "patent blue violet," which is injected subcutaneously before lymphography to enable the lymphatics to be visualized; it colors the skin and urine blue. The incidence of serious reactions to lymphography in 32 000 cases is shown in Table 7.

Myelography and ventriculography

Myelography and ventriculography are techniques that, irrespective of the agent used, have some unpleasant effects, including headache, nausea, and dizziness, which are frequent problems and are possibly more frequent in women, in people with multiple sclerosis, and in investigations at the higher levels of the central nervous system. Nevertheless, the nature and incidence of the adverse reactions depend on the contrast agent used, oily agents, the ionic water-soluble agents, and the non-ionic water-soluble agents. Today, MRI has substantially replaced these unpleasant invasive procedures (SEDA-19, 430).

The incidences of adverse effects in 4568 cases of lumbar myelography and 1232 cases of cervical myelography are shown in Table 8 and Table 9.

Oily media

Oily media are no longer used for myelography or other imaging techniques of the nervous system. Iofendylate was formerly widely used for myelography and to some extent for ventriculography. In the USA, where myelography was generally performed with large volumes of contrast agents, it was the custom to aspirate the iofendylate at the end of the investigation, whereas in some other countries smaller volumes were used under the assumption that these would be gradually absorbed. In patients with multiple sclerosis, myelography with iofendylate can cause particularly severe reactions.

Aseptic meningitis can occur 3–67 days after myelography, and in one case it was associated with evidence of cerebral vasospasm and infarction. An unusual ophthalmic complication in another patient followed the passage

of iofendylate into the region of the clivus and along the course of the optic nerve during cervical myelography; the patient had transient pain and flashes of light in the eye, followed by periorbital pain for 2 days. A month later, severe visual impairment with renewed pain occurred; the condition responded to systemic glucocorticoids (296).

Venous intravasation occurs rarely during lumbar myelography; pulmonary oil embolization has resulted and has also been described after ventriculography with iofendylate in a hydrocephalic child with a ventriculovenous shunt. In that case the symptoms were mild, but the agent can obstruct the valve and in any patient the medium should therefore be removed at the completion of the procedure.

Arachnoiditis is a recognized and much-discussed problem, which has given rise to group litigation. Extensive adhesions due to iofendylate have been described, leading to neurological complications and death; there are two cases on record with clinical changes resembling Sudeck's atrophy. Animal experiments have shown that the ability of iofendylate to cause arachnoiditis is especially pronounced if it is mixed with blood; it should therefore be avoided if there is the possibility that bleeding has occurred into the cerebrospinal fluid.

It is common to see evidence of iofendylate residues for many years after myelography. The residue problem extends to the skull and it is common to find symptomless deposits of iofendylate there after myelography; however, in several patients residues in the skull have apparently caused convulsions (SEDA-14, 424). They can also be associated with persistent headache (SEDA-8, 430) and perhaps with the development of vestibular disturbances many years later (SEDA-17, 538).

In two cases, ventriculography with iofendylate resulted in adhesions with obstruction to the outflow of cerebrospinal fluid (in one case at the level of the third ventricle, in the other at the level of the fourth) producing obstructive hydrocephalus (SED-12, 1180) (297).

An iofendylate cyst causing a thoracic radiculopathy has been reported (298).

- A 45-year-old woman had severe root pain at T10, which had gradually become more intense over the preceding 4 years. She had undergone spinal myelography about 30 years before. Clinical examination was normal. A plain X-ray of the thoracic spine showed a radio-opaque abnormality at the level of T10, which axial CT showed was in the vertebral canal, compressing the left posterolateral margin of the theca. At thoracic laminectomy, a well-circumscribed subarachnoid extramedullary cyst was identified, from which a small volume of oily material was removed. The cyst collapsed and its posterior wall was excised. Histology confirmed a benign arachnoid cyst. Within 24 hours the thoracic root pain had gone.

Recurrent febrile nodular non-suppurative panniculitis (Weber–Christian syndrome) has been described 1 month after myelography with iofendylate; the causal link was uncertain (299).

Persistent symptoms can be caused by residues of iofendylate after myelography; allergy with urticaria and anaphylactic episodes recurring for 17 years was described in one patient who was hypersensitive to iofendylate; after removal of most of the residue, the symptoms improved (300). In one unusual case of anaphylactic collapse, marked bilateral parotid enlargement was the presenting sign (SEDA-18, 442).

When metrizamide was used to outline the basal cisterns in association with computed tomography of the skull, headache occurred in about 50% of patients and vomiting in 26–56%, depending on the dose used; the symptoms occurred 2–6 hours after injection and cleared within 12 hours. Convulsions have occurred with this procedure (301).

Tolerance of non-ionic contrast media in myelography has been well documented (SEDA-22, 500). A report from India has documented the safety and diagnostic efficacy of the non-ionic monomer iohexol 7–10 ml (iodine 300 mg/ml) injected into the subarachnoid space in 25 patients (302). Only three patients developed minor adverse effects—headache and paresthesia in the legs.

Sialography

In randomized comparison of Lipiodol ultrafluid (ethiodized oil) with melumine diatrizoate 290 for sialography in 60 patients, pain and swelling of the parotid gland was more frequent after Lipiodol UF (303).

Extravasation of oil-based contrast agents used for sialography and dacryocystography can cause lipogranuloma formation (304).

- A four-year-old boy with epiphora had a left dacryocystogram with the iodinized oil-based contrast agent Lipiodol under general anesthesia. During injection, a false passage was inadvertently formed, with extravasation of the contrast agent from the lacrimal duct into the surrounding tissues. This was confirmed radiographically. He developed swelling and erythema, which gradually resolved over 6 months.

Iso-osmolar non-ionic dimers, such as iotrolan or iodixanol, are the safest contrast agents for such a procedure. Extravasation of these agents causes minimal tissue reaction.

Urography

The use of intravenous urography has been in decline for some years with the advent of high-quality real-time ultrasonography (SEDA-20, 417).

For retrograde and anterograde urography, only iodinated water-soluble contrast media should be used. The high-osmolar contrast agents, diatrizoate or iotalamate, are generally used in these procedures. Barium sulfate has been used for cystography in the past, but is inadvisable; if ureteric reflux occurs, the barium can become inspissated in the calyceal system of the kidney; in view of experimental findings, this might be expected to cause granulomatous reactions with fibrosis.

Retrograde urography is often followed by irritation and edema of the urethral and bladder mucosa. In animals this effect was maximal at 48 hours and persisted for at least 1 week. Factors that reduced the inflammatory response in the bladder were dilution of the medium and the use of smaller volumes instilled at lower pressure. In clinical use, diatrizoate has seemed to be less irritant than acetrizoate (305).

Retrograde pyelography can rarely cause deterioration of renal function, with acute renal insufficiency, particularly if there has been marked pyelorenal back flow; exceptionally, the complication can be fatal (306).

© 2006 Elsevier B.V. All rights reserved.

Retrograde pyelography with potassium bromide has caused renal insufficiency (SEDA-11, 413).

Small amounts of contrast agents can be absorbed after retrograde urography, mainly via the calyces. In one case, 12.5% of the contrast medium was absorbed (307). A severe generalized reaction has been reported after cystography with diatrizoate (SED-12, 1174) (308), and another in a patient with ureteric reflux given meglumine iotalamate; in the latter, there was circulatory collapse but it responded to simple change in posture and adrenaline was not required (SEDA-18, 445). Miliary dissemination of tubercle bacilli from an infected urinary system after retrograde pyelography with pyelovenous back flow is very rare. An anaphylactoid reaction to contrast medium injected into a ureter via a percutaneous nephrostomy has been reported (SEDA-19, 430).

Bladder rupture is a risk of cystourethrography. In two children with myelomeningoceles and ventriculoperitoneal shunts, bladder rupture had particularly serious consequences. The diatrizoate that was used passed into the peritoneal cavity and then via the shunt into the cerebral ventricles and subarachnoid space, causing tonic convulsions (SEDA-17, 538).

Autonomic dysreflexia (facial flushing, sweating, nasal congestion, headache and paroxysmal hypertension) can occur in quadriplegic patients in response to bladder distention during cystography (SEDA-19, 430).

Drug overdose

Fatal cases of accidental overdosage have been reported in infants; the complications leading to death were either pulmonary edema or convulsions. The latter can be due to hyperosmolarity (leading to hypertonic dehydration) or to the chemical toxicity of the contrast agent.

- In a fatal case, a massive overdose of 340 ml Renigrafin 76 was injected into a 7-year-old child with coarctation of the aorta, and computed tomography showed the presence of contrast agent in the brain (98).

A patient who was given 30 g of iopanoic acid, instead of 3 g, had severe nausea with vomiting and diarrhea but no more serious effects (SED-12, 1167) (309).

Drug–Drug Interactions

Antihistamines

Contrast media should not be mixed with antihistamines in a syringe, since precipitation can result (SED-8, 1034) (310).

Beta-blockers

Field experience, backed by a case-control study of 1991, strongly suggests that patients taking beta-blockers have a risk ratio of adverse reactions to contrast media of 2.7. Hypotension is the main effect, sometimes dangerously so, even with non-ionic media (SEDA-11, 411) (SEDA-17, 536) (311).

Cardiac glycosides

Diatrizoate and strophanthin K may have a synergistic toxic effect (312).

Heparin

Ionic contrast media cause temporary prolongation of clotting time in patients treated with heparin; this effect may last for 6 hours and may interfere with laboratory assays (132). Non-ionic media do not have this anticoagulant effect, and if blood is allowed to mix with a non-ionic medium in the syringe or catheter, thrombus formation can occur, which could be a potential cause of thromboembolism (SEDA-15, 502).

In contrast, in 664 patients undergoing percutaneous coronary intervention with insertion of a sirolimus-eluting stent, the addition of heparin was associated with significantly higher incidences of hematomas (8.5 versus 3.8%) and overall vascular complications (5.3 versus 0.01%), including pseudoaneurysm (2.6 versus 0.0%); more patients required surgical repair (1.8 versus 0.3%) and there was a trend toward a higher rate of blood transfusion (6.6 versus 2.6%) (313). The authors concluded that routine addition of low-dose heparin to contrast agents during percutaneous coronary intervention is associated with higher rates of bleeding and vascular complications.

Hydralazine

Hydralazine seems to increase the risk of acute cutaneous vasculitis in patients given iopamidol (314).

Interleukin-2

Prior interleukin-2 therapy can induce atypical contrast medium hypersensitivity in the form of toxic recall reactions of various types (SEDA-17, 537), and these cannot be prevented by glucocorticoid premedication (315).

Metformin

The use of contrast media in patients taking metformin should be carried out cautiously. Contrast-induced nephropathy can lead to retention of metformin and lactic acidosis. However, there is no conclusive evidence that intravascular contrast agents precipitate metformin-induced lactic acidosis in patients with normal serum creatinine concentrations (under 130 μmol/l). This complication was almost always observed in non-insulin dependent diabetic patients with abnormal renal function before injection of contrast media (4,316).

Lactic acidosis can occur after the use of intravascular iodinated contrast agents in patients taking metformin. Metformin is excreted by the kidneys, and renal insufficiency can lead to its retention, which can cause fatal lactic acidosis. The manufacturers have recommended that metformin should be withdrawn for 48 hours before and 48 hours after the administration of intravascular contrast media, which can cause renal damage, and treatment should not be restarted until normal renal function is confirmed. Reviews of reported cases of lactic acidosis after contrast administration have shown that there was pre-existing renal impairment in all cases. A retrospective evaluation of patients taking metformin who underwent

© 2006 Elsevier B.V. All rights reserved.

contrast angiography has also confirmed this observation (317). Of 33 patients, 29 had a normal serum creatinine before the angiographic procedure and none had a rise after angiography. Four had an abnormal serum creatinine before angiography; all four had a significant deterioration in renal function and died, two from unrelated causes and two from acute renal insufficiency and acidosis. The authors concluded that administration of contrast media is hazardous in diabetic patients with pre-existing renal impairment and that patients with normal renal function taking metformin are not at risk of lactic acidosis. They recommended that serum creatinine should be measured in all patients before angiography. In patients taking metformin with a normal serum creatinine, intravascular contrast is not contraindicated.

NSAIDs

Non-steroidal anti-inflammatory drugs may increase the risk of contrast nephropathy (SEDA-15, 502).

Papaverine

Ioxaglate has been reported to be precipitated by papaverine, which has been used in penile cavernosography (SEDA-11, 413), but some cases may have been due to an interaction between heparin and papaverine, perhaps not involving the contrast medium (SEDA-18, 444); in one case, the use of iopamidol 370 immediately after an injection of papaverine was followed by extensive intra-arterial thrombosis (SEDA-17, 537).

Pethidine

When pethidine is given with iodipamide, a myocardial infarction-like syndrome can occur due to spasm of the sphincter of Oddi (SED-8, 1026) (318).

Protamine

Protamine sulfate has a pH of 3–4 and causes precipitation of diatrizoic acid; if injected into a catheter containing diatrizoate in heparinized patients, it could cause a precipitate which in theory might result in an embolus.

Uricosuric drugs

Drugs that increase uric acid excretion may precipitate contrast nephropathy (SEDA-7, 452).

Interference with Diagnostic Tests

Urinalysis

Urinalysis after intravenous urography can give misleading results. Increased specific gravity, false positive tests for protein (with the sulfosalicylic acid and nitric acid ring methods, but not the bromophenyl dye test), and the presence of needle-like crystals have been reported. Pseudo-albuminuria can occur with a false-positive sulfosalicylic acid test (319).

Black copper reduction test

A positive result in the black copper reduction test, suggesting alcaptonuria, can follow the use of diatrizoate, iotalamate or iodipamide (320).

Urinary catecholamines

Methylglucamine-based contrast media interfere with the estimation of urinary catecholamines in patients with pheochromocytoma (SEDA-10, 423).

Para-aminohippuric acid

Diatrizoate can interfere with *para*-aminohippuric acid extraction studies (SEDA-15, 502) (321).

Iodine-containing medicaments

General Information

Iodine is a non-metallic halogen element (symbol I; atomic no 53) which exists as a near-black solid but readily sublimates, giving a purple-colored vapor. It is found in nature both free (for example in large amounts in seaweeds such as kelp and in low concentrations in seawater) and in minerals such as iodyrite (silver iodide) and Chile saltpetre (sodium iodide).

Iodine-containing medicaments

Iodine must be present in the normal diet to prevent iodine-deficiency goiter or cretinism, and iodine deficiency-related disorders are still a worldwide (although preventable) group of diseases that affect about 150 million people in at least 40 countries. The WHO sponsored a program to control these disorders by the year 2000 (1,2), and since 1990 there has been a remarkable progress in prevention of iodine deficiency disorders. However, by the year 2000 one-third of the population affected by iodine deficiency disorders still did not have access to iodized salt (3).

Scepticism about the introduction of population-wide programs to prevent iodine-deficiency disorders is occasionally encountered in regions of mild iodine deficiency, especially in Europe (4). The main arguments against introduction of iodized salt are a temporary rise in the incidence of hyperthyroidism (5), a possible increase in the incidence of Graves' disease, and the fact that the remission rates with antithyroid drug therapy will fall (6). The value of preventing mild iodine deficiency has been supported by a longitudinal study from Switzerland, in which 109 000 people in a defined catchment area were studied before and for 9 years after correction of mild iodine deficiency (7). The incidence of toxic nodular goiter increased in the first year by 27%, but thereafter there was a steady fall in the incidence of both toxic nodular goiter (–73%) and Graves' disease (–33%). The range of optimal iodine intake is fairly narrow. Mild and moderate iodine excess are probably associated with higher frequency of hypothyroidism (8).

Some drugs contain iodine in amounts that considerably exceed the optimum daily intake of inorganic iodine. Such drugs include:

- most radiographic contrast media
- amiodarone and benziodarone
- iodoquinoline
- iodine-containing antiseptics (for example povidone-iodine).

Radioactive iodine

Different forms of radioiodine have been used at different times, including ^{123}I, ^{125}I, and ^{131}I. Radioactive iodine is used to scan the thyroid gland and in the treatment of thyrotoxicosis. See in the monograph on Radioactive iodine.

Potassium iodide and potassium iodate

Potassium iodide is the inorganic iodide most commonly used in high dosage for acute thyrotoxicosis. Indeed, large amounts of iodine cause reduced organification of iodine and a temporary block of thyroid hormone secretion (Wolff–Chaikoff effect) and therefore result in a more rapid thyrostatic effect than synthesis inhibitors. Potassium iodine is also used for preoperative treatment of goiter, especially to reduce preoperative bleeding. It can be used in combination with thyrostatic drugs but should never be prescribed in combination with potassium perchlorate, since each abolishes the other's effects. The thyrostatic effects of iodide are evident even at a dose of 6 mg/day, but doses between 50 and 100 mg/day are usually recommended. In some cases of intolerance to higher doses, perchlorate can be used, for example for preoperative treatment.

Potassium iodide has been widely used in asthma and chronic bronchitis as an expectorant. There is considerable controversy about its efficacy. It should not be used in adolescent patients because of its potential to aggravate and induce acne and its effect on the thyroid gland. In view of its doubtful efficacy and definite toxicity, it would be preferable if physicians stopped prescribing it as an expectorant.

Potassium iodide and potassium iodate are commonly added to table salt to prevent iodine deficiency and associated thyroid disease.

Iodine in protecting the thyroid against radioiodine

Accidents with nuclear reactors or nuclear bombs can expose large numbers of people to several decay products of uranium, and iodine isotopes are among the most abundant compounds released in such reactions. It is therefore logical to use salts of stable isotopes of iodine to prevent the accumulation of radioiodine in a person or population at risk of such exposure. The accidents in Windscale (UK), Three Mile Island (USA), and

© 2006 Elsevier B.V. All rights reserved.

particularly Chernobyl (Ukraine) drew attention to such problems. The major question is therefore whether the potential adverse effects of stable iodine when given indiscriminately to large groups of people would outweigh the risk of radioiodine exposure. Stable iodine needs to be rapidly available when disasters occur, since, in order to be effective, it has to be given in sufficient amounts (100 mg) within a short time before or after (–12 to +3 hours) radioiodine exposure. Potassium iodate (KIO_3) is more stable than potassium iodide (KI), since the latter readily evaporates during prolonged storage. However, the dose recommended for radioprotection of 100 mg of iodine daily over several days (138 mg iodate per day) are close to retinotoxic doses of iodate reported in cases of accidental intoxication. In these doses iodate cannot be recommended. As an additive to salt for correcting iodine deficiency, much smaller doses of iodate are used (up to 1.7 mg/day), and in these doses iodate is probably safe (9).

The main adverse effects of stable iodine are shown in Table 1.

Iodine should be given to the general population if the risk of radioiodine exposure is sufficient (over 15–100 rem), but people with increased susceptibility to the adverse effects of iodine (previous thyroid disease or known serious allergies) should be excluded (10–15). In elderly people the benefit of stable iodine probably does not outweigh its potential adverse effects, while in pregnant women and infants the benefit to harm balance is not established; rapid evacuation of such people from fallout zones should be given the highest priority (SEDA-11, 358).

Tincture of iodine

Tincture of iodine (aqueous iodine oral solution, Lugol's solution) is a solution of iodine 5% plus potassium iodide 10% in water, which is used to reduce the vascularity of the thyroid gland in thyrotoxicosis before surgery.

Iodinated glycerol

Iodinated glycerol is used as a mucolytic agent in respiratory disorders, but its efficacy is controversial. Organically bound iodine is changed to unbound iodide after absorption.

Table 1 Adverse effects of iodine given for protection against radioiodine

Adverse effect	Susceptible individuals
Iodine-induced goiter	
Iodine-induced hypothyroidism	Fetus and neonate
Iodine-induced hyperthyroidism	People living in iodine-deficient areas; people with a history of hyperthyroidism
Sialadenitis and taste disturbances	
Nausea and abdominal pain	
Skin rashes	
Edema (including face and glottis)	
Allergic-like reactions (iodine fever, eosinophilia, serum sickness-like symptoms, vasculitis)	People with hypocomplementemic vasculitis

Iodoform

Iodoform is a lemon-yellow-colored crystalline organic salt of iodine (CHI_3), analogous to chloroform, with a saffron-like odor, used as an antiseptic.

Iodophors

Iodophors are labile complexes of elemental iodine with macromolecular carriers that both increase the solubility and provide sustained release of iodine. Povidone-iodine is a water-soluble iodophor that is used as an antiseptic and is said to be free of the undesirable effects of iodine tincture. However, iodine can be absorbed from it through burned areas (16), vaginal mucosa (17), oral mucosa (18), and in children even with normal skin (19). Povidone-iodine is discussed in a separate monograph under the title Polyvinylpyrrolidone.

Radiocontrast media

Many radiocontrast media contain iodine. These include iodixonal, iohexol, iomeprole, iopamidole, iopanoic acid, iopitridole, iopromide, iothalamate, iotrolan, ioversol, and ioxaglate. They are covered in a separate monograph.

General adverse effects

It has been estimated that in 1994 some 1.5 billion people in 118 countries were at risk of iodine deficiency, this being regarded as the world's most significant cause of preventable brain damage and mental retardation. Fortification of all salt for animal and human consumption has been chosen as the preferred method for the prevention of iodine deficiency disorders, and this approach is proving effective in reducing the incidence of such disorders. However, iodine supplementation is not without risks, which have been discussed (20) and which include allergic reactions and iodine-induced hyperthyroidism. It has been clearly shown that the benefits of iodine deficiency outweigh the risks on a population basis, but it is nevertheless evident that introduction of iodine supplementation is associated with clinical problems in individual subjects.

Because of its adverse effects, it is logical to omit iodine from all pharmaceutical formulations whenever possible, and at least clearly label its presence when it is necessary. The adverse effects of iodine include goiter and hypothyroidism (19,21), hyperthyroidism (SEDA-18, 176), neutropenia (22), metabolic acidosis (23), and generalized iododerma (16).

The term "iodism" covers a group of adverse effects that include irritation of the skin, the mucous membranes, and the conjunctiva. Allergic reactions are rare and mainly cause rashes, pruritus, fever, eosinophilia, and allergic vasculitis (24–27). Leukocytosis, swelling of the salivary glands, iodine coryza, and gastric upsets have also been reported. Headache can accompany the other reactions. In rare cases, jaundice, bleeding from the mucous membranes, and bronchospasm can occur. Inflammatory states may be aggravated by these adverse reactions.

Effects of iodine on thyroid function

Iodine excess can induce hyperthyroidism or hypothyroidism (SEDA-12, 355) (SEDA-13, 378). Pharmacological amounts of iodine induce only a temporary inhibition of thyroid hormone secretion, since even during continuous administration of iodine normal thyroid function reappears ("escape from inhibition"), at least in most healthy subjects. For some unknown reasons, thyroid function can remain suppressed, resulting in hypothyroidism, secondary hypersecretion of TSH, and development of goiter (28). Patients with autoimmune thyroiditis or partial thyroid resection and very young infants (or fetuses) are especially susceptible to iodine-induced hypothyroidism. That therapeutic doses of iodine could induce hyperthyroidism was already known in the nineteenth century shortly after its introduction for the prevention and treatment of iodine deficiency (5,29). Thereafter, similar observations were made in several other parts of the world when iodine supplementation was introduced in iodine-deficient areas. Such iodine-induced hyperthyroidism (the "Jod-Basedow" phenomenon) can also occur in patients with other thyroid diseases (especially multinodular goiter), even when the diet was sufficient in iodine before the excess intake of iodine. This can even be found in patients with apparently normal thyroid glands. The Jod-Basedow phenomenon is usually associated with a slight goiter, high concentrations of both free levothyroxine (T4) and triiodothyronine (T3) and a very low uptake of radioactive iodine. The disease disappears spontaneously weeks or months after interruption of the excess iodine (30–32). Such a disorder should be differentiated from the temporary increase in T4 and reciprocal fall in T3 that can occur 1–2 weeks after the administration of iodine or iodine-containing drugs and that is not associated with symptoms of thyroid dysfunction (33).

Organs and Systems

Cardiovascular

Cardiac dysrhythmias have been seen after accidental ingestion of a large amount of potassium iodide solution (34). In one case administration of iodide was associated with pulmonary edema and iododerma (SEDA-7, 190).

Endocrine

It has been estimated that in 1990 iodine deficiency affected almost one-third of the world's population and represented the greatest single cause of preventable brain damage and mental retardation. Fortification of all salt for animal and human consumption has been chosen as the preferred method for the prevention of iodine deficiency disorders, and this approach is effective in reducing the incidence of such disorders. However, iodine supplementation is not without risk, particularly iodine-induced hyperthyroidism and thyroiditis. The issue of benefit versus harm has been reviewed and the view, previously expressed, that the benefits of correcting iodine deficiency far outweigh risk of iodine supplementation has been reiterated (35). Complications of iodine administration are not confined to those taking dietary supplements to correct deficiency, but can also occur in those given iodine-containing contrast media and with the use of iodine-containing antiseptic solutions.

Shortly after the administration of iodine-containing drugs, there is a self-limited increase in serum thyroxine (T4), which sometimes exceeds the reference range, and a reciprocal fall in serum triiodothyronine (T3). This usually resolves spontaneously, but can persist during further treatment (so-called isolated hyperthyroxinemia). In some patients, true hyperthyroidism (increases in both T4 and T3 with clinical symptoms) occurs, for example in about 5% of patients taking long-term amiodarone, whereas evolution to iodine-induced hypothyroidism is less frequent (36–38). On the other hand, the frequency of iodine-induced hyperthyroidism can comprise about half of all cases of hyperthyroidism, at least in elderly patients taking several drugs (SEDA-7, 399).

The use of iodine has been held responsible for the increasing frequency of relapse of Graves' disease in the USA. Treatment of more severe cases of iodine-induced hyperthyroidism can be difficult, as thyroid synthesis inhibitors are not immediately active and ^{131}I cannot be used because of low thyroid uptake. The carefully supervised combination of perchlorate and methimazole is effective (39), but surgery has also occasionally been advocated.

A summary of the occurrence and epidemiology of iodine-induced hyperthyroidism has been published (40), based on the authors' experience in Tasmania, Zaire, Zimbabwe, and Brazil. Another review has more specifically examined the cardiac features of iodine-induced hyperthyroidism and has emphasized the importance of awareness, monitoring, and treatment of such hyperthyroidism in areas in which iodine supplementation has been recently introduced (41).

The complexity of the interaction between iodine intake and autoimmune thyroid disease has been highlighted by reports of evidence that iodide (compared with thyroxine) induces thyroid autoimmunity in patients with endemic (iodine deficient) goiter (42), while in those with pre-existing thyroid autoimmunity, evidenced by the presence of antithyroid (thyroid peroxidase) antibodies, administration of iodine in an area of mild iodine deficiency led to subclinical or overt hypothyroidism (43).

More importantly, in a study from Italy the use of iodine-containing disinfectants was responsible for transient neonatal hypothyroidism in more than 50% of cases identified (another common cause being transfer of maternal antibodies) (44). These findings led the authors to conclude that pregnant women should be advised of the adverse effects of using iodine-containing products and that their use should be generally discouraged.

Because of reports of severe hyperthyroidism after the introduction of iodized salt in two severely iodine-deficient African counties (Zimbabwe and the Democratic Republic of the Congo), a multicenter study has been conducted in seven countries in the region to evaluate whether the occurrence of iodine-induced hyperthyroidism after the introduction of iodized salt was a generalized phenomenon or corresponded to specific local circumstances in the two affected countries (45). Iodine deficiency had been successfully eliminated in all of the areas investigated and the prevalence of goiter had fallen markedly. However, it was clear that some areas were now exposed to iodine excess as a result of poor

© 2006 Elsevier B.V. All rights reserved.

monitoring of the quality of iodized salt and of the iodine intake of the population. In these areas, iodine-induced hyperthyroidism occurred only when iodized salt had been recently introduced.

This complication of iodine administration is not confined to those receiving dietary supplements. Two of 788 unselected patients from a relatively iodine-deficient area of Germany who underwent coronary artery angiography with an iodine-containing radiographic contrast agent developed hyperthyroidism within 12 weeks (despite the absence of the typical risk factors of advanced age, preceding nodular goiter, or a low serum TSH) (46). While this represents a relatively low incidence, this series highlights the importance of recognizing the role of iodine-containing drugs in inducing hyperthyroidism, even in developed countries.

Iodinated glycerol

After the administration of iodinated glycerol organically bound iodine is changed to unbound iodide, causing thyrotoxicosis, hypothyroidism, or goiter in some patients (47). Reversible hypothyroidism has been reported in nursing-home residents, without a history of thyroid disease, who had been taking iodinated glycerol as an expectorant (48). Hypothyroidism has been reported after long-term treatment with iodinated glycerol (49).

Iodophors

Extensive iodine absorption from povidone-iodine can cause transient hypothyroidism or in patients with latent hypothyroidism the risk of destabilization and thyrotoxic crisis (SEDA-20, 226) (SEDA-22, 263). Especially at risk are patients with an autonomous adenoma, localized diffuse autonomy of the thyroid gland, nodular goiter, latent hyperthyroidism of autoimmune origin, or endemic iodine deficiency (50).

Hyperthyroidism from povidone-iodine is rarer than hypothyroidism (SEDA-20, 226), but a history of long-term use of iodine-containing medications should be considered when investigating the cause of hyperthyroidism.

- A 48-year-old woman developed palpitation and insomnia (51). The clinical history, physical examination, and laboratory tests supported hyperthyroidism. Since July 1994 she had been combating constipation by improper use of an iodine-containing antiseptic cream for external use only. She had inserted povidone-iodine into her rectum by means of a cannula. The iodine-containing cream was withdrawn and she was given a beta-blocker. The palpitation resolved within 2 weeks and her plasma thyroid hormone concentrations normalized within 1 month.

Hyperthyroidism in this patient was probably triggered by improper long-term use of an over-the-counter iodine-containing cream.

Potassium iodide

Iodine-induced hypothyroidism has been described as the result of prolonged intake of potassium iodide and iodinated glycerol as mucolytics (52).

Patients with an underlying disorder of the thyroid gland may be more predisposed to this complication.

The case of a severe iodine-induced thyrotoxicosis in a patient who had been using iodine-containing eye-drops for more than 10 years has been reported (53).

Mouth and teeth

Occasionally, after a high dose of iodine, sudden swelling of the parotid and submandibular glands develops (54).

- Acute sialadenitis ("iodide mumps") has been described in a 70-year-old man who underwent femoral artery angiography with an iodine-containing contrast agent; he gave a history of a similar episode 24 hours after a previous angiogram (55).

This effect is thought to be a hypersensitivity reaction due to formation of a complex between iodide and plasma proteins.

Urinary tract

Iodinated radiographic contrast media can cause acute renal insufficiency, perhaps as a result of reduced renal blood flow, an intrarenal osmotic effect, or direct tubular toxicity (56). Diuretics, calcium channel blockers, adenosine receptor antagonists, acetylcysteine, low-dose dopamine, the dopamine D_1 receptor agonist fenoldopam, endothelin receptor antagonists, and captopril have all been used to prevent contrast nephropathy.

Skin

A complication of the use of alcoholic iodine solution has been described in three women undergoing cesarean section, who developed painful, superficial, inflammatory reactions on their buttocks after skin preparation for surgery with 10% iodine in alcohol (57). These lesions were believed to have been caused by pooling of the solution underneath the patients, topical skin damage being exacerbated by heat and occlusive drapes.

Induction and aggravation of acne is a typical reaction to iodide (58).

Iododerma, which is thought to be an allergic reaction, starts with an acneiform lesion, localized in the area of the sebaceous glands, which spreads to form verrucous granulomatous lesions (59,60). After discontinuation of iodide, the skin clears over a few weeks. In addition to this typical picture of iodide sensitivity, iodide can cause urticaria and erythema and even hemorrhagic rashes. In order to verify the etiology of the skin conditions in certain cases, sensitivity testing may be required, but is not without risk.

Immunologic

Allergy to iodides can occur (61,62).

Of 126 participants in a study of the metabolism of radiolabelled proteins, four repeatedly developed urticaria and other symptoms after potassium iodide administration (63). Two of them were challenged with oral potassium iodide and developed urticaria, angioedema, polymyalgia, conjunctivitis, and coryza. Ten control patients were also challenged without adverse effects.

- Delayed hypersensitivity to potassium iodide occurred in a 66-year-old man who was given a cough syrup, Elixifilin, which contained potassium iodide (130 mg/15 ml), as well

© 2006 Elsevier B.V. All rights reserved.

as theophylline and alcohol. Dyspnea, angioedema, itching, and erythema of the face and neck developed a few hours after the second dose. His symptoms disappeared 24 hours after treatment with parenteral glucocorticoids. Five hours after Elixifilin or iodide challenge, he developed edema of the face and neck, itching of the pharynx and eyes, and a sensation of heat (64).

Second-Generation Effects

Pregnancy

Iodine readily crosses the placenta, and the fetal concentration usually exceeds the maternal concentration. The placenta does not seem to have a regulating transfer mechanism, implying that excess maternal intake of iodine will also expose the fetus to iodine intoxication. This usually results in hypothyroidism and development of goiter. Such goiters may become very large and even create obstetrical problems during delivery or mechanical compression during early postnatal life (SEDA-4, 295) (SEDA-5, 328). In neonates iodine excess is a well-known cause of transient hypothyroidism. Iodine-containing antiseptics should therefore be avoided in both the delivery room and the neonatal ward. A similar warning against the use of iodine or iodine-containing drugs applies during lactation since iodine is actively secreted in milk.

Fetotoxicity

Large quantities of iodine reduce the organic binding of iodine (the Wolff–Chaikoff effect). Thus, the regular use of iodide during pregnancy can cause development of a goiter in the fetus. The size of the goiter in the child can be large enough to cause difficulty during delivery. Treatment of vaginitis with iodine-containing solutions in pregnant women can lead to goiter and hypothyroidism in the infant (17).

Neonatal goiter caused by the use of potassium iodine as an expectorant during pregnancy has been reported (65). The neonate, a girl, had acute hypothyroidism, with myxedema and respiratory distress. She was given levothyroxine for 6 months, with complete normalization of thyroid function.

Severe transient postnatal hypothyroidism has been reported in infants whose mothers have received high doses of iodine during pregnancy or multiple local applications of povidone-iodine during pregnancy and for delivery (SED-14, 472). Transient neonatal hypothyroidism during breastfeeding after postnatal maternal topical iodine treatment has also been reported (66).

- A baby girl was born prematurely at 29 weeks. Her weight, length, and head circumference were appropriate to her gestational age. Parenteral feeding was stopped at 20 days, and breastfeeding was gradually increased. TSH screening for congenital hypothyroidism on day 5 was negative (below 1 μU/ml; reference range 0.45–10.0), but a second screening on day 23 was high at 23 μU/ml. There were no signs of hypothyroidism and no palpable goiter. A confirmatory laboratory test on day 29 showed a high serum TSH concentration (288 μU/ml) and reduced concentrations of free thyroxine (2.8 ng/l; reference range 19–23) and free tri-iodothyronine (1.52 pg/ml; reference range 2.2–5.4). The mother had developed an abscess of the abdominal wall 1 week after cesarean section and had been treated with intravenous antibiotics and iodine tampons, 60 cm^2 daily to the abscess wound, containing about 10.5 mg of iodine. Maternal thyroid function was normal (TSH 1.59 μU/ml and free thyroxine 12 ng/l). Thyroid antibodies to thyroglobulin, TSH receptors, and thyroperoxidase were negative. Iodine concentrations in the maternal milk and infant urine were extremely high: 4410 (reference range 29–490) micrograms/l and 3932 (reference range below 185) micrograms/l respectively. Treatment with levothyroxine (25 micrograms/day) was started on day 32, breastfeeding was discontinued, and disinfection with iodine was stopped. Thyroid function normalized after 6 days, levothyroxine was withdrawn, and breastfeeding was restarted. Thyroid function remained normal over a follow-up period of 4 months.

Skin disinfection with iodine also caused goiter and hypothyroidism in five of 30 newborns under intensive care (67). Antiseptics containing iodine should be avoided not only during pregnancy and delivery but also after the delivery during breastfeeding.

Drug Administration

Drug overdose

- A patient who deliberately took potassium iodide solution 50 ml and a small dose of mefenamic acid (six capsules) as part of a suicide attempt developed acute renal insufficiency necessitating hemodialysis (68). Normal renal function returned after 10 days of hemodialysis.

The authors postulated that iodide toxicity had resulted in hemolysis and hemoglobinuria, which, together with acute interstitial nephritis secondary to inhibition of prostaglandin synthesis from mefenamic acid ingestion, had resulted in acute renal insufficiency. The mechanism of hemolysis resulting from toxic doses of iodine is not clear, although it may reflect inhibition of various red cell enzymes.

Interference with Diagnostic Tests

Thyroid function tests

Estimation of protein-bound iodine and tracer studies for the estimation of thyroid function are interfered with by the use of iodine-containing compounds (69).

Iodopropynylbutylcarbamate

General Information

Initially used as a preservative in wood paints and metalworking fluids, iodopropynylbutylcarbamate is being increasingly used in cosmetics (1).

Organs and Systems

Immunologic

Four contact allergic reactions were reported in a series of 3168 consecutively patch-tested patients (2). In another study there were 16 positive reactions (0.3%) in 4883 consecutive patients (3).

Ion exchange resins

General Information

The ion exchange resins colestyramine (rINN) and colestipol (rINN) are not absorbed, and their main adverse effects are therefore on the gastrointestinal tract. They can also interfere with the absorption of other drugs or fat-soluble vitamins.

Organs and Systems

Metabolism

The ion exchange resins tend to increase serum triglyceride concentrations, especially in patients with hypertriglyceridemia (1).

Nutrition

Serum total carotenoid and vitamin A concentrations fell by 30% in patients taking colestipol 30 g/day (2).

Acid–base balance

Colestyramine has been reported to have caused a hyperchloremic metabolic acidosis.

- A 70-year-old woman with a 2-year history of primary biliary cirrhosis confirmed by histological and immunological criteria took colestyramine sachets twice daily for 2 months and developed lethargy, confusion, and drowsiness (3). She had signs of chronic liver disease, portal hypertension, and hepatic encephalopathy. Laboratory investigations confirmed a metabolic acidosis (pH 7.15) and hyperchloremia. Multiple cultures failed to reveal sepsis, and a urinary pH of 4.85 together with tests of renal acidification excluded renal tubular acidosis. No other cause was found and she responded

© 2006 Elsevier B.V. All rights reserved.

to 600 mmol of sodium bicarbonate intravenously over 36 hours.

Hematologic

Inhibition of vitamin K absorption can cause vitamin K deficiency, leading to hypoprothrombinemia and hence to bleeding (4).

Gastrointestinal

Patients taking colestyramine often have constipation, abdominal discomfort, and heartburn, but dietary fiber, such as psyllium, can reduce the symptoms (5,6). Other effects are flatulence, nausea, and fecal impaction; a mild laxative may be needed, particularly in the elderly. Many other patients complain of anorexia and occasionally there is diarrhea. Doses of colestyramine higher than the 10–16 g normally used can cause steatorrhea (7).

A small child died when impacted resin obstructed the colon (SEDA-8, 935) (8).

The most common adverse effect of colestipol is constipation (30%). In the first months of therapy nausea and bloating can also occur. There is disappointingly poor adherence to therapy in young patients (9). The encapsulated form of the drug is better tolerated (10).

Liver

- A 65-year-old man with type IIa dyslipidemia who took flavored colestipol granules 2 scoops/day for 3 months developed asymptomatic hepatotoxicity (11). Several of his liver enzymes were raised to 10 times the upper limit of the reference range. One week after withdrawal of colestipol, his serum transaminases fell dramatically and 3 weeks later all his liver function tests were normal.

Rechallenge was not attempted, but other potential causes of hepatocellular injury were ruled out.

Musculoskeletal

A degree of osteoporosis or osteomalacia can occur because of reduced vitamin D absorption (12).

Drug–Drug Interactions

General

Ion-exchange resins do not have systemic adverse effects, but they can affect the absorption of other drugs from the gut, particularly if they undergo enterohepatic or enteroenteric recirculation, since they will adsorb them in the gut and prevent their reabsorption.

There is reason to anticipate problems if the resin is given along with acidic drugs and some other drugs that have a narrow safety margin, such as oral anticoagulants (coumarins), cardiac glycosides, and thyroid hormones (thyroxine, triiodothyronine). Interference with the absorption of other acidic drugs, including the barbiturates, naproxen, phenylbutazone and its congeners, and the thiazide diuretics, can almost certainly occur, but is of little or no clinical importance, since the doses of these drugs can easily be adjusted as time goes by, to allow for any reduction in absorption, or alternative drugs can be used. Interference with anticoagulants and cardiac glycosides presents the most serious problems, because they have a low therapeutic index. It has often been said that problems can be avoided provided the drugs are not given simultaneously; however, this is not true when the drug in question undergoes enterohepatic circulation, as is the case with digitoxin and phenprocoumon, as a result of which these substances are present in the gastrointestinal tract for a long time and can be exposed to an ion exchange resin at any time. The interval principle for other drugs is useful, but the interval should be at least 1 hour and in the case of thyroxine 4–5 hours, in which case the drug should be given before the resin.

Cardiac glycosides

Colestyramine and colestipol bind digoxin and digitoxin and can affect their absorption. When the ion exchange resins and digoxin are co-administered the absorption of digoxin is reduced (13). However, even when they are not administered together, the resins can bind cardiac glycosides that have re-entered the gut after absorption by virtue of enterohepatic recycling and enteral secretion, increasing their rate of elimination. This action has been used to treat digoxin toxicity (14–16), digitoxin toxicity (17), and toxicity from derivatives of digoxin (18).

Coumarin anticoagulants

The interaction of colestyramine with coumarins is due to the enterohepatic recirculation of coumarins, which is interrupted by colestyramine.

Phenprocoumon undergoes enterohepatic recycling, and its elimination can be enhanced by ion exchange resins, sometimes with fatal consequences (19).

Warfarin also undergoes enterohepatic recycling, and its elimination can be enhanced by ion exchange resins (20); this has been used to treat warfarin toxicity (21).

Folic acid

Malabsorption of folic acid has been reported in patients taking colestyramine (SEDA-13, 1326) (22).

In children taking colestipol supplementary folic acid may need to be provided (23).

Valproic acid

The systemic availability of valproic acid is reduced by colestyramine unless they are given 3 hours apart (24).

Ipecacuanha, emetine, and dehydroemetine

General Information

Ipecacuanha is an extract of the root of *Psychotria ipecacuanha*, also known as *Cephaelis ipecacuanha*, a member of the Rubiaceae. It contains the emetic alkaloids cephaeline and emetine. It has often been used as a home remedy for various purposes, and not only as an emetic. It is a traditional ingredient of some expectorants, since expectoration often accompanies vomiting. Misuse of ipecacuanha by patients with anorexia nervosa and bulimia has resulted in severe myopathy, lethargy, erythema, dysphagia, cardiotoxicity, and even death. Use in infancy generally seems safe.

Emetine, once the drug of choice for the treatment of amebiasis, despite marked cardiotoxicity, has largely been replaced by metronidazole and related compounds for this indication. Large doses of emetine can damage the heart, liver, kidneys, intestinal tract, and skeletal muscle. Allergic reactions and tumor-inducing effects have not been described. Dehydroemetine is a little less toxic but also less effective than emetine; its adverse effects are similar (SED-11, 594).

Gastrointestinal decontamination in acute toxic ingestion has been reviewed (1).

- Although ipecac generally seems to have a good safety profile, it can be associated with protracted vomiting. Other reported adverse effects include drowsiness, agitation, abdominal cramps, diarrhea, aspiration pneumonia, cerebral hemorrhage, pneumoperitoneum, and pneumomediastinum. Its use is not currently recommended (2).

Gastric lavage can be useful in some patients who have taken life-threatening doses of highly toxic substances. However, toxin absorption can be enhanced by gastric lavage. Reported adverse effects mainly include laryngospasm, hypoxemia, aspiration pneumonia, bradycardia, electrocardiographic ST segment elevation, and rarely mechanical injury to the gastrointestinal tract.

- Activated charcoal has gained popularity as a first choice for gut decontamination, based on its efficacy and relative lack of adverse effects. Poor patient acceptance is a disadvantage. Frequent vomiting can rarely become a problem.
- Saline laxatives (magnesium citrate, magnesium sulfate, sodium sulfate, and disodium phosphate) or saccharide laxatives (sorbitol, mannitol, lactulose) are also used in poisoned patients. Common adverse effects are abdominal cramps, excessive diarrhea, and abdominal distension. Dehydration and electrolyte imbalance in children, and hypermagnesemia and magnesium toxicity (with magnesium-based cathartics) have also been reported.
- Whole bowel irrigation to wash the entire gastrointestinal tract rapidly and mechanically is similar to the methods used by gastroenterologists to prepare patients for colonic investigation or bowel surgery. It is safe, even in children, pregnant women, and patients with cardiac or respiratory failure. Polyethylene glycol isotonic electrolyte solution is commonly used. Complications are

© 2006 Elsevier B.V. All rights reserved.

usually minor and include nausea, vomiting, abdominal distension and cramps, and anal irritation.

Organs and Systems

Cardiovascular

Cardiotoxicity is the most serious and dangerous adverse effect of emetine. The clinical signs are tachycardia, dysrhythmias, and hypotension. Deaths have been described. Electrocardiographic abnormalities occur in 60–70% of cases; increased T wave amplitude, prolongation of the PR interval, ST segment depression, and T wave changes are all common. It seems possible that emetine influences the cell permeability of sodium and calcium ions, and this could be the basis of its effect on cardiac automaticity and contractility and on the electrocardiogram (SED-11, 594). The symptoms of emetine toxicity suggest that an effect on intracellular magnesium concentrations could be another possible explanation, but there are no data to support this hypothesis (SED-11, 594).

Respiratory

Asthma can occasionally be induced by ipecacuanha; when the compound was more widely used in medicine this was a familiar problem for those compounding medicines (3).

Gastrointestinal

Nausea and vomiting are frequent, perhaps in as many as one-third of all cases. In about half the cases, diarrhea is induced or existing diarrhea aggravated. Melena can occur, but this seems unlikely to be drug-induced (SED-11, 594).

Skin

Dermatitis has been attributed to emetine (4), as has cellulitis at the site of injection (5).

Musculoskeletal

Complaints of weakness, tenderness, and stiffness of skeletal muscles, especially in the neck and shoulder, are common. Following emetine aversion therapy for alcohol abuse, muscle weakness and pathological changes in muscle biopsy specimens have been described (SED-11, 594).

A reversible myopathy secondary to abuse of ipecacuanha by individuals with eating disorders has been noted (SED-12, 945) (SEDA-17, 421); the active alkaloid may have been responsible.

Long-Term Effects

Drug abuse

Munchausen's syndrome by proxy involving syrup of ipecacuanha has been reported in an 18-month-old child who was brought by his mother with persistent vomiting for 4 weeks with generalized myopathy and pneumonia (6). Its over-the-counter availability, low cost, and effective emetic properties give this drug a high appeal for such abuse.

Drug Administration

Drug overdose

There is some suggestion of cardiac impairment with overdosage, presumably also myopathic. Forced emesis can lead to esophageal damage or even complete rupture; pneumomediastinum and pneumoperitoneum have therefore sometimes complicated induced emesis (SEDA-10, 326). A bizarre case of neonatal vomiting, irritability, and hypothermia was attributed to the mother having added ipecacuanha surreptitiously to her baby's feed; at any age, however, emetine in excess can be very irritant to the gastrointestinal tract, resulting, for example, in bloody diarrhea.

Drug–Drug Interactions

Activated charcoal

Activated charcoal, sometimes used to treat self-poisoning, binds the active ingredients of ipecacuanha and inactivates them, at least partly (7). The administration of ipecacuanha also delays the administration of charcoal (8). They should not be co-administered.

Ipratropium bromide

See also Anticholinergic drugs

General Information

Ipratropium hydrobromide is a quaternary amine, the semisynthetic isopropyl derivative of atropine, which has low lipid solubility and is poorly absorbed. It has anticholinergic properties and is used to treat asthma.

The metered dose of ipratropium is some 20 micrograms. Its limited availability accounts for its relative bronchial selectivity when ipratropium is given in low doses by the aerosol

© 2006 Elsevier B.V. All rights reserved.

route. In healthy volunteers, 120–280 micrograms given by intravenous injection reduced salivary secretion and increased heart rate. Inhaled doses, up to a total of 1.2 mg, had no significant effect on heart rate, although some patients reported dryness of the mouth (1). Only if substantial overdosage occurs (for example 1 mg by inhalation) do traces of generalized atropine-like effects begin to appear.

Ipratropium has established a place in the therapy of asthma as an alternative to $beta_2$-adrenoceptor agonist aerosols for patients who fail to respond adequately to these agents. Ipratropium may be more effective than $beta_2$-adrenoceptor agonists for patients with non-atopic asthma and chronic bronchitis. It has been reported to augment the effects of $beta_2$-adrenoceptor agonists when given by nebulized inhalation in acute asthma (2).

Therapeutic doses from an aerosol are free of systemic adverse effects because of the very low blood concentration after inhalation. Transient dryness of the mouth and scratching in the trachea can occur in up to 25% of patients receiving wet nebulizer treatment with the drug.

Therapeutic studies

There is continuing discussion about the role of inhaled antimuscarinic drugs combined with $beta_2$-adrenoceptor agonists in the treatment of acute asthma (3). Five trials involving 453 patients examined the efficacy of using a single dose (250 micrograms) of ipratropium bromide with a $beta_2$ agonist. There were no reductions in hospital admission rates when pooling the two trials that reported this outcome (RR = 0.93; CI = 0.65–1.32). In three trials in which pulmonary function was the major outcome measure, there was a significantly greater improvement in lung function at 60 minutes and 120 minutes after a single inhalation of a combination of an antimuscarinic drug and a $beta_2$ agonist. The addition of a single dose of an antimuscarinic drug was not associated with increased vomiting or tremor, but there was an apparent reduction in nausea (RR = 0.55; CI = 0.33–0.91). Five trials involving 366 children examined the effects of multiple treatments with combined ipratropium and a $beta_2$ agonist. Pooling of four trials using hospital admission as an outcome measure showed a 30% reduction (RR = 0.72; CI = 0.53–0.99). The authors cautioned that the total number and size of studies were small and that their conclusions could be modified by results of larger trials (3).

Comparative studies

Perennial rhinitis is common in both adults and children and is usually treated with intranasal corticosteroids, intranasal ipratropium bromide, antihistamines, intranasal cromones, and decongestants. Treatment-related adverse effects are common and monotherapy is often inadequate. There are few published studies of the comparative efficacy of rhinitis treatments.

Budesonide

Ipratropium bromide (42 micrograms per nostril bd) has been compared with budesonide (84 micrograms per nostril bd) for 6 months in a randomized, double-blind trial in 146 children with perennial rhinitis (4). Both treatments resulted in significant improvements in rhinorrhea, sneezing, and congestion (as rated by both patients and physicians) and improved quality of life. Budesonide achieved better control of sneezing than ipratropium throughout the study period and better control of congestion than ipratropium in the later part of the study. Of 36 patients who did not complete the study, largely for administrative reasons, six using ipratropium withdrew owing to lack of efficacy. There were no reports of systemic anticholinergic adverse effects. The commonest nasal adverse events in both groups were nasal congestion (23% with ipratropium and 18% with budesonide) and rhinitis (13% with ipratropium and 7% with budesonide). Of nasal adverse events considered to be related to treatment, epistaxis and nasal irritation were more common with budesonide (10 and 4% respectively) than with ipratropium (8 and 0%). Sneezing occurred in 5% of those using ipratropium and in none of those using budesonide, probably reflecting the better efficacy of budesonide for control of sneezing. Overall both drugs were well tolerated.

Ipratropium (42 micrograms per nostril tds), budesonide (84 micrograms per nostril bd), and ipratropium plus budesonide for 2 weeks have been studied in a randomized, double-blind, placebo-controlled trial in 533 patients with perennial rhinitis (5). As monotherapy, both ipratropium and budesonide produced significant reductions in rhinorrhea compared with placebo, and budesonide was more effective than ipratropium in reducing congestion and sneezing. Non-nasal adverse events occurred equally in all three groups. The incidences of epistaxis, nasal congestion, and nasal irritation were similar in all three groups (1–5%) but there was a greater incidence of nasal dryness (3 versus less than 1%) and blood-tinged mucus (4 versus 2%) with ipratropium. Combination therapy with ipratropium and budesonide reduced the severity and duration of rhinorrhea in 74 and 66% of patients compared with 57 and 50% for ipratropium, 64 and 54% for budesonide, and 47 and 38% for placebo. There were no other advantages for combination therapy over budesonide. Nasal adverse events occurred in all groups, including placebo, but patients who had two weeks of budesonide in the monotherapy arm of the study followed by combination therapy had more epistaxis (5%) and more nasal dryness (5%) than patients who had ipratropium before combination treatment. The authors concluded that combination therapy is superior to monotherapy, with no increase in adverse effects. However, the effect of combination therapy over monotherapy in this study is quite small and does not appear to have reached statistical significance. Nevertheless, most adverse effects seem to have been related to budesonide rather than to ipratropium. The addition of ipratropium in a patient already taking budesonide seems to be safe and may increase efficacy.

Salmeterol

A double-blind, double-dummy, parallel-group study in 144 patients with severe COPD (FEV_1 41% of predicted) has been conducted over 12 weeks to determine whether the combination of salmeterol 50 micrograms bd plus ipratropium 40 micrograms bd was better than salmeterol alone (6). At the beginning of treatment salmeterol

© 2006 Elsevier B.V. All rights reserved.

increased FEV_1 (at peak 7% of predicted) for over 12 hours. Salmeterol plus ipratropium produced a greater bronchodilator response (at peak 11% of predicted) than salmeterol alone during the first 6 hours after inhalation. There were significant improvements in daytime symptom scores and peak flows with both salmeterol and salmeterol plus ipratropium compared with placebo. Adverse events were similar in the treatment groups; headache (six patients with salmeterol plus ipratropium, four with salmeterol, and 11 with placebo) and cough were the most common drug-related adverse events. Over the 12 weeks, 35 patients had an exacerbation of COPD, 36% with placebo, 23% with salmeterol, and 13% with salmeterol plus ipratropium.

Organs and Systems

Respiratory

In some patients with atopic asthma, bronchoconstriction can follow the use of ipratropium (SEDA-9, 127).

There has been concern that ipratropium and other antimuscarinics may cause drying and inspissation of sputum with resulting sputum retention. In vitro studies show no effect on ciliary activity. In healthy subjects and patients with chronic bronchitis, inhaled ipratropium did not affect the rate of tracheobronchial clearance of a previously inhaled radioactive carrier aerosol. In studies using therapeutic doses for 2–14 days sputum volume and viscosity did not change (1).

Sensory systems

Pupillary dilatation has several times been reported, possibly because the spray enters the eye; it is risky in cases of glaucoma (7).

Blurred vision can occur in patients given ipratropium by inhaler (8).

- A 68-year-old man's visual acuity dramatically improved (20/100 to 20/40) after he discontinued ipratropium bromide, which he had been taking in a dose of two puffs every 6 hours for chronic obstructive pulmonary disease.

Angle-closure glaucoma precipitated by ipratropium has been reported following both nebulizer and pressurized aerosol treatment (9,10); however, a specific study showed that in asthmatic children with no pre-existing ocular abnormalities, the risk of an ocular adverse effect from nebulized ipratropium is extremely small (11). A Turkish group studied the acute effects of inhaled ipratropium bromide, given both by metered dose inhaler and nebulizer, in 21 men (mean age 61 years) with a smoking history of 47 pack-years and FEV_1 values less than 50% of predicted at baseline (12). They did not have glaucoma. The doses of ipratropium bromide were 40 micrograms by inhaler and 250 micrograms by nebulizer. Intraocular pressure was measured at baseline and 120 minutes after drug administration. There was no increase in pressure with either dose, but this does not exclude the possibility that there may be a more pronounced effect in patients who have glaucoma, nor that chronic administration may have a greater effect.

A bad taste in the mouth has been reported by 20–30% of patients.

Psychological, psychiatric

Ipratropium produces no significant impairment of cognitive or psychomotor function in elderly patients with chronic airway obstruction (SEDA-21, 187).

Gastrointestinal

One case of paralytic ileus has been reported (SEDA-15, 137).

Urinary tract

In elderly men, who may have prostatic hyperplasia, ipratropium should be used with caution since it can cause urinary retention (SEDA-14, 122) (13).

Drug Administration

Drug administration route

The removal of chlorofluorocarbons from industrial and household products underlies the 1987 "Montreal Protocol on Substances that Deplete the Ozone Layer". A reformulation of ipratropium bromide using an alternative, non-chlorofluorocarbon propellant, hydrofluoroalkane, 134a (1,1,1,2-tetrafluoroethane), has been compared with the marketed, chlorofluorocarbon-containing ipratropium bromide aerosol in a randomized, double-blind, placebo-controlled trial in 507 patients with moderate to severe obstructive airways disease (14). The patients were treated with hydrofluoroalkane/ipratropium bromide 42 micrograms, hydrofluoroalkane/ipratropium bromide 84 micrograms, hydrofluoroalkane/placebo, chlorofluorocarbon/ipratropium bromide 42 micrograms, or chlorofluorocarbon/placebo. The incidences of adverse clinical and laboratory events and significant cardiographic effects were not different across the groups.

A nasal spray (isotonic aqueous ipratropium pump) has been used in allergic and non-allergic rhinitis as well as the common cold. The spray caused no systemic adverse effects and only minor infrequent episodes of nasal dryness and epistaxis, which did not interfere with treatment (15,16).

Iprindole

See also Monoamine oxidase inhibitors

General Information

Iprindole is a 6,5,8 tricyclic compound, whose first two rings form an indole nucleus (SED-7, 27). It is of some theoretical interest, in that it is weak in its action on the amine pump mechanism. Adverse effects are reported as being similar to those of other tricyclic antidepressants (1,2).

Organs and Systems

Liver

The major adverse effect of serious concern has been jaundice. A review of 21 cases of liver damage during iprindole treatment showed that the onset was at 4–21 days after starting treatment (3). Recovery was rapid after withdrawal. Liver biopsy showed predominantly cholestasis. This complication seems to be similar to that seen after chlorpromazine. In one instance (4), jaundice was accompanied by a marked eosinophilia of 30% and laboratory signs suggesting some hepatocellular damage as well. Jaundice promptly recurred when the drug was re-administered. All the features of this case suggested an allergic reaction.

Irbesartan

See also Angiotensin II receptor antagonists

General Information

Irbesartan is a potent selective angiotensin II type 1 (AT_1) receptor antagonist. Its pharmacology is the same as that of other angiotensin II receptor antagonists (1). In the registration studies and other controlled trials adverse effects were not dose-related and not different from placebo.

An updated review of the pharmacology and therapeutic use of irbesartan in cardiovascular disorders has been published, including a brief section on drug tolerability, which referred to an unpublished postmarketing surveillance study in which 14% of the patients (1232 of 9009) had mostly mild adverse events (2). No further details were given on the nature of the adverse events.

Organs and Systems

Liver

Cholestasis with irbesartan has been reported (3).

- A 62-year-old woman developed deep icterus and hepatomegaly 1 month after starting to take irbesartan 300 mg/day. She had been hypertensive for 15 years and had no history of liver disease or risk factors for liver disease. Her bilirubin was 403 µmol/l, alkaline phosphatase 3193 IU/l, and aspartate transaminase 177

© 2006 Elsevier B.V. All rights reserved.

IU/l. Serology and autoimmune screens were negative, as were liver ultrasonography and computerized tomography. Cholangiopancreatography was normal. Irbesartan was replaced by amlodipine and metoprolol, and 2 months later she remained jaundiced (bilirubin 324 μmol/l). Liver biopsy showed portal tract expansion, minimal inflammation, ectatic ductules, and cholestatic rosettes. Within 16 weeks she fully recovered and continued to be anicteric more than 1 year later.

The temporal profile in this case and the lack of an alternative cause for liver dysfunction suggested a drug reaction.

Urinary tract

Renal insufficiency has been attributed to irbesartan.

- A 77-year-old woman took captopril 25 mg tds and furosemide 40 mg/day for decompensated heart failure (4). Irbesartan 75 mg/day then replaced captopril, and 3 days later she developed renal insufficiency. Irbesartan was withdrawn and her renal function normalized within 5 days. It was not stated whether her blood pressure also changed.
- A 78-year-old Caucasian man with insulin-treated type II diabetes, hypertension, and stable mild renal insufficiency took captopril 25 mg/day and torasemide 150 mg/day (5). His general physician substituted irbesartan 150 mg/day for the captopril. The basal average serum creatinine rose from 220 to 294 μmol/l 10 days after beginning irbesartan, and to 752 μmol/l 3 weeks later, at which stage he was admitted with acute renal insufficiency, oliguria, and edema with a 6 kg weight gain. Two days after withdrawal of irbesartan his creatinine reached a maximum of 907 μmol/l and then fell progressively to 570 μmol/l and never returned to basal values. The patient was started on chronic hemodialysis. Renal Doppler and MRI scans showed no renal artery stenosis, but there were signs of chronic renal ischemia, which may have contributed to the adverse drug reaction.

It is possible in the second case that irbesartan 150 mg/day produced abrupt and more pronounced inhibition of the renin–angiotensin system than the basal stable small dose of captopril 25 mg/day.

A further convincing case of ACE inhibitor-related renal insufficiency has been described with irbesartan and losartan (6).

- A 67-year-old woman with congestive heart failure developed oliguric renal insufficiency 2 days after the introduction of irbesartan. She rapidly recovered after withdrawal, and was then given losartan. The condition recurred shortly afterwards and subsided when losartan was stopped.

Drug–Drug Interactions

Simvastatin acid

A small well-designed study in 14 healthy subjects showed no significant effect of irbesartan on the single-dose pharmacokinetics of total simvastatin acid (7).

Iridaceae

See also Herbal medicines

General Information

The genera in the family of Iridaceae (Table 1) include *Crocus*, *Freesia*, and some types of lilies.

Table 1 The genera of Iridaceae

Acidanthera (acidanthera)
Alophia (alophia)
Aristea (aristea)
Belamcanda (belamcanda)
Calydorea (violet lily)
Chasmanthe (African cornflag)
Crocosmia (crocosmia)
Crocus (crocus)
Dietes (dietes)
Eleutherine (eleutherine)
Freesia (freesia)
Gladiolus (gladiolus)
Herbertia (herbertia)
Homeria (Cape tulip)
Iris (iris)
Ixia (African cornlily)
Libertia (libertia)
Nemastylis (pleatleaf)
Neomarica (neomarica)
Olsynium (grass widow)
Romulea (romulea)
Schizostylis (Kaffir lily)
Sisyrinchium (blue-eyed grass)
Sparaxis (wandflower)
Tigridia (peacock flower)
Trimezia (trimezia)
Watsonia (bugle-lily)

Crocus sativus

The stamens of *Crocus sativus* (Indian saffron) have been used primarily as a coloring and flavoring agent. Its potential use as an anticancer agent has been reviewed (1,2). No risks have been documented for daily doses up to 1.5 g, but 5 g is toxic, 10 g is abortive, and 20 g is lethal.

Iron oxide

General Information

Ultrasmall superparamagnetic particles of iron oxide (USPIOs) of median diameter no less than 50 nm have been studied as blood-pool agents and are given intravenously to enhance liver imaging in patients with cirrhosis and to visualize lymph nodes. They consist of non-stoichiometric microcrystalline iron oxide cores, which are coated with dextrans (in ferumoxides) or siloxanes (in ferumoxsils). The most common form of iron oxide used is magnetite, which is a mixture of Fe_2O_3 and FeO; a mixture of Fe_2O_3 and Fe_3O_4 can be used instead.

After injection, the particles accumulate in the reticuloendothelial system. Liver tumors have few or no reticuloendothelial cells and so there is a contrast between normal liver and tumor.

These contrast agents are well tolerated, with no serious adverse effects. The reported adverse effects include low back pain, vomiting and diarrhea, urticaria, flushing, dizziness, and muscle spasm (SEDA-20, 419). The incidence of adverse effects is higher with these particulate iron oxide agents than with gadolinium chelates. However, that is not a great cause for concern, since few of the reactions are severe and all are self-limiting.

Ferristene

The USPIO contrast agent ferristene (Abdoscan, Amersham) is effective and safe in delineating the gastrointestinal tract after oral ingestion. Different rectal formulations of ferristene with different viscosities and iron concentrations have been evaluated in a phase II clinical study, in which ferristene enemas (200–500 ml) and intravenous gadodiamide (0.1 mmol/kg) were used in the evaluation and staging of rectal cancer in 113 patients (1). Five patients had 10 adverse events, including rectal pain, diarrhea, edema, a phobic reaction, nausea, and a skin rash; all recovered without further therapy. The high-viscosity formulation (70 g of granules/l) was better than the low-viscosity formulation in tumor staging, but the iron concentration (30 or 59 micrograms/ml) of the contrast agent was less important.

Ferucarbotran

Ferucarbotran (carboxydextran coated iron oxide nanoparticles, SHU 555 C, Resovist, Schering AG) is a contrast agent that consists of iron oxide microparticles coated with carboxydextran. After intravenous injection it is sequestered by the reticuloendothelial system, mostly in the liver and spleen. MRI iron oxide causes loss of signal intensity, especially on T1 and T2 weighted images, and the contrast between the lesions and the surrounding tissues is increased owing to loss of signal in the healthy tissues.

Feruglose

Feruglose (NC100150, Clariscan, Nycomed, Oslo, Norway) has been given to 18 healthy men in doses of 2, 3, and 4 mg/kg (2). There were no significant adverse effects during or after the scans. However, NC100150 interferes with iron metabolism, since iron is incorporated into the body after biodegradation. NC100150 shows promise for myocardial perfusion analysis. Studies in animals have also suggested a role for NC100150 in the detection and localization of intra-abdominal bleeding (3).

Ferumoxtran

Ferumoxtran-10 (Combidex, Advanced Magnetics, Cambridge, MA) is an ultrasmall superparamagnetic iron oxide agent. It targets the reticuloendothelial system but also functions as a blood-pool agent. In a phase 2 study in 104 patients with focal liver or spleen pathology who underwent MRI with ferumoxtran-10 (0.8, 1.1, and 1.7 mg of iron per kg), 15% reported a total of 33 adverse events, most commonly dyspnea (3.8%), chest pain (2.9%), and rashes (2.9%) (4). There were no serious adverse events during the 48-hour observation period and no changes in vital signs, physical examination, or laboratory parameters. The authors concluded that ferumoxtran-10 is safe and well tolerated.

SHU 555 A

The diagnostic efficacy and safety of SHU 555 A has been investigated in 19 patients aged 43–89 years who had been referred for investigation of hepatocellular carcinoma (eight patients), liver metastases (four patients), liver hemangioma (four patients), cholangiocarcinoma (two patients), and focal nodular hyperplasia (one patient) (5). The dose of iron was 6.0–11.7 μmol/kg. Patients under 60 kg received 0.9 ml as a bolus intravenous injection and patients over 60 kg received 1.4 ml. None of the 19 patients reported any pain or discomfort at the injection site. One had a diffuse erythematous rash associated with a feeling of pressure in the thorax, which lasted for 30 minutes. There was a significant increase in systolic blood pressure (from 137 to 141 mmHg) 5 minutes after injection; it returned to normal within 4 hours. There was a statistically significant fall in diastolic blood pressure from 75 to 70 mmHg at 4 hours after the injection. These changes were not considered to be of clinical importance. There were also minimal changes in the

results of blood tests, which were not of clinical importance. High-quality diagnostic information was provided by the MRI examination.

Iron salts

General Information

Iron is a metallic element (symbol Fe; atomic no. 26). The symbol is derived from the Latin word for iron, ferrum.

Iron is found widespread in nature in ores such as almandine hercynite (iron aluminate); scorodite (iron arsenate); pyrites (iron disulfide); laterite (iron hydroxide); columbite (iron niobate); chromite, hematite, ilmenite, limonite, magnetite, mugearite, stilpnosiderite, and umber (iron oxides); lazulite (iron phosphate); babingtonite, crocidolite, cummingtonite, epidote, eudialyte, fayalite, gadolinite, glauconite, hornblende, hypersthene, olivine, pennine, piedmontite, and riebeckite (iron silicates); coquimbite, inkstone, and jarosite (iron sulfates); ankerite, arsenopyrites, bornite, chalcopyrite, pentlandite, and pyrrhotite (iron sulfides); marcasite (iron sulfite); and wolframite (iron tungstate).

The body has no physiological route for the excretion of excess iron, and iron overload is a constant risk of therapy. Long-term use of iron by any route in large amounts can lead to hemosiderosis, simulating hemochromatosis; the danger is greatest when the mucosal barrier is bypassed by parenteral injection. Even the safety of iron-fortified food is uncertain (SEDA-4, 171). As with other metals there is environmental exposure to iron in many forms. The use of iron cooking utensils is often considered a useful source of supplementary iron in the diet. Various iron oxides and hydroxides are used as pigments in cosmetics.

The molecular basis of iron overload and toxicity has been reviewed (1,2). Much attention has been paid to mechanisms of hemochromatosis (3,4). There have been reviews of the comparative tolerance and safety of iron salts (5) and their use in specific conditions, such as renal insufficiency (6).

In elderly people, iron deficiency is usually a sign of bleeding, and it is wiser to track down and correct the cause of the blood loss (for example gastric malignancy) than to prescribe iron, which can merely mask the problem and delay diagnosis.

In the following sections, adverse reactions are considered in connection with the types of iron therapy with which they have most commonly been associated, but any adverse effect of iron can in principle occur with any formulation or as a result of mixed medical and non-medical exposure.

Oral iron

New oral formulations with improved intestinal iron absorption are being marketed and their efficacy and toxicity are being studied (7).

Despite the use of recombinant erythropoietin, anemia remains a significant problem for patients with end-stage renal disease (8). Because oral iron formulations are relatively ineffective and poorly tolerated, intravenous iron dextran has been widely used, despite the risk of adverse effects.

Parenteral iron

Like oral iron, parenteral iron is used too widely. When iron is truly needed, oral administration is generally preferable (9). Intractable gastrointestinal intolerance to oral formulations, hyperemesis in pregnancy, very severe blood loss, and possibly ulcerative colitis are some of the few valid indications for parenteral iron. A low iron-binding capacity (for example due to prior saturating iron therapy or malnutrition), folic acid deficiency, and an allergic constitution predispose the patient to adverse reactions to parenteral iron. Iron injections have been reported to provoke hemolytic anemia in cases of paroxysmal nocturnal hemoglobinuria.

Most parenteral iron is administered intramuscularly, but intravenous injections have enjoyed a wave of popularity for no very good medical reason; it seems particularly likely to precipitate acute allergic or anaphylactic reactions in sensitive individuals, sometimes involving cardiac dysrhythmias, hypotension, circulatory collapse, and pulmonary edema.

The adverse effects of iron formulations have resulted in trials to optimize dose regimens. A large database of clinical variance reports from Fresenius Medical Care North America (FMCNA) has been analysed to determine the incidence of suspected adverse drug reactions of iron dextran and the associated patient characteristics, dialysis practice patterns, and outcomes (8). A case-cohort design was used, comparing individuals who had suspected adverse drug reactions with the overall population. Out of 841 252 intravenous iron dextran administrations over 6 months, there were 165 reported suspected adverse drug

results of blood tests, which were not of clinical importance. High-quality diagnostic information was provided by the MRI examination.

Iron salts

General Information

Iron is a metallic element (symbol Fe; atomic no. 26). The symbol is derived from the Latin word for iron, ferrum.

Iron is found widespread in nature in ores such as almandine hercynite (iron aluminate); scorodite (iron arsenate); pyrites (iron disulfide); laterite (iron hydroxide); columbite (iron niobate); chromite, hematite, ilmenite, limonite, magnetite, mugearite, stilpnosiderite, and umber (iron oxides); lazulite (iron phosphate); babingtonite, crocidolite, cummingtonite, epidote, eudialyte, fayalite, gadolinite, glauconite, hornblende, hypersthene, olivine, pennine, piedmontite, and riebeckite (iron silicates); coquimbite, inkstone, and jarosite (iron sulfates); ankerite, arsenopyrites, bornite, chalcopyrite, pentlandite, and pyrrhotite (iron sulfides); marcasite (iron sulfite); and wolframite (iron tungstate).

The body has no physiological route for the excretion of excess iron, and iron overload is a constant risk of therapy. Long-term use of iron by any route in large amounts can lead to hemosiderosis, simulating hemochromatosis; the danger is greatest when the mucosal barrier is bypassed by parenteral injection. Even the safety of iron-fortified food is uncertain (SEDA-4, 171). As with other metals there is environmental exposure to iron in many forms. The use of iron cooking utensils is often considered a useful source of supplementary iron in the diet. Various iron oxides and hydroxides are used as pigments in cosmetics.

The molecular basis of iron overload and toxicity has been reviewed (1,2). Much attention has been paid to mechanisms of hemochromatosis (3,4). There have been reviews of the comparative tolerance and safety of iron salts (5) and their use in specific conditions, such as renal insufficiency (6).

In elderly people, iron deficiency is usually a sign of bleeding, and it is wiser to track down and correct the cause of the blood loss (for example gastric malignancy) than to prescribe iron, which can merely mask the problem and delay diagnosis.

In the following sections, adverse reactions are considered in connection with the types of iron therapy with which they have most commonly been associated, but any adverse effect of iron can in principle occur with any formulation or as a result of mixed medical and non-medical exposure.

Oral iron

New oral formulations with improved intestinal iron absorption are being marketed and their efficacy and toxicity are being studied (7).

Despite the use of recombinant erythropoietin, anemia remains a significant problem for patients with end-stage renal disease (8). Because oral iron formulations are relatively ineffective and poorly tolerated, intravenous iron dextran has been widely used, despite the risk of adverse effects.

Parenteral iron

Like oral iron, parenteral iron is used too widely. When iron is truly needed, oral administration is generally preferable (9). Intractable gastrointestinal intolerance to oral formulations, hyperemesis in pregnancy, very severe blood loss, and possibly ulcerative colitis are some of the few valid indications for parenteral iron. A low iron-binding capacity (for example due to prior saturating iron therapy or malnutrition), folic acid deficiency, and an allergic constitution predispose the patient to adverse reactions to parenteral iron. Iron injections have been reported to provoke hemolytic anemia in cases of paroxysmal nocturnal hemoglobinuria.

Most parenteral iron is administered intramuscularly, but intravenous injections have enjoyed a wave of popularity for no very good medical reason; it seems particularly likely to precipitate acute allergic or anaphylactic reactions in sensitive individuals, sometimes involving cardiac dysrhythmias, hypotension, circulatory collapse, and pulmonary edema.

The adverse effects of iron formulations have resulted in trials to optimize dose regimens. A large database of clinical variance reports from Fresenius Medical Care North America (FMCNA) has been analysed to determine the incidence of suspected adverse drug reactions of iron dextran and the associated patient characteristics, dialysis practice patterns, and outcomes (8). A case-cohort design was used, comparing individuals who had suspected adverse drug reactions with the overall population. Out of 841 252 intravenous iron dextran administrations over 6 months, there were 165 reported suspected adverse drug

© 2006 Elsevier B.V. All rights reserved.

reactions, corresponding to an overall rate of about 20 per 100 000 doses. Hospital evaluation was required in 43 patients (26%), 18 (11%) required hospitalization, and one (0.6%) died. Dyspnea (43%), nausea (34%), vomiting (23%), flushing (27%), pruritus (25%), hypotension (23%), and neurological symptoms (23%) were the most common adverse reactions. Serious adverse reactions to intravenous iron dextran are rare and difficult to predict; the risk appears to depend on the specific formulation of intravenous iron dextran.

In a retrospective analysis of the incidence of adverse effects associated with 250 mg of ferric gluconate infused over 1–4 hours in 40 patients with severe chronic renal insufficiency, who received 79 treatments, four treatments in two patients were associated with adverse effects, including diarrhea, vomiting, low back pain, hypotension, and a burning sensation in the feet. The duration of the infusion did not influence the adverse effects profile.

Intramuscular iron

Iron compounds for intramuscular administration are iron sorbitol–citric acid complex (iron sorbitex), iron dextran, iron glycerin–citric acid complex, and iron polyisomaltose. The work on these formulations is largely old and has been reviewed in previous volumes in this series.

Intramuscular iron injections are often painful, can produce topical discoloration of the skin, and some local inflammation with lymphadenopathy. Rarely, more severe local reactions follow (SEDA-6, 224), such as transient lipomyodystrophy. An unpleasant metallic taste in the mouth is common and can persist for some hours or days. Some patients develop general symptoms, such as headache, flushing, sweating, nausea, vomiting, dizziness, generalized aches and pains, malaise, arthralgia, palpitation, and pericardial or abdominal pain. Although very rare, a severe anaphylactic reaction to intramuscular iron dextran can occur.

The safety and efficacy of iron dextran have been evaluated in patients on home renal replacement therapies, without any adverse effects (10).

Intravenous iron

Iron dextran is now the most commonly used iron compound for intravenous use, and most reported adverse reactions to intravenous iron relate to this formulation.

Local reactions to intravenous iron dextran include transient pain (in some 4% of cases) and phlebitis. The risk of the latter may be reduced by using saline instead of 5% dextrose as diluent. Nevertheless, deep vein thrombosis has been observed in a few patients infused with a dilution of iron dextran in normal saline (SED-8, 514).

Systemic reactions to iron dextran given intravenously are more common than those to intramuscular iron; they include non-immunological and immunological, immediate and delayed reactions. Flushing, a sensation of warmth, and a metallic taste are often associated with excessively rapid injection, but usually subside within less than a minute after slowing or stopping the injection. In about 1% of cases, including patients with no known prior exposure to dextran, life-threatening anaphylactoid reactions occur rapidly, with hypotension, cardiovascular shock, syncope, cyanosis, bronchospasm, respiratory arrest, urticaria, and angioedema; deaths have ensued. Milder allergic reactions comprise mild and transient hypotension, malaise, itching, and urticaria. Desensitization under an umbrella of glucocorticoids, antihistamines, and ephedrine has been carried out successfully (11).

Delayed systemic reactions to intravenous iron dextran appear to be more common, the reported incidence ranging from 5 to 15%. They start within 4–48 hours of injection and can last for 3–7 days. Characteristic symptoms are fever, arthralgia, myalgia, headache, and lymphadenopathy, singly or in combination, and a classic serum sickness has been seen (SEDA-16, 26). Chills may also occur and individual patients may experience dizziness, tinnitus, paresthesia, a feeling of stiffness in the arms and neck, pruritus, urticarial or other cutaneous eruptions, pallor, nausea, vomiting, and nasal irritation. There may be hepatosplenomegaly. These delayed reactions are more frequent in children and, for some reason, in patients of Chinese origin. They tend to be more severe in patients with low body weight given higher doses, and in patients with rheumatoid arthritis or other types of inflammatory disease.

Large doses of intravenous iron dextran and iron saccharate have been compared in a retrospective study of 379 patients who had attended peritoneal dialysis clinics in the past 5 years (12). Of these, 62 were selected to receive intravenous iron based on ferrokinetic markers of iron deficiency, non-adherence to oral iron, ineffectiveness of oral iron, or increased erythropoietin requirements. Intravenous iron was given as two injections of 500 mg each 1 week apart in 61 patients, 33 of whom received iron dextran, 23 iron saccharate, and five both iron dextran and iron saccharate. One patient developed anaphylaxis to a test dose of iron dextran and was excluded from further therapy. Blood samples were collected before and 3 and 6 months after iron infusions. Five of the 34 patients who received iron dextran developed minor adverse effects and one had an anaphylactic reaction to the test dose. Of the 23 patients who received iron saccharate, one had an anaphylactic reaction and two had transient chest pain, which subsided without therapy. There were more adverse effects with iron dextran (7.4% of injections) compared with iron saccharate (4.3% of injections), but this difference was not statistically significant. The number of episodes of peritonitis also increased during the 6 months after intravenous iron infusion, especially with iron dextran, compared with the number of episodes during the 6 months before iron infusions, although the difference was not statistically significant.

Other iron compounds for intravenous use

Saccharated iron oxide is strongly alkaline and hypertonic; if injected outside the vein it can cause marked local reactions. Significant serum hypophosphatemia has on occasion been observed during treatment, accompanied by reduced renal tubular reabsorption of phosphate. The mechanism of these changes, which were reversible after stopping the iron injections, has not been clarified (13).

Topical iron

Iron chloride is sometimes used topically as a hemostyptic after minor surgery. It can result in persistent brown staining at the site of application. Use of Monsel's solution (ferric subsulfate), another hemostyptic agent, can cause

© 2006 Elsevier B.V. All rights reserved.

fibrovascular proliferation accompanied by strongly pigmented macrophages after an interval of up to 3–5 weeks; the condition may be mistaken for malignant melanoma.

Organs and Systems

Cardiovascular

Intramuscular iron

The major hazard of the intramuscular use of iron sorbitex consists of severe systemic reactions with cardiac involvement, which may be fatal; they occur in up to 1% of cases, they start 10–30 minutes after injection and a patient who has received an injection must be monitored for an hour. Nausea, chest pain, profuse sweating, cardiac dysrhythmias, and loss of consciousness can occur. Cardiac complications include complete atrioventricular block, ventricular tachycardia, and ventricular fibrillation.

Intravenous iron

Non-transferrin-bound iron, which increases after intravenous ferric saccharate, has been suggested to act as a catalytic agent in oxygen radical formation in vitro, and may therefore contribute to endothelial impairment in vivo (14). The effect of ferric saccharate infusion 10 mg has been investigated in 20 healthy volunteers. Ferric saccharate caused a greater than four-fold increase in non-transferrin-bound iron and transient significant reduction in flow-mediated dilatation 10 minutes after infusion of ferric saccharate. The generation of superoxide in whole blood increased significantly 10 and 240 minutes after infusion of ferric saccharate by 70 and 53% respectively. Thus, infusion of iron leads to increased oxygen radical stress and acute endothelial dysfunction.

Respiratory

Spontaneously regressing bronchial necrosis with granuloma formation has been associated with the aspiration of a tablet of ferrous sulfate in a single case (15).

Acute respiratory distress syndrome has been attributed to iron (16).

- A 3.5-year-old girl was admitted after accidental ingestion of 50–60 tablets of ferrous sulfate 200 mg. She was unresponsive and her serum iron concentration was 138 μmol/l. She required resuscitation and ventilation and an intravenous infusion of deferoxamine was started at a rate of 15 mg/kg/hour, reducing to 5 mg/kg/hour 20 hours later, when the iron concentration was 27 μmol/l. At that time, her liver function deteriorated, with raised alanine transaminase activity (57 IU/l), raised bilirubin (56 μmol/l), and a coagulopathy with an INR of 2.7. She was given an infusion of *N*-acetylcysteine 12.5 mg/kg/hour and her hepatic function stabilized. After about 40 hours she had acute respiratory deterioration with tachypnea and hypoxemia. A chest X-ray showed widespread bilateral infiltrates. A diagnosis of acute respiratory distress syndrome was made.

Aspiration of iron tablets can produce an acute reaction in the airways since they are highly irritative; immediate removal bronchoscopy is necessary to avoid permanent damage (SEDA-16, 236). Lung damage has been reported in a man who had inhaled an oral iron formulation containing 350 mg of elemental iron (17).

- A 75-year-old man developed chest discomfort and hemoptysis. A chest X-ray showed left lower lobe collapse and fiberoptic bronchoscopy showed that the left endobronchial mucosa was friable, edematous, and golden-yellow, with interspersed erythematous ulcerated areas with marked contact bleeding. There was heavy deposition of yellow–brown pigment on the basement membrane of the superficial bronchial epithelium, on the basement membrane of the bronchial glands, and on fibrillar material in the stroma. Pigment deposition was greatest in the necrotic fragments of mucosa, but was also seen in viable mucosa. This material stained strongly for ferric ion with Perls' stain. Iron was withdrawn and the left lower lobe collapse improved.

Metabolism

In erythropoietic protoporphyria, iron can cause a relapse of symptoms (18). An involvement of iron overload in the pathogenesis of some cases of porphyria cutanea tarda has been suggested (19).

Hematologic

Latent folic acid deficiency can become manifest during iron therapy due to additional demand for the vitamin secondary to increased erythropoietic activity (20).

Intramuscular iron

Thrombocytopenia has been attributed to intramuscular iron (21).

- A 30-year-old woman had a hemoglobin concentration of 3.1 g/dl, a mean cell volume of 77 fl, a reticulocyte count of 2.13%, a platelet count of 426 $\times$ 10^9/l, a serum iron concentration of 5 ng/ml, a transferrin saturation of 1%, and a ferritin concentration of 8 ng/ml. She was intolerant of oral iron and was given intramuscular iron dextran, 100 mg/day for 8 days, when she developed asymptomatic thrombocytopenia (platelet count 20 $\times$ 10^9/l). Iron dextran was withdrawn and she took oral ferrous fumarate 200 mg/day plus ascorbic acid 120 mg/day. Within 2 days her platelet count improved.

Mouth and teeth

Most liquid ferrous products stain dental enamel, but this is usually reversible (22).

Gastrointestinal

Severe gastrointestinal necrosis and strictures after iron overdose are well described. However, mucosal injury in patients taking therapeutic iron has received only scant recognition, despite its widespread use. In 36 upper gastrointestinal tract biopsies from 33 patients (24 gastric, nine esophageal, one gastro-esophageal junctional, and two duodenal) there was characteristic brown crystalline iron material (23). Most of the biopsies (32 of 36) contained luminal crystalline iron adjacent to the surface epithelium or admixed with luminal fibrinoinflammatory exudate. In 30 biopsies there was crystalline iron deposition in the lamina propria, either covered by an intact

© 2006 Elsevier B.V. All rights reserved.

epithelium, subjacent to small superficial erosions, or admixed with granulation tissue. Three biopsies showed iron-containing thrombi in mucosal blood vessels. Erosive or ulcerative mucosal injury was present in 30 of 36 biopsies. The amount of iron accumulation in cases with mucosal injury was greater than in the cases without mucosal injury. About half of the patients (17 of 33) also had underlying infectious, mechanical, toxic, or systemic medical conditions that could have initiated or exacerbated tissue injury. Crystalline iron deposition was found in 0.9% of upper gastrointestinal endoscopic examinations (12 of 1300), and iron medication-associated erosive mucosal injury was present in 0.7% (nine of 1300). These results suggest that crystalline iron deposition in the upper gastrointestinal tract is not uncommon. It can cause or exacerbate a distinctive histological pattern of erosive mucosal injury, especially in patients with associated upper gastrointestinal disorders.

Oral iron

Though iron clearly does have the ability to irritate the mucous membranes, its widespread reputation for poor gastric tolerance is undeserved, generally reflecting its having been given in excess. Of patients taking up to 200 mg/day of elemental iron, only a few highly susceptible individuals will develop gastrointestinal adverse effects, and constipation is then the most usual feature. Higher doses can give rise to gastric discomfort, nausea, vomiting, or to either constipation or diarrhea. In sensitive individuals with complications in the upper gastrointestinal tract, histopathologically distinctive lesions are found in mucosal biopsies of the stomach and esophagus (24); there can be heavy iron accumulation within ulcer granulation tissue, in the connective tissue and blood vessels of the mucosal lamina propria, and within glandular and squamous epithelia. The appearance is similar to that seen after overdosage.

Oral iron can color the feces black, which can be mistaken for melena. Fewer gastrointestinal adverse effects occur if the iron dose is gradually increased to the desired level or if iron is taken with food, but since insoluble iron complexes may be formed with food it has been recommended that iron salts be taken between meals. Despite many claims for the better gastric tolerance of expensive iron formulations, it is still not entirely proven that they are any better tolerated than plain ferrous sulfate if the latter is properly dosed. Iron supplementation via a gastric delivery system did not produce any gastrointestinal adverse reactions while efficacy was similar to that of a ferrous sulfate elixir (25). Carbonyl iron has also been studied, although mainly as a means of reducing acute toxicity if such a product is accidentally taken by children (SEDA-16, 235). Iron protein succinylate is another iron derivative for oral use, providing protein-bound iron (26); it is more slowly absorbed than divalent iron, which probably explains the claimed improvement in gastrointestinal tolerability; again it is not at all clear that tolerance is truly improved as related to the amount of iron actually absorbed.

True gastrointestinal risks occur if a solid dosage form becomes lodged in the pharynx, esophagus, or intestinal diverticula; severe erosion can follow (SEDA-6, 224) (SEDA-20, 211). An accumulation of ferrous sulfate tablets with a non-soluble matrix has been the source of ileus in a case of Crohn's disease (SEDA-16, 236). This sort of risk is greatest with modified-release formulations and absent with liquid iron formulations; the latter should therefore be preferred in cases of delayed gastric emptying, pyloric stenosis, or diverticula of the alimentary tract.

Gut pigmentation has been attributed to an iron salt (27).

- An 80-year-old Japanese woman presented with epigastric discomfort and nausea. She had a history of hypertension, rheumatoid arthritis, iron deficiency anemia, chronic renal insufficiency, and had taken oral ferrous sulfite for 19 months. Endoscopic examination of the duodenum showed marked pigmentation of the duodenal mucosa. Histological examination showed that the pigment had histochemical features compatible with hemosiderin and was located mainly within macrophage lysosomes in the lamina propria. Ferrous sulfite was withdrawn and the pigmentation disappeared within 7 months.

Liver

There is much evidence that normal or even mildly increased amounts of iron in the liver can be damaging, particularly when combined with other hepatotoxic factors, such as alcohol, porphyrogenic drugs, or chronic viral hepatitis (28).

Oral iron

Chronic liver disease has been attributed to oral iron.

- A healthy 5-year-old girl, who had taken large doses of oral ferrous sulfate 300 mg five times a day (300 mg of elemental iron/day) for 5 years, developed severe hemosiderosis (29). Liver biopsy showed preserved lobular architecture, but the portal tracts were expanded by fibrosis and there was mild septal fibrosis. There was siderosis of the hepatic parenchymal cells and hemosiderin deposition in the Kupffer cells. She had no underlying hematological disease and her iron absorption was normal. HLA phenotypes and DNA analysis for the most common mutations associated with hemochromatosis excluded homozygous and heterozygous hereditary hemochromatosis. She was successfully treated by phlebotomy. Iron studies 10 years later were normal.
- A 22-year-old woman with adult-onset Still's disease and massive hyperferritinemia became progressively more anemic, with a fall in hemoglobin to 8.2 g/dl, and was given oral ferrous fumarate 300 g bd (30). She developed acute florid hepatitis with an intraparenchymatous histiocytic infiltration, which settled on withdrawal of the iron.

In the latter case iron may have exacerbated the macrophage hyperactivity that is presumed to be present in adult-onset Still's disease. Oral iron may be inadvisable in the acute phase of this disease.

Skin

Reversible skin eruptions have been described in occasional patients taking oral iron. One case presented with a generalized exanthematous pustular eruption following the use of ferrous fumarate (31), another with erythema

© 2006 Elsevier B.V. All rights reserved.

and lichenification on sun-exposed areas after taking sodium ferrous citrate (32). Both these cases developed 2 weeks after starting treatment; it was suggested that in the latter case iron itself or the transferrin iron complex (diferric transferrin) might have acted as a photosensitizer.

Musculoskeletal

Parenteral iron

Intramuscular iron

The possible sarcoma-inducing potential of intramuscular iron was fully discussed 15 years ago (SED-9, 375) (33) and no new information on the topic has come to light. The conclusion at that time was that the evidance linking intramuscular iron to sarcomatous change was scanty.

Intravenous iron

Saccharated ferric oxide, an intravenous formulation of iron that is used when oral iron is not effective in anemia, can cause osteomalacia during long-term use. The underlying mechanism of nephropathy leading to bone toxicity has recently been reviewed (34).

Oral iron

Although total dose infusions of iron (see the section on Intravenous iron under Immunologic) can cause rheumatoid arthritis to flare up, this has not been demonstrated with oral iron. However, a patient who has reacted in this way to an infusion can subsequently relapse if given oral iron.

Immunologic

Iron enhances the pathogenicity of micro-organisms, adversely affects the function of macrophages and lymphocytes, and enhances fibrogenic pathways, all of which may enhance hepatic injury due to iron itself or to iron alongside other factors.

Oral iron

Skin reactions to oral iron are extremely rare.

- A 40-year-old woman with iron deficiency anemia due to menstrual blood loss took oral iron for 3 months without any adverse effects (35). Nine months later she became anemic again and 2 hours after an oral dose of ferrous sulfate 525 g (105 mg of elemental iron) she developed generalized pruritus and an erythematous maculopapular rash. This recurred 1 week later, when she took ferrous protein succinilate 800 g (40 g of iron). Desensitization with oral iron was carried out. Skin prick tests and patch tests with iron formulations were negative. Two single-blind, placebo-controlled oral challenges were performed and she began to have similar cutaneous symptoms. A slow desensitization protocol, using increasing doses, was tolerated without adverse effects. Chronic oral iron therapy once a day for 9 months sustained the desensitized state and the anemia disappeared.

Parenteral iron

Intravenous iron

Patients with a history of allergy may be at risk of developing undesired immunological reactions, for example attacks of asthma, after parenteral iron dextran; however, the incidence of such reactions seems to be low, and the risk probably also exists with other iron compounds as well. A test infusion is not recommended as it may or may not detect susceptibility to immediate reactions and can itself elicit violent reactions.

There was at one time impressive but limited case evidence that systemic reactions to iron dextran might be more frequent in patients with rheumatic or other inflammatory diseases; no further evidence has been published. There might be confusion with the ability of intravenous iron to induce a flare-up of an existing rheumatic condition (see the section on Oral iron under Musculoskeletal).

Single dose infusions of iron dextran appear to have increased the occurrence of malaria in endemic regions. There was an increased mortality after oral or parenteral iron therapy in children with severe malnutrition (kwashiorkor), perhaps due to overwhelming infections (36). Reactivation of quiescent infections of various other types has been observed in African nomads following ferrous sulfate therapy (SEDA-4, 171). Iron dextran has similarly been associated with a flaring up of latent tuberculosis in children.

Persistent hypogammaglobulinemia has been described in a patient receiving gold; a year after drug withdrawal the gamma-globulin concentrations were still unchanged (37).

An insulin autoimmune syndrome, marked by presence of insulin antibodies and small granulomas in the skin, has been documented in Japanese cases, many of whom had also received penicillamine (38,39).

Intramuscular iron

Iron dextran administration is associated with a high incidence of adverse reactions, including anaphylaxis and death (5). Although it is the dextran rather than the iron that is believed to be the cause of these reactions, which raises the question of whether patients who are sensitive to iron dextran can safely be given another form of parenteral iron, namely sodium ferric gluconate in sucrose. In a double-blind, controlled trial sodium ferric gluconate in sucrose or placebo was given to 144 iron dextran-sensitive patients for comparison with 2194 patients who had been tolerant to iron dextran. Serum tryptase concentrations were also measured. Of 144 patients who were sensitive to iron dextran and who were exposed to sodium ferric gluconate in sucrose, three were intolerant; all had suspected allergic reactions, including one with a serious reaction. One dextran-sensitive patient had a suspected allergic reaction after placebo. In contrast, among the 2194 iron dextran-tolerant patients, reactions to sodium ferric gluconate in sucrose were significantly less common, with intolerance in seven patients, including five who had suspected allergic events, but none who had serious events. Two iron-dextran tolerant patients had allergic-like reactions to placebo. Two of the three suspected allergic events in the iron dextran-sensitive group were confirmed as mast cell-dependent, by a 100% increase in serum tryptase, while there were no confirmed allergic events in the iron dextran-tolerant group. Long-term exposure to sodium ferric gluconate in sucrose in iron dextran-sensitive patients resulted in intolerance in only one additional patient and no serious adverse events.

© 2006 Elsevier B.V. All rights reserved.

Patients with a history of iron dextran sensitivity had about seven-fold higher rates of reaction to both placebo and sodium ferric gluconate in sucrose compared with iron dextran-tolerant patients. However, logistic regression analysis, performed to account for the higher reaction rate to placebo, suggested that this increased reactivity was neither drug-specific nor immunologically mediated, but represented host idiosyncrasy. These results support the conclusions that reactions to sodium ferric gluconate in sucrose can be attributed to pseudoallergy, and that it is not a true allergen.

Iron dextran was particularly likely to cause hypersensitivity reactions when it was used in 537 dialysis patients (40), the most common adverse reactions were itching, dyspnea, wheezing, chest pain, nausea, hypotension, angioedema, dyspepsia, diarrhea, flushing, headache, cardiac arrest, and myalgia. Most of the reactions were mild, but of a subseries of 27 patients exhibiting adverse effects, three patients had to be hospitalized including the individual who had suffered cardiac arrest.

After intramuscular iron dextran, symmetrical allergic purpura of the lower limbs due to hypersensitivity vasculitis has been observed in a child (41).

Infection Risk

In a 10-year consecutive series of 263 allogeneic bone marrow transplant recipients, there were five cases of invasive mucormycosis (42). Only one infection occurred within the first 100 days after transplantation, while the rest complicated the late post-transplant course (median day of diagnosis, 343). Sites of infection were considered "non-classical" and included pulmonary, cutaneous, and gastric. There were no cases of fungal dissemination. Mucormycosis was the primary cause of death in three of the five patients. Corticosteroid-treated graft-versus-host disease, either acute or chronic, or severe neutropenia were present in all cases. However, compared with a matched control population, the most striking finding was severe iron overload in each patient. The mean serum ferritin concentration, transferrin saturation, and the number of transfused units of red cells in the study group were all significantly higher than in the control group. There was a striking association between the occurrence of mucormycosis in dialysis patients and the use of deferoxamine for the treatment of iron and/or aluminium overload. From experimental work and observational data, it appears that iron overload, either transfusional or due to dyserythropoiesis, may be an important risk factor in the development of mucormycosis in this transplantation patient population.

Long-Term Effects

Tumorigenicity

The risk of colorectal cancer due to iron has been specifically examined in a prospective investigation in more than 14 000 patients (43). Iron appears to confer an increased risk of colorectal cancer, and the localization of risk may be attributable to the mode of epithelial exposure. It seems that luminal exposure to oral iron increases the risk proximally, whereas an increased serum iron concentration increases the risk distally.

Genetic hemochromatosis constitutes a high risk factor for the development of hepatocellular carcinoma. It is widely accepted that venesection prevents the evolution of cirrhosis in hemochromatosis and indirectly protects against the development of hepatocellular carcinoma. However, three cases did not conform to the "siderosis-cirrhosis-carcinoma" sequence, and prompt and adequate iron depletion did not protect against the development of cancer (44).

- A 39-year-old army officer had bouts of palpitation and dizziness. There were no risk factors for chronic liver disease apart from a family history of hemochromatosis. His cardiovascular and nervous systems were normal but there was 5 cm hepatomegaly. Percutaneous liver biopsy showed grade 4 siderosis in parenchymal and non-parenchymal liver cells and a mild inflammatory infiltrate with minimal portal fibrosis. He had 45 liters of blood venesected over the next 18 months and a repeat biopsy 3 years later showed a non-cirrhotic liver with no stainable iron. He developed a non-resectable primary hepatocellular clear cell carcinoma 17 years after the initial diagnosis.
- The other two cases were male siblings. One presented with atypical chest pain and had 3 cm hepatomegaly. Liver biopsy showed parenchymal grade 4 siderosis with normal architecture. He had 170 liters of blood venesected over the next 27 years, but then his iron indices indicated reaccumulation. Ultrasound showed a hyperechoic lesion in the liver due to a moderately differentiated hepatocellular carcinoma. His elder sibling, who had grade 4 siderosis and normal hepatic architecture, also developed a well-differentiated hepatocellular carcinoma.

Second-Generation Effects

Pregnancy

The case once made against use of iron dextran in pregnancy because of a supposed risk of possible uterine cramps (SED-9, 377) or a greater risk of systemic reactions (SED-8, 513) has not been substantiated. However, in one case a pregnant woman had anaphylactic shock as a reaction to intravenous iron, and this resulted in fetal cerebral damage (SEDA-22, 246).

Susceptibility Factors

Age

Age is a possible risk factor regarding adverse reactions to total-dose infusions of iron dextran (45).

Renal disease

Iron deficiency is a common and important cause of poor response to erythropoietin in patients with severe chronic renal insufficiency, in whom oral iron supplements fail to correct iron deficiency (6). Ferric gluconate has a low adverse effects profile, but the recommended dose of 62.5–125 mg per treatment is not practical for patients

© 2006 Elsevier B.V. All rights reserved.

who are not on hemodialysis. In a retrospective analysis of the incidence of adverse effects associated with 250 mg of ferric gluconate infused over 1–4 hours in 40 patients with severe chronic renal insufficiency, who received 79 treatments, four treatments in two patients were associated with adverse effects, including diarrhea, vomiting, low back pain, hypotension, and a burning sensation in the feet. The duration of the infusion did not influence the adverse effects profile.

Other features of the patient

Iron toxicity can be expected if the amount of free iron released into the plasma exceeds the plasma iron-binding capacity. This is more likely to occur when using iron sorbitol–citric acid complex (iron sorbitex), since the iron is less firmly bound than with iron dextran. Several conditions associated with low iron-binding capacity, such as malnutrition (kwashiorkor, malnutrition syndrome) and previous or simultaneous oral iron therapy appear to predispose to the development of these toxic reactions. In addition, folic acid deficiency has been reported to be a predisposing factor (SED-9, 516), the likely mechanism being altered iron utilization secondary to folic acid deficiency, which results in an increased saturation of iron-binding capacity.

Drug Administration

Drug administration route

Oral iron

Although modified-release formulations seem to be better tolerated, this is almost certainly a reflection of their less complete absorption. Iron is best absorbed in the duodenum, and most of the iron in modified-release tablets is released only when the tablets reach the lower parts of the gastrointestinal tract (46).

Parenteral iron

Total dose infusion of iron

With total dose infusion, the amount of iron that is required is delivered in a single infusion rather than by intermittent therapy. Although iron concentrations can rise to very high values, for example 100 000 micrograms/ml (45), there are unlikely to be signs of iron intoxication (SED-8, 513).

However, toxic reactions to intravenous iron occur when ionized iron exceeds plasma binding capacity. With iron dextran, the iron moiety is so firmly bound to dextran that ionized iron does not exceed plasma iron-binding capacity even when total plasma iron concentrations are extremely high. However, there are adverse effects, which were at first underestimated; whenever possible other routes or methods of iron dextran administration should be preferred.

Immediate reactions occurred in nine of 40 adults, variously in the form of anaphylaxis, chills, malaise, hypertension, gastrointestinal reactions, epistaxis, or chest pain. Monitoring for these early reactions is always necessary, but elderly patients require particular attention since they are more likely to react in this way.

Symmetric allergic purpura following the intravenous infusion of iron dextran has exceptionally been noted. In children, transient hepatosplenomegaly has been described as a common finding.

An adverse effect on rheumatic disorders of intravenous iron is well documented (SEDA-12, 190), with exacerbation of joint symptoms, perhaps by promoting lipid peroxidation (47). Of 11 patients with rheumatoid arthritis who received a total dose infusion of iron for anemia, nine experienced an exacerbation of the synovitis, and the two other patients had an anaphylactic reaction. The exacerbations occurred 24–48 hours after completion of the iron dextran infusion and settled in all patients within 11 days. One of these patients had synovial flares when challenged with oral ferrous sulfate. In a single reported case, total dose iron infusion was followed by prolonged polyarthritis, mainly of the large joints, in a patient with no previous evidence of rheumatoid arthritis or ankylosing spondylitis (48). Despite prolonged glucocorticoid therapy, clinical resolution of the problem took 6 months. It may also be relevant that when an iron infusion was given to 20 dialysis patients several of them developed muscular aches, an influenza-like condition or joint pain (SEDA-17, 278).

Organ calcification has very rarely been described after use of iron dextran in uremic patients (SED-8, 515).

Iron overload due to transfusions

Symptoms and signs of iron overload in transfusion-dependent anemias occur after a total transfusion burden of about 100–150 units of blood (49).

Drug overdose

The toxicokinetics and toxicodynamics of iron poisoning have been reviewed (50).

Oral iron

Acute poisoning of children who have taken iron tablets found in the medicine cabinet or elsewhere in the home has repeatedly been reported. The tablets, often attractively coloured and sugar-coated, are readily assumed to be confectionery.

The number of young children who have accidentally swallowed iron has more than doubled since 1986, since when more than 110 000 children under 6 years who accidentally swallowed iron tablets were reported to poison control centers. Many of the children were hospitalized and at least 33 died. The children who died had swallowed as few as five to as many as 98 tablets. In some cases, toddlers found tablets within their reach in uncapped or loosely capped containers. In other cases a young child managed to open a container. In 1995 the number of cases of unintended ingestion of iron by children was estimated at some 22 000 in the USA alone (51). Acute toxicity is associated with free radical formation. Emetics, gastric lavage, and even surgery may be called for to remove the excess.

Much more common is chronic poisoning due to excessive intake over a long period, with deposition of iron within cells. Iron has a toxic effect in almost all organs, especially the liver, heart, and endocrine glands. Histological evidence of iron-mediated tissue damage

© 2006 Elsevier B.V. All rights reserved.

can be obtained before the clinical picture becomes evident. Combined management with ascorbic acid and deferoxamine can yield high rates of deferoxamine-induced urinary iron excretion without obvious adverse effects on the heart.

The FDA has proposed regulations requiring warning labels on iron formulations, such as tablets and capsules, and requiring unit dose packaging for products containing 30 mg or more of iron in each dosage unit (52). The proposed regulations apply to both dietary supplements and drugs containing iron, but not to iron-fortified foods, such as enriched flour. This proposal is based on findings that iron-containing drugs and supplements are the leading cause of accidental poisonings in children. In 1988–92, about 17% of childhood deaths reported to poison control centers in the USA were blamed on iron poisoning: in 1984–87 the incidence was only 5%.

The Consumer Product Safety Commission, which regulates child-resistant packaging for household substances, requires such packaging for any oral iron product that contains 250 mg or more iron per container. In addition, the FDA's proposed regulations would require manufacturers to wrap iron tablets and capsules containing more than 30 mg per dosage unit in individual units, such as in blister packs.

Drug–Drug Interactions

Antacids

Iron absorption is reduced by antacids (for example magnesium trisilicate and carbonate) (53).

Colestyramine

Iron absorption is reduced by colestyramine (54).

Penicillamine

Concomitant ingestion of iron reduces the copper-excretory effect of penicillamine (SED-12, 527) and penicillamine reduces iron absorption (55).

Tetracyclines

Concomitant oral administration of tetracyclines and iron grossly reduces the absorption of both, because complexes are formed (56,57); there should be an interval of 2–3 hours between the use of the two.

Interference with Diagnostic Tests

Urine

Urine can turn dark in color in the first 24 hours after parenteral iron injection. The reddish-brown color, which has been observed after the intramuscular injection of iron sorbitol–citric acid complex (SED-8, 515), is due to urinary excretion of part of the iron compound. It has to be distinguished from the black discoloration that may develop if urine of patients who have received iron-sorbitex is allowed to stand, assumed to be due to production of iron sulfide by bacterial growth. Phenomena of this kind are unlikely to occur after the use of iron dextran, which is not normally filtered by the renal glomerulus.

Blood grouping

If blood grouping is to be performed, samples should be taken before the intravenous iron dextran injection, since it interferes with the reaction.

Plasma discoloration

Single-dose infusion of iron dextran can cause plasma discoloration, which may be misinterpreted as a sign of severe hemolysis.

Calcium and phosphorus

In one case iron dextran administration falsely reduced total serum calcium concentration and increased the phosphorus concentration (58).

^{99}Tc-diphosphonate

The distribution of ^{99}Tc-diphosphonate in bone was reportedly altered by circulating iron dextran complex in an elderly woman patient undergoing scintigraphy (59).

Isepamycin

See also Aminoglycoside antibiotics

General Information

Isepamicin is similar to amikacin but has better activity against strains that produce type I 6′-acetyltransferase. It can cause nephrotoxicity, vestibular toxicity, and ototoxicity. However, it is one of the less toxic of the aminoglycosides (1). The antibacterial spectrum of isepamicin includes *Enterobacteriaceae* and staphylococci; anaerobes, *Neisseriae*, and streptococci are resistant (1). Isepamicin was as effective and safe as amikacin in the treatment of acute pyelonephritis in children and might prove an advantageous alternative in areas with a high incidence of resistance to other aminoglycosides (2).

Isepamicin is given intravenously or intramuscularly in a dosage of 15 mg/kg/day or 7.5 mg/kg bd. It is not bound to plasma proteins, it distributes in extracellular fluids, and it enters some cells (outer hair cells, kidney cortex) by an active transport mechanism (1); the transference of isepamicin to the bone marrow is excellent (3). Isepamicin is not metabolized and is renally excreted with a half-life of 2–3 hours in adults with normal renal function. Its clearance is reduced in neonates, and a dose of 7.5 mg/kg/day is recommended in children younger than 16 days. Its clearance is also reduced in elderly people, but no dosage adjustment is required. In patients with chronic renal impairment, isepamicin clearance is proportional to creatinine clearance.

The bone tissue penetration of isepamicin has been studied in an open, non-comparative study, and the results compared with microbiologic data to estimate the clinical efficacy of isepamicin in bone infections (4). In 12 subjects of similar age, body weight, height, and creatinine clearance, who were undergoing elective total hip replacement, a single parenteral dose of isepamicin 15 mg/kg achieved concentrations in both cancellous and cortical bone tissue greater than the minimum concentrations required to inhibit the growth of 90% of strains of most of the susceptible pathogens commonly involved in bone infections.

Organs and Systems

Sensory systems

Hereditary deafness is a heterogeneous group of disorders, with different patterns of inheritance and due to a multitude of different genes (5,6). The first molecular defect described was the A1555G sequence change in the mitochondrial 12S ribosomal RNA gene. Two cases of hearing loss after short-term exposure to isepamicin sulfate, an aminoglycoside with milder adverse effects than other aminoglycosides, have also been described in patients with the A1555G mutation (7).

Urinary tract

Fleroxacin had a protective effect on isepamicin-induced nephrotoxicity in rats (8).

Drug Administration

Drug dosage regimens

In a randomized, multicenter study 236 patients were randomly assigned to isepamicin in a calculated dose or a loading dose of 25 mg/kg (9). The calculated dose was estimated using a specific population model with a Bayesian method, including information about age, weight, height, sex, and serum creatinine. The Bayesian method was significantly more accurate and performed particularly well in ventilated patients and severely ill patients, compared with a loading dose of 25 mg/kg, in obtaining a first isepamicin peak concentration of 80 micrograms/ml in patients in an intensive care unit.

Isoetarine

General Information

Isoetarine is a beta-adrenoceptor agonist bronchodilator given orally in a modified-release formulation (SED-13, 363) (SEDA-21, 184). It is slightly more $beta_2$-selective than isoprenaline but has a beta-blocking metabolite.

When isoetarine was compared with salbutamol in the treatment of acute severe asthma in adults who received hourly nebulized isoetarine 5 mg or salbutamol 2.5 mg the two drugs were equally effective in relieving bronchoconstriction (SEDA-21, 184). However, adverse effects occurred in 36% of patients who used isoetarine and 4% of those who used salbutamol. The adverse effects included dizziness, nervousness, and bouts of palpitation, tremor, headache, and worsening shortness of breath.

Organs and Systems

Respiratory

In several patients, administration of isoetarine resulted in a pink coloration of the sputum, due to the presence of a reddish metabolite; in such cases, hemoptysis may be wrongly suspected (1).

Isoflurane

See also General anesthetics

General Information

Isoflurane is a potent inhalation anesthetic. An isomer of enflurane, it has many of the same adverse effects. It is hardly metabolized (about 0.2%), which has encouraged its prolonged use as a sedative agent or bronchodilator in patients with acute severe asthma. However, it may not be as inert in all patients.

Organs and Systems

Cardiovascular

Although atrial dysrhythmias have been reported in 3.9% of patients and ventricular dysrhythmias in 2.5% (1), the dysrhythmogenicity of isoflurane is less pronounced than that of halothane (2). Indeed, the incidence of dysrhythmias due to catecholamines in cardiovascular anesthesia and during oral surgery is reduced by using isoflurane rather than the other agents.

The most controversial adverse effect of isoflurane is its potential to cause coronary steal in patients with critical stenosis in the coronary circulation. Most recent work suggests that the risk of myocardial ischemia is not increased, as long as the hemodynamics, especially heart rate, are well controlled (3). However, there are still isolated reports, suggesting that the issue is not settled. In some cases isoflurane has caused a specific coronary steal even with good hemodynamic control (4).

Respiratory

Marked respiratory depression has been documented in children (5) and coughing associated with nausea and vomiting occurs in about 10% of subjects (1).

Like halothane, isoflurane is useful in cases of life-threatening acute severe asthma refractory to drug therapy.

- An 11-year-old girl with acute asthma, severe CO_2 narcosis, and ventricular fibrillation induced by hypoxemia was successfully treated with isoflurane in oxygen for 14 hours. Her recovery may have been due to bronchodilatation and the treatment that was possible because of the low dysrhythmogenic effect of isoflurane (6).

Nervous system

Seizures are uncommon with isoflurane, but reports continue to appear.

The neuromuscular blocking effects of vecuronium bromide can be enhanced by inhalation anesthetics.

- Symptoms suggestive of severe sensorimotor neuropathy developed in a 40-year-old woman 15 days after admission for a severe exacerbation of asthma (7). During this time she was given isoflurane 0.5–3% in oxygen, vecuronium bromide 4–6 mg/hour, and fentanyl 100 micrograms/hour. The neuropathy resolved spontaneously over the next 3 months.

In this case, isoflurane may have been the trigger.

- A fine tremor occurred when isoflurane was used in the management of a 3-year-old boy with pneumonia and underlying congenital myasthenia gravis (8).

Liver

Hepatic damage related to isoflurane anesthesia has very occasionally been described (9,10), including one report of hepatic necrosis and death (11). Hepatitis or hepatocellular injury has been described with all current volatile anesthetics. Among these, halothane-associated hepatitis has been best characterized and is probably caused by an immune reaction induced by hepatocyte proteins that have been covalently trifluoroacetylated by the trifluoroacetyl metabolite of halothane. The reactive acyl-halide metabolite of trifluoroacetic acid can trifluoroacetylate liver proteins, resulting in immune-mediated hepatic necrosis (12). However, isoflurane biotransformation to trifluoroacetate is less than 0.2%, compared with 15–20% for halothane.

In an interesting case report, clinical, histochemical, and immunohistochemical evidence supporting the role of trifluoroacetyl-modified proteins has been presented in a patient with hepatitis associated with isoflurane (13).

© 2006 Elsevier B.V. All rights reserved.

The role of CYP2E1 as the predominant route of metabolism of isoflurane to trifluoroacetic acid and inorganic fluoride ions has been confirmed using the enzyme inhibitor disulfiram as a metabolic probe in 22 adults randomized to either disulfiram 500 mg the evening before surgery or placebo. Anesthesia with 1.5% isoflurane lasted for an average of 8 hours. Postoperative plasma concentrations were increased and urinary excretion of trifluoroacetic acid was inhibited by 80–90% in the disulfiram group. Whether the use of disulfiram would reduce the incidence of hepatitis is unknown. Patients with increased activity of CYP2E1 or CYP2A6 appear to be at higher risk of isoflurane hepatotoxicity.

Acute hepatotoxicity has been reported with isoflurane (14). The authors hypothesized that induction of cytochrome P-450 by phenytoin had caused enhanced transformation of isoflurane to trifluoroacetic acid. They suggested that caution should be taken in the use of halogenated anesthetics in patients taking drugs that induce cytochrome P-450 isozymes.

- An obese 35-year-old diabetic woman developed isoflurane-induced hepatotoxicity (15). She had had four previous halothane anesthetics, the last two of which were associated with jaundice. She made a full recovery and during a subsequent anesthetic received an infusion of propofol. Unfortunately, trifluoroacetic acid antibody titers were not performed. Liver function does not appear to have been severely affected: peak alanine transaminase activity was 1410 IU/l.

Fatal hepatotoxicity associated with isoflurane has been reported (16).

- A 76-year-old woman with previous exposure to isoflurane 3 years earlier underwent an above-knee amputation for a liposarcoma using isoflurane anesthesia. On day 3 postoperatively she became febrile and confused. Bacterial cultures later showed *Staphylococcus aureus* in the sputum and *Escherichia coli* in the urine. Associated hypotension for 2 hours resolved with inotropic support and here renal function remained normal. On day 6 she became jaundiced and developed further hypotension. Despite intensive care treatment she died on day 7. An autopsy showed centrilobular necrosis consistent with drug-induced hepatitis. All liver serology was negative.

The clinical details in this case were similar to those seen in halothane hepatitis. The authors concluded that although there was no direct evidence that isoflurane was the causative agent, it was likely to have caused this type of hepatitis. Unfortunately, trifluoroacetic acid antibodies titers were not measured, because this test, if positive, would have confirmed the diagnosis.

Urinary tract

High concentrations of fluorine ions, potentially damaging to the kidney, can be found after prolonged use (17).

Four patients with renal dysfunction in an intensive care unit received isoflurane inhalation for sedation for 8–26 days. The concentrations of isoflurane used were 20–50% of the minimum alveolar concentration. Only small increases in fluoride ion concentration, the highest being 25 μmol/l, were recorded, well below the 50 μmol/l threshold associated with adverse effects on renal function (18).

Immunologic

Anaphylaxis has been reported in a patient who received isoflurane (19).

Body temperature

Malignant hyperthermia is a possible complication of isoflurane anesthesia (20).

Shivering after an anesthetic develops in as many as a half of patients recovering from isoflurane anesthesia. Most postoperative shivering appears to be thermoregulatory, although volatile anesthetics can themselves facilitate muscular activity. In 60 adult patients the incidence of postoperative shivering was 40% in a control group, 7% after physostigmine 0.04 mg/kg, zero after meperidine 0.5 mg/kg, and zero after clonidine 1.5 micrograms/kg (21). The centrally acting adrenoceptor agonist phenylpropylamine methylphenidate, the 5-hydroxytryptamine antagonist ketanserin, magnesium sulfate, doxapram, and hypercapnia also reduce the incidence of postoperative shivering.

Drug–Drug Interactions

Alfentanil and esmolol

The effects of alfentanil and esmolol on isoflurane requirements for anesthesia have been studied in a randomized trial in 100 patients (22). Alfentanil infusion to a targeted effect site concentration of 50 ng/ml, but not esmolol, reduced the minimum alveolar concentration of isoflurane required to suppress movement to surgical pain by 25%. The combination of esmolol and alfentanil caused a 74% reduction in isoflurane requirements. This study is interesting, because the beta-blocker esmolol had a profound effect on the isoflurane-sparing effects of alfentanil, while having little effect on its own.

Clonidine

In a randomized, double-blind, controlled trial in 61 patients, oral clonidine 5 micrograms/kg was given 90 minutes before surgery to reduce the concentration of isoflurane at which patients wake at the end of surgery by 8% (23). There was a 6–7 minute delay in waking in the clonidine group compared with the control group. Clonidine 2.5 micrograms/kg had no significant effect.

Rocuronium

The infusion requirements of rocuronium necessary to maintain twitch depression were reduced by 40% during anesthesia involving isoflurane (24). In another study in 60 patients undergoing maintenance anesthesia, isoflurane plus nitrous oxide anesthesia reduced the dosage requirement of rocuronium by 35–40% (25).

Suxamethonium

Isoflurane in nitrous oxide inhibited suxamethonium-induced muscle fasciculation in children (26).

Isometheptene

General Information

Isometheptene, used in the treatment of migraine, is an indirect sympathomimetic with a tyramine-like action and is also an agonist at alpha-adrenoceptors.

In one case an autonomic dysreflexic syndrome developed after the use of an isometheptene combination to treat migraine (1). In other respects its adverse reactions are similar to those of adrenaline and ephedrine.

Reference

1. Wineinger MA, Basford JR. Autonomic dysreflexia due to medication: misadventure in the use of an isometheptene combination to treat migraine. Arch Phys Med Rehabil 1985;66(9):645–6.

Isoniazid

See also Antituberculosis drugs

General Information

Isoniazid is the hydrazide of isonicotinic acid. It is a first-line drug for therapy and prophylaxis of tuberculosis. It is bactericidal for rapidly dividing mycobacteria, but bacteriostatic for "resting bacilli". Among non-tuberculous mycobacteria, only a few strains, such as *Mycobacterium kansasii*, are susceptible. As a rule, sensitivity should always be tested in vitro, since the minimum inhibitory concentration varies greatly.

© 2006 Elsevier B.V. All rights reserved.

Isoniazid diffuses rapidly into body fluids and cells, including cerebrospinal fluid. It is as effective against bacteria growing within cells as it is against bacteria in culture media. There is no cross-resistance between isoniazid and other antituberculosis drugs.

The daily dose of isoniazid is 5 mg/kg, with a maximum of 300 mg/day in adults with normal liver and kidney function. In children, 8–10 mg/kg/day is an appropriate dosage, with a maximum daily dose of 300 mg, since the metabolism of isoniazid in children is rapid. Untoward effects of isoniazid as a single antituberculosis drug can be evaluated in preventive tuberculosis therapy, since curative regimens usually consist of multiple drugs.

Pharmacokinetics

After oral administration, isoniazid reaches a peak plasma concentration of 3–5 micrograms/ml within 1–2 hours. It equilibrates into all body fluids and tissues and 75–95% is excreted in the urine within 24 hours. The most important urinary metabolites are products of acetylation (acetylisoniazid) and hydrolysis (isonicotinic acid). Isonicotinyl glycine, isonicotinyl hydrazones, and *N*-methylisoniazid appear in only small amounts. The rate of acetylation of isoniazid significantly alters its plasma concentrations and half-life. The mean half-life of isoniazid in rapid acetylators is about 70 minutes and in slow acetylators 3 hours.

General adverse reactions

In a survey of more than 2000 patients treated with isoniazid, the most frequent adverse effects were rash (2%), fever (1.2%), jaundice (0.6%), and peripheral neuropathy (0.2%). Seizures can also occur. Isoniazid prolongs the half-life of rifampicin and other drugs metabolized by the liver. Morbilliform, maculopapular, purpuric, and urticarial rashes, with or without fever, are considered to be of allergic origin. Hematological adverse effects consist of agranulocytosis, thrombocytopenia, pure red cell aplasia, and eosinophilia (SEDA-9, 268). Dyspnea, with thoracic pain, cough, fever, and eosinophilia, as well as micronodular densities in the chest X-ray, may also be due to an immunological process (1). Vasculitis associated with antinuclear antibodies has been observed, as well as arthritic symptoms (2). Liver injury (mainly hepatocellular) has been considered another form of hypersensitivity reaction, but usually occurs during combined antituberculosis treatment with rifampicin in combination with anticonvulsants or halothane, or in association with alcoholism. Some are of the opinion that the main factor that induces liver damage is the fast acetylator phenotype (3), while others have found no correlation (4). No increase in cancer deaths was observed in a series of 338 women treated with isoniazid for pulmonary tuberculosis (5). Isoniazid is a potent inhibitor of hepatic enzymes and interferes with the metabolism of many drugs (SEDA-8, 287) (SEDA-11, 271).

Organs and Systems

Respiratory

Symptoms suggestive of bronchial obstruction occur only very rarely during isoniazid treatment (1).

Nervous system

Untoward neurological effects (peripheral neuropathy and focal seizures) occur in 2% of patients if pyridoxine is not given and in 12–20% taking higher doses of isoniazid (10–15 mg/kg) (6).

Peripheral neuropathy due to isoniazid results from inhibition of the formation of the co-enzyme form of vitamin B6, pyridoxine. Numbness or tingling of the extremities in the "glove and stocking" distribution can occur early during treatment with isoniazid when pyridoxine is not given. Neuropathy was noted by several authors in up to 20% of malnourished patients and fast acetylators taking isoniazid in doses over 5–6 mg/kg. Only 2% of patients taking 5 mg/kg of isoniazid plus pyridoxine developed neuropathy. Symptoms generally consist of hyperesthesia, reduced vibration and position sense, and exaggerated or reduced tendon reflexes, but ataxia, muscle weakness, and even paralysis can develop (7). Shoulder–arm syndrome has also been described.

Neurohistology shows disappearance of synaptic vesicles, mitochondrial swelling or condensation, and fragmentation of axon endings. Alterations in the lumbar and sacral spinal ganglia and the spinal cord have also been reported (8).

The addition of pyridoxine to usual doses of isoniazid of 5 mg/kg/day in adults and 8–10 mg/kg/day in children markedly reduces neurotoxicity (9). Adherence to therapy is improved by prescribing combined tablets containing 20 mg of pyridoxine per 100 mg of isoniazid. In otherwise healthy people, prescription of pyridoxine is not mandatory. However, it should be routinely given to malnourished patients and those predisposed to neuropathy (for example pregnant women, elderly people, and people with diabetes, alcoholism, or uremia) (7).

Pellagra-associated encephalopathy has been suspected as an adverse effect of isoniazid administration in several patients with tuberculosis. Deficiency of niacin (nicotinic acid) is characterized by dermatitis, diarrhea, and dementia. Other symptoms can occur, such as seizures, hallucinations, spasticity, and glossitis. Pellagra induced by isoniazid is promoted by malnutrition or a vegetarian diet with low intake of the nicotinamide precursors tryptophan and nicotinic acid. Specific supplementation is essential (10).

Sensory systems

Optic neuritis and atrophy have occurred in patients taking isoniazid (11).

Psychological, psychiatric

Isoniazid can cause neuropsychiatric syndromes, including euphoria, transient impairment of memory, separation of ideas and reality, loss of self-control, psychoses (9), and obsessive-compulsive neurosis (12). Isoniazid should be used with caution in patients with pre-existing psychoses, as it can cause relapse of paranoid schizophrenia (13). Patients on chronic dialysis appear to be vulnerable to neurological adverse drug reactions, because of abnormal metabolism of uremic toxins. It is therefore recommended that a higher than usual dose of pyridoxine be given to patients on dialysis taking isoniazid (14,15).

© 2006 Elsevier B.V. All rights reserved.

Endocrine

Cushing's syndrome, gynecomastia, amenorrhea, and precocious puberty have been regarded as reflecting the enzyme-inhibitory activity of isoniazid, with resulting derangement of hormone metabolism in the liver.

Metabolism

Isoniazid can cause transient hyperglycemia in overdose (16).

In five volunteers taking isoniazid 15 mg/kg/day over a period of 6 weeks, serum cholesterol concentrations were reduced (SEDA-9, 268).

Hematologic

Agranulocytosis, thrombocytopenia, hemolytic anemia, sideroblastic anemia (17), pure red cell aplasia (18), methemoglobinemia, and eosinophilia can occur exceptionally during isoniazid treatment (SEDA-9, 268) (19). An acquired coagulation factor XIII inhibitor developed in a patient taking isoniazid and resulted in a bleeding disorder (20).

Gastrointestinal

No severe gastrointestinal adverse effects of isoniazid have been observed; symptoms are limited to such as epigastric distress, gastric burning, and dry mouth. Of 814 patients with pulmonary tuberculosis treated for 9 months with isoniazid and rifampicin, 18 had minor symptoms of gastrointestinal intolerance (21). Nausea can occur, particularly if the drug is taken before breakfast or in combination with other antituberculosis drugs; 5.5% of 912 patients taking a fixed tablet combination of isoniazid, protionamide, and diaphenyl sulfone plus rifampicin had sensations of fullness, nausea, or vomiting (22).

Liver

Abnormal liver function is the most commonly described adverse effect of isoniazid (23). It may be related to acetylator phenotype.

Hepatotoxicity caused considerable alarm after an episode in Washington DC, when 19 of 2231 government employees given isoniazid prophylaxis developed clinical signs of liver disease within 6 months; 13 were severely jaundiced and 2 died (23).

In a series of 13 838 individuals treated prophylactically, 114 developed overt hepatic disease (SED-9, 574) (24). There were 13 deaths, submassive necrosis in 9 cases, and massive necrosis in 4. The 20 other patients from whom hepatic tissue was available included 16 with moderately severe acute hepatocellular injury (four with a mixed hepatocellular-cholestatic pattern), and four with chronic hepatic damage (one with cirrhosis). The effects of liver disease before the onset of jaundice included vague digestive and "viral" disease-like complaints, some with and some without gastrointestinal symptoms. Jaundice was the presenting complaint in 10%, fever and rash were reported in under 4%, and there was a modest eosinophilia in about 10%. Liver damage was recognized during the first month of administration in 15% and during the second month in a further 31%. The other 54% had taken isoniazid for 2–11 months. Although liver damage in these patients may have been related to isoniazid, some probably had viral hepatitis.

In a study of isoniazid prophylactic therapy in Seattle, USA, only 11 patients of 11 141 had hepatotoxic reactions (25). The rate was 0.1% of those starting and 0.15% of those completing the course of therapy. The duration of therapy was not stated, but 10 of the 11 episodes occurred within 3 months of starting.

The mechanism responsible for hepatotoxicity is not known. A metabolite of isoniazid, acetylhydrazine, causes hepatic damage and may play a role. Alcoholic hepatitis is an aggravating factor. The sensitivity of chronic carriers of hepatitis B virus is controversial (26). In an investigation in which the urinary metabolic profile of isoniazid was assayed in patients who developed isoniazid-related liver damage, it was impossible to predict which patients would be susceptible. It was also impossible to show that rifampicin plays a significant role in inducing liver damage when added to isoniazid (27,28). Nevertheless, it is conceivable that enzyme induction by rifampicin alters the metabolism of isoniazid. Further risk factors are alcoholism, malnutrition, diabetes, previous liver damage, renal insufficiency, and drug abuse. Age is certainly another risk factor: hepatic damage seems to be rare in patients under the age of 20; the incidence of liver toxicity is 0.3% between the ages of 20 and 34, and increases with age to 1.2% between 34 and 49 and 2.3% over the age of 50 (9). Even in prophylaxis with isoniazid monotherapy, adverse effects are more frequent in patients aged over 35 years (29).

Liver damage usually appears 1–2 months after the start of therapy. In children, raised liver enzymes are common during the first few months of treatment, but withdrawal is seldom necessary. A careful watch should be kept for early symptoms of isoniazid-induced hepatitis, such as malaise, fatigue, nausea, and epigastric distress. The dangers of continuing isoniazid after the onset of symptoms of toxicity have been highlighted (30). The earliest symptoms of isoniazid toxicity should be clearly described to the patient, particularly to hepatitis B carriers, who may be more susceptible to hepatotoxicity (26).

It is advisable to measure the liver enzymes aspartate transaminase and alanine transaminase before treatment and monthly thereafter, for as long as isoniazid administration lasts. Isoniazid should be withdrawn if the transaminases increase to over five times normal (9).

Pancreas

Acute pancreatitis has been attributed to isoniazid (31,32).

- A 42-year-old Asian man developed clinical, biochemical, and imaging features of acute pancreatitis 11 days after starting to take rifampicin, isoniazid, and pyrazinamide for spinal tuberculosis (33). He had no history of excessive alcohol or other drug therapy. He improved after withdrawal of all drugs, but the pancreatitis recurred on reintroduction of isoniazid and resolved after withdrawal.

Causality here was difficult to establish. Pancreatitis has rarely been seen in patients who have taken an overdose

© 2006 Elsevier B.V. All rights reserved.

of isoniazid. Rifampicin, also used in this case, is more likely to cause pancreatitis in usual doses.

Urinary tract

Isoniazid can rarely cause renal damage (34).

Urinary retention is a rare complication of isoniazid overdose (35).

Skin

Morbilliform, maculopapular, or urticarial rashes have been observed in up to 2% of patients (9). In one study, acneiform eruptions developed in only 11 cases (1.4%), including 0.5% of patients taking isoniazid, 1.5% of patients taking rifampicin, and 0.6% of patients taking ethambutol (36).

Acquired cutis laxa has been mentioned in a single child taking isoniazid, but it was probably coincidental (37).

Erythema nodosum and purpura have been described in patients taking isoniazid (38).

Pellagra has been reported in a patient taking isoniazid, despite concomitant pyridoxine prophylaxis (39).

- A 52-year-old man developed pellagra with a classical photosensitive distribution after taking isoniazid for 14 months; the first 6 months being treatment for possible tuberculous meningitis, the rest to provide antituberculosis protection while glucocorticoids were given for possible neurosarcoidosis. He was said to take alcohol only occasionally and took pyridoxine throughout the entire period of treatment. He improved rapidly on withdrawal of isoniazid and supplementation with nicotinamide.

The authors noted that isoniazid-induced pellagra was first described in 1956, shortly after the introduction of isoniazid for the treatment of tuberculosis, but that subsequent reports have been very uncommon.

Isoniazid has also been reported to cause subepidermal blistering (40).

- A 63-year-old man developed bullous lesions on the trunk and limbs and a six-fold rise in liver enzymes 15 days after treatment for tuberculosis. His skin recovered and his liver enzymes returned to normal within 2 weeks of withdrawal of all treatment, but the abnormalities recurred when treatment was resumed. At this point a skin biopsy showed subepidermal blistering. Once again withdrawal of treatment led to improvement, and when treatment was resumed without isoniazid the improvement continued.

Desensitization to isoniazid has been attempted in some patients with drug fever or rashes. A procedure of rush desensitization over a few days or a week can be used, starting with 1 mg orally and increasing the dosage every second day (41) or even every few hours.

Musculoskeletal

Arthritic symptoms, with back pain, bilateral proximal interphalangeal joint involvement, arthralgia of the knees, elbows, and wrists, and the so-called "shoulder–arm" syndrome with cervicobrachial neuralgia can occur (9).

Rhabdomyolysis occurred in subjects with isoniazid poisoning in a retrospective analysis of 270 patients seen over a 5-year period at the Phillipine General Hospital in Manilla (42). Skeletal muscle creatine kinase activity was raised in 31 of the 52 evaluable subjects who had taken more than 2.4 g/day of isoniazid. Creatine kinase activity peaked on days 5–6 and fell thereafter. Two patients developed acute renal insufficiency and required dialysis. Seizures occurred in all patients, and their duration, but not their frequency, correlated with raised creatine kinase activity. However, it is likely that factors other than seizures contribute to rhabdomyolysis in patients with isoniazid poisoning.

Immunologic

The expansion or new development of tuberculous lesions during ultimately successful therapy has been termed a "paradoxical response." It is most often reported in relation to intracranial tuberculomata, but is probably most common in tuberculous lymphadenopathy. It is also described in tuberculous pleurisy and in parenchymal lung disease. In most cases, the problem eventually settles, but sometimes glucocorticoid therapy is used empirically.

A lupus-like syndrome or vasculitis, with arthritis, rheumatic pain, fever, pleurisy, and leukopenia, has been reported in patients taking isoniazid (38,43). Tests for antinuclear antibodies are useful to distinguish idiopathic systemic lupus erythematosus and drug-induced lupus-like syndromes. However, many patients taking isoniazid have antinuclear antibodies, usually without signs or symptoms of systemic lupus erythematosus. Isoniazid can also exacerbate pre-existing systemic lupus erythematosus (38,43). Long-term glucocorticoid treatment may be necessary if symptoms persist after withdrawal of isoniazid.

- Two Japanese patients developed pleural effusions while taking antituberculosis therapy and were believed to have isoniazid-induced lupus-like syndrome (44). This diagnosis was based on the presence of antinuclear antibody in the effusate, and in one patient, a positive lymphocyte stimulation test using isoniazid; in the other patient it was negative. Both had moderately strongly positive serum antinuclear antibodies (1:160). In the first patient, the effusion disappeared 2 weeks after withdrawal of isoniazid; in the other treatment was continued but the effusion nevertheless resolved in 10 weeks.

It is worth checking for evidence of lupus-like syndrome in patients with paradoxical responses to antituberculosis therapy but it remains to be seen how many cases would be explained by it.

Long-Term Effects

Mutagenicity

Isoniazid is not mutagenic (SEDA-6, 276), but patients taking combined isoniazid and rifampicin therapy for 3–10 months developed an increased rate of chromosomal aberrations in peripheral blood lymphocytes (SEDA-9, 276). However, this effect is not known to have clinical consequences.

© 2006 Elsevier B.V. All rights reserved.

Second-Generation Effects

Fertility

Isoniazid has no effect on fertility (SEDA-6, 276).

Pregnancy

Isoniazid is the safest antituberculosis drug for use during pregnancy (45,46). During pregnancy, isoniazid with ethambutol is considered to be the preferred combination (45).

Teratogenicity

Isoniazid diffuses into blastocytes, but no teratogenic effects have been reported (46).

Lactation

Isoniazid is the safest antituberculosis drug for use during lactation (45,46). However, as isoniazid passes into breast milk, a watch must be kept for adverse effects in the infant when a nursing mother is taking isoniazid (47). However, the serum concentrations that occur in children have no therapeutic effect and cannot be considered as a form of preventive chemotherapy in infants of mothers with active tuberculosis.

Susceptibility Factors

Genetic factors

People are divided genetically into rapid and slow acetylators of isoniazid, depending on the amount of *N*-acetyltransferase they have. The rate of acetylation of isoniazid depends on race, but is not influenced by sex or by age after childhood. In Eskimos and Japanese, fast acetylators predominate. Slow acetylation is the predominant phenotype in most Scandinavians, Jews, and North African Caucasians (9). Slow acetylators are homozygous for an autosomal recessive gene, while fast acetylators are homozygous or heterozygous for a dominant gene. In the case of isoniazid (which has a low hepatic extraction ratio) the rate of acetylation significantly alters its plasma concentrations and half-life. The mean half-life of isoniazid in rapid acetylators is about 70 minutes and in slow acetylators 3 hours. Despite this, there is probably no difference in the effectiveness of isoniazid in the two phenotypes. The relation between isoniazid toxicity and acetylator status continues to be discussed (3,4,6).

Drug Administration

Drug overdose

Acute poisoning with isoniazid in children (48) and adults (13,26,35) causes recurrent seizures, profound metabolic acidosis, coma, and even death. In adults, toxicity can occur with the acute ingestion of as little as 1.5 g of isoniazid. Doses larger than 30 mg/kg often produce seizures and 80–150 mg/kg or more can be rapidly fatal. The first signs and symptoms of isoniazid toxicity usually appear 0.5–2.0 hours after ingestion, by which time peak absorption occurs (49), and include nausea, vomiting, slurred speech, dizziness, tachycardia, and urinary retention, followed by stupor, coma, and recurrent tonic-clonic seizures. The seizures are often refractory to antiepileptic therapy. However, pyridoxine, 20–1500 mg per gram of isoniazid ingested, usually eliminates seizure activity and helps to correct the metabolic acidosis (50).

Drug–Drug Interactions

Antacids

Absorption of isoniazid can be inhibited by aluminium-containing antacids (51).

Barbiturates

Barbiturates which induce liver drug-metabolizing enzymes increase the rate of metabolism of isoniazid, rifampicin, or combined antituberculosis treatment, since they may result in accelerated breakdown of these drugs (52).

Benzodiazepines

In healthy volunteers, the half-life of triazolam was prolonged from 2.5 to 3.3 hours when it was given with isoniazid (SEDA-9, 267). However, isoniazid did not affect the pharmacokinetics of oxazepam.

Beta-adrenoceptor antagonists

Lipophilic beta-adrenoceptor antagonists are metabolized to varying degrees by oxidation by liver microsomal cytochrome P450 (for example propranolol by CYP1A2 and CYP2D6 and metoprolol by CYP2D6). They can therefore reduce the clearance and increase the steady-state plasma concentrations of other drugs that undergo similar metabolism, potentiating their effects. Drugs that interact in this way include isoniazid (53).

Carbamazepine

Patients taking carbamazepine can develop signs of carbamazepine intoxication; serum concentrations of carbamazepine are increased by isoniazid, probably through enzyme inhibition (54).

Disulfiram

In seven patients taking isoniazid 0.6–1.0 g/day for at least 1 month, disulfiram 0.5 g/day caused dizziness, disorientation, staggering, insomnia, irritability, listlessness, lethargy, and in one case hypomania (55). This interaction may have been due to inhibition of isoniazid metabolism by disulfiram or to a complex interaction with dopamine metabolism.

Ethosuximide

In one case, isoniazid increased blood concentrations of the antiepileptic drug ethosuximide and caused hiccups, anorexia, nausea, vomiting, insomnia, and an acute psychosis (SEDA-9, 267) (56). This may have been due to inhibition of ethosuximide metabolism by isoniazid.

Monoamine oxidase inhibitors

Isoniazid inhibits monoamine oxidase, and hence reduces tyramine metabolism; this effect is enhanced by co-administration of other monoamine oxidase inhibitors (57).

© 2006 Elsevier B.V. All rights reserved.

Phenazone

Isoniazid significantly reduces the hepatic clearance of phenazone (antipyrine) by about 40% (SEDA-9, 267).

Phenytoin

Isoniazid inhibits the parahydroxylation of phenytoin. Symptoms of phenytoin intoxication, such as dizziness, incoordination, or excessive sedation, can occur, particularly in patients who are slow acetylators (SEDA-11, 271). Dosages of phenytoin should be adjusted according to plasma concentrations (58).

Stavudine

A five-fold increase in the risk of distal sensory neuropathy has been reported in patients taking stavudine plus isoniazid (55 versus 11%) compared with patients taking stavudine without isoniazid (59). In nine of 12 patients, the neuropathy resolved on changing antiretroviral drugs. Peripheral neuropathy is a distressing complication during treatment with stavudine and the risk is considerably increased with co-administration of isoniazid. This combination of drugs should be avoided, if possible, in patients with tuberculosis and AIDS.

Food–Drug Interactions

Tyramine-containing foods

Adverse reactions during treatment with isoniazid have been noted after ingestion of several kinds of cheese (60,61). Flushing, palpitation, tachycardia, and increased blood pressure have been observed 0.5–2 hours after cheese. The symptoms generally disappear within 2–4 hours. Interference by isoniazid with monoamine oxidase, and hence with tyramine metabolism, has been incriminated.

Histamine-containing foods

Headache, palpitation, erythema, redness of the eyes, itching, diarrhea, and wheezing can occur with isoniazid after skipjack fish (*Thunnidae*) (60,62), probably because of the high histamine content of this fish.

Isoprenaline

See also Adrenoceptor agonists

General Information

As a non-selective beta-adrenergic receptor stimulant, isoprenaline produces a wide range of adrenergic effects. Those that involve the heart present the most marked problems in practice. Doses of up to 10 micrograms/minute are used to improve the peripheral circulation in shock. In respiratory disease, isoprenaline in sublingual tablets (up to 10 mg) and inhalers were used in the past, but have been supplanted by selective $beta_2$-adrenoceptor agonists. Isoprenaline inhalers sometimes provided more than the 20 micrograms needed for a maximum effect on the bronchi, resulting in adverse effects. Oral isoprenaline was also used to treat some forms of heart block, but is now obsolete.

© 2006 Elsevier B.V. All rights reserved.

Organs and Systems

Cardiovascular

Tachycardia, dysrhythmias, palpitation, flushing, and attacks of angina pectoris were disadvantages of isoprenaline when it was used in respiratory disease. Users tended to raise the dose (hence increasing the degree of cardiac toxicity), possibly because a metabolite (3-alpha-methylisoprenaline), which may act as a weak beta-blocker, accumulates and makes the original doses ineffective. Isoprenaline produces electrocardiographic changes compatible with myocardial infarction or can lead to ventricular fibrillation or even cardiac muscle necrosis if infusions are not given with the utmost caution (SED-12, 312) (1,2). Exceptionally, the tachycardia produced by an infusion of isoprenaline can be overshadowed by a reflex bradycardia, even while the drug is being given (SEDA-17, 163).

Respiratory

In relaxing bronchial smooth muscle, isoprenaline can impair the ventilation:perfusion ratio and aggravate hypoxemia even as it reduces airway resistance; thus, the patient may feel better but be worse off. In addition, paradoxical bronchospasm can occur, a response of this type having been found in 30% of patients in one series.

Nervous system

Headache, tremor, apprehension, dizziness, and faintness are common problems with isoprenaline.

Gastrointestinal

Quite apart from the fact that systemic adverse reactions appear to be more common when isoprenaline is given in the form of sublingual tablets, these commonly cause mouth ulcers. Their long-term use has also been reported on one occasion to have caused tooth destruction (SED-8, 305), but this was probably coincidental.

Second-Generation Effects

Teratogenicity

Isoprenaline has often been given in pregnancy, and animal studies do not suggest that it is teratogenic.

Susceptibility Factors

Isoprenaline is better avoided whenever stimulation of the heart or the central nervous system is undesirable, for example in patients with angina pectoris or thyroid disease. There is no reliable information on the risks in liver or renal disease.

Drug–Drug Interactions

Theophylline

The toxicity of isoprenaline in animals is increased if it is given with theophylline (3). There is no evidence of this in humans, although an interaction does occur at the cellular level (4).

Isopropamide iodide

General Information

A 5–10 mg oral dose of the anticholinergic drug isopropamide iodide produces typical anticholinergic adverse effects. In patients with Zollinger–Ellison syndrome the combination of cimetidine plus isopropamide 20–40 mg/day was generally more effective in suppressing acid secretion than cimetidine alone (1).

Organs and Systems

Urinary tract

The presence of isopropamide iodide in some over-the-counter cold remedies, for example alongside antihistamines, should be borne in mind as a hidden cause of urinary retention.

Immunologic

Isopropamide iodide can cause allergic reactions in patients who are sensitive to iodine.

Interference with Diagnostic Tests

Thyroid function

By virtue of its iodine content, isopropamide iodide can interfere with thyroid function tests.

Isopropanolamine

General Information

Isopropanolamine is used in cosmetics, hair perms, hair sprays, and in tanning lotions as a buffering agent.

Organs and Systems

Immunologic

- Contact dermatitis to a gel containing biphenylacetic acid, a non-steroidal anti-inflammatory agent, carbomer, and isopropanolamine has been reported (1). Patch tests showed a positive reaction to isopropanolamine (1% aqueous) on day 4. Patch-testing of 22 patients as controls showed one case of slight irritation.

Isoxepac

General Information

Evidence about the properties of the NSAID isoxepac is minimal; only increases in gastrointestinal blood loss over pretreatment levels have been described (1).

Reference

1. Mitchell H, Barraclough D, Muirden KD. Blood-loss studies for new non-steroidal anti-inflammatory drugs. Med J Aust 1982;1(8):328.

Isoxicam

See also Non-steroidal anti-inflammatory drugs

General Information

The oxicam NSAID isoxicam has a shorter half-life (30 hours) than piroxicam. However, there are large variations in half-life, clearance, and mean steady-state plasma concentrations. Except for edema, the incidence of adverse effects is unrelated to age (1).

Organs and Systems

Gastrointestinal

The main adverse effects of isoxicam are gastrointestinal (pain, dyspepsia, nausea, vomiting, stomatitis, constipation, and occasionally peptic ulcer), which occur in up to 80% of patients.

Skin

Serious skin reactions (Stevens–Johnson syndrome and Lyell's syndrome) caused temporary withdrawal of isoxicam in several countries, even though an analysis of 1800 patients with rheumatoid arthritis or degenerative joint disease failed to confirm an increased risk (2).

Isoxsuprine

See also Adrenoceptor agonists

General Information

Isoxsuprine is a beta$_2$-adrenoceptor agonist that also has antagonist action at alpha-adrenoceptors. It has been variously presented as a beta-agonist, a specific vasorelaxant, a uterine relaxant, and an agent that reduces blood viscosity. In high dosages it also inhibits platelet aggregation. There is slim evidence that isoxsuprine improves cognitive function and mental performance in a limited number of patients, but the practical benefit is minor. There is no convincing proof of its efficacy in patients with claudication. It has been widely used in horses for treating navicular syndrome and laminitis, with little evidence of efficacy (1).

Since its efficacy has been doubted with respect to both its vascular and its obstetric use, one must suspect that underdosage of the drug is the best explanation for the low reported incidence of adverse reactions, which are generally of the type regarded as anecdotal (nausea, vomiting, palpitation, dizziness, weakness). Minor facial flushing and tremor are common. As patients tend to increase the dosage gradually, diarrhea, vomiting, headache, vertigo, and rash can occur (SEDA-3, 177) (SEDA-7, 228). The important adverse reactions of isoxsuprine are tachycardia and orthostatic hypotension, but they occur only at high dosages.

Second-Generation Effects

Fetotoxicity

The beta-adrenoceptor agonist effect is sufficient to cause fetal tachycardia when isoxsuprine is given intravenously in late pregnancy, although one large survey suggested that it may be better tolerated by the mother (as regards cardiac and stimulant effects) than salbutamol (SED-12, 313). The fact that maternal blood

© 2006 Elsevier B.V. All rights reserved.

pressure can fall may reflect a direct relaxant effect on the blood vessels.

Isradipine

See also Calcium channel blockers

General Information

Isradipine is a dihydropyridine calcium channel blocker.

The MIDAS study (1) was a randomized trial of isradipine versus hydrochlorothiazide over 3 years in 883 patients, designed primarily to assess the effect on the rate of progression of medial intimal thickness in carotid arteries. The control of diastolic blood pressure was equivalent in both groups, but mean systolic blood pressure was 3.5 mmHg higher in isradipine group at 6 months, a significant difference that persisted throughout the study. This might explain the higher incidence of vascular events with isradipine, although there was no difference in the rate of progression of medial intimal thickness between the groups.

Drug–Drug Interactions

Ethanol

Studies in rodents and primates have suggested that calcium channel blockers, including darodipine, nifedipine, and verapamil, can attenuate the behavioral effects of ethanol. Isradipine seems to be the most effective. However, the results of published reports in man on the effects of calcium antagonists on the acute subject-rated, performance-impairing, and cardiovascular effects of ethanol have suggested that the behavioral effects of ethanol are not attenuated by verapamil, nifedipine, or nimodipine. The same conclusions have been reached from a study in nine healthy volunteers (2). Combined ethanol and isradipine produced increases in heart rate and reductions in blood pressure that were not observed with either drug alone. Isradipine significantly reduced peak breath alcohol concentrations, but it did not significantly alter the subject-rated performance-impairing effects of ethanol.

Phenytoin

An interaction of isradipine with phenytoin has been reported (3).

- A 21-year-old white man, who was taking phenytoin and carbamazepine for seizures, developed severe lethargy, ataxia, and weakness after isradipine was prescribed for blood pressure control. The interaction was verified 2 months later, when he was rechallenged with the same dose of isradipine, 2.5 mg bd, and developed the same symptoms. Phenytoin plasma concentrations were at the upper limit of the usual target range (maximum assayed 100 μmol/l) and did not fall when the dose of phenytoin was reduced while he was taking isradipine.

Both pharmacokinetic and pharmacodynamic mechanisms can explain these observations. Isradipine inhibits CYP450 isoforms that are responsible for the metabolism of phenytoin, and both isradipine and phenytoin can bind to calcium channels in the brain and thereby affect neurological function.

Itraconazole

See also Antifungal azoles

General Information

Itraconazole is a triazole antifungal drug. It is used orally to treat oropharyngeal and vulvovaginal candidiasis, pityriasis versicolor, dermatophytoses unresponsive to topical treatment, and systemic infections, including aspergillosis, blastomycosis, chromoblastomycosis, coccidioidomycosis, cryptococcosis, histoplasmosis, paracoccidioidomycosis, and sporotrichosis. It is also used to prevent fungal infections in immunocompromised patients.

Pharmacokinetics

The systemic availability of itraconazole and the bioequivalence of single 200 mg doses of itraconazole solution and two capsule formulations have been evaluated in a crossover study in 30 male volunteers (1). Itraconazole and hydroxyitraconazole were 30–37% more available from the solution and were greater than from either capsule formulation. However, the values of C_{max}, t_{max}, and half-lives were comparable. There were no differences in safety and tolerance. The normal t_{max} of itraconazole is 1.5–4 hours and serum concentrations are dose-related. Steady-state concentrations are reached after about 10–14 days and are high in comparison with those attained after single doses. With single daily dose treatment the half-life is 20–30 hours. Itraconazole is highly protein bound. The tissue concentrations in lung, kidney, liver, bone, spleen, and muscle are 2–3 times higher than the corresponding

© 2006 Elsevier B.V. All rights reserved.

serum concentrations. Concentrations in omentum and adipose tissue are particularly high, and higher concentrations are also found in various parts of the genital tract. Itraconazole is markedly keratinophilic; after withdrawal it will take 1–2 weeks before concentrations in the skin start to fall. Itraconazole concentrations in urine, saliva, eye fluids, and cerebrospinal fluid are low. Penetration of itraconazole into ocular tissues is low compared with those of ketoconazole and fluconazole (2,3). Itraconazole is degraded in the liver and excreted via the bile and to some extent in the urine. Its metabolism is not altered by renal dysfunction (4–6).

Observational studies

The pharmacokinetics, safety, and antifungal efficacy of intravenous itraconazole (400 mg for 2 days then 200 mg for 12 days), followed by 12 weeks of oral capsules (400 mg/day) have been investigated in 31 immunocompromised patients with invasive pulmonary aspergillosis (7). All received intravenous itraconazole and 26 then took oral itraconazole for a median of 79 days. Potentially therapeutic trough plasma itraconazole concentrations of 0.5 microgram/ml or more were achieved in 64% of the patients by day 2 and were generally maintained after switching to oral therapy. There was a complete or partial response in 15 patients. There were adverse events during intravenous therapy in 28 patients, and 13 had adverse events that were possibly related to the drug. The main events (at least 10% incidence) were fever, diarrhea, increased blood urea nitrogen, and nausea. Two of these 13 patients had intravenous therapy withdrawn. There were no consistent clinically relevant changes in laboratory parameters. During oral therapy, nine patients had similar adverse events that were possibly related to itraconazole. Treatment was withdrawn in seven patients because of adverse events during this phase. There were no deaths related to itraconazole.

The pharmacokinetics and safety of intravenous itraconazole for 7 days (200 mg bd for 2 days, then 200 mg od for 5 days), followed by itraconazole oral solution 200 mg od or bd for 14 days, have been assessed in 17 patients with hematological malignancies requiring antifungal prophylaxis (8). The mean trough plasma concentration at the end of the intravenous period was 0.54 microgram/ml. This concentration was not maintained during once-daily oral treatment but increased further during twice-daily treatment, with a trough itraconazole concentration of 1.12 micrograms/ml at the end of oral treatment. All patients had some adverse events, mainly gastrointestinal. The two patients who were withdrawn from the study during intravenous treatment both reported fever; one also had pneumonitis and died from pneumonia 2 weeks after withdrawal, but this was unrelated to the drug. Patients were withdrawn during oral treatment because of fever ($n = 3$), pneumonitis ($n = 2$), colitis ($n = 1$), and abdominal pain and diarrhea ($n = 1$). Biochemical and hematological abnormalities were frequent, but there were no consistent changes.

The efficacy and safety of intermittent itraconazole therapy have been investigated in 635 patients with onychomycosis (9). Intermittent itraconazole (400 mg/day for 1 week per month for 2 months) was effective and safe. Most adverse events were minor and occurred infrequently; there were no major changes in liver function tests.

Two dosages of itraconazole have been compared in the treatment of tinea corporis or tinea cruris in a multicenter, randomized, double-blind, parallel-group study, which showed that itraconazole 200 mg for 1 week (54 patients) is similarly effective, equally well tolerated, and at least as safe as the established regimen of itraconazole 100 mg for 2 weeks (60 patients) (10). In a similar study in tinea pedis or tinea manum, itraconazole 400 mg once a week (66 patients) and itraconazole 100 mg once every 4 weeks (69 patients) were both effective; the two schedules were equally well tolerated and safe (11).

Comparative studies

Amphotericin

Data on the safety of itraconazole have been collected in an open, randomized, multicenter study in 277 adults with cancer and neutropenia (12). Itraconazole oral solution (100 mg bd, $n = 144$) was compared with a combination of amphotericin capsules and nystatin oral suspension ($n = 133$). Adverse events were reported in about 45% of patients in each group. The most frequent were vomiting (14 versus 12 patients), diarrhea (12 versus 9), nausea (5 versus 12), and rash (2 versus 13 patients). There were no differences in liver function test abnormalities. Treatment had to be withdrawn because of adverse events (including death) in 34 patients who took itraconazole and 33 of those who took amphotericin plus nystatin; there were 17 deaths in each group and death was recorded as adverse event in 13 and 9 patients, respectively.

Itraconazole (400 mg intravenously for 2 days, 200 mg intravenously for up to 12 days, then 400 mg/day orally) and intravenous amphotericin deoxycholate (0.7–1.0 mg/kg) have been compared in 384 granulocytopenic patients with persistent fever in a randomized, multicenter trial (13). The median duration of therapy was 8.5 days. The incidence of drug-related adverse events (5 versus 54%) and the rate of withdrawal due to toxicity (19 versus 38%) were significantly lower with itraconazole. The most frequent reasons for withdrawal in patients taking itraconazole were nausea and vomiting (5%), rash (3%), and abnormal liver function tests (3%). Significantly fewer of the patients who received itraconazole had nephrotoxicity (5 versus 24%); however, more had hyperbilirubinemia (10 versus 5%). There was no difference in gastrointestinal adverse events between the two groups.

Itraconazole elixir 2.5 mg/kg bd ($n = 281$) has been compared with amphotericin capsules 500 mg qds ($n = 276$) for the prophylaxis of systemic and superficial fungal infections in a double-blind, randomized, placebo-controlled, multicenter trial for 1–59 days (14). While itraconazole significantly reduced the frequency of superficial fungal infections, it was not superior in reducing invasive fungal infections or in improving mortality. Adverse events were reported in 222 patients taking itraconazole (79%) and in 205 patients taking amphotericin (74%). The commonest adverse events were gastrointestinal, followed by rash and hypokalemia, with no

© 2006 Elsevier B.V. All rights reserved.

differences between the two regimens. In both groups, 5% of the adverse events were considered to be definitely drug-related. Comparable numbers of patients in the two groups permanently stopped treatment because of adverse events (including death), 75 (27%) in the itraconazole group and 78 (28%) in the amphotericin group. Nausea (9 and 11%) and vomiting (8 and 7%) were the most frequently reported adverse events that led to withdrawal. Biochemical changes were comparable in the two groups.

Other antifungal azoles

The safety of continuous itraconazole (50–200 mg/day for up to 3 months) in the treatment of onychomycosis and dermatomycosis has been reviewed, using published and unpublished data from clinical trials (15). The overall incidence of adverse events in patients who took continuous itraconazole (21%) differed little from that in patients who took either topical miconazole or oral placebo (18%). The most frequently reported adverse events were gastrointestinal disorders (6.7%), headache (4.2%), and skin disorders (2.7%). No data were given on the incidence of serious adverse events attributed to itraconazole. Among laboratory abnormalities, clinically significant rises in liver function tests occurred in 3.4% of 527 patients treated with itraconazole (2.6% in patients treated with 50–200 mg/day for dermatomycosis versus 6.6% in patients treated with 200 mg/day for 3 months for onychomycosis).

Oral fluconazole 400 mg qds and oral itraconazole 200 mg bd have been compared in a randomized, double blind, placebo-controlled trial in 198 patients with progressive non-meningeal coccidioidomycosis (16). Overall, 57% and 72% of patients responded to 12 months of therapy with fluconazole and itraconazole, respectively. Relapse rates after withdrawal did not differ significantly. Both drugs were well tolerated. Serious adverse events occurred in eight of 97 fluconazole-treated patients and six of 101 itraconazole-treated patients. They included raised liver enzymes, gastrointestinal disturbances, hypokalemia, and skin rash. Alopecia was reported in 15 of 97 patients taking fluconazole and in only four of 101 patients taking itraconazole. Similarly, dry lips were reported in 11 of 97 patients taking fluconazole and in none of 101 patients taking itraconazole. Both adverse events have previously been reported with fluconazole.

In a double-blind comparison in oropharyngeal candidiasis in 244 patients with AIDS, itraconazole oral solution and fluconazole capsules (each 100 mg/day for 14 days) were equally efficacious; there were no significant differences in adverse effects (17).

Itraconazole oral solution and fluconazole tablets have been compared in oropharyngeal candidiasis in HIV/AIDS patients in a prospective randomized, blind, multicenter trial (18). Both regimens of itraconazole oral solution (100 mg bd for 7 days or 100 mg od for 14 days) were equivalent to fluconazole (100 mg od for 14 days). Itraconazole oral solution was well tolerated.

Oral itraconazole solution has been compared with intravenous/oral fluconazole for the prevention of fungal infections in a randomized, controlled trial in adult liver transplant recipients, who were randomized to receive either oral itraconazole solution (200 mg bd) or intravenous/oral fluconazole (400 mg/day) (19). Prophylaxis was started immediately before transplant surgery and continued for 10 weeks after transplantation. Proven fungal infection developed in nine of 97 patients given itraconazole and in four of 91 patients given fluconazole. Mortality from fungal infection was very low and occurred in only one of the 188 patients. Except for more frequent gastrointestinal adverse effects (nausea, vomiting, diarrhea) with itraconazole, both drugs were well tolerated and neither was associated with hepatotoxicity. Mean trough plasma concentrations of itraconazole were over 250 ng/ml throughout the study and were not affected by H_2 histamine receptor antagonists or antacids.

Terbinafine

Itraconazole (28 patients) and terbinafine (27 patients) have been compared in a double-blind, randomized study in tinea capitis (20). The cure rates at week 12 were 86% and 78% respectively. Adverse events were mild and did not warrant discontinuation of therapy.

Placebo-controlled studies

In a double blind, randomized, placebo-controlled, multicenter trial in plantar or moccasin-type tinea pedis in 72 patients, itraconazole 200 mg bd was significantly more effective than placebo; its safety and tolerability were comparable with placebo (21).

General adverse effects

Most of the reported adverse effects of itraconazole are transient. Gastrointestinal reactions, mild dyspepsia, pyrosis, nausea, vomiting, diarrhea, and epigastric pain are not uncommon. In many of the published reports mention is made of increases in serum liver enzyme activities and hypertriglyceridemia, and symptomatic liver toxicity has been reported. Itraconazole does not induce drug-metabolizing enzymes and is a weaker inhibitor of microsomal enzymes than ketoconazole (4,22). In rats given doses of up to 160 mg/kg, there was no induction or inhibition of the metabolism of xenobiotics (SEDA-16, 285). Hypokalemia has often been reported, without an explanation of the mechanism. The use of higher doses (400 or even 600 mg/day) causes an increased incidence of adverse effects; among those documented at these dosages are severe hypokalemia, reversible adrenal insufficiency, and (in one published case) arrhythmias, the latter being connected with an interaction with terfenadine (SEDA-16, 295) (SEDA-18, 198). Skin rashes and pruritus have been reported. Tumor-inducing effects have not been described.

In patients taking itraconazole capsules for prolonged periods the common adverse effects were nausea and vomiting (in under 10%), hypertriglyceridemia (9%), hypokalemia (6%), raised transaminases (5%), rashes and/or pruritus (2%), headache or dizziness (under 2%), and foot edema (1%) (23).

In a study using the UK General Practice Research Database to determine rates of rare, serious drug-induced, adverse effects on the liver, kidneys, skin, or blood, occurring within 45 days of completing a prescription or refill in 54 803 users of either fluconazole or

© 2006 Elsevier B.V. All rights reserved.

itraconazole, one patient had an abnormal liver function test while taking itraconazole in whom a drug-induced etiology could not be ruled out, a rate of 3.2 per 100 000 prescriptions (95% CI = 0.6, 18) for serious adverse liver effects (24). Thus, itraconazole does not commonly have serious adverse effects on the liver, kidneys, skin, or blood.

Organs and Systems

Cardiovascular

Ventricular fibrillation has been attributed to itraconazole-induced hypokalemia (25).

- Pleural and subsequent pericardial effusion developed in a woman treated with itraconazole 200 mg bd for a localized pulmonary infection with *Aspergillus fumigatus* (SEDA-18, 282). After more than 9 weeks of treatment she developed a pericardial effusion, which necessitated drainage. Itraconazole was withdrawn. Six weeks later, and 2 weeks after the resumption of itraconazole, she developed signs of pulmonary edema and cardiac enlargement. These signs disappeared rapidly on discontinuation of itraconazole.

Studies in dogs and healthy human volunteers have suggested that itraconazole has a negative inotropic effect; the mechanism is unknown. A systematic analysis of data from the FDA's Adverse Event Reporting System (AERS) identified 58 cases suggestive of congestive heart failure in patients taking itraconazole (26). A simultaneous search did not identify any cases of congestive heart failure in patients taking fluconazole and ketoconazole, ruling out the possibility of a class effect. In consequence, the labeling of itraconazole has been revised. Itraconazole is now contraindicated for the treatment of onychomycosis in patients with evidence of ventricular dysfunction. For systemic fungal infections, the risks and benefits of itraconazole should be reassessed if signs or symptoms of congestive heart failure develop.

Nervous system

Headache due to itraconazole has been mentioned in some reports (27). Dizziness is an uncommon complaint, as are mood disturbances.

Psychological, psychiatric

Visual hallucinations with confusion have been reported in a 75-year-old woman, occurring on three separate occasions, each time about 2 hours after a 200 mg dose of itraconazole. Her symptoms abated spontaneously over about 8 hours (28).

Electrolyte balance

Hypokalemia, occurring either in isolation or with hypertension, has been reported regularly in a small fraction of patients (23). Marked ankle edema with weight gain was seen in a patient taking itraconazole 400 mg/day, in whom there was no explanation other than the use of the drug; after withdrawal of the itraconazole the symptoms disappeared. Hypokalemia and edema have also been observed in a number of patients taking high-dose therapy (600 mg/day) (SED-12, 680) (29) (SEDA-16, 295) (SEDA-17, 321) (4,25,29,30), associated with mildly depressed aldosterone concentrations (SED-12, 680) (SEDA-16, 295).

Gastrointestinal

Dyspepsia, pyrosis, nausea, vomiting, mild epigastric discomfort, and diarrhea can occur in patients taking itraconazole (31). These gastrointestinal complaints are generally mild, but they seem to be the most frequent adverse effects during treatment. The total incidence of adverse effects was 3–5% in patients treated for superficial mycosis and 8% in 99 patients treated for deep mycosis (SED-12, 680) (32). An incidence closer to 15% was reported in a multicenter trial (SEDA-17, 321).

In 50 women with acute vaginal candidiasis, adverse effects were reported in 17 (35%), nausea in seven, headache in six, dizziness in three, and bloating in three, while aspartate transaminase activity was raised in one (33).

Of 1108 patients with HIV treated for mucosal candidiasis, 239 reported gastrointestinal symptoms (34).

Pseudomembranous colitis has been reported in association with exposure to itraconazole (35).

- A 54-year-old man developed new abdominal pain and non-bloody diarrhea 1 month after exposure to a 7-day course of oral itraconazole 200 mg/day. He was taking stable chronic sertraline, valproic acid, and perphenazine, and had not taken antimicrobial drugs for 6 months. Flexible sigmoidoscopy after clinical progression showed pseudomembranes, and subsequent evaluation excluded other causes of diarrhea. Although *Clostridium difficile* culture and toxin assay were eventually negative, possibly because of delayed stool sampling, he responded to a 10-day course of anti-anaerobic drug therapy and was discharged with completely resolved symptoms.

The authors proposed that itraconazole had disrupted the resident fungal flora of the colon.

Liver

In most clinical reports, there were some cases of raised liver enzyme activities; the changes were transient or disappeared after withdrawal of itraconazole (36). More serious hepatotoxicity was not reported.

- Focal nodular hyperplasia of the liver has been reported in a 38-year-old woman who had taken itraconazole 200 mg/day for 4 months for a fungal infection of the fingernails (37). She had taken no other drugs in the year during which focal nodular hyperplasia developed.
- Of three patients, two women aged 62 and 57 and a man aged 75 years, who developed symptomatic hepatic injury 5–6 weeks after starting to take itraconazole, two had the biochemical pattern of cholestatic liver damage (38).

All itraconazole clinical trials sponsored by Janssen Research Foundation for the treatment of onychomycosis, in which there was an assessment of laboratory safety, have been analysed (39). There were no significant differences in the number of code 4 abnormalities (baseline

© 2006 Elsevier B.V. All rights reserved.

value is in the reference range and at least two values, or the last testing in the observation period, exceed twice the upper limit of the reference range) in liver function tests (alanine transaminase, aspartate transaminase, alkaline phosphatase, and total bilirubin). The incidence of all the code 4 abnormalities was under 2%. Itraconazole pulse therapy for onychomycosis appears to be safe, especially from the perspective of potential liver damage. In the itraconazole package insert, liver function tests are recommended in patients receiving continuous itraconazole for over 1 month. There is no such monitoring requirement for the pulse regimen, unless the patient has a history of underlying hepatic disease, the liver function tests are abnormal at baseline, or signs or symptoms suggestive of liver dysfunction develop at any time.

Skin

Different types of rash, including a case of acneiform rash, have been reported in patients taking itraconazole. In one case there were bloody bullae (SED-12, 680) (40–43).

- A 29-year-old man developed an infiltrative maculopapular eruption after 1 week of itraconazole 100 mg bd for tinea corporis (44). Itraconazole was withdrawn, and the lesions disappeared within 7 days. Scratch tests, patch tests, scratch-patch tests, and drug induced lymphocyte stimulation tests for itraconazole were negative; however, rechallenge with systemic itraconazole induced a maculopapular eruption on the face, hands, and the dorsa of the feet. Empty itraconazole capsules had no cutaneous effects, suggesting an allergic reaction to a metabolite of the compound.

Photosensitivity has been attributed to itraconazole (200 mg qds for 5 days), with reduced minimal erythema dose for both UVB (0.12 J/cm^2) and UVA (20.1 J/cm^2), negative photopatch testing, and a positive photochallenge (45). The authors proposed a photoallergic mechanism because earlier exposure to itraconazole had been uneventful. However, details about sun exposure during the first exposure and about the intensity of sun exposure during the oral photochallenge procedure were not given. The eruption responded to oral steroids, which is more typical of photoallergic than phototoxic reactions.

The risk of serious skin disorders has been estimated in 61 858 users of oral antifungal drugs, aged 20–79 years, identified in the UK General Practice Research Database (46). They had received at least one prescription for oral fluconazole, griseofulvin, itraconazole, ketoconazole, or terbinafine. The background rate of serious cutaneous adverse reactions (corresponding to non-use of oral antifungal drugs) was 3.9 per 10 000 person-years (95% CI = 2.9, 5.2). Incidence rates for current use were 15 per 10 000 person-years (1.9, 56) for itraconazole, 11.1 (3.0, 29) for terbinafine, 10 (1.3, 38) for fluconazole, and 4.6 (0.1, 26) for griseofulvin. Cutaneous disorders associated with the use of oral antifungal drugs in this study were all mild.

Sexual function

There are inconsistent reports about the effects of itraconazole on sex steroids. Concentrations of testosterone, corticosterone, and progesterone were unchanged in rats and in six dogs in whom possible endocrine effects were studied (SED-12, 680). On the other hand, the administration of itraconazole to seven male volunteers for 2 weeks did not produce detectable changes in plasma testosterone or cortisol concentrations. There was a slightly reduced cortisol response to ACTH stimulation 2 weeks after the start of high-dose itraconazole therapy (600 mg/day) in one of eight patients with severe mycosis (29).

Erectile impotence, with normal steroid concentrations, has been reported, as has a reduction in libido (SEDA-17, 321) (47).

Immunologic

Itraconazole 200 mg bd for 2 weeks caused a serum sickness-like reaction in a 53-year-old woman with Menière's disease (48).

Second-Generation Effects

Teratogenicity

Since embryotoxicity and teratogenicity have been found in rats, albeit after the administration of high doses, itraconazole should be avoided during pregnancy (SED-12, 681) (49).

Susceptibility Factors

Age

The safety, tolerability, and pharmacokinetics of itraconazole and its active metabolite hydroxyitraconazole after administration of itraconazole solution in hydroxypropyl-β-cyclodextrin have been investigated in a multicenter study in 26 infants and children aged 6 months to 12 years with mucosal candidiasis or at risk of invasive fungal disease (50). There was a trend to lower minimum plasma concentrations in children aged 6 months to 2 years. The systemic absorption of the solubilizer hydroxypropyl-β-cyclodextrin was less than 1%. Given at 5 mg/kg/day, this formulation provided potentially therapeutic concentrations in plasma, somewhat lower than those attained in adults, and it was well tolerated and safe.

Itraconazole 100 mg/day has been studied in 24 children with *Trichophyton tonsurans* tinea capitis (51). Itraconazole was well tolerated, but 15 children required re-treatment due to persistent infection.

The safety, pharmacokinetics, and pharmacodynamics of an oral suspension of cyclodextrin itraconazole (2.5 mg /kg od or bd for 15 days) have been investigated in an open, sequential, dose-escalation study in 26 children and adolescents, 5–18 years old, infected with HIV (mean CD4 count 128 $\times$ 10^6/l) with oropharyngeal candidiasis (52). Apart from mild to moderate gastrointestinal disturbances in three patients, cyclodextrin itraconazole was well tolerated. Two patients withdrew prematurely because of adverse events. The oropharyngeal candidiasis score fell significantly from a mean of 7.46 at baseline to 2.8 at the end of therapy, demonstrating antifungal efficacy in this setting. Based on these results, a dosage of 2.5 mg/kg bd was recommended for the treatment of oropharyngeal candidiasis in children aged 5 years and over.

© 2006 Elsevier B.V. All rights reserved.

The safety and efficacy of oral cyclodextrin itraconazole (5 mg/kg/day) as antifungal prophylaxis has been assessed in an open trial in 103 neutropenic children (median age 5 years; range 0–15 years) (53). Prophylaxis was started at least 7 days before the onset of neutropenia and continued until neutrophil recovery. Of the 103 patients, only 47 completed the course of prophylaxis; 27 withdrew because of poor compliance, 19 because of adverse events, and 10 for other reasons. Serious adverse events (other than death) occurred in 21 patients, including convulsions ($n = 7$), suspected drug interactions ($n = 6$), abdominal pain ($n = 4$), and constipation ($n = 4$). The most common adverse events considered definitely or possibly related to itraconazole were vomiting ($n = 12$), abnormal liver function ($n = 5$), and abdominal pain ($n = 3$). Tolerability of the study medication at end-point was rated as good (55%), moderate (11%), poor (17%), or unacceptable (17%). There were no unexpected problems of safety or tolerability.

Other features of the patient

Adverse effects due to drug–drug interactions are not expected in diabetic patients using insulin and oral hypoglycemic drugs that are not metabolized by CYP3A4 (for example tolbutamide, gliclazide, glibenclamide, glipizide, and metformin). The pharmacokinetic and safety data from clinical trials and postmarketing surveillance have been reviewed to assess the safety of itraconazole in diabetic patients with onychomycosis or dermatomycosis (54). Postmarketing surveillance, including all adverse event reports in patients taking itraconazole concomitantly with insulin or an oral hypoglycemic drug, revealed 15 reports suggestive of hyperglycemia and nine reports suggestive of hypoglycemia. In most patients there was no change in antidiabetic effect. From clinical trials in 189 diabetic patients taking itraconazole for various infections, one itraconazole-related adverse event was recorded; this was a case of aggravated diabetes in a renal transplant patient who was also taking ciclosporin.

Drug Administration

Drug formulations

Itraconazole is poorly soluble in water and highly lipophilic. It is available as capsules, as oral and parenteral solutions that both contain hydroxypropyl-β-cyclodextrin as a solubilizer.

Absorption of itraconazole from capsules depends on a low gastric pH and is reduced by fasting and improved by the presence of food and acidic beverages; it is unpredictable in patients with hypochlorhydria. The t_{max} occurs at 1.5–2 hours. When polyethylene glycol is used as a solvent, the absorption is not as good. Inadequate plasma concentrations are often found in patients receiving cytotoxic drug therapy, which predisposes them to mucositis, poor food intake, and vomiting. The absorption of oral itraconazole seems to be reduced in patients with AIDS (2,3).

Systemic absorption of the cyclodextrin carrier after oral administration is negligible. After intravenous administration the cyclodextrin is not metabolized and is almost completely eliminated by glomerular filtration within 24 hours. Although the cyclodextrin enhances the systemic availability of itraconazole, it can have gastrointestinal adverse effects when used in escalating dosages exceeding 400 mg/day.

A dose-ranging study of itraconazole in antifungal prophylaxis in 123 neutropenic patients with hematological malignancies has been reported (55). The dosing regimens included itraconazole capsules 400, 600, or 800 mg/day and itraconazole cyclodextrin solution 400 and 800 mg/day (with an additional loading with 800 mg of the capsule formulation for 7 days). Ten of twenty-eight patients taking 800 mg/day as a solution withdrew after 1–6 days with severe nausea and vomiting in temporal relation to ingestion of the drug. All the patients who discontinued the solution continued medication with itraconazole capsules in the same dosage without gastrointestinal adverse effects.

Drug–Drug Interactions

Amphotericin

The in vitro effects of the combination of amphotericin with itraconazole was tested using six strains of *A. fumigatus*, and an antagonistic effect was found after pretreatment for all strains in vitro and for one strain in a mouse model of aspergillosis (56).

The effect of the combination of itraconazole with amphotericin on liver enzyme activities has been studied retrospectively in 20 patients with hematological malignancies or chronic lung disease complicated by fungal infection or colonization (57). They took itraconazole 200–600 mg/day for a median of 143 (range 44–455) days. Nine had no abnormal liver function tests, including periods of high concentrations of itraconazole (over 5000 ng/ml) and its active hydroxylated metabolite; only one had received concomitant amphotericin. All of the 11 patients with liver function abnormalities had received concomitant amphotericin. For each patient, liver function abnormalities were greatest during the time of concomitant therapy with both antifungal drugs. Although liver enzyme abnormalities are uncommon with amphotericin (58), and although this retrospective analysis was subject to several flaws and potential biases, it nevertheless suggests that hepatotoxicity should be carefully monitored if itraconazole and amphotericin are co-administered.

Antihistamines

It seems likely that combining itraconazole with astemizole (59) and terfenadine (60,61) will lead to increased effects of these antihistamines (62).

Barbiturates

Barbiturates lower itraconazole concentrations (SED-12, 681) (4,22).

Benzodiazepines

The effect of itraconazole on the single oral dose pharmacokinetics and pharmacodynamics of estazolam has been studied in a double-blind, randomized, crossover study in

© 2006 Elsevier B.V. All rights reserved.

10 healthy male volunteers, who took oral itraconazole 100 mg/day or placebo for 7 days and on day 4 a single oral dose of estazolam 4 mg (63). Blood samplings and evaluation of psychomotor function by the Digit Symbol Substitution Test, Visual Analogue Scale, and Stanford Sleepiness Scale were conducted up to 72 hours after estazolam. There was no significant difference between the placebo and itraconazole phases in peak plasma concentration, clearance, and half-life. Similarly, psychomotor function was unaffected. These findings suggest that CYP3A4 is not involved to a major extent in the metabolism of estazolam.

In a study of the effects of itraconazole 200 mg/day and rifampicin 600 mg/day on the pharmacokinetics and pharmacodynamics of oral midazolam 7.5–15 mg during and 4 days after the end of the treatment, switching from inhibition to induction of metabolism caused an up to 400-fold change in the AUC of oral midazolam (64).

Bupivacaine

The interaction of itraconazole 200 mg orally od for 4 days with a single intravenous dose of racemic bupivacaine (0.3 mg /kg given over 60 minutes) has been examined in a placebo-controlled crossover study in 10 healthy volunteers (65). Itraconazole reduced the clearance of *R*-bupivacaine by 21% and that of *S*-bupivacaine by 25%, but had no other significant effects on the pharmacokinetics of the enantiomers. Reduction of bupivacaine clearance by itraconazole is likely to increase steady-state concentrations of bupivacaine enantiomers by 20–25%, and this should be taken into account in the concomitant use of itraconazole and bupivacaine.

Buspirone

The interaction of itraconazole with the active 1-(2-pyrimidinyl)-piperazine metabolite of buspirone has been studied after a single oral dose of buspirone 10 mg (66). Itraconazole reduced the mean AUC of the metabolite by 50% and the C_{max} by 57%, whereas the mean AUC and C_{max} of the parent drug were increased 14.5-fold and 10.5-fold respectively. Thus, itraconazole caused relatively minor changes in the plasma concentrations of the active piperazine metabolite of buspirone, although it had major effects on the concentrations of buspirone after a single oral dose.

Busulfan

Reduced elimination and increased toxicity of busulfan co-administered with itraconazole has been postulated (67).

Carbamazepine

Low and sometimes very low serum concentrations of itraconazole have been seen during concurrent therapy of itraconazole with carbamazepine (68).

Ciclosporin

The combination of itraconazole with ciclosporin leads to a marked increase in blood ciclosporin concentrations, and this can result in a rise in serum creatinine, clearly pointing to renal damage as a result of the high ciclosporin concentrations (SED-12, 681) (69,70–72). However, an interaction has not been demonstrated in all cases (73).

Two cases of rhabdomyolysis caused by itraconazole in heart transplant recipients taking long-term ciclosporin and simvastatin have been reported (74,75). To avoid severe myopathy, ciclosporin concentrations should be monitored frequently and statins should be withdrawn or the dosage should be reduced, as long as azoles need to be prescribed in transplant recipients. Patients need to be educated about signs and symptoms that require immediate physician intervention.

Citrate-phosphate buffer

The citrate-phosphate buffer used to facilitate the absorption of dideoxyinosine (didanosine), prescribed for the treatment of AIDS, may interfere with the absorption of itraconazole (76).

Clarithromycin

A report of three HIV-negative patients has suggested that concomitant therapy with itraconazole and clarithromycin can lead to increased clarithromycin exposure, with an increased metabolic ratio, possibly related to itraconazole's effect on CYP3A4 (77). Nevertheless, in none of the three reported individuals were there adverse effects from this presumed interaction.

Clozapine

Itraconazole 200 mg had no significant effect on serum concentrations of clozapine 200–550 mg/day or desmethylclozapine in 7 schizophrenic patients (78).

Digoxin

Itraconazole inhibits the elimination of digoxin, eventually leading to toxicity (4,79–82) (SEDA-18, 198).

Itraconazole increases the digoxin $AUC_{0–72}$ by about 50%, and reduces its renal clearance by about 20% (83). Apart from inhibition of the renal secretion of digoxin, which is probably mediated by inhibition of P glycoprotein, a study in guinea pigs also showed significantly reduced biliary excretion of digoxin by itraconazole, suggesting that the interaction between itraconazole and digoxin may not only be due to a reduction in renal clearance, but also to a reduction in the metabolic clearance of digoxin by itraconazole (84).

The importance of this interaction has been emphasized by a report of two renal transplant patients who had digoxin toxicity when they took itraconazole concurrently (85).

Famotidine

Famotidine 40 mg/kg/day reduced the peak and trough concentrations of itraconazole 200 mg/kg/day by about 35% in 18 patients undergoing chemotherapy for hematological malignancies (86).

Fentanyl

Fentanyl is a substrate of CYP3A4, CYP2C9, and CYP2C19. However, in one study, the pharmacokinetics

© 2006 Elsevier B.V. All rights reserved.

and pharmacodynamics of fentanyl 3 micrograms/kg were similar after itraconazole 200 mg and placebo in 10 healthy volunteers (87).

- An interaction of itraconazole with fentanyl has been reported in a 67-year-old man with cancer on a stable dose of transdermal fentanyl 50 micrograms/hour (88). He took itraconazole 200 mg bd for oropharyngeal candidiasis, and 24 hours later developed signs of opioid toxicity, which was reversed by withdrawal of fentanyl and replacement with short-acting opioids.

This may be an interaction to which only some individuals are susceptible.

Flucytosine

The activity of itraconazole against black fungi can be augmented by combining it with flucytosine; the combination has prevented the development of flucytosine resistance (89).

Glucocorticoids

Itraconazole can inhibit the metabolic clearance of glucocorticoids by interfering with CYP3A4 and can directly inhibit steroidogenesis, thereby causing serious adverse effects. The effects on different glucocorticoids differ.

Budesonide

Two patients with cystic fibrosis developed profound adrenal failure and impairment of inhaled steroid clearance, resulting in paradoxical Cushing's syndrome, after long-term treatment with itraconazole and inhaled budenoside (90,91). Pituitary–adrenal axis and gonadal function was then assessed in 37 patients treated with itraconazole with or without budesonide (92). An adrenocorticotropic hormone (ACTH) test (tetracosactide 250 micrograms) was performed in 25 patients with cystic fibrosis taking itraconazole and budesonide and in 12 patients taking itraconazole alone (6 with cystic fibrosis and 6 with chronic granulomatous disease). Mineralocorticoid and gonadal steroid function were evaluated by measurements of plasma renin activity and follicle-stimulating hormone, luteinizing hormone, progesterone, estradiol, testosterone, and serum inhibin A and B concentrations. ACTH tests performed as part of a pretransplantation program in a further 30 patients with cystic fibrosis were used as controls. Eleven of the twenty-five patients who took both itraconazole and budesonide had adrenal insufficiency. None of the patients taking itraconazole alone and none of the control patients with cystic fibrosis had an abnormal ACTH test. Mineralocorticoid or gonadal insufficiency was not observed in any patient. Only one patient with an initial pathological ACTH test subsequently normalized; the other 10 patients improved but had not achieved normal adrenal function 2–10 months after itraconazole had been withdrawn.

The effects of itraconazole on the pharmacokinetics and cortisol-suppressing activity of budesonide by inhalation were further investigated in a randomized, double-blind, two-phase, crossover study in 10 healthy subjects who took oral itraconazole 200 mg/day or placebo for 5 days (93). On day 5, 1 hour after the last dose of itraconazole or placebo, they took budesonide 1000 micrograms by inhalation. Plasma budesonide and cortisol concentrations were measured up to 23 hours. Itraconazole increased the mean total AUC of inhaled budesonide 4.2-fold (range 1.7–9.8) and the peak plasma concentration 1.6-fold compared with placebo. The mean half-life of budesonide was prolonged from 1.6 to 6.2 hours. The suppression of cortisol production after inhalation of budesonide was significantly increased by itraconazole compared with placebo, with a 43% reduction in the AUC of plasma cortisol from 0.5 to 10 hours and a 12% reduction in the cortisol concentration measured 23 hours after budesonide, at 8 a.m. Thus, itraconazole markedly increased the systemic exposure to inhaled budesonide. This interaction resulted in enhanced systemic effects of budesonide, as shown by suppression of cortisol production.

Dexamethasone

Itraconazole markedly increases both systemic exposure to dexamethasone and its effects. This interaction has been investigated in a randomized, double-blind, placebo-controlled, crossover study (94). Eight healthy volunteers took either oral itraconazole 200 mg od or placebo for 4 days. On day 4, each subject was given oral dexamethasone 4.5 mg or intravenous dexamethasone sodium phosphate 5.0 mg. Itraconazole reduced the systemic clearance of intravenous dexamethasone by 68%, and increased its AUC and prolonged its half-life more than three-fold; the AUC of oral dexamethasone was increased nearly four-fold and its half-life nearly three-fold. Morning plasma cortisol concentrations at 47 and 71 hours after dexamethasone were significantly lower after itraconazole than placebo.

Methylprednisolone

The interaction of itraconazole with oral methylprednisolone has been examined in a randomized, double-blind, crossover study in 10 healthy volunteers taking either oral itraconazole 200 mg/day or placebo for 4 days (95). On day 4 each subject took methylprednisolone 16 mg. Itraconazole increased the total AUC of methylprednisolone 3.9-fold compared with placebo, the peak plasma methylprednisolone concentration 1.9-fold, and the half-life 2.4-fold. This effect was probably through inhibition of CYP3A4.

Similar effects were found in a study of the effects of itraconazole on the kinetics of intravenous methylprednisolone in a double-blind, randomized, crossover study in nine healthy volunteers (96). Itraconazole (200 mg for 4 days) increased the AUC of methylprednisolone (16 mg on day 4) 2.6-fold, and the $AUC_{12–24}$ 12-fold. The systemic clearance of methylprednisolone was reduced to 40% by itraconazole and the half-life was increased from 2.1 to 4.8 hours. The mean morning plasma cortisol concentration was only 9% of that during the placebo phase. Thus, concomitant itraconazole greatly increased exposure to methylprednisolone during the night-time and led to enhanced adrenal suppression.

The effects of oral itraconazole (400 mg on the first day, then 200 mg/day for 3 days) on the pharmacokinetics of a single oral dose of methylprednisolone 48 mg have

© 2006 Elsevier B.V. All rights reserved.

been studied in 14 healthy men in a two-period, crossover study (97). Plasma cortisol concentrations were determined as a pharmacodynamic index. Itraconazole significantly increased the mean AUC of methylprednisolone from 2773 to 7011 hours.ng/ml and the half-life from 3.2 to 5.5 hours. Cortisol concentrations at 24 hours were significantly lower after the administration of methylprednisolone with itraconazole than after methylprednisolone alone (24 versus 109 ng/ml).

Prednisolone

The effects of oral itraconazole (400 mg on the first day then 200 mg/day for 3 days) on the pharmacokinetics of a single oral dose of prednisolone 60 mg or methylprednisolone 48 mg have been studied in 14 healthy men in a two-period, crossover study (97). Plasma cortisol concentrations were determined as a pharmacodynamic index. The disposition of prednisolone was unchanged.

The effects of itraconazole on the pharmacokinetics and pharmacodynamics of oral prednisolone have been investigated in a double-blind, randomized, crossover study (98). Ten healthy subjects took either oral itraconazole 200 mg od or placebo for 4 days. On day 4 they took oral prednisolone 20 mg. Itraconazole increased the plasma AUC of prednisolone by 24% and its half-life by 29% compared with placebo. The peak plasma concentration and time to the peak of prednisolone were not affected. Itraconazole reduced the mean morning plasma cortisol concentration, measured 23 hours after prednisolone, by 27%.

The minor interaction of itraconazole with oral prednisolone is probably of limited clinical significance. The susceptibility of prednisolone to interact with CYP3A4 inhibitors is considerably smaller than that of methylprednisolone, and itraconazole and probably also other inhibitors of CYP3A4 can be used concomitantly with prednisolone without marked interaction.

Grapefruit juice

The effect of grapefruit juice on the systemic availability of itraconazole capsules has been investigated in a randomized, two-way, crossover design in 11 healthy volunteers (99). Grapefruit juice reduced the mean itraconazole $AUC_{0–48}$ by 43% and the mean hydroxyitraconazole $AUC_{0–72}$ by 47%. Grapefruit juice also significantly delayed the mean itraconazole t_{max} from 4 to 5.5 hours. The mechanisms for the impaired absorption of itraconazole in the presence of grapefruit juice remain to be elucidated; however, grapefruit juice is acidic and an inhibitor of CYP3A4.

Unexpectedly, in another study, grapefruit juice did not affect the pharmacokinetics of itraconazole in 22 healthy men while orange juice reduced the C_{max}, t_{max}, and AUC (100).

Haloperidol

The effects of itraconazole 200 mg/day for 7 days on the steady-state plasma concentrations of haloperidol and its reduced metabolite have been investigated in schizophrenic patients receiving haloperidol 12 or 24 mg/day (101). Itraconazole significantly increased trough plasma concentrations of both haloperidol and reduced haloperidol (17 versus 13 ng/ml and 6.1 versus 4.9 ng/ml respectively). There was no change in clinical symptoms, but neurological adverse effects of haloperidol were significantly increased during itraconazole co-administration. Similar findings in a similar study were reported for bromperidol and its reduced metabolite, although there were no differences in clinical symptoms or neurological adverse effects during concomitant itraconazole therapy (102).

Omeprazole

In 11 healthy volunteers, omeprazole 40 mg reduced the systemic availability of itraconazole 200 mg; these two drugs should therefore not be used together (103).

Oral contraceptives

Itraconazole can delay withdrawal bleeding in women using oral contraceptives (104). An analysis using data from a spontaneous adverse drug reaction reporting system in the Netherlands and logistic regression analysis showed an odds ratio of 85 (CI = 32, 230) for delayed withdrawal bleeding in women who used both drugs concomitantly compared with woman who used neither oral contraceptives nor itraconazole. Nine of the ten reports of delayed withdrawal bleeding concerned oral contraceptives containing desogestrel. In an open, crossover study in 10 young healthy subjects, fluconazole 150 mg increased the serum concentrations of ethinylestradiol at a close of 30–35 micrograms/day (105).

Phenytoin

Low and sometimes very low serum concentrations of itraconazole have been seen during concurrent therapy of itraconazole with phenytoin (68). At the same time, phenytoin concentrations may themselves be lowered when it is used with itraconazole (68).

Quinidine

In vitro studies have suggested that the oxidation of quinidine to 3-hydroxyquinidine is a specific marker reaction for CYP3A4 activity. In six healthy young men the pharmacokinetics of a single oral dose of quinidine 200 mg were studied before and during daily administration of itraconazole 100 mg (106). Itraconazole reduced quinidine total clearance, partial clearance by 3-hydroxylation, and partial clearance by *N*-oxidation by 61, 84, and 73% respectively.

Rifamycins

Rifampicin 600 mg/day for 14 days had a very strong inducing effect on the metabolism of a single dose of itraconazole 200 mg, indicating that these two drugs should not be used concomitantly (107).

Ropivacaine

The effects of clarithromycin (250 mg bd) and itraconazole (200 mg od) for 4 days on the pharmacokinetics of ropivacaine (given intravenously as a single dose of 0.6 mg/kg on day 4) have been studied in a double-blind, three-way, crossover study in eight healthy volunteers (108). There were no significant changes in the

© 2006 Elsevier B.V. All rights reserved.

pharmacokinetics of ropivacaine after clarithromycin or itraconazole. Although clarithromycin and itraconazole inhibited formation of the (*S*)-2′,6′-pipelodoxylidide metabolite of ropivacaine, there were no significant changes in the pharmacokinetics of ropivacaine itself.

Saquinavir

The HIV protease inhibitor saquinavir has limited and variable oral systemic availability and ritonavir, an inhibitor of CYP450 and P glycoprotein, is widely used to increase its systemic exposure. A small pilot study in three HIV-infected patients has suggested that oral itraconazole can have similar effects on the oral availability of saquinavir (109). Concomitant use of itraconazole 200 mg/day with a combination of saquinavir and two nucleoside reverse transcriptase inhibitors led to a 2.5- to 6.9-fold increase in the AUC of saquinavir, a 2.0- to 5.4-fold increase in peak plasma concentrations, and a 1.6- to 17-fold increase in trough plasma concentrations. The effect of itraconazole on saquinavir was comparable to that of ritonavir.

Selegiline

The effects of itraconazole (200 mg/day for 4 days) on the pharmacokinetics of selegiline (10 mg on day 4) have been investigated in a randomized, placebo-controlled, crossover study (110). Itraconazole did not alter the pharmacokinetics of selegiline and its primary metabolites, desmethylselegiline and 1-metamfetamine. In human liver microsomes, itraconazole did not inhibit the formation of either metabolite. These findings suggest that selegiline is not susceptible to interactions with CYP3A4 inhibitors.

Statins

Itraconazole increases the risk of skeletal muscle toxicity of some statins by increasing their serum concentrations, but not all statins are equally affected. Concomitant use of atorvastatin, lovastatin, and simvastatin with itraconazole should be avoided or the doses should be reduced; fluvastatin and pravastatin have much less potential than other statins for clinically significant interactions with itraconazole and other CYP3A4 inhibitors; the effects of cerivastatin are intermediate.

In a randomized, open, three-way, crossover study, 18 healthy subjects took single doses of cerivastatin 0.8 mg, atorvastatin 20 mg, or pravastatin 40 mg without or with itraconazole 200 mg (111). Concomitant cerivastatin + itraconazole and pravastatin + itraconazole produced small increases in AUC, C_{max}, and half-life (up to 51%, 25%, and 23% respectively). However, itraconazole markedly increased atorvastatin AUC (150%), C_{max} (38%), and half-life (30%). Thus, itraconazole markedly increases systemic exposure to atorvastatin, but results in only modest increases in the plasma concentrations of cerivastatin and pravastatin.

Atorvastatin

Itraconazole increases serum concentrations of atorvastatin by inhibiting CYP3A4. In a randomized, double-blind, crossover study in 10 healthy volunteers, itraconazole 200 mg increased the AUC and half-life of atorvastatin 40 mg about three-fold, with a change in C_{max} (112). The AUC of atorvastatin lactone was increased about 4-fold, and the C_{max} and half-life were increased more than 2-fold. Itraconazole significantly reduced the C_{max} and AUC of 2-hydroxyatorvastatin acid and 2-hydroxyatorvastatin lactone and increased the half-life of 2-hydroxyatorvastatin lactone. The concomitant use of itraconazole and other potent inhibitors of CYP3A4 with atorvastatin should therefore be avoided, or the dose of atorvastatin should be reduced accordingly.

Cerivastatin

Cerivastatin uses a secondary CYP2C8-mediated metabolic pathway, which is unaffected by itraconazole (113). The effects of itraconazole on the pharmacokinetics of cerivastatin and its major metabolites have been investigated in a randomized, double-blind, crossover study (114). Inhibition of the CYP3A4-mediated M-1 pathway led to raised serum concentrations of cerivastatin, cerivastatin lactone, and metabolite M-23, resulting in increased concentrations of active HMG-CoA reductase inhibitors. However, the effect was modest.

Fluvastatin

The effects of itraconazole 100 mg on the pharmacokinetics of fluvastatin 40 mg have been studied in a randomized, placebo-controlled, crossover study in 10 healthy volunteers (115). Itraconazole had no significant effect on the C_{max} or total AUC of fluvastatin, but slightly prolonged its half-life.

Lovastatin

The effects of itraconazole 100 mg on the pharmacokinetics of lovastatin 40 mg have been studied in a randomized, placebo-controlled, crossover study in 10 healthy volunteers (115). Itraconazole, even in this low dosage, greatly increased plasma concentrations of lovastatin and its active metabolite, lovastatin acid, and increased the C_{max} of lovastatin about 15-fold and the total AUC by more than 15-fold; similarly, the C_{max} and total AUC of lovastatin acid were increased about 12-fold and 15-fold respectively.

Pravastatin

The effects of itraconazole 200 mg on the pharmacokinetics of pravastatin have been studied in a randomized, double-blind, crossover study in 10 healthy volunteers (116). Itraconazole slightly increased the AUC and C_{max} of pravastatin, but the changes were not statistically significant; the half-life was not altered.

Simvastatin

The effects of itraconazole 200 mg on the pharmacokinetics of simvastatin have been studied in a randomized, double-blind, crossover study in 10 healthy volunteers (116). Itraconazole increased the C_{max} and AUC of simvastatin and simvastatin acid at least 10-fold. The C_{max} and AUC of total simvastatin acid (naive simvastatin acid plus that derived by hydrolysis of the lactone) were

© 2006 Elsevier B.V. All rights reserved.

increased 17-fold and 19-fold respectively, and the half-life was increased by 25%.

In two cases, rhabdomyolysis was caused by itraconazole in heart transplant recipients taking long-term ciclosporin and simvastatin (74,75). To avoid severe myopathy, ciclosporin concentrations should be monitored frequently and statins should be withdrawn or the dosage should be reduced, as long as azoles need to be prescribed in transplant recipients. Patients need to be educated about signs and symptoms that require immediate physician intervention.

Tacrolimus

Tacrolimus concentrations and toxicity are affected by itraconazole (117).

- In a 17-year-old man with cystic fibrosis who received a hepato-pulmonary transplant, there was an interaction of itraconazole 600 mg bd with tacrolimus (118). High trough concentrations of tacrolimus were noted, despite the relatively low dosage (0.1–0.3 mg/kg/day).
- Another patient experienced an interaction of tacrolimus 0.085 mg /kg bd with itraconazole 200–400 mg per day, with resulting ketoacidosis, neutropenia, and thrombocytopenia, requiring the withdrawal of both drugs (119).
- A 30-year-old man with a renal transplant had a more than two-fold increase in blood tacrolimus concentrations after starting to take itraconazole 200 mg/day, accompanied by a reduced glomerular filtration rate and biopsy-proven tacrolimus-associated tubulopathy (120).

Because of the narrow therapeutic index of tacrolimus, blood concentrations should be monitored particularly carefully when itraconazole is co-administered, and the dosage of tacrolimus may have to be altered (121).

The interaction of itraconazole (100 mg bd) with tacrolimus has been studied in 28 heart or lung transplant recipients (122). Tacrolimus blood concentrations were monitored on alternate days for up to 21 days after the start of itraconazole therapy ($n = 18$) or withdrawal ($n = 10$). The dose of tacrolimus was adjusted with the aim of keeping the 12-hour trough blood concentration at 7–12 micrograms/ml. The mean dose of tacrolimus during itraconazole therapy fell significantly from 8.4 to 2.9 mg/day. There was no significant change in serum creatinine or liver function tests. In patients in whom itraconazole was withdrawn, the mean dose of tacrolimus required increased significantly from 4.7 to 8.8 mg/day. Thus, substantial changes in the dose of tacrolimus were required both when itraconazole was begun and when it was withdrawn, and it was difficult to maintain tacrolimus blood concentrations within the target range during the first 2 weeks. However, major toxicity or rejection did not occur. Co-administration of itraconazole may reduce the cost of post-transplant immunosuppression. This interaction is probably due to inhibition of CYP3A4 by itraconazole.

Vinca alkaloids

Enhanced and potentially life-threatening neurotoxicity of vinca alkaloids through concomitant therapy with itraconazole has been the subject of several compelling reports (123–126). Enhancement of vincristine neurotoxicity results in polyneuropathy and paralytic ileus (80,127,128). The interaction is reversible, and readministration of vinca alkaloids may be safe after a prolonged washout (123). The mechanism has not been formally elucidated, but may be either competition for oxidative metabolism, leading to increased systemic exposure (129), or inhibition of the transmembrane P glycoprotein efflux pump (130), leading to increased intracellular concentrations of vinca alkaloids (130). The concomitant use of itraconazole and vinca alkaloids is therefore contraindicated.

Two adults with acute lymphoblastic leukemia developed unusually severe neurotoxicity caused by vincristine, which was probably the result of an interaction with itraconazole suspension (127).

Warfarin

Itraconazole can alter warfarin concentrations.

- Following the addition of itraconazole to a treatment regimen comprising warfarin, ranitidine, and terfenadine, cardiac dysrhythmias developed in a 62-year-old man. The signs and symptoms included prolongation of the QT interval and ventricular fibrillation (SEDA-18, 198).

This particular regimen apparently resulted in a second interaction, since unexpectedly very high concentrations of terfenadine were found (SEDA-18, 283). The phenomenon has been described by others, with a marked rise in terfenadine serum concentrations, and increased toxicity of the drug during concurrent ingestion of itraconazole. The mechanism is not known, but it is likely to be related to inhibition of CYP3A4 (62).

Zolpidem

Zolpidem is mainly transformed by CYP3A4. However, itraconazole 200 mg did not alter the pharmacokinetics and pharmacodynamics of zolpidem 10 mg in 10 healthy volunteers (131). Therefore, zolpidem may be used in normal or nearly normal doses together with itraconazole.

Ivermectin

General Information

Ivermectin, a dihydroavermectin B1, is an effective microfilaricide used in the treatment of strongyloides, scabies, and all types of filariasis except *Dipalonema (Mansonella) perstans* infections.

Over a number of years, ivermectin has shown excellent results in the treatment of onchocerciasis, both in controlled studies and in the field, including use in the WHO-sponsored program of treatment. This experience has provided a thorough picture of its adverse effects. The effective dosage is of the order of 50–200 micrograms/kg. After a single oral dose, skin microfilariae remain at low levels for up to 9 months.

As antihelminthic drugs go, ivermectin can be considered a reasonably safe drug, and it is generally better tolerated than diethylcarbamazine. Clinical experience has often shown relatively little toxicity, although mild adverse effects, presumably due to the killing of the microfilariae, involve at least one-third of patients; some work has suggested that neutrophil activation may play a role in the development of these reactions (1). It has also been well tolerated in combinations, for example when given with albendazole in order to kill adult worms (which cannot be achieved with ivermectin alone) or with diethylcarbamazine for bancroftian filariasis (SEDA-20, 281).

The principal reservation from the start was that ivermectin has a long half-life and that some late effects might occur in certain individuals. During the early phases it was recommended that in areas where the drug had been widely used the health workers involved should continue to observe patients for a time, in case problems did arise, but no late complications have in fact been documented.

Mode of action

The mode of action of ivermectin has been reviewed (2). It has tentatively been identified as agonism at GABA receptors, with inhibition of ion channels that control specific nerve cell connections. The functioning of chloride channels should thus be altered in most organisms, leading to paralysis and death of parasites. Several sites of action have been proposed:

- a postsynaptic agonist site either on the receptor or in its immediate neighborhood;
- a presynaptic site of activation of GABA release;
- potentiation of GABA binding to its receptor.

Another mechanism of action involves the binding of ivermectin to P glycoprotein.

Observational studies

Among the published studies some have specifically sought to define the pattern of adverse effects. In one such study (3), although a single dose of the drug was combined in some patients with diethylcarbamazine, the adverse effect pattern was similar to that when ivermectin was used alone (SEDA-18, 312). There now seem to be some circumstances in which a single low dose of ivermectin is sufficient to have a prolonged effect, for example in loaiasis a dose of 150 micrograms/kg resulted in a very much reduced level of microfilaria as much as a year later, and seemed to eliminate the infestation entirely in more than half the users (4,5). If further work confirms the validity of this approach, the adverse reactions problem may be lessened, since at these doses the few reactions experienced were limited to the skin and joints, although some calabar-like swellings were also noted.

Brugia malayi

In an open study from India 21 asymptomatic microfilaria carriers (with counts of 109–6934/ml of blood) were treated with a single oral dose of ivermectin 400 micrograms/kg and a single oral dose of diethylcarbamazine 6 mg/kg for infection with *Brugia malayi* (6). Twelve hours after treatment microfilaria counts fell by 96–100% in all patients and 12 patients had become afilaremic. All had an adverse reaction, lasting up to 48 hours after treatment: fever ($n = 20$), myalgia ($n = 19$), headache ($n = 17$), lethargy ($n = 15$), chills ($n = 13$), sweating ($n = 11$), anorexia ($n = 11$), sore throat and pharyngeal congestion ($n = 10$), arthralgia ($n = 6$), giddiness ($n = 4$), nausea and vomiting ($n = 3$), abdominal pain ($n = 2$), and cough ($n = 1$). Postural hypotension, lasting 1 day, was noted in two individuals. Transient dilated and painfully inflamed lymphatic channels, which stood out in cords, were seen in two individuals. Most adverse effects were mild and self-limiting.

Loa loa

The use of ivermectin and its adverse effects in patients infected with *Loa loa* have been reviewed (7). It was concluded that ivermectin in a single dose of 150–300 micrograms/kg is effective in reducing microfilaria counts by over 90% with suppressed counts to 25% of pretreatment values after 1 year. An even more sustained effect can be reached by more frequent dosing. There is also some evidence that ivermectin in higher doses (400 micrograms/kg twice yearly) can affect the adult *Loa loa*. Tolerance to ivermectin is generally excellent, but serious adverse effects, especially encephalopathy, can occur, principally in more heavily infected individuals.

Onchocerciasis

The impact of 5 years of annual community treatment with ivermectin on the prevalence of onchocerciasis and onchocerciasis-associated morbidity in the village of Gami (Central African Republic) has been assessed (8). Pruritus, onchocercal nodules, and impaired vision were all significantly reduced by annual treatment with ivermectin.

In a study of the effect of ivermectin on adult *Onchocerca* worms (9) the following regimens were compared:

- 150 micrograms/kg yearly (reference group; $n = 166$)
- 400 micrograms/kg then 800 micrograms/kg yearly ($n = 172$)
- 150 micrograms/kg 3-monthly ($n = 161$)
- 400 micrograms/kg then 800 micrograms/kg 3-monthly ($n = 158$)

After 3 years of treatment more female worms had died in those who were treated every 3 months than in the reference group; female worms were also less fertile. There was no difference between the two groups of patients who were treated yearly. There were no serious adverse events, even at high doses. However, subjective complaints of visual disturbances, such as blurred vision, ocular pain, or dyschromatopsia, were more frequent in those who were given 800 micrograms/kg than in those who were given 150 micrograms/kg; the effects lasted less than 1 week. Detailed ocular examination showed no differences between patients from the reference group and the three other groups.

Sarcoptes scabiei

In an uncontrolled open study 101 patients with scabies were treated with a single oral dose of ivermectin 200 micrograms/kg and then followed at 3 days and at 2 and 4 weeks (10). Two weeks after the start of treatment 89 patients were completely free of scabies, while another three had only mild lesions and pruritus with negative skin scrapings. The other nine patients had persistent pruritus and new lesions and were treated with a second dose, with a complete cure in all cases after 4 weeks. Twelve patients reported minor adverse effects, consisting of drowsiness ($n = 4$), arthralgia and bone aches ($n = 2$), dyspnea ($n = 3$), headache ($n = 1$), nausea ($n = 1$), and blurred vision ($n = 1$). The adverse effects were mostly reported at the first follow-up and were easily tolerated. Ivermectin appears to be a safe and effective treatment for scabies in a dose of 200 micrograms/kg, although a second dose is necessary for complete cure in a few patients.

- An 11-year-old girl developed severe crusted Norwegian scabies (11). Gamma-benzene hexachloride lotion and topical keratolytics had no significant

© 2006 Elsevier B.V. All rights reserved.

effect. She was given a single oral dose of ivermectin 6 mg/kg with dramatic effect. The pruritus subsided in 4 hours and the lesions started to clear 2 days later. A second dose of 6 mg was given after 3 weeks when no skin lesions were found anymore. The only adverse effect was some edema of the skin after the first dose, which did not occur after the second dose, suggesting that the reaction was more related to the intensity of the infection then to the effect of the drug itself.

Outbreaks of scabies in elderly people require special management for disease control. Owing to the frequent failure of repeated non-synchronized therapeutic efforts with conventional external antiscabie treatments, special eradication programs are required. The management of outbreaks of scabies with allethrin, permethrin, and ivermectin has been evaluated (12). Healthy infested people ($n = 240$) were treated once simultaneously with an external scabicide, such as allethrin or permethrin; this was effective in 99%. Those with crusted scabies ($n = 12$) were hospitalized and treated with systemic ivermectin or ivermectin plus permethrin; seven patients received ivermectin twice after an interval of 8 days and one received permethrin three times. Unfortunately, no details of adverse effects were given.

Strongyloidiasis

The efficacy and adverse effects of ivermectin 200 micrograms/kg, repeated 2 weeks later, have been studied in 50 patients with chronic strongyloidiasis, aged 30–79 years (13). The eradication rate was 96% at 2 weeks after the first dose and 98% after the second dose. There was no recurrence after follow-up of 4 months. One patient had nausea and vomiting 3 hours after the first dose and again after the second dose, but they were transient and required no therapy. In four patients there were mild laboratory abnormalities (slight increases in liver function tests in two, microscopic hematuria in one, and mild leukopenia and lymphocytosis in one). Of the 50 patients 12 were positive for human T lymphotropic virus type-I.

Wuchereria bancrofti

Early-stage elephantiasis caused by bancroftian filariasis in a 27-year-old traveller was treated with a single-dose oral combination of ivermectin 24 mg plus albendazole 400 mg, followed by albendazole 800 mg for 21 days (14). To avoid a severe Mazzotti-like reaction, he was given oral glucocorticoids and antihistamines for 3 days. He had a transient rash, pruritus, and mild hypotension on the days after the initial treatment, but otherwise remained well and the swelling subsided. Within 1 month he was free of symptoms. At the last follow-up examination, 3 years after treatment, there was no clinical or laboratory evidence of relapse. The authors thought that this type of treatment should be evaluated on a wider scale, given the minimal adverse events and apparent therapeutic efficacy.

The efficacy of annual mass chemotherapy with a combination of diethylcarbamazine and ivermectin on bancroftian filariasis in rural southern India has been studied, as has the supplementary role of controlling the vector mosquito *Culex quinquefasciatus* (15). Nine villages, topographically and ecologically similar but reasonably isolated from each other, were selected and split into three comparable groups of three villages each. Group A received chemotherapy with diethylcarbamazine at about 6 mg/kg and ivermectin at 400 micrograms/kg. Group B received chemotherapy and vector control. The most important vector-breeding sites were soakage pits, which were treated with expanded polystyrene beads. Minor vector-breeding sources, such as domestic or irrigation wells, were treated by adding larvae-eating Talapia fish or a commercial insecticide based on *Bacillus sphaericus*. Group C received no intervention. After the first round of treatment, combination chemotherapy alone caused a 60% drop in the annual filarial transmission potential, whereas the combined strategy reduced the transmission potential by 96%. After two rounds of treatment, the reduction in transmission potential was similar with the two strategies (about 91–96% reduction), whereas the prevalence of microfilaremia was reduced by 88–92%. Adverse events after combination therapy were reported in 20% of those who had taken diethylcarbamazine and ivermectin for the first time. The patients with adverse events had increased microfilarial counts. The most common adverse effects were headache (72% of adverse events), giddiness (67%), fever, and weakness. The incidence of adverse events among those taking combination therapy for a second time was relatively low (5.5%). The adverse events were also less severe in the second round than in the first. When antifilarial treatment was withdrawn in the third and final year of the study, transmission was resumed in the absence of vector control, whereas no infective female mosquitoes were detected in villages with vector control. Vector control, although obviously not cost-effective in the short term, could therefore play an important supplementary role in an integrated program, by preventing re-establishment of transmission after chemotherapy has been completed.

Comparative studies

Sarcoptes scabiei

In a randomized trial a single oral dose of ivermectin (200 micrograms/kg) has been compared with 1% gamma-benzene hexachloride lotion for topical application overnight in 200 patients with scabies (16). The patients were assessed after 48 hours, 2 weeks, and 4 weeks. After 4 weeks, 83% showed marked improvement with ivermectin, compared with 44% of those treated with gamma-benzene hexachloride. There were no adverse events reported with gamma-benzene hexachloride. Headache was reported only once with ivermectin.

In 80 children aged 6 months to 14 years a single dose of ivermectin 200 micrograms/kg was compared with topical benzyl benzoate for the treatment of pediatric scabies in a randomized, controlled trial (17). Ivermectin cured 24 of 43 patients and topical benzyl benzoate cured 19 of 37 patients at 3 weeks after treatment. There were no serious adverse effects with either treatment, although benzyl benzoate was more likely to produce local skin reactions. These results are in line with those of another study, in which 18 children aged 14 months to 17 years with either scabies ($n = 11$) or cutaneous larva migrans ($n = 7$) were

© 2006 Elsevier B.V. All rights reserved.

treated with a single dose of ivermectin 150–200 micrograms/kg (18). A single oral dose cured 15 patients, and three patients with crusted scabies required a second dose. None had significant adverse reactions.

Wuchereria bancrofti

In a study in which doses of 200 or 400 micrograms were used, with or without diethylcarbamazine, for *Wuchereria bancrofti* infection, there was a higher than average incidence of reactions (and a higher incidence with ivermectin than with diethylcarbamazine), but this perhaps reflected an unusually high success rate or the severity of the original infection (19). For similar reasons, repeated courses of treatment tend to show a falling incidence of adverse effects. Normally, such general symptoms as fever, weakness, anorexia, malaise, and chills occur in a substantial minority of patients on a first course, while at least one-third have muscle and/or joint pains. Vertigo, dyspnea, diarrhea and abdominal disturbances affect a few patients. The severity of adverse effects is not related to serum concentrations of the drug (20), which again reflects the fact that they are largely a consequence of the parasitic breakdown, rather than toxic effects of ivermectin.

Placebo-controlled studies

Emesis, ataxia, and mydriasis are cardinal signs of ivermectin toxicity. The safety, tolerability, and pharmacokinetics of escalating high-dose ivermectin have been studied in 68 healthy subjects in a randomized, double-blind, placebo-controlled study (21) in the following doses:

- 30 mg fasted ($n = 15$)
- 60 mg fasted ($n = 12$)
- 90 mg fasted ($n = 12$)
- 120 mg fasted ($n = 12$)
- 30 mg fed ($n = 11$)

Ivermectin was generally well tolerated. Quantitative pupillometry ruled out any mydriatic effect of ivermectin. There was no nervous system toxicity associated with oral ivermectin at any of the doses. There were no serious clinical or laboratory adverse events. Three of the fifty-one subjects who took ivermectin fasted reported minor adverse gastrointestinal events: fecal abnormality ($n = 1$), nausea ($n = 1$), and vomiting ($n = 1$); six reported minor neurological adverse events: headache ($n = 4$), anxiety ($n = 1$), and dizziness ($n = 1$). There were no adverse events in the subjects who took ivermectin 120 mg. The absorption of ivermectin was about 2.5 times higher when it was given after a high-fat meal.

Sarcoptes scabiei

In a randomized, double-blind comparison of the efficacy of oral ivermectin and topical gamma-benzene hexachloride 53 patients were randomly allocated to either a single oral dose of ivermectin 150–200 micrograms/kg and a placebo topical solution, or a single dose of gamma-benzene hexachloride topical solution 1% and placebo tablets (22). Patients who did not fulfil the criteria for clinical cure within 15 days, defined as the absence of both pruritus and clinical lesions or a reduction in signs and symptoms to a mild degree, repeated the initial treatment. Of the 53 patients 43 completed the study (19 of those treated with ivermectin and 24 of those treated with gamma-benzene hexachloride). After 15 days 74% of the patients treated with ivermectin and 54% of the patients treated with gamma-benzene hexachloride were considered to be cured. At 29 days both treatments were equally effective, with cure rates of 95% and 96% respectively. Adverse effects were mild and transient in both groups. One of the patients treated with ivermectin had hypotension, one had abdominal pain, one had vomiting, and one complained of headache. There were no abnormalities on routine laboratory testing.

Wuchereria bancrofti

In a double-blind, placebo-controlled study in Ghana single doses of ivermectin 150–200 micrograms/kg and albendazole 400 mg, either separately or in combination, were given to 1425 individuals for *Wuchereria bancrofti* infection (23). Of these, 340 were microfilariae-positive before treatment. Ivermectin and ivermectin plus albendazole both produced statistically significant reductions in mean microfilaria counts at follow-up; the effect of ivermectin was longer lasting. Albendazole produced a non-significant reduction. Adverse reactions were few and mostly mild, and there were no severe reactions.

General adverse effects

Acute symptoms, often flu-like or affecting the skin, are related almost entirely to the release of toxic products and allergens from the killed filariae, and can affect two-thirds of patients; in conditions in which this type of reaction does not occur one may suspect that the drug is ineffective. The mechanism of the effects also explains why they tend to occur early and sometimes briefly, that is immediately after the microfilariae die. For similar reasons, these effects are most severe in patients with a high microfilaria count (24).

Despite the sometimes transient and apparently tolerable nature of the skin effects, they can persist in patients requiring long-term treatment, for example for onchocerciasis, and under these conditions they are sufficient to impair compliance with treatment (SEDA-21, 317).

The effects of age, sex, dosing round, time of day, and distance from the nurse monitor on adverse event reporting during mass ivermectin administration in Achi in South-East Nigeria have been examined (25). There was a significant increase in adverse reporting with age, but not sex. Fewer adverse effects were reported after starting at night than after starting by day. There was no significant effect of distances up to 1 km on adverse events reporting. Both compliance and adverse reporting were less after the second dosing round than after the first. These variables should be included in the standardization of adverse events reporting.

Onchocerciasis

Although adverse reactions after ivermectin in onchocerciasis are usually less severe than after diethylcarbamazine, they still affect a significant number of patients with onchocerciasis after the first dose. With subsequent treatments, these reactions become less frequent and

© 2006 Elsevier B.V. All rights reserved.

severe. The so-called Mazzotti reaction, which is often seen after treatment of *Onchocerca volvulus* with diethylcarbamazine or ivermectin, is characterized by fever, tachycardia, hypotension, adenitis, pruritus, arthralgia, a papular or urticarial rash, and lymphedema. It is ascribed to an inflammatory host response to microfilarial killing and tends to be more severe in those who have greater numbers of parasites. The roles of chemoattractants, such as eotaxin, RANTES, and MCP-3, in the recruitment of eosinophils to the site of parasite killing has been studied in 13 patients with onchocerciasis and two control subjects before and after ivermectin (26). There were adverse reactions in eight patients, but none were severe. The reactions were fever (54%), pruritus (62%), rash (46%), and lymphedema (46%). There was no significant postural hypotension. There was endothelial expression of both RANTES and eotaxin after ivermectin, suggesting that these chemoattractants have an important role in eosinophil recruitment into the skin during killing or degeneration of parasites after ivermectin.

A role for the release of *Wolbachia* bacterial endosymbionts has been suggested in the pathogenesis of the Mazzotti reaction (SEDA-26, 345). There was a good correlation between *Wolbachia* DNA, serum TNF-alfa, and the antibacterial peptides calprotectin and calgranulin after treatment with ivermectin or diethylcarbamazine, supporting a role for *Wolbachia* products in mediating these inflammatory responses (27).

There has been an epidemiological survey of the endemicity of human onchocerciasis and the effects of subsequent mass distribution of ivermectin in villages of the Nzerem-Ikpem community in Nigeria (28). Of 1126 people studied, 527 were positive for skin microfilariae, 329 had a leopard skin (characterized by focal skin depigmentation), 385 had nodules, and 167 had onchodermatitis. There were adverse effects in 362 patients (19%): pruritus in 13%, limb swelling in 8.5%, facial swelling in 2%, weakness in 4.8%, nausea and vomiting in 3.4%, headache in 5.8%, diarrhea in 3.4%, and rheumatism in 3.5%. There were no severe reactions.

Organs and Systems

Cardiovascular

Supine and postural tachycardia with postural hypotension can occur; in one large study, such effects were found in three of 40 patients (SEDA-14, 262) (SEDA-22, 327). In another there was hypotension in 13 of 69 cases (SEDA-20, 280), but in some series these effects have not been observed at all (SEDA-17, 356). A massive community study in Ghana noted hypotension in only 37 of nearly 15 000 patients treated (29). Transient electrocardiographic changes are sometimes seen.

Respiratory

In the treatment of *Wuchereria bancrofti* filariasis in 23 patients with single doses up to 200 micrograms/kg respiratory capacity was evaluated; there was a transient but significant fall in vital capacity some 24–30 hours after administration, apparently due to bronchodilatation (30). Frank dyspnea occurred in 2% of cases in the study cited above (3). In other studies, a few patients have developed a transient cough and in others pneumonitic patches have been seen in the chest X-ray (SEDA-18, 313).

Nervous system

Headache and vertigo are very common and even usual as part of the flu-like reaction to ivermectin.

A puzzling reaction was recorded in a small hospitalized Canadian population of elderly subjects treated for scabies with a single dose of ivermectin (150–200 micrograms/kg). Within 6 months, 15 of the 47 patients had died. All those who died had developed a sudden change in behavior, with lethargy, anorexia, and listlessness before death (31). The effect may have been an artefact with some extraneous cause, and it is notable that other groups using this treatment for scabies have not recorded similar reactions.

Loa loa encephalopathy

When treating *Loa loa* infections on a large scale with ivermectin, the encephalopathy that was a much-feared complication with diethylcarbamazine again seems to occur, especially with heavily infected or older individuals (32). For this reason, mass use of ivermectin in areas of endemic *Loa loa* infection is no longer recommended (33).

Ivermectin appears to promote the passage of *Loa loa* microfilaria into the cerebrospinal fluid, with a maximum after 3–5 days, followed by an intense allergic reaction to the dying microfilaria. The Mectizan Expert Committee defined a definite case of *Loa loa* encephalopathy related to ivermectin as having to satisfy two criteria:

1. encephalopathy in which there is microscopic evidence of vasculopathy in the brain associated with *Loa loa* microfilaria;
2. the onset of symptoms of disturbed nervous system function within 5 days after treatment with ivermectin, progressing to coma without remission.

A probable case of *Loa loa* encephalopathy was defined as having to satisfy four criteria:

1. coma in a previously healthy individual;
2. the onset of nervous system signs within 5 days of treatment with ivermectin progressing to coma;
3. an initial microfilaremia of over 10 000/ml, or 1000/ml in a blood sample taken within 2 months of treatment;
4. the presence of *Loa loa* microfilaria in the CSF.

Clinically common features of this condition are impaired consciousness appearing 3–4 days after treatment and lasting for 2–3 days.

There is no consensus on the proper management of ivermectin-associated *Loa loa* encephalopathy, and it is uncertain if co-administration of glucocorticoids is of any use. In several patients with more severe reactions, conjunctival hemorrhages were seen.

A systematic examination of the conjunctivae in 1682 patients complaining of any adverse reactions showed that these hemorrhages were closely correlated with the pretreatment microfilaria counts. This sign can be found 2 days after treatment and may thus single out patients susceptible to encephalopathy and needing closer follow-up. Although the incidence of such cases is very low (in

© 2006 Elsevier B.V. All rights reserved.

the order of 1 in 10 000 treated patients), this serious adverse effect makes mass treatment of *Loa loa* infection problematic, and also mass treatment of onchocerciasis in areas in which *Loa loa* is endemic. To illustrate this point three probable cases of *Loa loa* encephalopathy after ivermectin treatment for onchocerciasis have been described (34). All three were young men treated with ivermectin 150 micrograms/kg in a mass-treatment campaign in onchocerciasis.

- A 26-year-old previously healthy man developed nervous system symptoms in the form of an inability to stand or eat and stiffness of the neck by the third day. On the fourth day he had difficulty swallowing and speaking. On the fifth day he could not speak and was incontinent of urine. He was given dexamethasone, diazepam, furosemide, and atropine. On the sixth day he became comatose. On the ninth day he developed a high fever, and was given penicillin and tube-feeding. His condition gradually worsened and he died on the 21st day. Serum microfilaria counts on day 13 after treatment were still high (3600/ml), and live *Loa loa* (10/ml) were found in the CSF.
- A 32-year-old man with alcoholism had a very high pretreatment serum microfilaria count (50 000/ml). After starting ivermectin he took to his bed and would not speak. On the third day he developed a fever, possibly attributed to malaria and treated with chloroquine. On the fourth day he was unable to stand, and alternately restless or somnolent; his CSF contained live *Loa loa* microfilaria. He became more incoherent and fidgety and had a marked grasp reflex. Later in the day he developed spastic hypertonia. On the fifth day he became incontinent and still would not speak. Over the following days he gradually improved and 4 months later had no neurological abnormalities, although his relatives found that his behavior had changed and that he was much calmer then in the past. An electroencephalogram on day 15 showed periodic diffuse discharges of large amplitude during hyperventilation and on day 146 an asymmetric tracing with focal activity in the right parieto-occipital area, which worsened during hyperventilation. On day 233 the electroencephalogram was normal.
- An 18-year-old previously healthy man was given ivermectin. On the second day he was unable to work and stayed at home. On the third day he was found unconscious in bed, incontinent of urine and feces. On the fourth day he did not move and had absent pain sensation. There was hypertonia in the arms with marked cogwheeling. On the fifth and sixth days there was a swinging horizontal movement of the eyeballs, but otherwise he appeared to improve. On the seventh day he could stay seated in bed with help and spoke several sentences. He could perform slow voluntary movements and his muscle strength and sensation returned to normal, although the cogwheel phenomenon still persisted. He gradually returned to normal over the following weeks. After 5 months the neurological examination was normal but he still complained of headaches and episodic amnesia. His pretreatment serum microfilaria counts were high (152 940/ml) and the CSF collected on the fourth day contained live *Loa loa* microfilaria. An electroencephalogram on the 19th day was slow with spontaneous, diffuse, paroxysmal, monomorphic theta activity, lasting 2–3 seconds. An electroencephalogram on the 105th day showed improvement, but focal abnormalities persisted in the left occipital region. On the 159th day all previously recorded abnormalities had disappeared.

Sensory systems

Careful ophthalmological examination shows a striking increase in the number of microfilariae in the anterior chamber of the eye in a significant minority of patients, and a new inflammatory infiltrate can appear during treatment in already damaged areas of the retina (SEDA-15, 334). However, no permanent ocular sequelae have been documented. Most of the other ophthalmic symptoms, including edema and local inflammation, are those of the primary infection.

Conjunctival hemorrhages have been recorded in patients living in areas in which loiasis is endemic. Although ivermectin is usually well tolerated, these patients had serious adverse reactions after taking ivermectin, including an encephalopathy similar to that seen after treatment with diethylcarbamazine. In retrospect, these cases all had high *Loa loa* microfilaremia and *Loa loa* microfilariae in the cerebrospinal fluid. The authors suggested that ivermectin might have provoked the passage of *Loa loa* microfilariae into the cerebrospinal fluid. In a subsequent study of 1682 patients with loiasis treated with ivermectin 150 micrograms/kg, conjunctival hemorrhages were found in 41, nine of whom had previously received a microfilaricidal drug (35). The initial mean *Loa loa* microfilaremia was 14 900 microfilariae/ml (range 0–182 400; median 37 500), compared with 14.5 microfilariae/ml (range 0–97 600; median 0) in those without conjunctival hemorrhage. In addition, male sex and *Dipalonema perstans* microfilaremia were associated with conjunctival hemorrhages. There was a close relation between conjunctival hemorrhages and retinal lesions. Based on observations in three patients who all developed coma after ivermectin the authors suggested that retinal lesions may reflect what occurs in the cerebral circulation in patients with high *Loa loa* microfilaremia and neurological problems after ivermectin.

Hematologic

When 28 Sudanese patients were treated with a single dose of ivermectin for onchocerciasis they developed a prolonged prothrombin time, which continued to lengthen significantly during the next 4 weeks; there were no changes in other clotting parameters (36). After a month, two of them developed hematomas, which continued to enlarge for the next 3–4 days. Both of these patients had received ivermectin 150 micrograms/kg. One was given a transfusion; the swellings in both cases resolved within a week. For a time it was considered that the prothrombin changes observed in some such cases were a potential problem; more recent work suggests that the prolongation of prothrombin ratio is in fact hardly more than with placebo, and that in fact ivermectin merely has a mild effect on vitamin K metabolism and

© 2006 Elsevier B.V. All rights reserved.

little effect on coagulation (37). However, lymphadenitis has been noted in a few patients. In one Guatemalan study of biannual treatment of the population to eradicate *Onchocerca volvulus* infection, upper limb edema was noted in nearly 20% of cases receiving the treatment for the first time (38).

Gastrointestinal

In the late stages of *Strongyloides* hyperinfection, ileus can develop and hamper the absorption of oral medication (39).

- A 39-year-old Afro-Caribbean man with stage IVB T cell lymphoma due to HTLV-1 infection had invasive Strongyloides hyperinfection that did not respond to oral ivermectin plus albendazole because of concurrent ileus. He was treated with two 6 mg doses of a veterinary formulation of ivermectin subcutaneously. There were no adverse effects, apart from pain at the injection site.

Urinary tract

Proteinuria is unusual but has been described; it was detected 14 days after a single dose and disappeared during follow-up (SEDA-18, 313).

Observations that proteinuria and hematuria may occur in patients with filariasis bancrofti and loiasis, which may exacerbate after treatment with diethylcarbamazine or ivermectin, led to the study of kidney function in patients with onchocerciasis before and after treatment with ivermectin (40). The occurrence of renal abnormalities was studied in a population-based study in a meso-endemic village (40% microfilaria carriers), in a group of patients with a generalized or hyper-reactive form of onchocerciasis, and in 46 patients treated with ivermectin in a single oral dose of 150 micrograms/kg. All individuals in all three study groups were examined clinically and had skin snips, serological testing for onchocerciasis, and nodulectomy (when relevant). Tests for malaria, schistosomiasis, intestinal nematodes, and hepatitis B, and serum glucose, creatinine, IgE, and electrophoresis were also performed. The urine was tested for erythrocytes, leukocytes, protein, nitrites, pH, glucose, ketone bodies, urobilinogen, and creatinine. All the patients underwent renal ultrasound examination. There was no difference in renal function and renal ultrasound between patients with and without onchocerciasis. A raised urinary protein concentration (over 70 mg/g of creatinine) was common and occurred in 47% of the patients with onchocerciasis and 63% of the patients without onchocerciasis. In the 46 patients treated for onchocerciasis with a single dose of 150 micrograms/kg there was a slight but statistically significant increase in total urine protein after 2 and 5 days, especially in 16 patients with high pretreatment skin microfilaria counts. The abnormalities were minor and insignificant. Neither onchocerciasis itself nor treatment with ivermectin was associated with abnormalities of renal function.

Skin

A degree of pruritus, soreness, or burning sensation is common with ivermectin, and rashes or skin edema can occur, while pre-existing conditions of this type can be aggravated (SEDA-17, 355) (SEDA-22, 327). The skin over hematomas can be discolored. Swelling of the limbs and face, like the dermatological symptoms, is probably a reaction to breakdown products of the helminth (SEDA-20, 280).

Patients with severe skin involvement ("sowda") as a facet of their onchocerciasis can experience transient aggravation of the condition, but the course is favorable, and they are less likely to have the same problem if it is later necessary to repeat treatment (SEDA-20, 281).

Rashes and swelling of the lymph nodes seem to be more common in patients with AIDS who take ivermectin (41).

Musculoskeletal

Joint or bone pains are common but usually mild; in one study myalgia occurred in 33% of cases and arthralgia in 33% (3).

Reproductive system

Orchitis or epididymitis with scrotal tenderness occurs in a few patients as a manifestation of the acute reaction as the parasite succumbs (SEDA-17, 356) (SEDA-22, 327).

Second-Generation Effects

Teratogenicity

There is no evidence of second-generation injury from ivermectin, but it is prudent to avoid it in pregnant women.

Lactation

Only a small amount of ivermectin is excreted in the breast milk (42) and it has been suggested that it is unnecessary to exclude lactating mothers from mass chemotherapy with ivermectin.

IX 207-887

General Information

IX 207-887 (10-methoxy-4*H*-benzo-(4,5)-cyclohepta-(1,2–6)-thiophene-4 ylidene acetic acid) is a slow-acting drug for use in rheumatoid arthritis. Its mechanism of action involves inhibition of the release of interleukin-1. Adverse effects have occurred in 22% of cases, most commonly skin reactions, but also hepatitis and gastrointestinal disorders (1).

Japanese encephalitis vaccine

See also Vaccines

General Information

During the last half century, Japanese encephalitis has been recognized as an important arboviral disease in man in Japan, China, Korea, Thailand, India, Nepal, Sri Lanka, and Vietnam. In 1954, Japanese encephalitis vaccine of the mouse brain type for human use was licensed in Japan. However, there was strong criticism of mouse brain vaccine, which has continued for many years. Therefore, in 1965, the Nippon Institute of Biological Products and the Biken Foundation implemented more advanced purification procedures, such as alcohol precipitation and ultracentrifugation.

Three types of Japanese encephalitis vaccine are currently produced:

1. mouse brain-derived inactivated vaccine, commercially available;
2. cell culture-derived inactivated vaccine;
3. cell culture-derived attenuated vaccine, produced and used exclusively in China.

The Chinese cell culture-derived inactivated vaccine is produced in primary hamster kidney cells; a highly purified Vero cell culture-derived inactivated vaccine is under clinical development in France. A Chinese live-attenuated vaccine is also produced in primary hamster kidney cells. The efficacy of one dose is 80%, and the efficacy of two doses, given 1 year apart, is 97.5%; this vaccine was evaluated in a randomized trial in 26 239 children, half of whom received the vaccine and half served as controls, and its adverse effects have been reviewed (SEDA-22, 350).

In 1965, a special surveillance team was formed by the Japanese Ministry of Health and Welfare to investigate adverse events following the administration of Japanese encephalitis vaccine. No severe adverse event was reported among 21 396 vaccinees of whom 18 401 were adolescents and children under 18 years of age. Some mild reactions (fever, malaise, abdominal symptoms) were noted in 1.2% of the vaccinees. Using a countrywide hospital network, the surveillance team studied any severe neurological disease occurring within 1 month after receipt of the vaccine. During 1957–66, 26 cases (nine cases of meningitis, ten cases of convulsions, five cases of polyneuropathy, and two cases of demyelinization) were analysed. No evidence was provided showing a causative relation between these clinical syndromes and Japanese encephalitis immunization. The incidence of neurological disease was considered minor compared with the millions of doses distributed annually in Japan (1).

Since 1989, urticaria and/or angioedema of the extremities, face, and oropharynx, and respiratory distress have been reported from Europe, North America, and Australia as a new pattern of adverse effects. Collapse due to hypotension has required hospitalization in several cases, and erythema multiforme and erythema nodosum have also occurred; the reported rates of such adverse effects varied markedly in different countries (respective ranges 0.7–12 per 10 000 and 50–104 per 10 000). The vaccine constituents responsible for the adverse effects have not yet been identified.

Japanese encephalitis vaccine has been reviewed (2). A supplementary volume of the journal Vaccine has dealt with results presented at a WHO meeting held in Bangkok, Thailand, in 1998 (3–6). Comprehensive data were provided on the epidemiological and virological situation in southeast Asia and Australia, control measures, vaccine production capacities, and different vaccines against Japanese encephalitis. Adverse events after the use of inactivated mouse brain vaccine (the only vaccine that is currently licensed for international use) have been reviewed in detail (3).

Organs and Systems

Nervous system

Postmarketing surveillance data of adverse events after Japanese encephalitis immunization in Japan and the USA have been compared (7). The rates of total reported adverse events were 2.8 per 100 000 doses in Japan and 15.0 per 100 000 doses in the USA. In Japan, 17 neurological disorders were reported from April 1996 to October 1998 (0.2 per 100 000 doses), whereas in the USA there were no serious neurological adverse events temporally associated with Japanese encephalitis vaccine from January 1993 to June 1999. Rates for systemic hypersensitivity reactions were 0.8 and 6.3 per 100 000 doses in Japan and the USA respectively.

Acute disseminated encephalomyelitis after Japanese encephalitis immunization has been reported from Japan.

- A 6-year-old girl and a 5-year-old boy had drowsiness, paresthesia, and gait disturbance 14 and 17 days respectively after immunization with Japanese encephalitis vaccine. Treatment with prednisolone improved the clinical findings (8,9).

Another report included seven cases of acute disseminated encephalomyelitis after administration of Japanese encephalitis vaccine between 1968 and 1990 (10). Three other cases of neurological complications after the use of Japanese encephalitis vaccine have been reported in Denmark. In two cases the clinical picture was consistent with acute demyelinating encephalomyelitis (SEDA-21, 334).

The rate of neurological complications seen in Japan in 1965–73 was of the order of 1 per 2.3 million vaccinees, and in Denmark the rate was 3 per 175 000 immunized individuals (one of them with a predisposition to multiple sclerosis) (11).

Two deaths from acute anaphylaxis and four cases of acute encephalopathy or acute disseminated encephalomyelitis (two fatal), temporally related to Japanese encephalitis immunization, have been reported from the Republic of Korea (3). The live-attenuated vaccine developed and used in China had 98% efficacy in a two-dose schedule. Concern that a live vaccine derived from an encephalitogenic virus might lead to vaccine-associated encephalitis could not be addressed satisfactorily, even

© 2006 Elsevier B.V. All rights reserved.

in a study of 26 000 children. During efficacy studies in different geographic areas of China and in different years, the observations were combinable: the average encephalitis risk after live-attenuated Japanese encephalitis vaccine was 1.59 per 100 000 vaccinees.

Immunologic

Hypersensitivity reactions (generalized urticaria or angioedema) after the use of Japanese encephalitis vaccine have been reported from some countries (see Table 1); the vaccine constituents responsible for these events have not been identified (12). There has been a detailed report of the adverse effects, mainly allergic mucocutaneous reactions, of Biken vaccine in Danish travellers and US Marine Corps personnel (SEDA-22, 351).

The Advisory Committee on Immunization Practices (ACIP) has recommended that vaccinees should be observed for 30 minutes after immunization and that medications to treat anaphylaxis should be available (12) [http://www.cdc.gov/mmwr/PDF/rr/rr4201.pdf]. A personal history of allergic disorders should be considered when weighing the risks and benefits of the vaccine for an individual. Japanese encephalitis vaccine should not be given to persons who had a previous adverse reaction after receiving Japanese encephalitis vaccine or a previous hypersensitivity reaction to other vaccines of neural origin.

In Japan, children who had immediate-type allergic reactions to Japanese encephalitis vaccine had antigelatin IgE in their sera. However, the immunological mechanism of non-immediate-type allergic reactions that consist of cutaneous signs developing several hours or more after Japanese encephalitis immunization is not yet clear. Serum samples taken from 28 children who had non-immediate-type allergic skin reactions have been compared with serum samples taken from 10 children who had immediate-type reactions (13). All the children who had had immediate-type reactions had antigelatin IgE and IgG. Of 28 children who had had non-immediate-type reactions, one had antigelatin IgE and nine had antigelatin IgG. These results suggest that some children who develop non-immediate-type allergic reactions have also been sensitized to gelatin.

Table 1 Allergic reactions after Japanese encephalitis immunization

Country	Estimated number of vaccines	Number of reactions	Estimated rate per 100 000 vaccines
Denmark	42 000	21	50
Sweden	15 000	1	7
UK	1950	1	51
Australia			
Nationwide	3400	4	118
Fairfield Hospital	601	3	499
Canada			
University of Calgary	96	1	1042
USA			
Travellers	1328	2	151
Army	526	1	190
Army and dependents (Okinawa)	35 253	220	624
Total	100 154	254	254

Susceptibility Factors

An association between reactions to Japanese encephalitis vaccine and a history of urticaria or allergic rhinitis has been identified (14).

Josamycin

See also Macrolide antibiotics

General Information

In a randomized open study, 325 children aged 2–15 years with acute tonsillitis and a positive test for *Streptococcus pyogenes* antigen were treated with josamycin 25 mg/kg bd for 5 days, or penicillin 50 000–100 000 IU/day for 10 days; in five patients taking josamycin treatment was withdrawn because of gastrointestinal adverse events (nausea/vomiting) (1).

Organs and Systems

Liver

Cholestatic hepatitis has been attributed to josamycin (2).

Biliary tract

In female rats josamycin caused bile duct proliferation at a high dose of 1460 mg/kg (3).

Juglandaceae

See also Herbal medicines

General Information

The family of Juglandaceae contains three genera:

1. *Carya* (hickory)
2. *Juglans* (walnut)
3. *Pterocarya* (pterocarya).

Juglans regia

The fresh fruit-shell of *Juglans regia* (English walnut) contains the naphthoquinone constituent juglone, which is mutagenic and possibly carcinogenic. The juglone content of dried shells has not yet been studied adequately.

In a placebo-controlled study in 60 Persian hyperlipidemic subjects, walnut oil encapsulated in 500 mg capsules reduced plasma triglyceride concentrations by 19–33% of baseline (1).

Adverse effects

Hyperpigmentation and contact dermatitis have been attributed to *J. regia* (2) as has dermatitis bullosa (3).

A brown orange pigmentation occurred in a patient who used the bark of *J. regia* for cleaning teeth (4).

Kanamycin

See also Aminoglycoside antibiotics

General Information

Kanamycin can be used for short-term treatment of severe infections caused by susceptible strains (for example *Escherichia coli*, *Proteus* species, *Enterobacter aerogenes*, *Klebsiella pneumoniae*, *Serratia marcescens*, and *Mima-Herellea*) that are resistant to other less ototoxic aminoglycosides. It is not indicated for long-term therapy, for example in tuberculosis.

Organs and Systems

Neuromuscular function

Like the other aminoglycosides, kanamycin has neuromuscular blocking properties, particularly if given directly into the peritoneum (1). However, it seems to be less dangerous in this respect than neomycin or streptomycin.

Sensory systems

Kanamycin causes mainly cochlear damage (2). After prolonged administration (for example 1 g for periods of 30–180 days) the frequency of this adverse reaction is higher than 40%. Vestibular toxicity occurs in less than 10% of cases treated with usual doses and is generally reversible soon after withdrawal.

Gastrointestinal

Presurgical bowel preparation with oral kanamycin is seldom practiced and can be followed by an intestinal malabsorption syndrome (3). Only negligible amounts of kanamycin are absorbed through an intact intestinal mucosa, but increased systemic availability and potential toxicity can result from the presence of ulcerated or denuded areas.

Urinary tract

Kanamycin causes very little nephrotoxicity after short courses of treatment with daily doses of less than 15 mg/kg; if total doses of 30 g or more are given, the incidence of renal damage can be 50% or higher (1).

Immunologic

Sensitization (rash, drug fever) after parenteral administration of kanamycin is less frequent than with streptomycin. Anaphylaxis has only rarely been described. Cross-allergy with the other aminoglycosides is frequent (4).

Kaolin

General Information

Kaolin, commonly given together with pectin in the treatment of diarrhea, is generally regarded as safe.

The absorbent properties of kaolin could result in the binding of other drugs that are given at about the same time. For example, kaolin adsorbs mefenamic acid and flufenamic acid, phenylbutazone, indometacin, and methiazinic acid (1). One should not therefore be surprised if it reduces the effect of any non-steroidal anti-inflammatory agent, requiring an increase in dosage by 50–100% to maintain efficacy. The reduction of lincomycin absorption is quite drastic, perhaps amounting to 90% of the dose given (2).

Organs and Systems

Respiratory

Industrial exposure to kaolin can cause lung damage. In more than 2000 kaolin workers from east central Georgia the presence of ventilatory impairment was related to the presence of complicated pneumoconiosis, employment in clay calcining, and cigarette smoking (3). In those who worked with calcined clay, there was an increased prevalence of abnormal FEV_1, but not FVC, compared to both wet and dry processors, which could not be explained by either cigarette smoking or the presence of pneumoconiosis. However, the magnitude of abnormality in the calcined clay workers was unlikely to lead to disabling impairment. Of those who had been exposed for more than 3 years, 90 had simple pneumoconiosis and 18 had complicated pneumoconiosis, adjusted prevalences of 3.2 and 0.63% respectively. Dry processing was associated with a greater risk of pneumoconiosis than wet processing.

In one case, multiple pulmonary kaolin granulomata developed secondary to the use of a liquid kaolin suspension for pleural poudrage to treat recurrent spontaneous pneumothoraces, presumably because the kaolin entered the lung through pleuro-alveolar or pleuro-bronchial openings (4).

Kebuzone

See also Non-steroidal anti-inflammatory drugs

General Information

Kebuzone is an NSAID that is related to phenylbutazone. Allergic reactions, gastrotoxicity, nephrotoxicity, local reactions with necrosis (1), and liver damage have been reported (SED-11, 176) (2). The Japanese authorities have asked that the package insert should indicate that this drug must be used only as a last resort when other anti-inflammatory agents and uricosuric drugs are ineffective (SEDA-12, 83).

Organs and Systems

Liver

In 20 cases of kebuzone-induced liver damage, biopsy showed hepatocellular damage with or without cholestasis, reactive hepatitis, or cholangiolitis (3). There was hepatitis with central lobular necrosis in one case. In five patients, a lymphocyte proliferation test was positive.

Skin

Nicolau syndrome (embolia cutis medicamentosa) is a very rare complication of intramuscular injections, in which there is extensive necrosis of the injected skin area, perhaps due to accidental intra-arterial and/or para-arterial injection; it usually occurs in children (4). Nicolau syndrome has been reported in three patients who had received intramuscular injections of kebuzone (5).

Ketamine

See also General anesthetics

General Information

Ketamine is a short-acting anesthetic that is widely used by emergency physicians (1) and can be given intravenously, intramuscularly, orally, and even nasally (2). Multiple ketamine anesthetics may be safe (3).

Subanesthetic low-dose ketamine is being used increasingly often for acute pain therapy, day-case surgery, and chronic pain management. Ketamine is now available in chiral (*S*+ and *R*–) forms as well as the standard racemic form. *S*-ketamine has twice the analgesic potency of racemic ketamine and four times that of *R*-ketamine. Thus, low dose *S*-ketamine may avoid adverse effects while providing high-quality analgesia.

The pharmacology of ketamine, including its adverse effects, has been reviewed (4), as has the use and adverse effects of *S*-ketamine in the intensive care unit (5).

Ketamine relaxes smooth muscles in the airways and may therefore be a useful induction agent in children with asthma (6). If endotracheal intubation is required, lidocaine 1–2 mg/kg intravenously before intubation has been recommended, although the use of a laryngeal mask airway may be more appropriate. When used in combination with midazolam by infusion, ketamine provides analgesia and prevents and relieves bronchospasm (7).

The addition of ketamine to bupivacaine for spinal anesthesia has been studied in 60 patients undergoing spinal anesthesia for insertion of intracavitary brachytherapy implants for cervical carcinoma (8). They were randomly assigned to receive either bupivacaine 10 mg or bupivacaine 7.5 mg plus ketamine 25 mg. Motor recovery was significantly quicker in the ketamine group. Blood pressure was significantly lower in the bupivacaine group 5 minutes after administration, and perioperative intravenous fluid requirements were significantly higher. Patients given ketamine reported more sedation and dizziness, both intraoperatively and postoperatively. There were no nightmares or dissociative features. Overall satisfaction was better with bupivacaine. The study was abandoned after 30 patients, because of the high rate of adverse effects with ketamine. Although ketamine had local anesthetic-sparing properties, its adverse effects made it unsuitable for intrathecal administration.

When added to standard doses of morphine and a non- steroidal analgesic, *S*-ketamine 0.5 mg/kg had no additional benefit in a randomized, double-blind study in 30 patients undergoing anterior cruciate ligament repair (9).

Organs and Systems

Cardiovascular

Tachycardia and hypertension are common after anesthetic induction with ketamine, although the hypertension can be limited by the addition of diazepam (10). Nodal dysrhythmias can also occur (11). Because of possible

© 2006 Elsevier B.V. All rights reserved.

reduced cardiac and pulmonary performance, ketamine should be avoided in critically ill patients (12). Pulmonary vasoconstriction and increased ventricular preload secondary to ketamine can be deleterious (13).

The effects of intramuscular premedication with either clonidine 2 micrograms/kg or midazolam 70 micrograms/kg on perioperative responses to ketamine anesthesia have been assessed in a placebo-controlled study in 30 patients (14). Clonidine significantly reduced intraoperative oxygen consumption, mean arterial pressure, and heart rate compared with midazolam and placebo. Thus, clonidine was as effective as midazolam, the standard drug used for this purpose, in reducing the undesirable sympathetic stimulation of ketamine.

Oral clonidine, 2.5 or 5.0 micrograms/kg, 90 minutes before ketamine 2 mg/kg has been compared with placebo in 39 patients (15). In those given clonidine 2.5 micrograms/kg, heart rate responses were reduced compared with placebo (maximum heart rate 97 versus 76 beats/minute). In those given clonidine 5 micrograms/kg, heart rate responses were less (maximum heart rate 97 versus 77 beats/minute) and mean arterial pressure was lower (121 versus 141 mmHg), and there were fewer nightmares and less drooling.

Respiratory

Apnea occurred after the intramuscular injection of ketamine 4 mg/kg to sedate a healthy 4-year-old boy (16). This case illustrates the need for adequate monitoring and preparation for emergency airway management when using ketamine for sedation.

Nervous system

Ketamine causes a significant rise in cerebrospinal fluid pressure, increased electroencephalographic activity, and possibly epileptiform discharges (17).

Delayed acute intracranial hypertension has been described after ketamine anesthesia (18).

Oral ketamine is an effective analgesic in patients with chronic pain. In 21 patients with central and peripheral chronic neuropathic pain treated with oral ketamine, the starting dose was ketamine 100 mg/day, titrated upward by 40 mg/day increments every 2 days until a satisfactory effect was achieved, or until adverse effects became limiting (19). Nine patients discontinued ketamine because of intolerable adverse effects, including psychotomimetic symptoms, such as "elevator" effect or dissociative feelings, somnolence or insomnia, and sensory changes such as taste disturbance and somatic sensations.

In a study of 21 outpatients with refractory neuropathic pain treated with oral ketamine, 17 reported adverse events (20). The most common were light-headedness, dizziness, tiredness, headache, a nervous floating feeling, and bad dreams. The adverse effects were sufficiently important to prevent ten patients from continuing with the trial.

Neurotoxicity due to focal lymphocytic vasculitis has been reported close to the catheter injection site in a patient who received intrathecal ketamine infusion for chronic cancer pain (21).

- A 72-year-old woman with abdominal pain due to peritoneal malignant mesothelioma was given patient-controlled analgesia with morphine and then a thoracic epidural infusion of bupivacaine 0.125% and morphine 0.04 mg/ml at a rate of 6–12 ml/hour, with minor success. A thoracic intrathecal catheter was inserted for infusion of bupivacaine 0.25% plus morphine 0.12 mg/ml at a rate of up to 3.5 ml/hour. The morphine concentration was increased to 0.3 mg/ml and then clonidine 3 micrograms/ml was added. Satisfactory pain relief was finally achieved by adding ketamine 1 mg/ml, containing benzethonium chloride as a preservative. The mean daily intrathecal dose of ketamine was 67 mg. After 7 days she had an acute psychotic reaction and the ketamine was withdrawn. There were no neurological deficits. She died 10 days later. There was focal lymphocytic vasculitis in the spinal medullary tissue, in the nerves, and in the leptomeninges of the thoracolumbar spinal cord.

This neurotoxicity could have been due to the preservative benzethonium chloride or the ketamine. However, several other agents, including bupivacaine, morphine, and clonidine, were also given intrathecally, so causality was not proven, even though the other agents have not been associated with this problem.

There have been several attempts to understand the pathophysiology of schizophrenia using subanesthetic doses of ketamine to probe glutaminergic function in healthy and schizophrenic volunteers; no long-term adverse consequences were attributable to ketamine (22).

Psychological, psychiatric

In a randomized, double-blind, crossover study of cognitive impairment in 24 volunteers who received *S*-ketamine 0.25 mg/kg, racemic ketamine 0.5 mg/kg, or *R*-ketamine 1.0 mg/kg, the ketamine isomers caused less tiredness and cognitive impairment than equianalgesic doses of racemic ketamine (23). In addition, *S*-ketamine caused less reduction in concentration capacity and primary memory.

A placebo-controlled study of low-dose ketamine infusion in ten volunteers showed formal thought disorder and impairments in working and semantic memory (24). The degree of thought disorder correlated with the impairment in working memory.

Psychotomimetic effects

The psychotomimetic effects of ketamine, apart from encouraging illicit use, can lead to distressing psychic disturbances, particularly in children (13); there can be nightmares, delirium, and hallucinations (25). Oral ketamine is an effective analgesic in patients with chronic pain. In 21 patients with central and peripheral chronic neuropathic pain treated with oral ketamine, the starting dose was ketamine 100 mg/day, titrated upward by 40 mg/day increments every 2 days until a satisfactory effect was achieved, or until adverse effects became limiting (19). Nine patients discontinued ketamine because of intolerable adverse effects, including psychotomimetic symptoms, such as "elevator" effect or dissociative feelings, somnolence or insomnia, and sensory changes such as taste disturbance and somatic sensations.

© 2006 Elsevier B.V. All rights reserved.

The pharmacological effects of the *R*- and *S*-enantiomers of ketamine have been compared in 11 subjects who received *R*-ketamine 0.5 mg and then *S*-ketamine 0.15 mg, separated by 1 week (26). Before and after each drug administration they were subjected to a painful stimulus using a nerve stimulator applied to the right central incisor tooth. Pain suppression was equal with the two drugs. The subjects reported more unpleasant psychotomimetic effects with *S*-ketamine and more pleasant effects with *R*-ketamine. Seven of eleven subjects preferred *R*-ketamine, while none preferred *S*-ketamine. These results suggest that the neuropsychiatric effect of ketamine may be predominantly due to the *S*-enantiomer, and that *R*-ketamine may be a better alternative. This study is in direct distinction to earlier work suggesting that *R*-ketamine is responsible for most of the undesirable neuropsychiatric side effects of ketamine.

A placebo-controlled study in 10 healthy young men showed a linear relation between ketamine plasma concentrations of 50–200 ng/ml and the severity of psychotomimetic effects (27). The psychedelic effects were also similar to those observed in a previous study of dimethyltryptamine, an illicit LSD-25 type of drug, and were a function of plasma concentration rather than simply an emergence phenomenon. Clinically useful analgesia was obtained at plasma concentrations of 100–200 ng/ml. At plasma concentrations of 200 ng/ml, all subjects had lateral nystagmus. When ketamine is given in large doses, patients rapidly become unresponsive, and so the effects described in this study are usually only observed during the recovery phase.

There have been several attempts to understand the pathophysiology of schizophrenia using subanesthetic doses of ketamine to probe glutaminergic function in healthy and schizophrenic volunteers; no long-term adverse consequences were attributable to ketamine (22).

Prevention

There have been several attempts to attenuate the unpleasant psychological adverse effects that occur after sedation with ketamine.

Prior use of benzodiazepines or opiates limits the psychotomimetic effects of ketamine. There has been a double-blind, placebo-controlled study of the role of lorazepam in reducing these effects after subanesthetic doses of ketamine in 23 volunteers who received lorazepam 2 mg or placebo, 2 hours before either a bolus dose of ketamine 0.26 mg/kg followed by an infusion of 0.65 mg/kg/hour or a placebo infusion (28). The ability of lorazepam to block the undesirable effects of ketamine was limited to just some effects. It reduced the ketamine-associated emotional distress and perceptual alterations, but exacerbated the sedative, attention-impairing, and amnesic effects of ketamine. However, it failed to reduce many of the cognitive and behavioral effects of ketamine. There were no pharmacokinetic interactions between subanesthetic doses of ketamine and lorazepam.

The effect of intravenous midazolam 0.05 mg/kg on emergence phenomena after ketamine 1.5 mg/kg intravenously for painful procedures has been assessed in a randomized, double-blind, placebo-controlled study in 104 children (29). Midazolam was given 2 minutes after the ketamine. There was no significant difference between the two groups in levels of agitation. The overall rate of agitation was low, but probably high enough to detect any significant differences between the groups.

The neuropsychiatric effects of ketamine were modulated by lamotrigine, a glutamate release inhibitor, in 16 healthy volunteers (30). Lamotrigine 300 mg was given 2 hours before ketamine 0.26 and 0.65 mg/kg on two separate days. There were fewer ketamine-induced perceptual abnormalities, fewer schizophreniform symptoms, and less learning and memory impairments. Mood-elevating effects were increased with lamotrigine. The authors commented that the results were experimental and that further studies are needed to confirm the potential benefits in a larger group of patients.

The hypothesis that the unpleasant emergence phenomena that often accompany the use of ketamine, including odd behavior, vacant stare, and abnormal affect, would be reduced by the use of a selected recorded tape played during the perioperative period has been tested in 28 adults (31). The incidence of dreams was higher when the recorded tape was connected. This report emphasizes the current recommendations that a quiet room with minimal stimuli is best for reducing emergence phenomena after ketamine sedation.

Endocrine

In a double-blind, randomized, placebo-controlled crossover comparison of the effects of ketamine and memantine in 15 male volunteers, ketamine increased serum prolactin and cortisol concentrations, whereas memantine and placebo did not (32).

Liver

Serum enzyme activities (alkaline phosphatase, aspartate transaminase, alanine transaminase, and gamma-glutamyl transpeptidase) were raised in 14 of 34 patients anesthetized with ketamine; the significance of this is unknown (33).

Long-Term Effects

Drug abuse

Media reports suggest that in some countries the non-medical (illicit) use of ketamine has greatly increased (34).

Drug Administration

Drug administration route

The addition of ketamine to bupivacaine for spinal anesthesia has been studied in 60 patients undergoing spinal anesthesia for insertion of intracavitary brachytherapy implants for cervical carcinoma (8). They were randomly assigned to receive either bupivacaine 10 mg or bupivacaine 7.5 mg plus ketamine 25 mg. Motor recovery was significantly quicker in the ketamine group. Blood pressure was significantly lower in the bupivacaine group 5 minutes after administration, and perioperative

© 2006 Elsevier B.V. All rights reserved.

intravenous fluid requirements were significantly higher. Patients given ketamine reported more sedation and dizziness, both intraoperatively and postoperatively. There were no nightmares or dissociative features. Overall satisfaction was better with bupivacaine. The study was abandoned after 30 patients, because of the high rate of adverse effects with ketamine. Although ketamine had local anesthetic-sparing properties, its adverse effects made it unsuitable for intrathecal administration.

Drug–Drug Interactions

Alfentanil

The interaction of ketamine with the respiratory depressant effect of alfentanil has been studied in eight healthy men, who received alfentanil as a continuous computer-controlled infusion aiming at a plasma concentration of 50 ng/ml and either an infusion of racemic ketamine increasing step-wise through 50, 100, and 200 ng/ml or placebo (35). Alfentanil caused hypoventilation by reducing respiratory rate, and this was antagonized by ketamine in a concentration-dependent manner. This combination may be effective in overcoming the adverse effects of either agent individually.

Haloperidol

The interaction of the dopamine antagonist haloperidol 5 mg orally with subanesthetic doses of ketamine has been studied in a placebo-controlled study in 20 healthy volunteers over 4 days (36). Haloperidol pretreatment reduced impairment of executive cognitive functions produced by ketamine and reduced the anxiogenic effects of ketamine. However, it failed to block the ability of ketamine to produce psychosis, perceptual changes, negative symptoms, or euphoria, and it increased the sedative and prolactin responses to ketamine. These results imply that ketamine may impair executive cognitive functions via dopamine receptor activation in the frontal cortex, but that the psychoactive effects of ketamine are not mediated via dopamine receptors, but rather via NMDA receptor antagonism.

Ketanserin

General Information

Ketanserin is a selective 5-HT_2 receptor antagonist with antihypertensive action. Because it antagonizes the vasoconstriction and platelet aggregation induced by 5-HT and increases erythrocyte deformability, its potential usefulness in peripheral vascular disease has been extensively investigated, although never convincingly demonstrated. It has been reported to be beneficial in pre-eclampsia (1).

Most of the adverse effects attributable to ketanserin seem, not surprisingly, to be on the central nervous system. They include drowsiness, fatigue, headache, sleep disturbances, and dry mouth. Other complaints include dizziness, light-headedness, lack of concentration, and dyspepsia. A gradual increase in dosage is therefore recommended. These adverse effects occur in about 10% of patients and lead to withdrawal of the drug in 3–4% (SEDA-17, 243).

Organs and Systems

Cardiovascular

Dose-related prolongation of the QT interval on the electrocardiogram occurs in roughly one-third of patients taking ketanserin (2). Several cases of ventricular dysrhythmias with QT prolongation, leading to syncope, have been reported (SED-11, 392) (SED-12, 473), but the exact incidence of significant ventricular dysrhythmias on the basis of QT prolongation during ketanserin therapy is unknown.

Drug–Drug Interactions

Ecstasy

In 14 healthy subjects, ketanserin attenuated the perceptual changes, emotional excitation, and acute adverse responses induced by ecstasy, but had little effect on positive mood, well-being, extroversion, and short-term sequelae (3). Body temperature was lower with ecstasy plus ketanserin than with ecstasy alone.

Potassium-wasting diuretics

Prolongation of the QT interval by ketanserin is more pronounced when it used in combination with potassium-wasting diuretics (4). This combination must therefore be avoided.

Ketobemidone

General Information

Ketobemidone is an opioid receptor agonist, with pharmacokinetics and potency similar to morphine. Combined with the antispasmodic drug, *N*,*N*-dimethyl-3,3-diphenyl-1-methylallylamine chloride, ketobemidone is often used in Scandinavia.

In a study of postoperative pain relief, ketobemidone equalled morphine and pethidine with respect to efficacy of analgesia and adverse effects, such as shivering, nausea, and vomiting (SEDA-16, 81).

© 2006 Elsevier B.V. All rights reserved.

Organs and Systems

Respiratory

Early cough in 40 of 121 patients given ketobemidone for postoperative analgesia has been reported. Four of the patients found it severe and distressing. The lower frequency of cough in patients previously exposed to ketobemidone in the premedication may reflect tachyphylaxis (SEDA-17, 81).

Ketoconazole

See also Antifungal azoles

General Information

Ketoconazole was the first azole available for oral administration. However, it has been supplanted by newer azoles with fewer adverse effects and more reliable absorption from the gastrointestinal tract. Even after years of use, new adverse effects (often related to high doses and/or newer indications) continue to be reported.

Ketoconazole is water-soluble at a pH of below 3. Its oral absorption is influenced by the acidity of the stomach contents, and the concomitant administration of histamine H_2 receptor antagonists, proton pump inhibitors, antacids, or food affects its absorption. A high carbohydrate meal ingested with ketoconazole reduces total drug absorption, while a high lipid meal increases it. Erratic absorption is particularly apparent in patients with AIDS. Peak serum concentrations are seen within 2–3 hours. The half-life is about 8 hours. CSF penetration is less than 10% (1). Ketoconazole is extensively metabolized in the liver and excreted in the bile in an inactive form; less than 1% of the active drug is excreted in the urine. Clearance is not significantly altered by renal dialysis (1).

In man, higher doses of ketoconazole affect cortisol/cortisone and androgen/testosterone substrates. This finding has led to the use of ketoconazole in Cushing's disease and prostate cancer, but the phenomenon is also responsible for some of the adverse effects, especially those associated with higher doses and prolonged use (SED-12, 677). The potency of ketoconazole in inhibiting P450 isozymes (such as CYP3A4) is a cause of interactions with several other drugs.

Use in non-infective conditions

The efficacy of ketoconazole 400 mg qds in the early treatment of acute lung injury and acute respiratory distress syndrome has been investigated in a randomized, double-blind, placebo-controlled trial in 234 patients (2). Ketoconazole was safe but had no effects on mortality, lung function, or the duration of mechanical ventilation.

Because of its potent inhibitory effects on adrenal steroidogenesis by interference with cytochrome CYP450, ketoconazole controls hypercortisolism when surgery is contraindicated or unsuccessful. The effects of oral ketoconazole 200–1200 mg qds for 65–83 months in three patients who had residual or recurrent Cushing's disease after surgical treatment have been reported (3). The dosage of ketoconazole was adjusted according to the clinical response and 24-hour urinary excretion of free cortisol. All three patients had good clinical and biochemical responses to therapy with ketoconazole and had no adverse effects.

General adverse effects

Gastrointestinal complaints, including anorexia, nausea, gastralgia, and constipation are the most frequent adverse effects of ketoconazole. Hepatotoxicity, varying in degree from mild disturbances of liver function tests to hepatitis and rare cases of fulminating hepatic necrosis, has been reported. Some cases have been reported in the first weeks of treatment, but duration of treatment is of importance and in prolonged courses of treatment, monitoring is advisable. With the use of high doses, especially for longer periods of time, the effects of interference with hormonal balance should be watched for. Adrenal insufficiency has been reported even with low-dose treatment. Pruritus and skin reactions have been reported, but do not in general cause major problems. Hypersensitivity reactions are rare. Tumor-inducing effects have not been reported.

Organs and Systems

Respiratory

Patients undergoing esophagectomy are at increased risk of acute lung injury, perhaps related to increased concentrations of thromboxane in the postpulmonary circulation. In 38 consecutive patients undergoing esophagectomy, perioperative ketoconazole, which inhibits thromboxane synthesis, reduced the incidence of acute lung injury (4).

Nervous system

Headache, dizziness, nervousness, and somnolence have been reported (SED-11, 573). The incidences are low. Encephalopathy can occur as a result of severe liver damage.

Sensory systems

Eyes

Papilledema has been reported in one patient taking ketoconazole. The condition cleared on withdrawal of ketoconazole and recurred on resumption 2 months later (SEDA-18, 284).

Psychological, psychiatric

In one patient taking a high dosage for prostate cancer, weakness was associated with mental disturbances, notably confabulation and disorientation in time and space (SEDA-13, 233).

Endocrine

Gynecomastia was occasionally observed in men when ketoconazole first became available. Ketoconazole has a marked effect on steroid concentrations, including a change in the testosterone/estradiol ratio, and this is most likely to be the basis of the gynecomastia. A lowering of testosterone serum concentrations and

© 2006 Elsevier B.V. All rights reserved.

a reduced response of testosterone concentrations to human gonadotropin have been shown (SED-11, 573) (5). Various studies have shown suppression of testosterone, androstenedione, and dehydroepiandrosterone, with reciprocal increases in gonadotrophins.

Reductions in serum and urinary cortisol concentrations have been reported in patients taking ketoconazole and signs of hypoadrenalism have been seen during high-dose treatment. However, it is not clear whether the asthenia syndrome described in the past (severe muscle weakness, most pronounced in the legs, fatigue, apathy, and anorexia) is related to hypoadrenalism. In some cases, hypoadrenalism has been described shortly after the start of low-dose treatment. Substitution therapy may be required, since simple withdrawal of ketoconazole may not redress hormonal balance quickly enough.

Various studies have shown that ketoconazole interferes with 17- and 20-hydroxylases and inhibits mitochondrial 11-α-hydroxylase and cytochrome P450-dependent steroid hydroxylase enzymes (SED-12, 677) (6) (SEDA-12, 228) (SEDA-14, 234).

Because of its effects on the pituitary/adrenal system, ketoconazole has been used in the long-term control of hypercortisolism of either pituitary or adrenal origin (SED-12, 677). In seven patients with Cushing's disease and one with an adrenal adenoma, ketoconazole 600–800 mg/day for 3–13 months produced rapid persistent clinical improvement (7). Plasma dehydroepiandrosterone sulfate concentrations and urinary 17-ketosteroid and cortisol excretion fell soon after the start of treatment, and remained normal or nearly so throughout treatment. Urinary tetrahydro-11-deoxycortisol excretion rose significantly. Plasma cortisol concentrations fell. Plasma ACTH concentrations did not change and individual plasma ACTH and cortisol increments in response to CRH were comparable before and during treatment. The cortisol response to insulin-induced hypoglycemia improved in one patient and was restored to normal in another. The patients recovered normal adrenal suppressibility in response to a low dose of dexamethasone during ketoconazole treatment.

The effect of ketoconazole appears to be mediated by inhibition of adrenal 11-β-hydroxylase and 17,20-lyase, and in some unknown way it prevents the expected rise in ACTH secretion in patients with Cushing's disease (SEDA-12, 228) (SEDA-17, 323). It may, however, cause such a rapid reduction in serum cortisol concentrations that a crisis is precipitated, and patients' adrenal function should be carefully monitored. While ketoconazole (400–800 mg/day) may be a good alternative to other adrenal steroid inhibitors, patients should be observed for signs of hepatotoxicity. Acute adrenal crisis occasionally occurs (8).

Because ketoconazole has antiandrogenic properties, it is particularly suitable for women, in whom it has few effects on menstruation and does not cause hirsutism. In men, however, long-term inhibition of androgen production can be disruptive, especially if it leads to gynecomastia and hypogonadism. Combination with aminoglutethimide and metyrapone has been advocated in order to avoid these effects (SEDA-17, 323).

Ketoconazole (400 mg/day) has been used for the treatment of hirsutism and acne in women, but adverse effects, such as headache, nausea, loss of scalp hair, hepatitis, and biochemical changes, were impressive (9–11).

Hematologic

Fatal aplastic anemia has been reported during ketoconazole therapy (12).

Gastrointestinal

Nausea, mild gastrointestinal symptoms, and vomiting can occur in patients taking ketoconazole; diarrhea has been reported, but the incidence is low (SED-12, 678). The incidence of gastrointestinal complaints is higher with the use of daily doses above 800 mg (13).

Liver

Mild and often transient rises in serum liver enzyme activities are not uncommon in patients taking ketoconazole; the incidence is reported to be about 10–15% (SEDA-12, 229). This figure is higher than originally thought (SED-11, 573) (14), the newer figures probably representing a greater awareness of the risk rather than a true increase; it is possible, however, that the use of higher doses plays a role (SED-12, 678).

The incidence of symptomatic hepatic injury associated with ketoconazole is estimated to be about one in 10 000 treated cases (SEDA-18, 284). Biochemically, the pattern was hepatocellular in 54%, cholestatic in 16%, and mixed cholestatic-hepatocellular in 30%. Histology (14 cases) showed a predominantly hepatocellular pattern in 57%, with extensive centrilobular necrosis and mild to moderate bridging (14,15). Lethal cases of toxic hepatitis and a case necessitating transplantation have been reported (14,16,17).

- A girl developed fatal liver failure while taking ketoconazole for Cushing's syndrome (18). The authors proposed using metyrapone when temporary control of hypercortisolism is required in childhood and adolescence.

A cohort study of the risk of acute liver injury among users of oral antifungal drugs has been performed in the general population of the General Practice Research Database in the UK (19). The cohort included 69 830 patients, free from liver and systemic diseases, who had received at least one prescription for oral griseofulvin, fluconazole, itraconazole, ketoconazole, or terbinafine between 1991 and 1996. Five cases of acute liver injury occurred during the use of oral antifungal drugs. Two of the patients were taking ketoconazole, another two itraconazole, and one terbinafine. The incidence rates of acute liver injury were 134 (CI = 37, 488) per 100 000 person-months for ketoconazole, 10 (CI = 2.9, 38) for itraconazole, and 2.5 (CI = 0.4, 14) for terbinafine. One case was associated with past use of fluconazole. Ketoconazole was the antifungal drug that was associated with the highest relative risk, 228 (CI = 34, 933) compared with the risk among non-users, followed by itraconazole and terbinafine, with relative risks of 18 (CI = 2.6, 73) and 4.2 (CI = 0.2, 25) respectively.

Skin

The risk of serious skin disorders has been estimated in 61 858 users, aged 20–79 years, of oral antifungal drugs identified in the UK General Practice Research Database

© 2006 Elsevier B.V. All rights reserved.

(20). They had received at least one prescription for oral fluconazole, griseofulvin, itraconazole, ketoconazole, or terbinafine. The background rate of serious cutaneous adverse reactions (corresponding to non-use of oral antifungal drugs) was 3.9 per 10 000 person-years (95% CI = 2.9, 5.2). Incidence rates for current use were 15 per 10 000 person-years (1.9, 56) for itraconazole, 11.1 (3.0, 29) for terbinafine, 10 (1.3, 38) for fluconazole, and 4.6 (0.1, 26) for griseofulvin. Cutaneous disorders associated with the use of oral antifungal drugs in this study were all mild.

Pruritus and occasional rashes can occur in patients taking ketoconazole (21). Rare cases of a fixed drug eruption have been reported (SED-12, 678) (22) (SEDA-17, 323).

Musculoskeletal

- Muscle weakness and diffuse myalgia were reported in a 17-year-old man with multiple endocrine neoplasia syndrome type 1 taking ketoconazole for oral candidiasis. The electromyogram showed a distinct myopathic pattern. Withdrawal of the ketoconazole was followed by rapid improvement (SEDA-17, 323).

In rats, high doses (80 mg/kg) caused syndactyly in one experiment (SED-11, 574). There are insufficient data to determine whether there might be a harmful effect in humans.

Second-Generation Effects

Lactation

Ketoconazole can be found in the milk of lactating dogs receiving ketoconazole; there are insufficient data to decide whether harm might ensue to the breast-fed child.

Susceptibility Factors

Age

Because ketoconazole interferes with steroid synthesis and vitamin D metabolism, ketoconazole should not be used in children. It is not approved for use in children and there is no pediatric dosage range based on pharmacokinetic information in this population.

Sex

Liver complications may be more common in elderly people, in women, or in subjects in whom liver function is already compromised for other reasons.

Other features of the patient

Ketoconazole interferes with steroidogenesis, and those who are critically ill (23) or HIV-positive (24) are particularly susceptible to adrenal insufficiency from the use of ketoconazole.

Drug–Drug Interactions

Aciclovir

Ketoconazole seems to have a synergistic antiviral effect when it is taken with aciclovir (25).

Alcohol

A disulfiram-type reaction of ketoconazole with alcohol has been reported (SEDA-12, 231).

Amphotericin

Combination of ketoconazole with amphotericin reportedly leads to antagonism, particularly if ketoconazole therapy precedes amphotericin (26).

Antacids

Co-administration of antacids reduces the absorption of ketoconazole (13).

Antihistamines

Ketoconazole can increase the concentrations of astemizole and terfenadine by inhibition of CYP3A4. High concentrations of terfenadine can cause cardiac toxicity. Increased plasma concentrations of unmetabolized terfenadine prolong the QT interval and carry the risk of torsade de pointes and other fatal ventricular arrhythmias (13).

Ebastine (10 and 20 mg/day) had no clinically important effect on QT_c interval in adults, including elderly people, children, and patients with hepatic or renal impairment, and co-administration with ketoconazole or erythromycin did not lead to significant changes in the QT_c interval (27,28).

The pharmacokinetic and pharmacodynamic interactions of emedastine difumarate and ketoconazole have been investigated in 12 healthy volunteers (29). Emedastine difumarate 4 mg was given orally for 10 consecutive days, and on days 6–10 ketoconazole 200 mg bd was co-administered. Emedastine steady-state pharmacokinetics were slightly altered by ketoconazole: the AUC rose by about 33% and total clearance fell by about 30%, with no change in the half-life, suggesting that the volume of distribution also changed; this pattern could have arisen from protein binding displacement. However, there was no change in the QT_c interval after 5 days of co-treatment. The authors concluded that concomitant treatment with emedastine and ketoconazole in subjects with normal QT intervals could therefore be undertaken without special precautions.

When single doses of erythromycin (333 mg) or ketoconazole (200 mg) were given to healthy men who used levocabastine, two sprays per nostril (0.05 mg/spray) bd for 6 days, there were no changes in the pharmacokinetics of levocabastine or in the QT_c interval (30).

Ketoconazole affects plasma concentrations of loratadine, a non-sedating antihistamine, but appears to be devoid of any electrocardiographic effects (31). In a randomized, single-blind, multiple-dose, three-way, crossover study, concomitant administration of loratadine 10 mg qds and ketoconazole 200 mg bd resulted in significantly increased mean loratadine plasma

© 2006 Elsevier B.V. All rights reserved.

concentration by 307% and desloratadine plasma concentrations by 73%; ketoconazole plasma concentrations were unaffected by loratadine. Despite increased concentrations of loratadine and its metabolite, there were no statistically significant differences in the electrocardiographic QT_c interval.

Benzodiazepines

In a double-blind, crossover kinetic and dynamic study of the interaction of ketoconazole with alprazolam and triazolam, two CYP3A4 substrate drugs with different kinetic profiles, impaired clearance by ketoconazole had more profound clinical consequences for triazolam than for alprazolam (32). By the same mechanism ketoconazole also inhibits the metabolism of midazolam (33).

Calcium channel blockers

The effects of ketoconazole 200 mg on the pharmacokinetics of nisoldipine 5 mg have been investigated in a randomized, cross-over trial (34). Pretreatment with and concomitant administration of ketoconazole resulted in 24-fold and 11-fold increases in the AUC and C_{max} of nisoldipine, respectively. The ketoconazole-induced increase in plasma concentrations of the metabolite M9 was of similar magnitude. Thus, ketoconazole and other potent inhibitors of CYP3A should not be used concomitantly with nisoldipine.

In an intestinal perfusion study of the effect of ketoconazole 40 μg/ml on the jejunal permeability and first-pass metabolism of (*R*)- and (*S*)-verapamil 120 μg/ml in six healthy volunteers, ketoconazole did not alter the jejunal permeability of the isomers, suggesting that it had no effect on the P-glycoprotein mediated efflux. However, the rate of absorption increased, suggesting inhibition by ketoconazole of the gut wall metabolism of (*R/S*)-verapamil by CYP3A4 (35).

Carbamazepine

Serum concentrations of ketoconazole are reduced by concomitant use of drugs that induce hepatic microsomal enzymes, such as carbamazepine. There may at the same time be a change in serum carbamazepine concentration (13,25).

Ciclosporin

The fact that ketoconazole inhibits cytochrome P450 accounts for some of its interactions. Ketoconazole increases ciclosporin concentrations, enhancing the risk of renal impairment, as shown by a fall in creatinine clearance (SED-12, 678) (6,13,25,36).

The effect of ketoconazole in ciclosporin-treated kidney transplant recipients has been the subject of a prospective randomized study (37). In 51 ketoconazole-treated patients and 49 controls there was a similar frequency of acute rejection episodes. However, in the control group, rejection episodes were more recurrent, with a poorer response to treatment. Acute ciclosporin nephrotoxicity was more common in the ketoconazole group, but this was encountered more at induction and rapidly reversed on further reduction of the dose of ciclosporin. Chronic graft dysfunction was significantly less in the ketoconazole group during the first year, but by the end of the study the difference was not statistically significant. Hepatotoxicity was similar in the two groups. Serum concentrations of cholesterol, low-density lipoprotein, and triglycerides were lower in the ketoconazole group. The authors concluded that long-term low-dose ketoconazole in ciclosporin-treated kidney transplant recipients is safe and cost-saving.

Citalopram

The effect of ketoconazole on the pharmacokinetics of citalopram has been studied in a double-blind, three-way, crossover trial in 18 men and women (38). The subjects received three treatments with a 14-day washout period: a single dose of ketoconazole 200 mg plus placebo, a single dose of citalopram 40 mg plus placebo, and a single dose of ketoconazole 200 mg plus a single dose of citalopram 40 mg. There were no changes in the pharmacokinetics of citalopram after co-administration of ketoconazole, suggesting that ketoconazole and other CYP3A4 inhibitors can be safely co-administered with citalopram.

Clozapine

The interaction of ketoconazole (400 mg/day for 7 days) with clozapine has been evaluated in five patients with schizophrenia given a single dose of clozapine 50 mg at the end of ketoconazole therapy (39). Ketoconazole did not significantly change the disposition of clozapine or its metabolism to its principal metabolites, desmethylclozapine and clozapine-*N*-oxide.

Donepezil

Donepezil 5 mg produced no change in plasma concentrations of ketoconazole 200 mg (40).

Erythromycin

If erythromycin and ketoconazole, both CYP3A4 inhibitors, are taken in combination, there will be an even more dramatic effect on the metabolism of other drugs, such as terfenadine and astemizole, midazolam and triazolam, and ciclosporin.

Halofantrine

Halofantrine, a highly lipophilic antimalarial drug with poor and erratic absorption, is metabolized to its equipotent metabolite desbutylhalofantrine and this is inhibited by oral ketoconazole (41).

Histamine H_2 receptor antagonists

Co-administration of histamine H_2 receptor antagonists reduces the absorption of ketoconazole (13).

HIV protease inhibitors

The effects of co-administration of ketoconazole 400 mg and amprenavir 1200 mg, which is mostly metabolized by CYP3A4, have been studied in an open, randomized, balanced, single-dose, three-period, crossover study in 12 healthy men (42). Co-administration of the two drugs increased the amprenavir AUC by 31% and reduced its C_{max} by 16%. Amprenavir increased the AUC of

© 2006 Elsevier B.V. All rights reserved.

ketoconazole by 44% and increased its half-life and C_{max} by 23% and 16% respectively. Thus, co-administration of amprenavir and ketoconazole result in statistically significant increases in the AUCs of both agents, but the clinical significance of these changes remains to be investigated.

The pharmacokinetic interaction of fluconazole 400 mg od and indinavir 1000 mg tds has been evaluated in a placebo-controlled, crossover study for 8 days; there was no significant interaction (43).

The effect of ketoconazole (200 and 400 mg qds) on plasma and cerebrospinal fluid concentrations of ritonavir (400 mg bd) and saquinavir (400 mg bd) have been investigated in a two-period, two-group, longitudinal pharmacokinetic study in 12 HIV-infected patients (44). Ketoconazole significantly increased the AUC and trough concentrations of ritonavir and prolonged its half-life (by 29%, 62%, and 31% respectively). It produced similar changes (37%, 94%, and 38% respectively) in the kinetics of saquinavir. Ketoconazole significantly increased the ritonavir CSF concentration at 4–5 hours after the dose by 178% (from 2.4 to 6.6 ng/ml), with no change in the paired unbound plasma concentration (26 ng/ml). The changes were not related to ketoconazole dose or plasma exposure. The corresponding changes in saquinavir CSF concentrations were not significant. The authors concluded that ketoconazole inhibited the systemic clearance of ritonavir and, because of the disproportionate increase in CSF concentrations compared with the increase in plasma concentrations, that there was greater inhibition of drug efflux from the CSF.

A study in seven HIV-infected men who took saquinavir 600 mg tds in addition to two other antiretroviral drugs and concomitant ketoconazole (200 mg qds for 7 days, followed by 400 mg qds for another 7 days) showed no significant differences in peak and trough concentrations of saquinavir after the addition of ketoconazole (45). There was substantial inter-subject variability in the study, and the authors concluded that saquinavir concentrations may be unpredictable in individual patients and that drug monitoring may be required for optimizing saquinavir treatment.

Ifosfamide

The effect of ketoconazole on the CYP-mediated metabolism of ifosfamide to 4-hydroxyifosfamide and the ultimate cytotoxic ifosforamide mustard, and its deactivation to 2- and 3-dechloroethylifosfamide has been studied in a randomized, crossover study in 16 patients, who received intravenous ifosfamide 3 g/m^2/day, either alone or in combination with ketoconazole 200 mg bd 1 day before treatment and during 3 days of concomitant administration (46). Ketoconazole did not affect the fraction metabolized or exposure to the dechloroethylated metabolites and thus did not alter the pharmacokinetics of ifosfamide or its metabolism.

Isoniazid

Combined administration of ketoconazole with isoniazid can lead to increased concentrations of the latter, and there are possibly also alterations in ketoconazole concentrations (SED-12, 678) (25).

Methylprednisolone

The effect of ketoconazole on steroid metabolism is reflected in other interactions. Ketoconazole increases the total amount of methylprednisolone in the body (SED-12, 678) (47).

Oral contraceptives

The reported reduction in the effect of oral contraceptives (SEDA-12, 231) concurs with the effect of ketoconazole on steroid metabolism; the effect seems to be mild and may be mainly of importance during the use of formulations with low estrogen content (SED-12, 678) (48).

Phenazone

Ketoconazole reduces the clearance of phenazone (antipyrine) (SED-11, 574) (49).

Phenytoin

Serum concentrations of ketoconazole are reduced by concomitant use of drugs that induce hepatic microsomal enzymes, such as phenytoin. There may at the same time be a change in serum phenytoin concentration (SED-12, 678) (13,25,50).

Proton pump inhibitors

Co-administration of proton pump blockers reduces the absorption of ketoconazole (13).

Reboxetine

Reboxetine is metabolized by CYP3A4. In 11 healthy volunteers, ketoconazole increased the AUC of reboxetine by about 50% and increased its half-life (51). The adverse effects profile of reboxetine was not altered by ketoconazole.

Rifamycins

Serum concentrations of ketoconazole are reduced by concomitant use of drugs that induce hepatic microsomal enzymes, such as rifampicin. There may at the same time be a change in rifampicin serum concentration (SED-12, 678) (13,25,36).

Ropivacaine

Ketoconazole 400 mg caused a minor reduction in the clearance of ropivacaine, which is mostly metabolized by CYP1A2 (52).

Statins

In two cases, rhabdomyolysis occurred after co-administration of simvastatin 20 mg/day and ketoconazole (53).

Theophylline

The combination of ketoconazole with theophylline was reported to have reduced theophylline concentrations, suggesting increased metabolism of theophylline (SEDA-13, 234). This is surprising, since one would have expected ketoconazole to have inhibited the metabolism of theophylline, if at all. However, in 10 healthy, non-smoking men aged 18–40 years

© 2006 Elsevier B.V. All rights reserved.

aminophylline 6 mg/kg intravenously before and after they had taken oral ketoconazole 200 mg/day for 7 days caused no change in the half-life or clearance of theophylline (54), so there is probably no important interaction between these two drugs.

Tolterodine

Tolterodine is eliminated by two different oxidative metabolic pathways: hydroxylation, catalysed by CYP2D6, and *D*-alkylation, catalysed by CYP3A. The pharmacokinetics and safety of tolterodine and its metabolites in the absence and presence of ketoconazole have been investigated in healthy volunteers with deficient CYP2D6 activity (poor metabolizers) (55). Clearance of tolterodine fell by 60% during co-administration of ketoconazole, resulting in a 2.1-fold increase in AUC. Thus, caution is needed when ketoconazole and other potent inhibitors of CYP3A are used concomitantly with tolterodine.

Tretinoin

A potential interaction of ketoconazole with tretinoin (all-trans retinoic acid), resulting in slowed metabolism, is probably not of importance (56).

Warfarin

Potentiation of the effects of warfarin has been reported in one case (SED-12, 678) (57), but absence of interference with anticoagulants was also claimed.

Ziprasidone

Ziprasidone is oxidatively metabolized by CYP3A4, but it does not inhibit CYP3A4 or other isoenzymes at clinically relevant concentrations. The effect of ketoconazole 400 mg qds for 6 days on the single-dose pharmacokinetics of ziprasidone 40 mg has been evaluated in an open, placebo-controlled, crossover study in healthy volunteers (58). Ketoconazole caused a modest increase in the mean AUC (33%) and the mean C_{max} (34%) of ziprasidone. This effect was not considered clinically relevant and suggests that other inhibitors of CYP3A4 are unlikely to affect the pharmacokinetics of ziprasidone significantly. Most of the reported adverse events were mild. The adverse events that were most commonly reported in subjects who took the drugs concomitantly were dizziness, weakness, and somnolence. There were no treatment-related laboratory abnormalities or abnormal vital signs during the study and at the 6-day follow-up evaluation.

Zolpidem

Zolpidem is metabolized by CYP3A. Ketoconazole 200 mg bd impaired the clearance of zolpidem 5 mg and enhanced its benzodiazepine-like pharmacodynamic effects. In contrast, itraconazole 100 mg bd and fluconazole 100 mg bd had small effects on zolpidem kinetics and dynamics (59).

Ketolides

General Information

The ketolides cethromycin (ABT-773) and telithromycin are semisynthetic derivatives of 14-membered-ring macrolide antibiotics, members of the macrolide-lincosamide-streptogramin-B, MLS(B), class of antimicrobials, but they differ from macrolides by having a 3-keto group instead of an L-cladinose group on the erythronolide A ring (1–3). In a study of the efficacy of the ketolides HMR 3004 (previously RU 004) and telithromycin (HMR 3647, previously 66 647) against beta-lactamase-producing *Haemophilus influenzae*, the in vitro activity of both ketolides against 30 clinical isolates was comparable to that of azithromycin and superior to clarithromycin and erythromycin A. Furthermore, HMR 3004 and HMR 3647 were both active in a murine model of experimental pneumonia, as assessed by pulmonary clearance of beta-lactamase producing *H. influenzae* (4).

Telithromycin has a good spectrum of activity against respiratory pathogens, including penicillin-resistant and erythromycin-resistant pneumococci, intracellular bacteria, and atypical bacteria. It has an absolute oral availability of 57% in young and elderly subjects (5), and the rate and extent of absorption is unaffected by food (6). It penetrates rapidly into bronchopulmonary, tonsillar, sinus, and middle ear tissues/fluids, achieves high concentrations at sites of infection, and concentrates within polymorphonuclear neutrophils. In a dosage of 800 mg/day it is well tolerated across all patient populations, and adverse events, most commonly diarrhea, nausea, dizziness, and vomiting, are generally mild to moderate in intensity and seldom lead to treatment withdrawal (7–9).

Organs and Systems

Cardiovascular

Telithromycin causes prolongation of the QT interval, especially in elderly patients with predisposing conditions (2).

Long-Term Effects

Drug tolerance

In subjects receiving oral telithromycin (800 mg/day for 10 days), high drug concentrations were detected in the saliva indicating a good therapeutic profile for throat infections. Quantitative ecological disturbances in the normal microflora during administration of telithromycin were moderate, and no overgrowth of yeasts or *Clostridium difficile* occurred. However, resistant bacterial strains emerged (10).

The in vitro activity of cethromycin was very similar to that of telithromycin, with an MIC_{90} of 0.5 mg/l or less for all bacteria examined, except methicillin-resistant *Staphylococcus aureus*, *Enterococcus faecalis*, *Enterococcus faecium*, *H. influenzae*, and *Bacteroides* species. However, the antichlamydial activity of cethromycin was greater than that of telithromycin (11).

Drug–Drug Interactions

Cytokines

Cytokines modify phagocyte activity and may interfere with the immunomodulating properties of antibacterial agents. In an in vitro study, TNF-α and GM-CSF reduced the inhibitory effect of telithromycin on oxidant production by polymorphonuclear neutrophils, suggesting an effect of telithromycin downstream of the priming effect of cytokines. In addition, TNF-α and GM-CSF moderately impaired the uptake of telithromycin by polymorphonuclear neutrophils; the inhibitory effect of these two cytokines seemed to be related to the activation of the p38 mitogen-activated protein kinase (12).

Ketoprofen

See also Non-steroidal anti-inflammatory drugs

General Information

The spectrum of adverse effects of ketoprofen is similar to that of ibuprofen.

Ketoprofen was originally approved for over-the-counter sales in the USA by the FDA, but in the same year, in Italy, the Ministry of Health transferred two ketoprofen-containing products from non-prescription to prescription status (SEDA-20, 93). The reasons for this difference are not clear.

Organs and Systems

Respiratory

A fatal asthmatic reaction has been described (1), and severe bronchospasm with respiratory and cardiac arrest has been reported in a young man with a history of mild asthma after he took ketoprofen (2). Topical application can provoke asthma in predisposed subjects (3).

Even topical formulations of NSAIDs should be avoided in patients with a history of analgesic-induced asthma (4).

- A 74-year-old woman with a history of sinusitis, nasal polyps, and analgesic-induced asthma had a sudden life-threatening attack of asthma 2 hours after the application of a 2% ketoprofen adhesive tape. Asthma had not previously occurred when she had used a 0.3% ketoprofen adhesive patch.

Nervous system

Retention of salt and water, sometimes with reversible pseudotumor cerebri, can occur with ketoprofen (5).

Gastrointestinal

The overall frequency of adverse reactions was 15–50% in different trials; gastrotoxicity predominated, at a frequency of 6.5–42% (6–8), even after rectal administration. In some epidemiological studies, ketoprofen in prescription doses was more gastrotoxic than other NSAIDs (SEDA-18, 99).

There are very few data on the gastrointestinal toxicity of over-the-counter doses of ketoprofen. In an endoscopic short-term study in healthy subjects ketoprofen was associated with significant gastrointestinal toxicity (9). Another endoscopic study showed that the *R*-enantiomer of ketoprofen has less gastrointestinal toxicity than the racemic mixture or the *S*-enantiomer while retaining good analgesic activity (SEDA-22, 116).

Local symptoms, including rectal bleeding, can accompany treatment with ketoprofen suppositories (8.3% of patients) (6).

Liver

Hepatotoxicity has rarely been reported with ketoprofen (SEDA-17, 110).

Urinary tract

Like many other NSAIDs, ketoprofen can cause acute interstitial nephritis (10). Renal insufficiency and the nephrotic syndrome due to membranous glomerulonephritis (an unusual cause of NSAID-induced nephrotic syndrome) have been described in an elderly patient taking long-term ketoprofen (SEDA-12, 86).

As topical NSAIDs can be absorbed via the skin, they cannot be considered safe in high-risk patients, in whom all NSAIDs are contraindicated.

- A 62-year-old woman developed acute renal insufficiency after using topical ketoprofen for 5 days (11). She had several predisposing factors to NSAID-induced acute renal insufficiency, such as advanced age, chronic renal impairment due to polycystic kidney disease, and treatment with an ACE inhibitor and furosemide.

Ketoprofen use has been followed by red discoloration of urine (SEDA-16, 110).

Skin

Topical ketoprofen can cause contact dermatitis and photodermatitis, like other NSAIDs (SEDA-18, 104) (SEDA-22, 116). Data from Sweden have confirmed the photosensitizing potential of topical gel formulations of ketoprofen and have included a number of reports of contact dermatitis (12). In some cases ketoprofen can be responsible for very prolonged photosensitivity after only a single application (13).

Toxic epidermal necrolysis has been described with ketoprofen (SEDA-21, 105).

Drug Administration

Drug administration route

Studies on a modified-release formulation of ketoprofen showed a similar pattern of adverse effects to the usual formulations (SEDA-12, 86).

An injectable form of ketoprofen has acceptable tolerability (6,7), but about 4.5% of patients have local reactions.

© 2006 Elsevier B.V. All rights reserved.

Drug overdose

A 64-year-old woman had auditory and visual hallucinations, persecutory delusions, and slurred speech after she took an overdose of ketoprofen; her psychiatric symptoms resolved within 48 hours (14).

Drug–Drug Interactions

Aspirin

Concurrent administration of aspirin reduces ketoprofen protein binding and increases its clearance. Salicylate also reduces the metabolic conversion of ketoprofen to its conjugates and their renal elimination, and enhances its conversion to non-conjugated metabolites (15).

Co-triamterzide

Irreversible renal insufficiency has been reported in an elderly patient who took ketoprofen in combination with co-triamterzide (triamterene + hydrochlorothiazide) (16). The interaction with triamterene is well documented (SEDA-12, 80) and co-administration with ketoprofen has proved dangerous.

Warfarin

Although data from healthy subjects indicate no interaction of ketoprofen with warfarin, severe gastrointestinal bleeding and a prolonged prothrombin time have been attributed to this combination (SEDA-13, 81).

Ketorolac

See also Non-steroidal anti-inflammatory drugs

General Information

Ketorolac is, like several other NSAIDs, promoted as a non-narcotic analgesic. This is merely a marketing ploy, which does not reflect any special characteristics, except that it is one of many NSAIDs that can be given parenterally. A pyrrolizine carboxylic acid derivative, it is structurally and pharmacologically related to tolmetin, zomepirac, and indometacin. The trometamol salt of ketorolac enhances its solubility and allows parenteral administration; single intramuscular injections are better tolerated than morphine.

Opinions on the safety of ketorolac in EC drug regulatory authorities are conflicting (SEDA-18, 104) (1). However, the risk of adverse effects is higher when ketorolac is used in higher doses, in elderly subjects, and for more than 5 days (SEDA-21, 105).

Other information on the benefit-to-harm balance of parenteral ketorolac tromethamine as a postoperative analgesic has been provided by three studies (SEDA-21, 105). The overall risk of gastrointestinal and operative site bleeding and acute renal insufficiency associated with parenteral ketorolac and a parenteral opiate were relatively small.

The most commonly reported symptoms are somnolence, headache, dizziness, nausea, dyspepsia, and abdominal pain. Edema, hyperkalemia, diarrhea, sweating, self-limiting wheezing, and itching have also been reported occasionally (SEDA-12, 86) (SEDA-16, 110) (SEDA-17, 111).

There are contrasting data on the benefit-to-harm balance of parenteral ketorolac as an analgesic (SEDA-21, 105). This prompted regulatory review of ketorolac in many countries, leading to revision of labelling, dosage recommendations, and prescribing practices. The use of ketorolac should be limited in dosage and duration; in elderly patients it should probably not be used at all. It is important for prescribers to understand that increasing the dosage of ketorolac beyond the label recommendations (60–120 mg/day for a maximum of 2–5 days) will not provide better efficacy, but will increase the risk of serious adverse reactions (2).

Organs and Systems

Sensory systems

Reversible hearing loss with tinnitus and headache were described in a woman with a predisposition to ototoxicity in end-stage renal disease (SEDA-21, 106).

Hematologic

Ketorolac prolongs bleeding time reversibly. The clinical significance of the effect of ketorolac on hemostasis in perioperative use is still imperfectly understood. Serious bleeding, either at the operative site or in the gastrointestinal tract after perioperative administration of ketorolac, has been documented in several reports (SEDA-18, 105) and in controlled studies (SEDA-20, 93). Concomitant use of anticoagulants increases the risk of bleeding (SEDA-18, 105).

Gastrointestinal

Gastric lesions (endoscopically demonstrated erosions, ulcers, and giant duodenal or gastric ulcers) have been described in healthy volunteers (SEDA-14, 94) and patients (SEDA-18, 105) treated with parenteral ketorolac (SEDA-14, 94); gastric damage is dose-related (SEDA-17, 112). A case-control study on hospitalization for upper gastrointestinal tract bleeding and/or perforation provided further evidence of the unfavorable benefit-to-harm balance of ketorolac compared with other NSAIDs. Ketorolac was five times more gastrotoxic than all other NSAIDs. The relative risk with intramuscular ketorolac was higher than with oral ketorolac (SEDA-22, 117).

Further evidence of the unfavorable benefit-to-harm balance of ketorolac compared with other NSAIDs has been provided by another case-control study on first-time hospitalization for gastroduodenal ulcer (documented by endoscopy, radiology, surgery, or autopsy), with or without bleeding or perforation. Of all the NSAIDs used in outpatients the highest rate ratio for lesions of any degree of severity was seen with piroxicam (4.6; 95% CI = 1.4, 8.3); ketorolac ranked second highest (3.4; 95% CI = 1.4, 8.3). For patients who suffered hemorrhage or perforation, the highest rate ratio observed was for ketorolac (5.9; 95% CI = 2.1, 16) (3).

Colonic ulceration with massive bleeding has been reported in a woman who received ketorolac intramuscularly (SEDA-21, 106).

Urinary tract

There have been several reports of impaired renal function in patients taking ketorolac (SEDA-17, 112) (SEDA-18, 105) (SEDA-22, 117). The severity varies from slight to severe forms of renal insufficiency, which may even occur after a single dose of 30 mg. Because recent major surgery is considered a risk factor for renal insufficiency, particularly in elderly patients, the use of ketorolac, or other NSAIDs, for postoperative pain management is warranted only in carefully selected patients. Furthermore, a case report confirmed that oral ketorolac can cause acute renal insufficiency in young subjects without any predisposing factors (SEDA-21, 106).

Immunologic

Anaphylaxis and anaphylactoid reactions have been reported (SEDA-17, 112).

Second-Generation Effects

Pregnancy

As ketorolac crosses the placental barrier, it should not be used in pregnant women. When it is given to mothers during labor, it significantly inhibits platelet aggregation in the neonate (SEDA-14, 94).

Susceptibility Factors

Other features of the patient

Children undergoing tonsillectomy had a significant increase in the risk of major postoperative hemorrhage without beneficial effects, compared with opioid analgesics (SEDA-21, 106).

Several reports have documented the high risk of ketorolac in patients with a history of asthma, nasal polyposis, and sensitivity to aspirin or any other NSAID (SEDA-18, 105). Exacerbation of chronic asthma has been reported after the use of ketorolac eye-drops (SEDA-21, 106).

Drug–Drug Interactions

Lithium

Reports of lithium neurotoxicity resulting from an interaction with ketorolac have been published (SEDA-22, 117) (4).

In a pharmacokinetic study in healthy volunteers ketorolac increased the concentration of lithium in both serum and erythrocytes, which may reflect concentration of the drug in the nervous system more accurately. Ketorolac can therefore increase the risk of adverse reactions of lithium (5), as do many other NSAIDs.

Ketotifen

See also Antihistamines

General Information

Ketotifen was originally developed as a drug that would inhibit the release of vasoactive substances from mast cells, as an oral alternative to cromoglicate, but its actions in asthma are probably attributable to its antihistaminic effect (SED-13, 423) (SEDA-22, 194), which occurs within minutes after administration and lasts for up to 12 hours. It also stabilizes mast cells, preventing histamine release, inhibits eosinophil accumulation in the lungs of animals exposed to platelet-activating factor, and reverses beta-adrenoceptor tachyphylaxis (1). It is classified as an antiallergic drug and is used as a prophylactic medicine.

Some trials have suggested that ketotifen has similar efficacy to cromoglicate in asthma (2) and also a small steroid-sparing effect (3). It is more effective than placebo in the treatment of atopic dermatitis (4). The normal therapeutic dose is 1–2 mg/day.

Conjunctival injection, headache, and rhinitis are common. Allergic reactions, stinging, discharge, eye pain, and photophobia occurred in less than 5% of patients. The most common adverse effects noted in long-term clinical trials are sedation and weight gain (SEDA-7, 1).

In young children (with an average age 16 months) effective doses of ketotifen produced adverse effects similar to those seen in adults, including dry mouth (28%) and sometimes increased appetite (5). In a series of 257 older children, increased weight was reported in 17, sedation in 13, and nausea in 3 (6). An evaluation of postmarketing surveillance of ketotifen in the UK showed, however, that the percentage of adverse effects reported in children was rather lower than in adults, sedation occurring in only 6% at the beginning of treatment. The corresponding figure in adults was 14.2% (7).

Organs and Systems

Nervous system

There is considerable controversy about the frequency and severity of sedation. Although it is commonly reported when ketotifen is started (23% in one study), its incidence falls during the first 2 months to about 6%. Only 2–3% of patients discontinue therapy for this reason (8). In a study involving 1791 patients, with allergic paroxysmal asthma, somnolence occurred in 13%. This effect started early in treatment and wore off in more than one-third of the patients (2).

Ketotifen produced seizures in a 5-year-old epileptic boy with allergic rhinitis. This was not specific to ketotifen but the result of H_1 receptor blockade. Administration of D-chlorphenamine increased the number of epileptic discharges seen on the electroencephalograph. It is recommended that centrally acting H_1 receptor antagonists should be avoided in epileptic patients, especially children (9).

Two cases of seizures in children induced by ketotifen have been reported (10).

- A 3-month-old boy was given ketotifen (0.1 mg/kg/day) for atopic dermatitis and after 8 days developed tonic spasms of a mixed flexor extensor type, consisting of flexion of the neck and arms with extension of the legs more than 10 times a day. Each seizure lasted for 5–15 minutes. An electroencephalogram showed a hypsarrhythmic trace. Ketotifen was withdrawn and the seizures were successfully controlled with ACTH and valproic acid. An MRI scan was normal.
- A 3-month-old boy was given ketotifen, 0.1 mg/kg/day, for asthmatic bronchitis. After 10 days his facial movements altered and 1 month after ketotifen was started tonic spasms began. His seizures consisted of a sudden contraction, usually bilateral and symmetrical involving the muscles of the neck, trunk, and limbs. An electroencephalogram showed a hypsarrhythmic trace. He was treated with ACTH and clonazepam without benefit. Ketotifen was withdrawn and ACTH and clonazepam were replaced with valproic acid. This resulted in seizure control, after which the electroencephalogram showed no abnormal discharges. Blood tests and an MRI scan were normal.

There is evidence that the central histaminergic neurons play an important role in inhibiting convulsions in the immature brain, where the GABA system is less effective than in the adult brain. Histamine acts via an H_1 receptor and other H_1 receptor antagonists can cause seizures. The authors proposed that ketotifen induces infantile spasms by antagonizing H_1 receptors.

Urinary tract

A single case of drug-induced cystitis has been reported. The patient had never taken tranilast, and the symptoms resolved on stopping ketotifen and recurred when the drug was restarted. Aseptic pyuria was found and cystoscopy revealed significant reddening over the urinary bladder (11).

Drug Administration

Drug overdose

Eight cases of overdose have been reported in which the patients took doses ranging from 10 to 120 mg (12). The plasma concentrations were considerably higher than those after therapeutic doses. The symptoms of overdose were drowsiness, confusion, coma, dyspnea, bradycardia and tachycardia, hyperexcitability, convulsions, and nystagmus. Six patients were treated with gastric lavage and after supportive treatment all eight patients made a full recovery within 12 hours of admission.

Labetalol

See also Beta-adrenoceptor antagonists

General Information

Labetalol is a non-selective alpha- and beta-adrenoceptor antagonist; these actions reside in four different enantiomers.

Labetalol is less likely to increase airways resistance in patients with bronchial asthma or to reduce peripheral blood flow. However, it can produce postural hypotension (SEDA-3, 166–7), and paresthesia of the scalp (1,2) and perioral numbness (3) have been described.

Organs and Systems

Cardiovascular

Labetalol is generally used effectively as an antihypertensive drug without reports of high vascular resistance, even in patients with pheochromocytoma. However, a case of pheochromocytoma with increased systemic vascular resistance and reduced cardiac index has been described (4).

- A 36-year-old man with a pheochromocytoma underwent adrenalectomy. After induction of anesthesia he was given intravenous labetalol 30 mg, and after intubation his blood pressure rose from 147/85 to 247/150 mmHg, his systemic vascular resistance index rose from 1958 to 3458 dyn·sec^{-1} m^2 cm^5, and his cardiac index fell to 3.6 l min^{-1} m^2. During tumor resection, he was given sodium nitroprusside to reduce his blood pressure. After tumor resection, his blood pressure fell to 77/52 mmHg and his systemic vascular resistance index to 1635 dyn·sec^{-1} m^2 cm^5. His blood pressure was effectively controlled with dobutamine.

This case affords a reminder that intravenous labetalol can increase the systemic vascular resistance and cause a hypertensive crisis. In these cases, labetalol should be replaced with a pure alpha-blocker or another vasodilator, to prevent the possibility of cardiovascular complications.

Neonatal cardiac arrest was precipitated in one case by labetalol (5).

Electrolyte balance

Three cases of severe hyperkalemia have been reported in renal transplant recipients taking labetalol for acute hypertension (6) and life-threatening hyperkalemia has been reported after intravenous labetalol (7).

- A 28-year-old man with severe hypertension and end-stage renal disease was given two intravenous doses of labetalol 20 mg 1 hour apart for malignant hypertension. The serum potassium concentration before treatment was 6.2 mmol/l, but 8 hours after labetalol it rose to 9.9 mmol/l and he developed left bundle branch block, ventricular tachycardia, and hypotension. He was given intravenous calcium gluconate, sodium bicarbonate, and lidocaine and reverted to sinus rhythm. The potassium concentration after 2 hours was 8.0 mmol/l. After hemodialysis the potassium concentration fell to 6.1 mmol/l.

In a retrospective chart review in 103 transplanted patients from January to November 1994, hypertension requiring perioperative treatment was observed in 51 cases (8). Treatment for hyperkalemia was necessary in 13 of the 38 patients who were treated with labetalol, compared with 11 of the 65 who were treated with another antihypertensive treatment.

Patients with end-stage renal disease on dialysis can have an enhanced hyperkalemic response to labetalol, which is partly attributable to electrochemical disturbances in the cells, characterized by an increase in intracellular sodium and chloride and a fall in intracellular potassium.

Liver

Eleven cases of hepatotoxicity have been reported with labetalol (9). Acute hepatitis has been described in an East-Asian man (10).

- A 50-year-old man with chronic hepatitis B infection, a hemiparesis due to a hemorrhage in the left basal ganglia, and a high systolic blood pressure was given intermittent intravenous labetalol followed by oral therapy (200 mg bd). After 1 week, his aspartate transaminase, alanine transaminase, and bilirubin started to rise. Ultrasonography of the liver and gallbladder was normal. Labetalol was withdrawn, and all the liver function tests normalized within a few days.

Prior hepatitis B infection may have predisposed this patient to labetalol-induced liver toxicity.

Musculoskeletal

Two children developed a proximal myopathy and rhabdomyolysis, which resolved on withdrawal of labetalol (11).

Immunologic

Antinuclear and antimitochondrial antibodies develop not uncommonly during long-term administration of labetalol (12).

Second-Generation Effects

Fetotoxicity

Labetalol has a high transplacental transfer rate.

- A single intravenous dose of labetalol 30 mg given to a woman with severe pregnancy-related hypertension 20 minutes before cesarean section was associated with significant neonatal beta-adrenoceptor blockade (hypoglycemia, bradycardia, and hypotension), and there were high labetalol concentrations in the umbilical cord blood (150–180 ng/ml) (13).
- An infant was born dead to a woman given intravenous labetalol 50 mg, which lowered her blood pressure from 170/110 to 115/85 mmHg before surgery (14).

Oral labetalol is well tolerated in pre-eclampsia, but if intravenous treatment is necessary, a small dose (5–10 mg) should be used initially and titrated up as necessary.

Lamiaceae

See also Herbal medicines

General Information

The genera in the family of Lamiaceae (Table 1) include basil, catnip, germander, lavender, mints, origanum, rosemary, sage, skullcap, and thyme.

Hedeoma pulegoides and *Mentha pulegium*

The volatile oil of pennyroyal (prepared from *Hedeoma pulegoides* or *Mentha pulegium*) is a folk medicine used as an abortifacient. The doses that are required for this effect can cause serious symptoms, including vomiting, seizures, hallucinations, renal damage, hepatotoxicity and shock; deaths have also occurred (1,2).

Adverse effects

The hepatotoxicity of pulegone, the principal constituent of pennyroyal oil, has been demonstrated in animal studies and reported in humans (3).

Two cases of serious or fatal toxicity have been described in two infants who had been treated with herbal tea containing pennyroyal oil (4). One infant developed fulminant liver failure with cerebral edema and necrosis; the other infant developed hepatic dysfunction and a severe epileptic encephalopathy.

Lavandula angustifolia

The volatile oil of *Lavandula angustifolia* (lavender) contains linrayl acetate and linalool, and lavender also contains coumarins. It has been used in aromatherapy to treat insomnia and headaches, and may have small beneficial effects (5).

Adverse effects

Patch tests with lavender oil from 1990 to 1998 in Japan were positive in 3.7% of cases (6). In five of 11 positive cases in 1997 and eight of 15 positive cases in 1998, the patients had used dried lavender flowers in pillows, drawers, cabinets, or rooms.

- A 53-year-old patient with relapsing eczema had contact allergy to various essential oils used in aromatherapy (7). Sensitization was due to previous exposure to lavender, jasmine, and rosewood. Laurel, eucalyptus, and pomerance also produced positive tests, without previous exposure.

Contact dermatitis has been attributed to a lavender oil pillow (8), and to lavender in an analgesic gel (9).

Mentha piperita

The oil of *Mentha piperita* (peppermint) contains cineol, limonene, menthofuran, menthol, and menthone. It has been used as a carminative and antispasmodic for esophageal spasm and irritable bowel syndrome (10).

Adverse effects

Contact dermatitis has been attributed to menthol in peppermint (11).

Salvia species

In China, the root of *Salvia miltiorrhiza* (danshen) has been used traditionally for the treatment of coronary diseases.

The leaf of *Salvia officinalis* (sage) contains 1.0–2.5% of essential oil, consisting of 35–60% of thujone.

Adverse effects

A patient taking warfarin and who had taken a decoction of *S. miltiorrhiza* presented with a prolonged bleeding time and melena (12) and other cases have been reported (13). Pharmacodynamic and pharmacokinetic studies in rats have shown that danshen increases the absorption rate constant, AUC, C_{max}, and half-lives of both *R*- and *S*-warfarin, and reduces their clearances and apparent volumes of distribution (14,15).

Thujone can cause toxicity when the herb is taken in overdose (more than 15 g per dose) or for a prolonged period. Pregnancy is listed as a contraindication to the use of the essential oil or alcoholic extracts of *S. officinalis*.

Scutellaria species

The *Scutellaria* species (skullcap) include over 40 members, which contain a variety of flavonoids and terpenoids, the latter including scutellariosides and smithiandienol. Some also contain pyrrolizidine alkaloids (see separate monograph), which have repeatedly been implicated in veno-occlusive disease of the liver.

Adverse effects

Although Western skullcap formulations are supposed to come from *Scutellaria lateriflora*, it is unclear whether it is responsible for the liver damage that has been associated with skullcap. In the UK, the American germander (*Teucrium canadense*) has been widely used to replace *S. lateriflora* in commercial skullcap materials and products. In one UK case of skullcap-associated hepatotoxicity, the material was found to come from *T. canadense*. This raises the possibility that other cases of skullcap toxicity may also have involved *Teucrium* rather than *Scutellaria* (16).

Respiratory

- A 53-year-old Japanese man, who had taken skullcap intermittently for hemorrhoids, developed recurrent interstitial pneumonitis (17). Re-challenge, after he had stopped taking the herbal remedy and had become symptom free, resulted in a high fever and signs and symptoms of interstitial pneumonitis. Transbronchial lung biopsy showed lymphocytic alveolitis with eosinophilic infiltration. The symptoms subsided again after withdrawal.

Liver

Skullcap has repeatedly been associated with hepatotoxicity, and veno-occlusive disease has been reported (18).

- A 28-year-old man presented with jaundice after taking six tablets of skullcap (together with zinc and pau d'arco) daily for the previous 6 months to help his multiple sclerosis. His liver enzymes were raised and hepatitis A, B, and C serologies were negative. He developed progressive liver failure and received a transplant but died shortly after. His explanted liver showed fibrous stenosis and obliteration of most of the terminal venules with extensive perivenular fibrosis, indicative of veno-occlusive disease.

Teucrium species

Teucrium species (germander) contain a variety of iridoids, monoterpenoids, diterpenoids, and sesquiterpenoids.

© 2006 Elsevier B.V. All rights reserved.

Adverse effects

The hepatotoxicity of germander has been well documented. An animal study suggests that the hepatotoxicity resides in one or more reactive metabolites of its furanoditerpenoids (19).

In France, many cases of hepatitis have been associated with the normal use of *Teucrium chamaedrys* (wall germander). The frequency of this adverse effect has been estimated at one case in about 4000 months of treatment (20). Two cases of hepatitis in women who had been taking germander daily for 6 months have been reported from Canada (21). Although most cases are not serious, deaths have been reported (22), and progression to liver cirrhosis has also been described (23).

Seven patients developed hepatitis after taking *T. chamaedrys* and had no other cause of liver damage (24). The hepatitis was characterized by jaundice and a marked increase in serum transaminases 3–18 weeks after taking germander. Liver biopsies in three patients showed hepatic necrosis. After withdrawal of germander the jaundice disappeared within 8 weeks and recovery was complete in 1.5–6 months. In three cases, germander was followed by prompt recurrence of hepatitis.

- A 62-year-old man had taken a tea made from *T. capitatum* for 4 months when he developed anorexia, nausea, and malaise (25). He also noted dark urine and jaundice. He was admitted to hospital with acute icteric hepatitis. A liver biopsy showed bridging necrosis, inflammatory infiltration, and bile emboli. After withdrawal of the herbal tea he made a full recovery within 3 months.

Several other cases have been reported (26–30).

Lamivudine

See also Nucleoside analogue reverse transcriptase inhibitors (NRTIs)

General Information

Lamivudine (3TC) is a nucleoside analogue reverse transcriptase inhibitor that has been widely used against HIV infection which also has antiviral effects against hepatitis B (1).

Observational studies

In a 24-week phase I/II study, 89 children aged 3 months to 17 years (median 7.3 years) were treated with lamivudine for 24 weeks in dosages of 1–20 mg/kg/day (2). Dosages over 20 mg/kg/day were not tested because of reported neutropenia in adults at this dosage (3). Lamivudine was generally well tolerated in these children. Ten children were withdrawn because of presumed adverse effects: three because of increased serum transaminase activities, three because of neutropenia, and two because of hyperactivity. One child became ataxic shortly after the start of therapy, and one developed pancreatitis during hospitalization for acute cryptosporidiosis. All of these events resolved with supportive care on withdrawal of lamivudine, except one case of hepatitis, which persisted up to 10 months after withdrawal. Treatment was discontinued temporarily in other patients because of pancreatitis ($n = 2$), rashes ($n = 2$), neutropenia ($n = 1$), anemia ($n = 1$), and increased serum transaminase activities ($n = 1$). On resolution of the presumed adverse reaction, the drug was reintroduced in all of these cases without further problems. There were no significant hematological or biochemical changes. Neither the incidence nor the severity of the observed adverse events was dose-related. The assignment of causality to lamivudine of most of the adverse events was complicated by intercurrent conditions and concomitant medications.

In a study of the efficacy of lamivudine (25, 100, or 300 mg/day for 12 weeks) in the treatment of chronic hepatitis B virus infections, lamivudine was similarly well tolerated in 32 patients (4). Only minor non-specific non-dose-related adverse reactions were observed. In addition, there were mild asymptomatic increases in serum activities of amylase, lipase, and creatine kinase, which in most cases resolved despite continued therapy.

Comparative studies

The safety and efficacy of lamivudine (300–600 mg/day) in combination with zidovudine (600 mg/day) in the treatment of antiretroviral-naive and zidovudine-experienced HIV-infected persons has been compared with zidovudine monotherapy in two placebo-controlled studies of 129 and 223 patients (5,6). There were no significant differences in the incidence or severity of adverse effects between patients taking zidovudine alone or in combination with lamivudine. In both studies gastrointestinal symptoms, notably nausea, were the most commonly observed adverse reactions, occurring in 5–11% of zidovudine-experienced patients and 23–29% of antiretroviral drug-naive individuals. Although one antiretroviral drug-naive patient taking combined therapy had an asymptomatic rise in pancreatic amylase activity, acute pancreatitis was not observed in either study. Grade 1 peripheral neuropathy was reported in one zidovudine-experienced patient taking low-dosage lamivudine (150 mg bd) and zidovudine.

Organs and Systems

Hematologic

A case report has provided strong evidence that lamivudine can on rare occasions cause severe anemia; the mechanism is unclear (7).

Gastrointestinal

In a 1-year trial of lamivudine in 10 children with vertically acquired chronic hepatitis B, lamivudine made serum hepatitis B viral DNA undetectable in all the patients within 24 weeks (8). Serum alanine transaminase activity returned to the reference range within 36 weeks. Although nausea and vomiting were reported in one child, it was not necessary to withhold treatment.

Liver

Lamivudine is used orally to treat chronic hepatitis B in adults and children (9). It increases the rate of loss of hepatitis B e antigen and seroconversion in compensated chronic carriers, with improvement of histology at a similar rate to interferon alfa. However, the tyrosine-methionine-aspartate-aspartate (YMDD) mutation prevents efficacy and can cause flares of hepatitis. The indications for treatment must therefore be established with care and only by those who have expert knowledge of the disease, the drug, and the YMDD mutation.

Nails

Paronychia has been reported in 12 HIV-infected patients who had taken lamivudine only for 3 months before the onset of symptoms (10). Microbiological investigations for fungi or bacteria were negative. All were treated with topical antiseptics; surgical procedures were performed in four. Five patients healed without recurrence,

© 2006 Elsevier B.V. All rights reserved.

while the paronychia recurred in six. There was no mention of withdrawal of lamivudine. The causative role of lamivudine in the development of paronychia in these patients remains obscure.

Long-Term Effects

Drug tolerance

The incidence of viral resistance to lamivudine increases with the duration of therapy in patients with chronic hepatitis B (11). However, the effect of viral resistance on hepatic synthetic function has not been well defined. In 38 patients (26 with cirrhosis) in an open study there was an initial antiviral response in all patients (hepatitis B virus DNA became undetectable by a hybridization assay), and nine of 22 (41%) hepatitis B e antigen-positive patients underwent hepatitis B e antigen seroconversion. In 29 patients with undetectable serum hepatitis B viral DNA at the end of the study, the mean serum albumin concentration rose from 40 to 43 g/l, corresponding to a yearly increase of 1.85 g/l; this was largely attributable to an increase in the cirrhotic patients. Resistance to lamivudine developed in nine patients. Suppression of viral replication by lamivudine improves hepatic synthetic function in chronic hepatitis B patients, but emergence of drug resistance is associated with a rapid fall in serum albumin.

Lamotrigine

See also Antiepileptic drugs

General Information

Lamotrigine is widely used in the management of partial and generalized seizures. It has a favorable tolerability profile, even though neurological adverse effects and hypersensitivity reactions are sometimes troublesome. Its pharmacology, clinical pharmacology, adverse effects, and interactions have been reviewed (1). Its adverse events are primarily neurological, gastrointestinal, and dermatological and are typically mild or moderate and transient, with the exception of a potentially serious rash. Maculopapular or erythematous skin rashes occur in about 12% of children and are the most common reason for withdrawal. More severe forms of rash, including Stevens–Johnson syndrome, occur occasionally, with a three-fold higher incidence in children (about 1%) than adults (about 0.3).

Observational studies

Among 11 316 patients in a postmarketing surveillance study that included 3994 patients followed for 6 months or longer, the main events leading to drug withdrawal were rash ($n = 210$), drowsiness ($n = 74$), nausea ($n = 66$), dizziness ($n = 63$), headache ($n = 61$), vomiting ($n = 33$), ataxia ($n = 32$), malaise ($n = 29$), and aggression ($n = 26$). Rare serious adverse events included Stevens–Johnson syndrome in 12 cases, neutropenia in 4, thrombocytopenia in 3, and disseminated intravascular coagulation in 2. Leukopenia, a meningitic reaction, acute renal insufficiency, hepatotoxicity, and a lupus-like reaction occurred in one patient each (2).

In an open study, there were adverse events (details not given) in two of 30 patients with serum lamotrigine concentrations between 16 and 39 μmol/l, and in 5 of 11 patients with serum concentrations between 39 and 86 μmol/l (3). This is one of the few studies to have provided preliminary evidence for a relation between serum lamotrigine concentrations and the risk of adverse effects.

The efficacy of lamotrigine as monotherapy has been studied retrospectively in 83 children (mean age 8.7 years) with focal epilepsy ($n = 43$), generalized epilepsy ($n = 32$), or not classified ($n = 8$) (4). The median follow-up period was

© 2006 Elsevier B.V. All rights reserved.

8 months (mean = 8.5). Rash was the most common adverse effect, in five patients; two patients discontinued treatment. There were no cases of Stevens–Johnson syndrome.

Lamotrigine has been used as maintenance monotherapy for rapid-cycling bipolar disorder in 324 patients (open label) and 182 patients (double-blind) with rapid-cycling bipolar disorder (5). In all, 265 patients reported adverse events during the open phase. The most common adverse events (over 10%) were headache, infection, influenza, nausea, abnormal dreams, dizziness, and rash. During the double-blind phase 122 patients reported adverse events, equally with lamotrigine and placebo.

In 44 patients with profound mental retardation a retrospective assessment of adjunctive lamotrigine (272 mg/day) showed a significant reduction in seizure frequency from 10.1 to 5.8 seizures per month (6). There were no treatment-related changes in laboratory parameters, vital signs, or body weight, and no serious rashes. In three of five patients there was worsened self-injurious behavior, requiring drug withdrawal.

Lamotrigine has been studied in 32 children with epilepsy refractory for at least 1 year to other antiepileptic drugs (7). Adverse effects were uncommon, and there were no skin rashes.

The efficacy and safety of lamotrigine have been prospectively evaluated in 41 children and young adults (aged 3–25 years) with drug-resistant partial epilepsies (8). Lamotrigine withdrawal was mainly due to lack of efficacy (46%); only two patients developed a transient skin rash, which did not require withdrawal.

The adverse effects of lamotrigine have been surveyed retrospectively in 2701 patients in five tertiary referral epilepsy centers in the UK; 1326 were excluded because lamotrigine and/or comparators had been begun outside the study centers (9). The most common adverse events were rash (10%), dizziness, ataxia, and diplopia. There were four cases of life-threatening adverse events: one case each of hepatic insufficiency, acute exacerbation of ulcerative colitis, disseminated intravascular coagulation, and renal insufficiency caused by rhabdomyolysis and myoglobinuria. The mortality rate was 1.7 per 100 patient-years and the standard mortality ratio was 10.4, similar to other antiepileptic drugs (gabapentin and vigabatrin). No deaths were directly attributable to lamotrigine.

In an open randomized study in 417 patients over 2 years old who took lamotrigine or carbamazepine monotherapy for new-onset epilepsy there was similar efficacy (65% were free of seizures with lamotrigine and 73% with carbamazepine) (10). Although the patients taking lamotrigine tended to have fewer adverse events than those taking carbamazepine (52 versus 60%), the difference was not significant. Somnolence was the only adverse event reported at an incidence of over 5% and it was more frequent in patients taking carbamazepine (11 versus 4% with lamotrigine).

Comparative studies

In a 48-week, double-blind, monotherapy trial of 260 patients with newly diagnosed epilepsy, the proportion withdrawn because of adverse events was 11% in the lamotrigine group (9% with rash) and 21% in the carbamazepine group (13% with rash). Somnolence was more frequent with carbamazepine (22 versus 12%), but the incidence of other common complaints (headache, weakness, rash, nausea, dizziness) did not differ between groups (11). Although it was concluded that lamotrigine is tolerated better than carbamazepine, in this and other trials a design that involved twice-daily dosing may have placed carbamazepine at a disadvantage in the comparison.

In a multicenter, double-blind comparison of lamotrigine and phenytoin (titrated over 6 weeks from starting dosages of 100 and 200 mg/day respectively) in 181 patients with newly diagnosed epilepsy there were comparable seizure freedom rates and comparable trial discontinuation rates with the two drugs (12). Skin rashes leading to withdrawal occurred in 12% of patients assigned to lamotrigine and in 5% of those assigned to phenytoin, but the risk associated with lamotrigine might have been overestimated, owing to an excessively high starting dose. Central nervous system adverse effects were more common with phenytoin, the difference being statistically significant for weakness (29 versus 16%), somnolence (28 versus 7%), and ataxia (12 versus 0%).

A review of the manufacturer's safety database from the adult clinical trial program has been published (13). In placebo-controlled add-on trials involving a total of 1555 patients, the most common adverse events were dizziness (35 versus 15% on placebo), headache (26 versus 21%), diplopia (25 versus 6%), ataxia (20 versus 6%), nausea (19 versus 9%), blurred vision (14 versus 4%), rhinitis (11 versus 8%), somnolence (10 versus 7%), rashes (10 versus 5%), and vomiting (10 versus 5%). Dizziness and rashes led to withdrawal most commonly, each in 2% of patients. Dizziness, diplopia, nausea, blurred vision, and headache occurred more commonly in patients co-medicated with carbamazepine than in those co-medicated with other drugs. In randomized comparative monotherapy studies, somnolence, weakness, dizziness, and ataxia occurred less often with lamotrigine than with carbamazepine or phenytoin, whereas insomnia was slightly more frequent with lamotrigine. Withdrawals due to adverse events were fewer with lamotrigine than with the other drugs. Rash associated with lamotrigine typically occurred within the first 8 weeks. Exceeding the currently recommended slow dosage escalation guidelines and co-administration of valproate are risk factors for rashes. In adults, the incidence of Stevens–Johnson syndrome was approximately 1:1000, but higher rates (1 in 50 to 1 in 300) have been reported in children (SEDA-22, 89).

In a multicenter, double-blind, monotherapy trial in 150 elderly patients with newly diagnosed epilepsy (mean age 77 years) lamotrigine (median dosage 100 mg/day) was better tolerated than carbamazepine (400 mg/day) (14). The drop-out rate for adverse events was 18% with lamotrigine compared with 42% with carbamazepine. Patients taking lamotrigine had a lower incidence of skin rashes (3 versus 19%), somnolence (12 versus 29%), and dizziness (10 versus 17%). Lamotrigine may be a better choice for initial treatment in elderly people, although the toxicity of carbamazepine might have been overestimated by giving a non-modified-release formulation twice daily. Seizure control was comparable with the two drugs, but statistical power was insufficient to demonstrate equal efficacy.

© 2006 Elsevier B.V. All rights reserved.

In 126 patients with carbamazepine-resistant or valproate-resistant epilepsy given lamotrigine, 50% during add-on therapy and 53% during lamotrigine monotherapy had at least 50% reduction in total seizures (15). There were adverse events in 49 patients, including respiratory tract infections ($n = 11$), dizziness ($n = 8$), headache ($n = 7$), diplopia ($n = 5$), tremor ($n = 5$), somnolence ($n = 4$), insomnia ($n = 4$), nausea ($n = 4$), and weakness ($n = 3$). Treatment was discontinued in nine patients because of adverse events, in five cases because of rash.

Cognitive adverse effects of lamotrigine and valproate have been compared in a double-blind, randomized, placebo-controlled study in 30 healthy volunteers who took lamotrigine 50 mg, valproic acid 900 mg, or placebo for 12 days (16). Lamotrigine had a relatively good cognitive profile but no different from that of valproic acid at the doses tested. Lamotrigine was associated with a selective general psychostimulant effect. As this study was performed in healthy volunteers taking a low dose, and conducted over a very short time, its conclusions are not generalizable to patients with epilepsy taking long-term treatment.

In a double-blind comparison of gabapentin and lamotrigine in 309 patients with new-onset partial or generalized seizures, the target doses were gabapentin 1800 mg/day and lamotrigine 150 mg/day (17). Severe adverse events were reported in 11% of patients taking gabapentin and 9.3% of patients taking lamotrigine. Two patients had serious adverse events thought to be related to the study drug; one took an overdose of gabapentin and the other had convulsions with lamotrigine. The most frequent treatment-related adverse events in both treatment groups were dizziness, weakness, and headache; 11% of patients taking gabapentin and 15% of those taking lamotrigine withdrew because of adverse events. There was an increase of over 7% in body weight from baseline in 14% of the patients taking gabapentin and 6.6% of those taking lamotrigine. There were benign skin rashes in 4.4% of those taking gabapentin and 11% of those taking lamotrigine.

Placebo-controlled studies

Lamotrigine has been used as maintenance monotherapy for rapid-cycling bipolar disorder in 324 patients (open label) and 182 patients (double-blind) with rapid-cycling bipolar disorder (5). In all, 265 patients reported adverse events during the open phase. The most common adverse events (over 10%) were headache, infection, influenza, nausea, abnormal dreams, dizziness, and rash. During the double-blind phase 122 patients reported adverse events, equally with lamotrigine and placebo.

The analgesic efficacy of lamotrigine in painful HIV-associated distal sensory polyneuropathy has been studied, given anecdotal reports of its efficacy, in a randomized, double-blind, placebo-controlled study (18). Of 42 subjects, 13 did not complete the 14-week study. Of those who took lamotrigine five dropped out because of rashes and one because of a gastrointestinal infection. The rashes were mild or moderate morbilliform rashes and resolved after withdrawal.

Organs and Systems

Nervous system

The most common adverse effects of lamotrigine include dizziness, weakness, headache, diplopia, ataxia, blurred vision, and somnolence (SEDA-18, 65) (SEDA-20, 63) (19). These effects resemble those seen with carbamazepine and can result from an adverse pharmacodynamic interaction. Tolerability is better when lamotrigine is given as monotherapy or with drugs other than carbamazepine; however, tremor develops in some patients taking valproate in combinations (SEDA-18, 66). During monotherapy, serum lamotrigine concentrations associated with intolerable adverse effects (mostly headache, dizziness, and ataxia) were 0.4–18.5 μg/ml and overlapped widely with those tolerated in other patients (20).

Irritability and aggressive behavior occur occasionally, and mentally retarded patients are possibly at greater risk (SEDA-22, 88). Rare central nervous system effects include insomnia, psychosis (SEDA-20, 63), downbeat nystagmus (SEDA-22, 89), movement disorders (SEDA-21, 72), and a Tourette-like syndrome. Lamotrigine can increase seizure frequency and severity in children with severe myoclonic epilepsy (SEDA-21, 72).

- A 47-year-old man developed a rash, fever, and rigors after taking lamotrigine (50 mg/day at maintenance) for 1 month (21). The reaction subsided after withdrawal, but 3 days later he complained of left shoulder pain and numbness in the left arm. The pain worsened over the next 3 weeks and then subsided. Thereafter, he developed weakness of the left arm with muscle wasting and signs of denervation in the biceps, infraspinatus, and supraspinatus. The condition was diagnosed as neuralgic amyotrophy. Almost complete recovery occurred over 8 months.

It is possible that the initial hypersensitivity reaction in this case determined focal neuronal involvement at the brachial plexus.

Worsening seizures

In a multicenter study, lamotrigine aggravated seizures in children with severe myoclonic epilepsy (22). Of 21 patients with severe myoclonic epilepsy given lamotrigine in dosages of 2.5–12.5 mg/kg/day, seizures were worsened in 17. The frequency of convulsive seizures increased by more than 50% in eight of 20 patients and myoclonic seizures worsened in six of 18. Of five patients who improved in at least one seizure type, four had concomitant worsening of more incapacitating seizures. The drug was withdrawn in 19 patients, with consequent improvement in 18. These findings suggest that lamotrigine is inappropriate in severe myoclonic epilepsy.

Paradoxical seizure aggravation may occur in other types of epilepsy.

- In a 5-year-old girl with benign rolandic epilepsy, the addition of lamotrigine (0.5–5 mg/kg/day) to valproate resulted in a temporary reduction in seizure frequency (23). However, her school performance deteriorated insidiously, with poor memory and concentration, clumsiness, stuttering, and emotional lability. After 4 months she developed new daily brief absence-like episodes,

© 2006 Elsevier B.V. All rights reserved.

with staring, dropping of the head and jaw, and flickering of the eyelids, without loss of consciousness. Ictal electroencephalography showed anterior-predominant 3 Hz sharp slow wave complexes. Withdrawal of lamotrigine resulted in rapid improvement of cognitive function and gradual remission of the new attacks.

- A 9-year-old girl with Lennox–Gastaut syndrome, who had initially had an improvement in seizure frequency, insidiously developed myoclonic status epilepticus after the lamotrigine dosage was increased from 15 to 20 mg/kg (24). Withdrawal of lamotrigine resulted in rapid disappearance of status.
- Two patients (age unspecified) with severe epileptic encephalopathy who had improved on lamotrigine in combination with valproate developed continuous myoclonic jerks after 2–3 years; these were ascribed to high serum concentrations of lamotrigine (65 and 69 μmol/l) (25).

In the last report, the causative role of the drug is difficult to assess, because no mention was made of whether myoclonus regressed after reducing the dosage.

Sleep disorders

Insomnia is a recognized adverse effect of lamotrigine. Among 109 patients treated with lamotrigine in an adult tertiary referral center, 7 had insomnia of sufficient severity to require a change of therapy (26). The symptom occurred shortly after the start of treatment, was dose-dependent, and resolved after withdrawal or dosage reduction. Unlike previous reports, in which insomnia occurred in patients with impaired cognition, no predisposing factor could be identified.

In another report, two boys aged 6 and 8 years developed severe difficulties in falling asleep and fragmented sleep (in one case associated with scary dreams) after being stabilized on lamotrigine, 8 mg/kg (27). These disturbances improved when the dosage was reduced.

Tics

Tics are a rare adverse effect of lamotrigine.

- Three boys and two girls (mean age 7 years) developed simple motor tics (associated with verbal tics in two cases) within 10 months of starting lamotrigine (maintenance dosage 4–18 mg/kg) (28). When lamotrigine was withdrawn, the tics resolved within 3 months in three cases (with recurrence after rechallenge in one child) and improved in one. In the fifth child, improvement occurred despite continuation of treatment. Two of the affected patients had acquired epileptic aphasia syndrome, one had expressive and receptive language dysfunction, one had a static encephalopathy, and one had no mental or neurological impairment.

These data suggest that children with severe language dysfunction may be at increased risk of developing lamotrigine-induced tics.

- A 51-year-old man developed blepharospasm 4 months after starting lamotrigine, while taking a maintenance dosage of 500 mg/day (29). The condition cleared 4 weeks after withdrawal.
- Lamotrigine (250–324 mg/day) caused Tourette syndrome in three children aged 7, 8, and 12 years; in the 12-year-old boy, the syndrome was accompanied by behavioral abnormalities suggestive of obsessive-compulsive disorder (30). All the symptoms disappeared when the dosage was reduced to 175–225 mg/day and recurred on rechallenge with higher dosages.
- Two young men (aged 18 and 22 years) with epilepsy had disabling myoclonic jerks after taking lamotrigine after 2–3 years of therapy when their plasma lamotrigine concentrations rose to about 70 μmol/l (31).
- A retrospective survey yielded five cases of tics in three men and two women aged 2.5–12 years) within the first 10 months of therapy (4–17 mg/kg/day) (32). Four had simple motor tics and one had mostly vocal tics (gasping sounds) with normal laryngoscopic evaluation. In three cases the tics resolved completely within 1 month of drug withdrawal and recurred in two after reintroduction. A fourth had gradual improvement over 4 months after withdrawal; in the fifth, simple motor tics improved spontaneously with a reduction in dose.

Psychological, psychiatric

The cognitive and behavioral effects of lamotrigine 150 mg/day have been compared with those of carbamazepine 696 mg/day in 25 healthy adults in a double-blind, crossover, randomized study with two 10-week treatment periods (33). Lamotrigine had significantly fewer cognitive and behavioral adverse effects than carbamazepine, and 48% of the variables favored lamotrigine. The differences encompassed cognitive speed, memory, graphomotor coding, neurotoxic symptoms, mood, sedation, perception of cognitive performance, and other quality-of-life perceptions. The cognitive and behavioral changes favored lamotrigine over carbamazepine, but the magnitude of the observed effects was modest, although it could be relevant in some patients.

Endocrine

In two children with cranial diabetes insipidus, desmopressin requirements fell while they were taking lamotrigine (34). Lamotrigine may act at voltage-sensitive sodium channels and reduce calcium conductance. Both of these mechanisms of action are shared by carbamazepine, which can cause hyponatremia secondary to inappropriate secretion of antidiuretic hormone.

Metabolism

In a prospective evaluation of the effect of lamotrigine 3.5–14.2 mg/kg on growth in 103 children and adolescents aged 1.6–16 years with epilepsy treated with lamotrigine monotherapy for 6–71 months, the children had normal growth, although the study had several methodological shortcomings (35).

Hematologic

Aplastic anemia occurred in one patient who had recovered 7 years earlier from bone-marrow aplasia ascribed to carbamazepine (SEDA-20, 63). Severe pure red cell aplasia in a patient with heterozygous beta-thalassemia reversed rapidly after lamotrigine withdrawal; however,

© 2006 Elsevier B.V. All rights reserved.

lamotrigine did not affect hematology parameters in another patient with the same condition (SEDA-20, 64). In two other cases of anemia associated with increased platelet counts the role of lamotrigine could not be ascertained (SEDA-22, 89).

There have been a few reports of leukopenia or neutropenia, and one case of septic shock secondary to leukopenia possibly due to lamotrigine (SEDA-20, 64).

- An 11-year-old girl with congenital left renal agenesis, epilepsy from cortical dysgenesis, and chronic hepatitis B and C, developed a skin rash and agranulocytosis (white cell count 3.1×10^9/l, lymphocytes 92%, and monocytes 8%) 15–20 days after starting to take lamotrigine (36). She recovered rapidly after drug withdrawal.

An inappropriately high starting dose (50 mg/day) may have contributed to this reaction.

Lamotrigine has been associated with agranulocytosis (37).

- A 59-year-old woman, with seizures after resection of a low-grade glioma, chemotherapy, and radiotherapy 2 years before, took lamotrigine 300 mg/day for 9 weeks and developed an agranulocytosis. The lamotrigine serum concentration was 2.2 μg/ml (usual target range 1–15 μg/ml). A bone marrow biopsy showed a hypocellular marrow with reduced myelopoiesis, a shift to the left, and normal cytogenetics. Over the next few days she developed a fever but no infection. She recovered after 10 days, having been given granulocyte-colony-stimulating factor and prophylactic antibiotics for 7 days.
- A 29-year-old woman with Blackfan–Diamond anemia developed an erythroblastopenic crisis after taking phenytoin on two separate occasions and then again after taking lamotrigine (38). The proposed mechanism was inhibition of dihydrofolate reductase, and the crisis responded to treatment with folinic acid. Lamotrigine was then continued without ill effect.
- Reversible agranulocytosis developed in a 30-year-old woman who had taken lamotrigine 100 mg/day for 6 weeks and valproate 250 mg/day for 2 weeks (39). Her white cell count fell from 6.7×10^9/l at 4 weeks to 2.6×10^9/l at 6 weeks and the absolute neutrophil count was 580×10^6/l. The white cell count recovered after withdrawal of lamotrigine; the valproate was continued.

Liver

Liver toxicity from lamotrigine is extremely rare. Acute hepatic necrosis occurred in the context of a hypersensitivity reaction that also involved the skin (SEDA-20, 64).

Four children developed reversible lamotrigine-associated hepatotoxicity (40). One had pre-existing encephalitis and the other three had multiple medical and neurological problems, fever and infections, were taking many other drugs, and had very frequent seizures; two had epilepsia partialis continua. The information given was insufficient to assess the role of lamotrigine in the pathogenesis of the hepatic dysfunction.

Reversible hepatotoxicity occurred in three children taking lamotrigine (41). In one there was severe hepatic failure. The liver abnormalities resolved after withdrawal.

Pancreas

Pancreatitis was reported in a 26-year-old man who had taken lamotrigine for 5 months, but cause and effect was dubious (SEDA-19, 61).

Skin

The rates of lamotrigine-related rash have been analysed from 12 multicenter studies of bipolar depression in 1955 patients taking open-label lamotrigine, 1198 taking lamotrigine in controlled studies, and 1056 taking placebo (42). In controlled studies, the rates of benign rash were 8.3% for lamotrigine and 6.4% for placebo. There were no serious rashes. In the open studies 13% ($n = 257$) had rashes with lamotrigine and one was reported as a mild form of Stevens–Johnson syndrome that did not require hospitalization. Thus, the risk of severe allergic rashes with lamotrigine is low, provided that there is a low initial dose and slow upward titration.

A rash, usually urticarial or maculopapular, is the most common event leading to early withdrawal of lamotrigine. In add-on trials, rashes occurred in up to 15% of patients and led to withdrawal in 2%. Six patients who developed a rash with lamotrigine later had similar rashes after exposure to structurally unrelated anticonvulsants, such as phenytoin and barbiturates (SEDA-22, 89). In 12 patients with probable Alzheimer's disease and seizures and 16 with other neurological disorders, lamotrigine caused three cases of mild rashes (43).

Published and unpublished cases of Stevens–Johnson syndrome ($n = 43$) and toxic epidermal necrolysis ($n = 14$) associated with lamotrigine have been reviewed (44). The patients with Stevens–Johnson syndrome were younger than those with toxic epidermal necrolysis (21 versus 31 years); the median time to onset for both reactions was 17 days; the median dosage at onset (50 mg for Stevens–Johnson syndrome, 87.5 mg for toxic epidermal necrolysis) did not differ significantly. Valproate comedication was present in 74% and 64% of patients with Stevens–Johnson syndrome and toxic epidermal necrolysis respectively. In three patients, toxic epidermal necrolysis occurred in the context of the anticonvulsant hypersensitivity syndrome.

An expert panel has reviewed published and unpublished data on the incidence and risk factors for lamotrigine-induced rash (45). An allergic skin rash occurs in about 10% of patients, usually in the first 8 weeks. In clinical trials, the incidence of rashes leading to hospitalization, including those associated with hypersensitivity syndrome, was about 1:300 in adults (one third as Stevens–Johnson syndrome) and 1:100 in children (50% as Stevens–Johnson syndrome). The risk increased with excessively rapid dosage titration and in patients comedicated with valproate. Up to March 1997, the manufacturer had received a total of 150 postmarketing reports of possible cases of Stevens–Johnson syndrome or toxic epidermal necrolysis, and 46 of these were in children aged 12 years or under. Of the 46 children, three were reported as having toxic epidermal necrolysis, 40 as

© 2006 Elsevier B.V. All rights reserved.

Stevens–Johnson syndrome, and 3 as suggestive of Stevens–Johnson syndrome; two deaths were reported. Rashes associated with one or more symptoms of hypersensitivity reactions occurred in 19 children. Of 29 patients with Stevens–Johnson syndrome, toxic epidermal necrolysis, or hypersensitivity reactions, for whom precise details were available, 83% were taking lamotrigine with concomitant valproate and 85% were taking lamotrigine dosages higher than recommended.

- A 33-year-old woman, who had taken valproate for 3 years, developed Stevens–Johnson syndrome soon after starting to take lamotrigine 150 mg/day (46). Lamotrigine was withdrawn and prednisolone given; the signs and symptoms progressively resolved over 10 days.

Although serious skin rashes have been reported with traditional anticonvulsants, the risk of Stevens–Johnson syndrome and toxic epidermal necrolysis with these drugs appears to be lower than with lamotrigine. Data from the Saskatchewan Health Plan suggest that the risk of serious rashes is in the order of 0.9:1000 (1.4:1000 in children) for phenytoin, 0.6:1000 (1.4:1000 in children) for carbamazepine, and 0:1000 for valproate, but Stevens–Johnson syndrome constituted only a small minority of these cases (47).

The panel agreed on the following conclusions

(1) most skin rashes from lamotrigine are benign and resolve on withdrawal;
(2) serious skin rashes occur almost entirely during the first 8 weeks and increased vigilance is recommended during this period;
(3) death from skin rashes is extremely rare (under 10 known cases);
(4) a mild rash can progress to a severe rash or to systemic involvement; fever, lymphadenopathy, facial edema, vomiting, or raised liver enzymes may indicate a hypersensitivity reaction and can precede the appearance of a rash;
(5) the following features suggest the development of a serious rash: mucous membrane lesions, blistering or peeling, facial edema, lymphadenopathy, raised liver enzymes, and leukopenia or thrombocytopenia;
(6) the risk of a rash, and possibly also serious rashes, is increased with excessive initial dosages or too fast rates of titration, combination with valproic acid (particularly in the absence of enzyme-inducing drugs), and possibly a history of skin or allergic reactions to another anticonvulsant; physicians should follow dosing instructions carefully, and be aware that dosing varies according to whether lamotrigine is added to valproate, an enzyme-inducing antiepileptic drug (such as phenytoin), or both, or is used as monotherapy;
(7) potential risks and benefits should be discussed with the patient, who should be informed about symptoms suggestive of hypersensitivity;
(8) if a rash appears, the patient should be seen by a physician within 24 hours and, if necessary, a specialist opinion should be sought; suspected cases of Stevens–Johnson syndrome and toxic epidermal necrolysis should be hospitalized for specialist care;
(9) blood chemistry and hematology may be useful to detect systemic involvement;
(10) if no alternative explanation exists, the rash should be presumed to be due to lamotrigine and the drug should be withdrawn; in patients with a rash nontypical of drug-induced rashes, lamotrigine can be continued cautiously under close monitoring if its use is deemed essential.

Fast dose escalation rate and co-administration of valproate are the most important risk factors for skin reactions. Patients should be warned to report immediately any sign of hypersensitivity, such as rash, fever, or lymphadenopathy. In selected patients who have experienced a mild rash, rechallenge with lower initial doses and slower escalation can be attempted under close supervision (48), but this should be done only when the drug is absolutely necessary, owing to the risk of serious reactions. For adults taking valproate (with or without other anticonvulsants), the dose escalation rate currently recommended by the manufacturer is 25 mg on alternate days during weeks 1 and 2, followed by 25 mg daily during weeks 3 and 4, with further increments by 25–50 mg every 1–2 weeks up to the usual maintenance dose of 100–200 mg/day (Europe) or 100–400 mg/day (USA) (49). For adults taking enzyme inducers without valproate, the escalation rate is 50 mg/day during weeks 1 and 2 followed by 50 mg bd during weeks 3 and 4, with further increments by 100 mg daily every 1–2 weeks up to the usual maintenance dose of 200–400 mg/day (Europe) or 300–500 mg/day (USA). For children aged 2–12 years, starting dosages are 0.15 mg/kg/day in the presence of valproate and 0.3 mg/kg bd in the presence of enzyme inducers without valproate (50).

Data on skin reactions from the German registry have confirmed that the risk of serious rashes is reduced by slower dose escalation (51). In 1993 there were five cases of Stevens–Johnson syndrome or toxic epidermal necrolysis, all in patients who were also taking valproate, among 1270 new patients taking lamotrigine, that is one per 254 recipients. After the recommended starting dose with valproate was reduced by a factor of four, the rates of Stevens–Johnson syndrome or toxic epidermal necrolysis fell to two of 15 500 recipients in 1994 and two of 34 700 recipients in 1995. However, this apparent change in incidence could have been explained in part by additional factors, such as greater risk awareness and consequent more cautious use of the drug, prompter withdrawal at first appearance of a rash and possibly changes in ascertainment rates.

Safe reintroduction of lamotrigine proved possible in seven young people (aged 5–19 years) who had previously had a mild rash associated with a first course (52). The lamotrigine was withdrawn immediately when the rash was identified and was subsequently reintroduced after 47–236 days using a slow escalation regimen, starting with 0.1 mg/day. Lamotrigine was successfully reintroduced without recurrence of persistent rash and without any adverse effects in all seven cases.

Hair, nails, sweat glands

Hair loss and hirsutism have been reported rarely with lamotrigine (SEDA-18, 66) (SEDA-19, 71).

© 2006 Elsevier B.V. All rights reserved.

Sexual function

- A 37-year-old schizoaffective woman taking lamotrigine monotherapy developed loss of libido and an unpleasant feeling when her erogenous zones were touched when the dosage of lamotrigine was increased from 200 to 400 mg/day (53). Surprisingly, no attempt was made to determine whether the condition could be reversed by lowering the dosage.

The authors speculated that this effect could have been related to inhibition of serotonin reuptake by lamotrigine.

Immunologic

A phenytoin-like hypersensitivity syndrome with skin rash, leukocytosis, and laboratory evidence of liver and kidney dysfunction has been attributed to lamotrigine (SEDA-22, 89).

Twenty-six lamotrigine-associated reactions consistent with the features of the anticonvulsant hypersensitivity syndrome have been reviewed, including nine previously published (54). The patients were aged 3.5–74 (mean 28) years and 14 were female. Valproate was used as comedication in 60%. Fever was present in all patients, a skin rash in 77% (with Stevens–Johnson syndrome or toxic epidermal necrolysis in five cases), hematological abnormalities in 69% (including eosinophilia in 19%), liver abnormalities in 65%, renal involvement in 23%, disseminated intravascular coagulation in 15%, and musculoskeletal disorders in 8%. Multiorgan involvement was present in 46%. One patient died. Overall, the characteristics of the syndrome were comparable to that induced by aromatic anticonvulsants, except for a somewhat higher incidence of severe skin rashes and a lower frequency of eosinophilia and lymphadenopathy.

- A 35-year-old man with Lennox–Gastaut syndrome developed tender cervical lymphadenopathy 14 weeks after lamotrigine was introduced, when the dosage was increased to 200 mg/day (55). Frozen section examination of a biopsy specimen 10 weeks later suggested lymphoma, but further histopathological investigations documented lymphoid hyperplasia consistent with a diagnosis of pseudolymphoma, which resolved 1 month after withdrawal.

This seems to have been the first report of pseudolymphoma associated with lamotrigine.

Systemic hypersensitivity reactions to lamotrigine can be severe.

- A 27-year-old woman developed disseminated intravascular coagulation, fever, rash, and hepatic dysfunction 11 days after starting lamotrigine (56). The drug dosage was not stated.
- A 17-year-old girl with a history of bipolar disorder developed fever, lymphadenopathy, skin rash, diarrhea, and acute renal insufficiency requiring dialysis after taking lamotrigine for 4 weeks (57). Renal biopsy showed acute interstitial nephritis with focal granulomas; colonic biopsy showed colitis and ileitis with non-necrotizing epithelioid granulomas.
- Severe hypersensitivity affecting the skin, lymph nodes, and liver has been reported with lamotrigine in a 36-year-old man, who had taken high doses of sodium valproate and lamotrigine for about a month (58). Skin tests were negative with both drugs, but lymphocyte stimulation tests were twice positive with lamotrigine. Later re-exposure to sodium valproate was tolerated.

Drug-induced lupus-like syndrome has been associated with lamotrigine (59).

- A 57-year-old woman, who had taken lamotrigine 2 mg/kg/day for about 2 years developed arthralgia affecting the small joints of the hands, wrists, and knees, an erythematous skin rash, myalgia, and Raynaud's phenomenon. Serum antinuclear antibodies were positive (1:320, speckled pattern), as was anti-Ro/SSA. Rheumatoid factor and anticardiolipin antibodies were negative and serum complement was normal. Lamotrigine was withdrawn and the symptoms and abnormal tests gradually normalized.

Multiorgan failure

Multiorgan failure and disseminated intravascular coagulation have been described occasionally with lamotrigine. Although these were originally considered to be secondary to seizure activity and not to lamotrigine itself (SEDA-13, 154), in at least three recent cases the drug was probably implicated (SEDA-20, 64) (60). In two affected children the presentation included fever, rash, hepatic and renal dysfunction, hypoalbuminemia, intravascular coagulation, and changes in alertness.

Death

Sudden unexplained death in epileptic patients taking lamotrigine has been considered to be related to the underlying disease and not to its treatment (SEDA-21, 72).

Long-Term Effects

Drug withdrawal

Psychomotor inhibition after rapid withdrawal of lamotrigine has been reported (61).

- A 26-year-old man with refractory generalized seizures had taken lamotrigine since the age of 22. At age 26, during presurgical evaluation with video-electroencephalography, lamotrigine was withdrawn and valproic acid 1200 mg/day and levetiracetam 1000 mg/day were continued. After 5 days he became anhedonic and had hyperhidrosis of the hands. He claimed that he had the impression that he was floating or that he was drunk. He had visual hallucinations, with stars in both visual fields, but no diplopia. He had a tremor and a slight tachycardia. Biological and toxicological results were unremarkable. An electroencephalogram ruled out status epilepticus.

The interpretation of this case is confounded by the use of levetiracetam at the onset of the symptoms. In addition, his symptoms appeared just after an admission for video-electroencephalography, during which he suffered at least one generalized tonic-clonic seizure. Thus, his symptoms could have been a mild form of postictal psychosis.

© 2006 Elsevier B.V. All rights reserved.

Second-Generation Effects

Pregnancy

Plasma lamotrigine concentrations in one woman fell during pregnancy and increased about six-fold after delivery; such changes could affect the clinical outcome (62).

Changes in lamotrigine clearance before, during, and after pregnancy were retrospectively analysed in 12 pregnancies (63). There was a significant (over 65%) increase in apparent clearance between preconception and the second and third trimesters. In 11 pregnancies higher doses of lamotrigine were required to maintain therapeutic concentrations. In the postpartum period, apparent clearance returned to the preconception baseline, and lamotrigine doses had to be reduced.

Teratogenicity

There were birth defects in eight of 123 offspring exposed to lamotrigine polypharmacy during the first trimester of pregnancy (95% CI = 3, 13%) and in none of 40 exposed to monotherapy (CI = 0, 11%) (64). The wide confidence intervals indicate that sample size was not sufficiently large to determine whether lamotrigine has a lower teratogenic risk than other anticonvulsants.

The results of a prospective study on the outcomes in pregnant women exposed to lamotrigine have been published (65). The report included 168 outcomes in women exposed to lamotrigine monotherapy and 166 after pregnancies exposed to lamotrigine polytherapy during the first trimester. Three of 168 neonates (1.8%) exposed to lamotrigine monotherapy had major birth defects (95% CI = 0.5, 5.5%). There were five major birth defects in 50 neonates (10%) after lamotrigine polytherapy with valproic acid during the first trimester (95% CI = 3.7, 23%). The proportion of major defects on exposure to lamotrigine polytherapy without valproate during the first trimester was 5 of 116 (4.3%) (95% CI = 1.6, 10%). There were no specific patterns of major birth defects in any subgroup or within the register as a whole. Thus, it appears that lamotrigine-exposed women have a relatively low frequency of major birth defects and that the combination of lamotrigine and valproic acid could potentially be especially detrimental in this respect. However, the wide confidence intervals preclude a firm conclusion. Moreover, there were several methodological limitations to this study, such as lack of standardization in outcome ascertainment and other potential sources of bias.

Fetotoxicity

The outcomes of pregnancy in 53 women exposed to lamotrigine included 4 spontaneous abortions, 13 induced abortions (none because of a prenatally detected defect), 34 newborns without birth defects, and 2 newborns with unspecified defects (66). No information on co-medication was given, and more data are required for risk assessment.

Lactation

The breast milk to plasma lamotrigine concentration ratio is about 0.6, and in breast-fed infants serum drug concentrations reach about 30% of maternal concentrations. Although no toxicity has been reported in these infants, close observation is warranted (SEDA-22, 88) (62).

Susceptibility Factors

Age

In adults, the incidence of Stevens–Johnson syndrome was approximately 1:1000, but higher rates (1 in 50 to 1 in 300) have been reported in children (SEDA-22, 89).

The effects of lamotrigine in children have been reviewed (67). Its efficacy has been demonstrated in 13 studies in 1096 children with a variety of seizure types. Generally, lamotrigine treatment in these trials was at higher initial doses and faster dose escalations than are currently recommended. Most adverse events associated with lamotrigine were mild to moderate and did not result in withdrawal. In placebo-controlled, add-on trials 85% of those who took lamotrigine had an adverse event compared with 83% of those who took placebo. Lamotrigine was associated with an increased risk of adverse events in the nervous system (dizziness, tremor, ataxia, and diplopia), gastrointestinal tract (nausea), and urinary tract (infection). Skin rash was reported more often with lamotrigine than placebo and more often by children than by adults.

Other features of the patient

Exceeding the currently recommended slow dosage escalation guidelines and co-administration of valproate are risk factors for rashes.

Drug Administration

Drug overdose

The effects of overdosage of lamotrigine include sedation, ataxia, diplopia, nausea, vomiting, hypertonia, nystagmus, and prolongation of the QRS complex (SEDA-18, 66). Cardiac rhythm should be monitored. Multiple oral dosing with activated charcoal enhances lamotrigine elimination, but its value in overdose is unknown.

The manifestations of acute lamotrigine overdose can mimic the anticonvulsant hypersensitivity syndrome (68).

- A 49-year-old man with bipolar disorder inadvertently took four daily doses of lamotrigine 2700 mg each. He developed a low-grade fever, a skin rash, and periorbital edema. He had a leukocytosis, raised liver enzymes, and acute renal insufficiency. He recovered fully after lamotrigine withdrawal and steroid therapy.

Postmortem blood and tissue concentrations of lamotrigine have been reported in a case of suicide attributed to "mixed drug toxicity" with carbamazepine, lamotrigine, paroxetine, and thioridazine (69). The blood lamotrigine concentration was 155 μmol/l. Two other individuals with high postmortem blood lamotrigine concentrations, who did not die of an overdose, were also taking valproate.

Severe encephalopathy due to lamotrigine overdose has been reported (70).

- A 55-year-old woman taking lamotrigine and valproate for partial epilepsy took an overdose of lamotrigine and

© 2006 Elsevier B.V. All rights reserved.

became stuporose. A CT scan was unremarkable and the cerebrospinal fluid was normal. Electroencephalography showed generalized slowing without epileptiform activity. The serum valproate concentration was 65 μg/ml and the lamotrigine concentration 32 μg/ml. A toxicology screen was negative. Lamotrigine was withheld and she remained unresponsive for 3 days, when she awoke disoriented. On day 5 she was alert and fully oriented (serum lamotrigine 15 μg/ml).

Drug–Drug Interactions

Carbamazepine

The effects of other antiepileptic drugs on the pharmacokinetics of lamotrigine have been studied in 62 patients with epilepsy (71). Carbamazepine, phenytoin, and phenobarbital, all enzyme inducers, increased the oral clearance of lamotrigine, individually by 58% and in combination by nearly 200%.

The time-course of de-induction following the step-wise withdrawal of carbamazepine in patients treated concomitantly with lamotrigine has been analysed (72). This study was part of an active-control, monotherapy trial. Patients taking carbamazepine were given lamotrigine to attain a target dose of 500 mg/day, while carbamazepine was withdrawn in weekly 20% decrements. After withdrawal, lamotrigine was continued as monotherapy for a further 12 weeks. Of 156 patients, 76 were assigned to lamotrigine, 43 of them completed the withdrawal to monotherapy, and 28 of these 43 successfully completed the study. In a subset analysis of completers, lamotrigine concentration increased by 62% in those who had taken carbamazepine. These differences were significantly different and occurred when carbamazepine plasma concentrations were very low or undetectable.

Cimetidine

The effect of cimetidine on the pharmacokinetics of lamotrigine has been studied in 10 healthy men (73). Cimetidine had no effect on the pharmacokinetics of lamotrigine.

Ketamine

Because some of the cognitive effects of ketamine may be mediated through increased glutamate release, lamotrigine, which inhibits glutamate release, has been used to reduce the neuropsychiatric effects of ketamine in 16 healthy subjects (74). Lamotrigine significantly reduced ketamine-induced perceptual abnormalities and increased its immediate mood-elevating effects.

Lithium

The effect of lamotrigine on steady-state lithium pharmacokinetics has been studied in 20 healthy adult men (75). Lamotrigine did not significantly change the pharmacokinetics of lithium.

Methsuximide

The interaction of methsuximide with lamotrigine has been studied in 16 patients aged 9–19 years with a variety of seizure types and syndromes (76). The mean lamotrigine serum concentration before starting or after stopping methsuximide was 54 μmol/l and the mean concentration while taking methsuximide was 25 μmol/l. Methsuximide lowered the serum lamotrigine concentration in every case, with a mean fall of 53% (range 36–72%). In some patients this led to a deterioration in seizure control when methsuximide was added or an improvement in seizure control after methsuximide was withdrawn. The mechanism is thought to be induction of metabolism.

Oral contraceptives

Plasma concentrations of lamotrigine were reduced in seven women taking an oral contraceptive (mean reduction 49%, range 41–64%), probably through induction of glucuronide conjugating enzymes (77).

Phenobarbital

The effects of other antiepileptic drugs on the pharmacokinetics of lamotrigine have been studied in 62 patients with epilepsy (71). Carbamazepine, phenytoin, and phenobarbital, all enzyme inducers, increased the oral clearance of lamotrigine, individually by 58% and in combination by nearly 200%.

Phenytoin

The effects of other antiepileptic drugs on the pharmacokinetics of lamotrigine have been studied in 62 patients with epilepsy (71). Carbamazepine, phenytoin, and phenobarbital, all enzyme inducers, increased the total oral clearance of lamotrigine, individually by 58% and in combination by nearly 200%.

Choreoathetosis is a rare adverse effect of some anticonvulsants, but has especially been associated with phenytoin. In a retrospective survey, three of 39 adults and one of 38 children developed choreoathetosis acutely when lamotrigine was added to phenytoin or vice versa (78). The effect was reversible by withdrawing one of the drugs. It was calculated that the risk of choreoathetosis is increased more than 50-fold when these drugs are combined, possibly owing to a pharmacodynamic interaction.

The time-course of de-induction following the step-wise withdrawal of phenytoin in patients treated concomitantly with lamotrigine has been analysed (72). This study was part of an active-control, monotherapy trial. Patients taking phenytoin were given lamotrigine to attain a target dose of 500 mg/day, while phenytoin was withdrawn in weekly 20% decrements. After withdrawal, lamotrigine was continued as monotherapy for a further 12 weeks. Of 156 patients, 76 were assigned to lamotrigine, 43 of them completed the withdrawal to monotherapy, and 28 of these 43 successfully completed the study. In a subset analysis of completers, lamotrigine concentration increased by 160% in patients who had previously taken phenytoin. These differences were significantly different and occurred when phenytoin plasma concentrations were very low or undetectable.

Rifampicin

The effects of rifampicin on the pharmacokinetics of lamotrigine have been studied in 10 healthy men (73).

© 2006 Elsevier B.V. All rights reserved.

Rifampicin induced the glucuronidation of lamotrigine, increasing total clearance about two-fold.

Valproate

Effects of valproate on lamotrigine

Co-administration of valproate is one of the most important risk factors for skin reactions to lamotrigine; valproate co-medication was present in 74 and 64% of patients with Stevens–Johnson syndrome and toxic epidermal necrolysis respectively (44).

Valproate reduced the oral clearance of lamotrigine by about 70%, but the effect was not related to the concentration of valproate (hence the rather misleading title of the paper, that is there was an effect but it did not appear to be concentration-related) (71). There was no effect on lamotrigine clearance when a single enzyme inducer was combined with valproate, but combinations of enzyme inducers had almost the same effect in the presence or absence of valproate. Consistent with this result, it has also been shown that the effect of valproate on the clearance of lamotrigine is independent of valproate dose and steady-state concentration in 28 patients with intractable epilepsy (79). However, in contrast to these findings, there were good relations between the dose of valproate 200–1000 mg/day and the increase in lamotrigine AUC and the prolongation of half-life in eight patients with epilepsy (80).

Twenty-six lamotrigine-associated reactions consistent with the features of the anticonvulsant hypersensitivity syndrome have been reviewed, including nine previously published (54). The patients were aged 3.5–74 years (mean 28) and 14 were female. Valproate was used as co-medication in 60%.

Effects of lamotrigine on valproate

In a study of 400 serum concentrations from 372 patients taking lamotrigine and valproic acid, lamotrigine was associated with a slight reduction in valproate serum concentrations (81). However, the size of the effect was probably of no clinical significance.

Effects of the combination of lamotrigine with valproate

The tolerability of lamotrigine added to valproate has been assessed in 108 mostly adult patients (82). The median starting dose was 21 mg/day and upward titrations were usually made at 2-week intervals; although these were more cautious than in earlier studies, in many patients the initial dose or titration rate still exceeded those currently recommended by the manufacturer. Adverse events led to withdrawal in 14 patients, including seven of 14 who had a rash. Other adverse events included fatigue (12%), gastrointestinal symptoms (9%), dizziness, headache, and insomnia (3% each). Serious events were hallucinations (two patients), increased liver enzymes (two patients), irritability, and leukopenia (one patient each). These results suggest that, with cautious dosage escalation, lamotrigine can be added to valproate with acceptable safety. In this study, the incidence of rash was not higher than that seen among 310 patients in whom lamotrigine was added to other drug regimens not including valproate (13 versus 14%).

In an open prospective trial, patients with partial seizures who had not responded to lamotrigine or valproate given separately responded well to the combination; this was not due to an effect of valproate on serum lamotrigine concentrations, because after adjusting dosages based on clinical response the serum concentrations of both drugs were lower during combination therapy (83). Hand tremor developed in all 13 patients who took the combination, compared with three of 20 who took valproate without lamotrigine and none of 17 who took lamotrigine without valproate. These findings confirm that valproate plus lamotrigine is a valuable combination in patients unresponsive to either drug alone, partly because of a pharmacodynamic interaction. Patients co-medicated with valproate should be treated with a lower starting dose of lamotrigine and with slower dosage escalation to minimize the risk of a skin rash. Maintenance lamotrigine dosage requirements are also reduced by valproate co-medication. Although tremor is common, it can be maintained within acceptable limits by adjusting the dosage of either drug.

Diagnosis of Adverse Drug Reactions

The usual target range for plasma lamotrigine concentrations is 4–16 μmol/l (1–4 μg/ml).

Lansoprazole

See also Proton pump inhibitors

General Information

Lansoprazole is a proton pump inhibitor. Its safety profile has been reviewed based on premarketing clinical studies, and has to be regarded with the reservations appropriate to this type of material. In 4749 patients the most frequent adverse effects were headache (4.7%), diarrhea (3.2%), abdominal pain (2.2%), pharyngitis (1.8%), and nausea (1.4%); some patients had upper respiratory complaints or suffered anxiety or depression, or myalgia (1). The adverse reaction profile appears to be closely similar to that of omeprazole.

Lansoprazole 15 and 30 mg/day were more effective than placebo, but not misoprostol 200 micrograms qds, for the prevention of NSAID-induced gastric ulcers in a multicenter, double-blind, placebo-controlled trial in 537 patients without *Helicobacter pylori* infection who were long-term users of NSAIDs (2). However, adverse effects were significantly more frequent (31% versus less than 20%) and treatment adherence significantly less (71% versus more than 90%) in patients taking misoprostol. The most commonly reported adverse effects in all groups were diarrhea, abdominal pain, and nausea.

Drug–Drug Interactions

Roxithromycin

The effect of lansoprazole on roxithromycin concentrations in plasma and gastric tissue have been investigated in 12 healthy volunteers who took lansoprazole 30 mg bd with or without roxithromycin 300 mg bd over 6 days (3). The medications were well tolerated, with only mild adverse events. The more frequent adverse events were nausea, bloating, and diarrhea. Lansoprazole and roxithromycin did not alter the systemic availability of each other. However, lansoprazole increased the local concentration of the antibiotic in the stomach.

Latanoprost

See also Prostaglandins

General Information

Latanoprost is an analogue of $PGF_{2\alpha}$, used to treat glaucoma. The use of latanoprost and unoprostone in the treatment of open-angle glaucoma and ocular hypertension has been reviewed (1). More data on safety are needed to calculate its benefit-to-harm balance.

Latanoprost caused reduced intraocular pressure by 20–40% in adults with open-angle glaucoma or ocular hypertension, but its efficacy and safety in children have not been widely reported. Most children reported so far gained little benefit on intraocular pressure from latanoprost, but older children and those with juvenile-onset open-angle glaucoma do gain a significant ocular hypotensive effect. Systemic and ocular adverse effects in children using latanoprost are infrequent (2).

Organs and Systems

Cardiovascular

Two patients in their seventies developed hypertension during treatment with topical latanoprost (dosage not stated) for open-angle glaucoma; both were also taking tocopherol (vitamin E) supplements. Neither had a previous history of hypertension (3). The authors commented that it is likely that systemic absorption of topical latanoprost could cause hypertension. Self-medication with vitamin E has been reported to aggravate or precipitate hypertension.

Respiratory

Latanoprost rarely causes systemic effects. However, it aggravated respiratory symptoms in a patient with chronic bronchitis and emphysema, with improvement after latanoprost was withdrawn (4).

Nervous system

Three cases of headache after latanoprost have been described (5).

- A 65-year-old man with primary open-angle glaucoma intolerant of dipivefrin and beta-blockers used latanoprost in both eyes at bedtime. He had no prior history of migraine, but he began to have headaches, the frequency and severity of which increased until they were occurring daily. The pain was not relieved by over-the-counter or narcotic analgesics, and he was virtually incapacitated. Latanoprost was discontinued and he had almost immediate relief, with only one migraine during the following week, and he was headache-free for the next 10 months. He then agreed to rechallenge. After the second night of latanoprost therapy his headache recurred, and therapy was withdrawn 2 days later when he had incapacitating pain. Headache did not recur within 4 months of follow-up.
- A 65-year-old man with primary open-angle glaucoma, using levobunolol hydrochloride 0.5%, was given a nighttime dose of latanoprost. The next morning he awoke with a severe bifrontal throbbing headache, photophobia, and slight blurring of vision. The headache intensified, and 4 days later a CT scan was normal. On the sixth day he stopped using latanoprost. His headache disappeared within 24 hours and did not recur during follow-up for 1 year.
- A 54-year-old woman with primary open-angle glaucoma, using betaxolol hydrochloride 0.5%, had mild progression of visual field loss in her left eye. Latanoprost was added nightly to her left eye. A few hours after the first dose she was awakened by a severe unilateral pounding headache extending from the left eye and brow to the left cranium. There were no associated neurological symptoms. The headache resolved spontaneously the next day, but recurred on three nights after instillation of latanoprost. On the fourth night the headache did not occur. She continued to use latanoprost, and the headache did not return.

Sensory systems

Corneal damage

Four patients treated with latanoprost developed dendritiform epitheliopathy, a sign of corneal toxicity; the lesions reversed in 1–4 weeks after latanoprost withdrawal (6).

Three cases of *Herpes simplex* keratitis developed during latanoprost therapy (7).

- One patient, with a history of *H. simplex* keratitis, had recurrence with latanoprost (4 months); the infection resolved on withdrawal but recurred on rechallenge.

© 2006 Elsevier B.V. All rights reserved.

- The second patient, with a history of *H. simplex* keratitis, had bilateral recurrence with latanoprost (1 month); antiviral therapy did not eradicate the infection until latanoprost was withdrawn.
- The third patient developed the infection after 1 month; the keratitis cleared on withdrawal of latanoprost and antiviral therapy; reinstitution of latanoprost with prophylactic antiviral medication (valaciclovir) kept the cornea clear, but as soon as the antiviral drug was discontinued, *H. simplex* virus keratitis reappeared.

Although the mechanism is unclear, it is known that inhibitors of prostaglandin synthesis reduce recurrence of epithelial *H. simplex* infections and prostaglandins may stimulate their occurrence.

Iris pigmentation

Latanoprost can produce darkening of the iris in 10–25% of patients treated for 0.5–2 years. The incidence of iris pigmentation differs between eyes with differently colored irises: green–brown, yellow–brown, and blue–brown eyes, in that order, have the highest incidences, whereas eyes with uniformly blue, grey, or green irises are much less affected, even after 2 years of treatment. About 60% of eyes with an initial green–brown iris will have increased pigmentation within 1 year. The corresponding figure for initially blue–brown eyes is about 20%. All patients who have developed increased pigmentation of the iris have been withdrawn from studies, and during follow-up for up to almost 3 years the change in iris pigmentation has been stable without signs of reversibility or further increase. Nevi and freckles have not changed color or size. Apart from the change in color the iris looks normal and pigmentation dispersion has not been observed. No cell proliferation is involved and the change in color is due to melanogenesis. It has been concluded that the change in iris pigmentation is unlikely to cause any long-term consequence besides the cosmetic one. The possibility of late loss of pigment and induction of a pigmentary glaucoma also seems unlikely; melanocytes in the iris are continent and do not release melanin (8). In an observational cohort study of 43 patients, 30 had a definite acquired iris anisochromia (9).

The time of onset of the changes in iris pigmentation can be as early as 3 months. The earliest reported change in iris color occurred in a 78-year-old woman, whose iris color changed from blue–green to brown–green within 4 weeks (10). The pigmentation is irreversible. In a 50-year-old man with peripheral iris darkening after latanoprost treatment, the darkening did not change appreciably for several years after withdrawal (11).

The fine structure of an iridectomy specimen from a 65-year-old woman treated with latanoprost has been reported (12). She received latanoprost for 13.5 months and the drug was withdrawn because of iris color change. She underwent cataract surgery 16 months after stopping the drug and a sector iridectomy was obtained. The authors found some melanocytes with atypical features, including nuclear chromatin margination, prominent nucleoli, and invagination of the nucleoli. These characteristics are also seen in precancerous lesions, in the normal ageing iris, and in patients with glaucoma.

The mechanism of iris pigmentation due to latanoprost is unknown. In an in vitro experiment using uveal melanocytes, the addition of latanoprost increased melanin content, melanin production, and tyrosinase activity (13). Alpha-methyl-para-tyrosine, an inhibitor of tyrosinase (the enzyme that transforms tyrosine to levodopa), completely prevented the latanoprost-induced stimulation of melanogenesis.

Of 17 patients requiring filtering surgery for primary open-angle glaucoma randomized to receive latanoprost ($n = 8$) or alternative medications ($n = 9$) for 3 months before surgery, all had peripheral iridectomy specimens, and there were color changes in one case (14). No morphological changes or cellular proliferation were found in any specimen.

Iris cyst associated with latanoprost has been described in a 76-year-old woman (15). Latanoprost was given for 5 weeks, and during a re-examination a large iris cyst was observed in her right eye. The cyst disappeared 3 weeks after latanoprost withdrawal.

Uveitis

In four patients with complicated open-angle glaucoma, in whom anterior uveitis appeared to be associated with latanoprost, the uveitis was unilateral and occurred only in the eye receiving latanoprost in three patients. In one patient, latanoprost was used in both eyes, and the uveitis was bilateral (16). Four of five eyes had a history of prior inflammation and/or prior incisional surgery. All patients were rechallenged. The uveitis improved after withdrawal and recurred after rechallenge in all eyes. The authors concluded that topical prostaglandin analogues may be relatively contraindicated in patients with a history of uveitis or prior ocular surgery. There may also be a risk in eyes that have not had previous uveitis or incisional surgery.

Optic disc and macular edema

A case of bilateral optic disc edema has been described (17).

- A 64-year-old woman was included in a randomized, double-blind trial of drugs used in the treatment of ocular hypertension. After 3 months, examination of the optic nerve showed bilateral edema. She had been using latanoprost 0.0005% eye-drops at night to both eyes. Latanoprost was withdrawn and the disc edema resolved at 1 week.

Cystoid macular edema developed in two patients treated with topical latanoprost for glaucoma (18). Latanoprost was withdrawn, and the cystoid macular edema was treated with topical corticosteroids and ketorolac, with improvement in visual acuity. The macular edema resolved in both cases.

Cystoid macular edema has been reported in four other patients shortly after they started to use latanoprost (19) and other reports have appeared (20–24). A possible explanation is enhanced disruption of the blood–aqueous barrier induced by latanoprost (23).

A review of the published literature (28 eyes in 25 patients) has shown that in all cases there were other associated risk factors, so that a definitive conclusion about a causal relation cannot be reached (25). Nevertheless, latanoprost should be used with caution in patients with risk factors for cystoid macular edema and special surveillance is necessary.

Skin

Hyperpigmentation of the eyelids can occur during latanoprost therapy.

- A 62-year old Korean woman treated with latanoprost for 4 months developed eyelid pigmentation in both upper and lower eyelids of both eyes (26). There was no increase in iris pigmentation. The eyelid pigmentation gradually diminished after withdrawal, but minimal brownish coloration remained along the lower eyelid folds in both eyes at 4 months.
- A 75-year-old woman with open-angle glaucoma who had used latanoprost for 15 months reported that the skin around her eyes was much darker than on the rest of her face (27). The darkening had occurred gradually. Latanoprost was withdrawn; 1 month later there was a discernible lightening of the periocular skin and 2 months after withdrawal the skin was significantly lighter.

Hair

Eyelashes

Latanoprost causes growth of lashes and ancillary hairs around the eyelids, with greater thickness and length of lashes, additional rows of lashes, and conversion of vellus to terminal hairs in canthal areas and regions adjacent to lashes. As well as increased growth, there is also increased pigmentation. Vellus hairs on the lower eyelids also undergo increased growth and pigmentation. Latanoprost caused changes in eyelashes in 26% of 194 patients over 12 months; the changes included increased length, thickness, density, and color (14).

Latanoprost therapy for 2–17 days can cause changes comparable to chronic therapy. The increased number and length of visible lashes are consistent with the ability of latanoprost to induce and prolong anagen growth in telogen (resting) follicles while producing hypertrophic changes in the involved follicles. Laboratory studies suggest that the initiation and completion of the effects of latanoprost on hair growth occur very early in the anagen phase and that the likely target is the dermal papilla.

Latanoprost can even reverse alopecia of the eyelashes (28).

- A 53-year-old woman, with glaucoma and loss of the eyelashes secondary to alopecia following an allergic response to ibuprofen was given latanoprost (29). After 3 weeks her eyelashes were noticeable and 2 months later full growth had occurred.
- Quantitative analysis of eyelash lengthening in 17 patients treated with latanoprost showed a significant increase in eyelash length in the treated eyes (30).

Increased pigmentation of the eyelashes has been reported in a patient treated with latanoprost (31).

Sweat glands

Heavy sweating occurred in a 6-year-old boy with aniridia and glaucoma during treatment with latanoprost eye-drops (32). Other combinations of drugs for glaucoma had been ineffective in reducing the intraocular pressure. He was given latanoprost eye-drops (dose not stated) at night in combination with a beta-blocker during the day. However, at night he had very heavy sweating. His pyjamas had to be changed regularly about 1–2 hours after he went to sleep. When latanoprost was withdrawn, the heavy sweating resolved. When it was restarted, the heavy sweating recurred.

The author commented that systemic absorption occurred for the most part through the mucous membranes of the nose and throat, since the sweating was less severe when the boy's lacrymal points were compressed for 10 minutes after the administration of latanoprost.

Infection risk

Two cases of *H. simplex* virus dermatitis of the periocular skin have been reported in patients using latanoprost (33). Cases of *H. simplex* keratitis are mentioned above, under sensory systems.

Latex

General Information

Latex is present in many medical devices, including surgical and examination gloves, catheters, intubation tubes, anesthesia masks, and dental fillers. Reported allergic reactions range from contact urticaria to anaphylaxis (1). There has been a marked worldwide increase during recent years in the rate of reactions to latex. These reactions are due to either or both:

1. The formulation chemicals (vulcanizers, stabilizers, preservatives). These cause mainly local delayed hypersensitivity reactions. However, some of these chemicals are also carcinogenic, and may have more serious and not immediately apparent consequences.
2. Proteins in the latex. These can cause generalized systemic allergic reactions, including anaphylaxis, which can be severe and life-threatening.

Latex condoms degrade over time. Such degradation has a significant effect on the product's ability to provide a barrier to sexually transmitted agents, including human immunodeficiency virus (HIV). The FDA has issued a final regulation requiring that the labelling of latex condoms shall contain an expiry date based on physical and mechanical testing performed after exposing the product to varying conditions that age latex, both on the outside packaging and on the individual packaging (2). The agency has also stipulated that if a latex condom contains spermicide and if the expiry date based upon spermicidal stability testing is different from the expiry date based on latex integrity testing, the product shall bear only the earlier expiry date.

Organs and Systems

Urinary tract

Urethritis has been described in patients with urinary catheters containing latex (3). In 100 men, the incidence of urethritis with latex catheters was 22% compared with 2% in patients managed with silicone catheters. In all cases, symptoms developed within 12 hours of use and urine specimens were sterile.

Immunologic

Severe anaphylactic reactions have been reported in response to dental work (latex dental dams), barium enemas (latex enema devices), and numerous surgical procedures involving mainly latex gloves and catheters. The two major contributing factors appear to be a hereditary disposition and occupational exposure. The latter has increased rapidly owing to progress in medical technology, the associated increase in the use of medical devices, and increased awareness among health-care professionals of the need to wear protective gloves during various procedures. This increased exposure has meant that a growing number of people have become sensitized to latex proteins; in one study, 6–7% of surgical personnel and 18–40% of patients with spina bifida were sensitive to latex (4). Particularly high-risk circumstances appear to be direct contact of a latex device or air-borne particles from a latex device (for example corn starch carrying latex proteins) with mucous membranes or with tissues exposed as a result of surgical procedures.

FDA investigations, which eventually identified natural latex/natural rubber (NLNR) allergy as an emerging public health concern, were started in response to voluntary reports submitted by physicians, nurses, and technologists (5). The first reports described deaths that

© 2006 Elsevier B.V. All rights reserved.

occurred during barium enema procedures, before the administration of barium. Over the past decade, the FDA has received more than 1700 reports of severe allergic reactions, including 16 deaths, related to medical devices containing latex. The deaths all occurred in 1989 among children with spina bifida and were caused by a reaction to the latex cuffs used on the tip of barium enema catheters.

In Australia, regulatory changes have been proposed for the labeling and safety requirements of latex-containing devices that directly or indirectly come into contact with body tissues (6). Most latex-containing devices are in this category, and include tubes, catheters, empty containers, syringes, medical gloves, and devices such as condoms and diaphragms. The FDA is requiring all medical devices containing latex to be labeled as such and to carry a caution that latex can cause allergic reactions (7). The FDA has also urged manufacturers of latex containing medical devices to set the protein levels in their products as low as possible. The FDA also requires that "hypoallergenic" claims should not be attached to medical devices, because they incorrectly imply that the devices may be safely used by people who are sensitive to latex.

Lauraceae

See also Herbal medicines

General Information

The genera in the family of Lauraceae (Table 1) include cinnamon and sassafras.

Cinnamonum camphora

Camphor is a white crystalline substance, obtained from the tree *Cinnamonum camphora* (camphor tree), but the name has also been given to various volatile substances found in different aromatic plants.

Camphor has been used as a substance of abuse for many centuries, both by ingestion and by inhalation. Today it is found in many non-prescription vaporized or topical "cold cures," topical musculoskeletal anesthetic rubs, "cold sore" formulations, sunscreens, and mothballs. It has also been used to procure an abortion (1).

Adverse effects

The acute effects of ingesting camphor were described by Louis Lewin in "Phantastica" (1924):

> After ingestion of 1.2 grains [72 g] the following symptoms occur: an agreeable warmth of the skin, general nervous excitation, a desire to move, tickling of the skin, and a peculiar feeling of ecstasy similar to drunkenness. One addict said that "he saw his destiny full of great possibilities clearly and distinctly before his eyes." This state continued for one and a half hours. After ingestion of 2.4 grains there was an urgent desire to move. All movements were generally facilitated, and when walking the limbs were lifted far more than necessary. Intellectual thought was impossible. There was a flood of ideas, chasing each other with great rapidity, without any one being analysed. The individual lost perception of his identity. After vomiting, awareness returned, although distraction, forgetfulness and vacancy of mind persisted. On awaking the state of intoxication seemed to have been extraordinarily long and full of events of which the subject did not remember any. After 3 hours he was able to pull himself together and return to full consciousness, but the effect on the brain was so potent that unconsciousness and convulsions again occurred within an hour and lasted for half an hour, after which the subject gradually regained his full mental faculties and normal muscle function.

Lewin also described the effects of chronic abuse:

> Loss of the sense of location and brief gaps in memory usually succeed gastric irritation and convulsions when camphor is taken habitually. The lost memories finally reappear, but in a very strange fashion, so that, according to the statement of an addict, all affairs, events, and things that he had forgotten seemed new, as if he had had no previous knowledge of them. Even after he recognized all the members

of his family, the objects in his room seemed unfamiliar, as if they had just been given to him. In Slovakia convulsive states similar to epilepsy are so common in consumers of camphor that all cases of similar fits are directly attributed to it.

Nervous system
Convulsions can occur after transdermal absorption of camphor (2).

- A 20-month-old girl developed status epilepticus after ingesting camphor and required ventilation. She was treated with intravenous diazepam and phenobarbital and nasogastric-activated charcoal and made a complete neurological recovery (3).

Liver
Hepatotoxicity occurred in a 2-month-old baby after a camphor-containing cold remedy was applied to the skin; liver function tests returned to normal after the remedy was withdrawn (4).

Chronic ingestion of camphor can mimic Reye's syndrome (5).

Skin
Contact dermatitis has been reported from the use of camphor in ear-drops (6). Photo-distributed skin eruptions have been reported after use of a sunscreen containing camphor (7).

Drug overdose
In children exposure to as little as 500 mg of camphor can be fatal (8). More commonly, a dose of 750–1000 mg is associated with seizures and death. Products that contain 10% camphor contain 500 mg in 5 ml.

After taking an unknown amount of a 10% camphor spirit (maximum dose 200 ml), a 54-year-old woman became comatose, having developed tonic-clonic seizures and respiratory failure (9). After gastric lavage, hemoperfusion was performed with amberlite XAD4 but did not alter either the pharmacokinetics of camphor or the course of the intoxication.

Laurus nobilis

Laurus nobilis (laurel) has well-known analgesic, diaphoretic, antipyretic, and diuretic effects (10), and is widely used in rheumatic, pyrexial, and infective disorders (11), as well as in the perfume and soap industries (10).

Adverse effects
Laurel oil obtained from the berries of *L. nobilis* is a potent skin sensitizer, owing to the presence of allergenic sesquiterpene lactones, and is usually seen in aromatherapists or their clients (12–14).

- A 55-year-old woman developed erythema and edema over her knees (12). She had applied laurel oil, obtained from a herbalist, to her knees to relieve joint pain 15 days earlier. After 3 days, the erythema and edema had begun to appear. She had erythema, edema, and papules over her patellae, and eczema around the eye. She was treated with an oral antihistamine and a topical glucocorticoid. Two days later, the lesions worsened and systemic glucocorticoid therapy was needed. The lesions started to heal, leaving slight postinflammatory hyperpigmentation. Patch-testing was performed with a European standard series and commercial laurel oil 1 month later. There was a +++ reaction to the oil only, and no reaction to either fragrance mix or *Myroxylon pereirae* resin in the standard series. The same formulation of laurel oil was negative on patch-testing in 15 control subjects.

Sassafras albidum

Sassafras albidum (sassafras) root contains 1–2% of volatile oil, which in turn consists largely of safrole, a weakly hepatocarcinogenic agent in laboratory animals. Some metabolites of safrole have mutagenic activity in bacteria and weak hepatocarcinogenic effects in rodents. The carcinogenic effect is primarily mediated by the formation of 1′-hydroxysafrole, followed by sulfonation to an unstable sulfate that reacts to form DNA adducts; these metabolites are formed by CYP2C9 and CYP2E1, the latter contributing three-fold more to the metabolic clearance than the former (15).

In one case sassafras tea caused sweating (16).

In Germany, the health authorities have proposed the withdrawal of sassafras-containing medicines, including homeopathic products up to D3, from the market (17). Of particular concern is the uncontrolled availability of sassafras oil because of its use in aromatherapy. Internal use of sassafras oil in recommended doses up to 12 drops/day can lead to a daily intake up to 0.2 g of safrole (18).

Lauromacrogols

General Information

Lauromacrogols are mixtures of monolauryl esters of macrogols. They have the following general formula: $C_{12}H_{25}(OCH_2CH_2)_nOH$. Each is named after the number n in its formula. For example, in lauromacrogol 400 (polidocanol), $n = 400$. They have been used as surfactants, spermicides, solvents, and non-ionic emulsifiers.

Lauromacrogol 9 has been used as a sclerosant and local anesthetic.

Lauromacrogol 400 (polidocanol) has been used as a solvent and non-ionic emulsifier that contains 95% hydroxypolyethoxydodecane and 5% ethyl alcohol. In medicaments it has been used as a topical anesthetic, an antipruritic, and a sclerosant.

Organs and Systems

Immunologic

Contact allergic reactions to lauromacrogol 400 have been reported (1). Patch-testing can yield irritant reactions. In a retrospective study of 8739 patients tested with a topical drug patch test series, 3186 patients were tested with 0.5% lauromacrogol 400 in water (2). There was slight irritation in 0.88%, weakly positive reactions in 0.97%, and strongly positive reactions in 0.25%. In 6202 patients tested with a 3% solution of lauromacrogol 400 in petrolatum, there was slight skin irritation in 0.48%, weakly positive reactions in 1.77%, and strongly positive reactions in 0.34%. Among the 649 patients tested with both formulations, concurrence was moderate.

Laxatives

General Information

Laxatives can be classified according to their several mechanisms of action:

- bulk-forming laxatives, such as bran, methylcellulose, *Plantago* extracts (ispaghula and psyllium), and sterculia;
- stimulant laxatives, such as the anthraquinones (senna and dantron), bisacodyl, docusate sodium (also a fecal softener), and sodium picosulfate; cascara, castor oil, oxyphenisatin, and phenolphthalein are obsolete stimulant laxatives;
- fecal softeners, such as arachis oil and the obsolete liquid paraffin;
- osmotic laxatives, such as lactulose, lactitol, the polyethylene glycols, magnesium salts, sodium citrate, and phosphates.

General adverse effects of laxatives

If laxatives of any type are heavily used, not necessarily to the point of abuse, diarrhea will be common, as well as a tendency to nausea and fluid and electrolyte imbalance. The possibility of laxative-induced colonic injury, with damage to the autonomic nervous innervation of the large intestine, has been much discussed and was probably a problem with the violent cathartics formerly used (podophyllin, aloes, and cascara), but is not on record with the laxatives normally used today. Chronic abuse of laxatives, such as senna, can cause changes in colonic structure and function.

Habitual, usually secretive, abuse of laxatives is much more common in women than in men and there is overlap with the anorectic/bulimic syndrome. Abuse of irritant agents such as senna and cascara have been the commonest varieties (SED-10, 704), but many proprietary laxatives have been abused. Abuse can lead to a condition characterized by chronic diarrhea, hypokalemia, and fluid depletion. The features also include hypomagnesemia, hypocalcemia, and hypoalbuminemia, with thirst, lassitude, weight loss, edema, and occasionally osteomalacic bone pain and clubbing. In one small series of cases of laxative abusers, pseudo-Bartter's syndrome was induced; the complications included confusion, convulsions, muscle weakness (with or without paralysis or rhabdomyolysis), and

© 2006 Elsevier B.V. All rights reserved.

bone changes; hypokalemia and hypophosphatemia were common, and when the laxatives were withdrawn some patients suffered prolonged edema (1).

Bulk-forming laxatives

The bulking agents include vegetable fiber products (such as bran), paraffin and methylcellulose (which absorbs water into the intestinal tract), agar (which expands to form a gel), and psyllium seeds or other mucilaginous plant products. Bulking agents are largely free of adverse effects, but any non-absorbable agent can aggravate symptoms associated with pre-existent intestinal stricture. Abdominal bloating due to bacterial fermentation of unabsorbed carbohydrate is a common sequel to excessive intake. The sugar content of some bulk laxatives can be sufficient to impair diabetic control; the vegetable matter in other preparations can cause bezoars and is potentially allergenic.

Plantago species (psyllium and ispaghula)

Plantago seeds are widely used as bulk laxatives under the names of "psyllium" (from *Plantago psyllium* or *Plantago indica*) and "ispaghula" (from *Plantago ovata*).

Psyllium husk combined with microencapsulated paraffin has been compared with standard psyllium for the treatment of constipation in a randomized, double-blind study (2). There was a significant increase in the weekly number of defecations with the combined formulation, which was well tolerated; no adverse effects were reported.

The efficacy, speed of action, and acceptability of ispaghula husk, lactulose, and other laxatives in the treatment of simple constipation in 394 patients have been studied by 65 general practitioners (3). Ispaghula was used by 224 patients and other laxatives by 170. After 4 weeks of treatment ispaghula husk was assessed by the GPs to be superior to the other laxatives. In patients' assessment, ispaghula users had a higher proportion of normal stools and less soiling than patients using other laxatives. Diarrhea and abdominal pain and gripes and were less common with ispaghula. Distension, flatulence, indigestion, and nausea were equally frequent in the two groups.

Esophageal obstruction by a bezoar after ingestion of psyllium has been reported (4).

- A 69-year-old man with Parkinson's disease developed severe dysphagia after taking granules of the bulk laxative Perdiem (82% psyllium and 18% senna formulated as granules). Disimpaction of the bezoar was performed via a rigid endoscope under general anaesthesia.

Occupational exposure to *Plantago* species has resulted in sensitization, with symptoms ranging from rhinitis and lacrimation to more severe respiratory compromise. This problem arises in a more serious form among the personnel of pharmaceutical factories processing psyllium (SEDA-16, 426), and eosinophilia has also been recorded. The allergen appears to reside in the endosperm or embryonic seed components and not in the husk, which is the laxative component; in principle, therefore, it should be feasible to supply a non-antigenic form of purified psyllium husk (SEDA-17, 423).

Ingestion of psyllium has been associated with rare cases of generalized urticarial rash and anaphylactic shock (5,6). The possibility that the intestinal absorption of lithium and other drugs may be inhibited by psyllium should also be considered (7).

Sterculia

The family of *Sterculia* plants yield a fiber that has bulk laxative effects.

Esophageal obstruction after ingestion of sterculia has been reported (8).

- A 91-year-old man presented with complete esophageal obstruction after taking a tablespoonful of sterculia granules (Normacol) without water. There was no predisposing esophageal disease. The severity of obstruction was such that endoscopic clearance was not possible, and the patient required gastrotomy and manual disimpaction of the lower esophagus.

Stimulant laxatives

All of the anthraquinones can cause cramping and abdominal discomfort. Chronic use can be associated with melanosis coli. The urine can be colored red. The possibility of colonic injury has been discussed (see General adverse effects of laxatives in this monograph). Hepatitis, confirmed by rechallenge, has been reported, possibly due to re-absorption of rhein anthron produced in the intestine (SEDA-16, 425).

The Food and Drug Administration (FDA) has ruled that the stimulant laxatives aloe (including aloe extract and aloe flower extract) and cascara sagrada (including casanthranol, cascara fluidextract aromatic, cascara sagrada bark, cascara sagrada extract, and cascara sagrada fluid extract) in over-the-counter formulations are not safe and effective or are misbranded (9).

Anthranoid derivatives occur in various laxative herbs (such as aloe, *Cascara sagrada*, medicinal rhubarb, and senna) in the form of free anthraquinones, anthrones, dianthrones, and/or O- and C-glycosides derived from these substances. They produce harmless discoloration of the urine. Depending on intrinsic activity and dose, they can also produce abdominal discomfort and cramps, nausea, violent purgation, and dehydration. However, they are all mutagenic and carcinogenic and should not be used in the long term.

In an epidemiological study, chronic abusers of anthranoid laxatives (identified by the detection of pseudomelanosis coli) had an increased relative risk of 3.04 (95% CI = 1.18, 4.90) for colorectal cancer (10).

Anatomical changes in the colon have been reported in patients taking chronic stimulant laxatives, defined as laxative ingestion more than three times a week for a year or more (11). Loss of haustra, which suggests neuronal injury, or damage to colonic longitudinal musculature, was seen in eight of 29 patients who used a variety of diphenylmethane and anthranoid laxatives but in none of the 26 patients who were not using these drugs. In 18 consecutive patients who were chronic users of stimulant laxatives, there was loss of haustra in 15 who took bisacodyl, phenolphthalein, senna, or casanthranol.

© 2006 Elsevier B.V. All rights reserved.

Aloe species

Aloe species contain laxative anthranoid derivatives, the main active ingredient being isobarbaloin. Large doses are claimed to cause nephritis and use during pregnancy is discouraged, since intestinal irritation might lead to pelvic congestion. Aloe is thought to aggravate hemorrhoids.

- Melanosis coli occurred in a 39-year-old liver transplant patient who took an over-the-counter product containing aloe, rheum, and frangula (12). The typical brownish pigmentation of the colonic mucosa developed over 10 months. The medication was withdrawn and follow-up colonoscopy 1 year later showed normal-looking mucosa. However, a sessile polypoid lesion was found in the transverse colon. Histology showed tubulovillous adenoma with extensive low-grade dysplasia.

Bisacodyl (rINN)

Bisacodyl increases peristalsis by a direct effect on the small intestine. Its only specific adverse effect is abdominal cramping, which a minority of patients find troublesome. As with other laxatives, however, heavy or chronic use can derange the system in various ways, for example hypokalemia with rhabdomyolysis (SEDA-16, 425).

Bisacodyl tablets plus an unrestricted diet and a phosphate enema has been compared with Picolax (sodium picosulfate + magnesium citrate) plus clear fluids in a randomized, single-blind trial in bowel preparation for colonoscopy in 66 children aged 18 months to 16 years (13). Bowel cleansing was significantly better with Picolax. Compliance with both regimens was excellent. Bisacodyl produced significantly more abdominal pain. Some children given Picolax reported vomiting ($n = 3$) and were distressed because of lack of solid food ($n = 6$). The other adverse effects included abdominal discomfort and fecal incontinence.

Bisacodyl suppositories can make the rectal mucosa appear inflamed (14), and this can be mistaken for idiopathic proctitis. However, the effect is transient.

Cascara sagrada

Cascara sagrada has been reported to cause liver damage (15).

- A 48-year-old man developed cholestatic hepatitis and hypertension shortly after he started to use the herbal laxative *Cascara sagrada*, which contains an anthracene glycoside. He took 1 capsule (425 mg of aged *C. sagrada* bark) tds for 3 days and subsequently developed right upper quadrant pain, nausea, abdominal bloating, anorexia, and jaundice. The *Cascara* was withdrawn, but his symptoms persisted and his liver function tests were abnormal. One week later, he developed ascites and jaundice and underwent liver biopsy, which showed moderately severe portal inflammation, intracanalicular bile stasis, portal bridging fibrosis, and mild steatosis. He gradually improved without specific treatment, and 3 months later his ascites and jaundice had resolved.

Dantron (rINN)

Dantron is a synthetic analogue of the anthraquinones. All are bacterial mutagens, and dantron, in addition to being genotoxic as assessed by DNA repair testing, induces intestinal tumors in animals (SED-11, 788) (16). Emodin, aloe-emodin, and dantron probably act by inhibiting the catalytic activity of topoisomerase (17).

Therefore, the anthraquinones should no longer be used, except to treat constipation in patients with terminal cancer (18). For this purpose, dantron is available as co-danthramer (BAN; dantron + poloxamer 188) and co-danthrusate (BAN; dantron + docusate sodium).

Oxyphenisatine (rINN)

Oxyphenisatine, once a very widely used laxative, was withdrawn before 1980 in most countries because of chronic persistent/active hepatitis; a full account will be found in volumes in this series from 1971.

Phenolphthalein (rINN)

Phenolphthalein was once widely used as a laxative for self-treatment, often camouflaged in chocolate and thus liable to abuse or accidental use; it is now obsolete. Skin rashes of various types are repeatedly reported, sometimes with pruritus. Pigmentation defects have been described. The most serious albeit rare adverse effect on the skin to have been reliably documented is toxic epidermal necrolysis. A fixed drug eruption with bullous erythema multiforme is associated with auto-sensitization, and direct intracellular immunofluorescence is found (19). A hypothesis that phenolphthalein might increase the risk of development of adenomatous colorectal polyps has not been confirmed (20).

The Federal Institute for Drugs and Medical Devices in Germany has recommended that marketing authorizations for phenolphthalein products be revoked, in view of its potential toxic effects (21), including genotoxicity and carcinogenicity (22). Further to the actions taken in the USA and France to withdraw laxative products containing phenolphthalein, the following measures have been taken (23).

Canada After reviewing the benefits and risks associated with the use of phenolphthalein-containing laxatives, Health Canada concluded that there is a risk that phenolphthalein may cause cancer in humans; therefore authority to sell and distribute these products has been revoked.
European Union At a Pharmacovigilance Working Party meeting in September 1997, it was indicated that national competent authorities were either considering immediate suspension of phenolphthalein or were discussing with the relevant marketing authorization holders voluntary withdrawal down to the wholesale level. If voluntary action was not agreed by marketing authorization holders, the national competent authorities concerned would consider suspension of the products.
Japan Manufacturers voluntarily withdrew products containing phenolphthalein.

Rheum palmatum (medicinal rhubarb)

Rhubarb contains the anthranoids, sennosides and rhein. In a study of patients taking regular doses of rhubarb-containing Kampo medicines (extracts or decoctions) and patients taking excess doses, there was tolerance to initial stimulant pain in the abdomen during excess use (24). The authors proposed that the absence of tenderness on pressure over the umbilical region could predict increasing or excess use of rhubarb.

© 2006 Elsevier B.V. All rights reserved.

In 14 616 patients who used various Kampo medicines, some of which contained rhubarb, there was no association between the use of rhubarb and the development of gastric carcinoma (25).

Senna

The leaves and fruits of *Cassia angustifolia* and *Cassia senna* contain sennosides, which are laxative anthranoid derivatives. Mutagenicity testing of sennosides has produced negative results in several bacterial and mammalian systems, except for a weak effect in *Salmonella typhimurium* strain TA102 (26,27). There was no evidence of reproductive toxicity of sennosides in rats and rabbits (28). When a standardized formulation containing senna pods (providing 15 mg of sennosides per day) was given to breastfeeding mothers, the suckling infants were only exposed to a non-laxative amount of rhein, which remained a factor of 1000 below the maternal intake of this active metabolite (29). A well-defined purified senna extract was not carcinogenic when given orally to rats in daily doses up to 25 mg/kg for 2 years (30).

Senna is widely used in fairly low doses without serious problems; it is also used in a very high dosage form (X-Prep) to clear the colon before radiological examination. In this form it is generally well tolerated, but it should not be used if there is any predisposition to colonic rupture.

The safety and efficacy of senna have been reviewed (31). Its rhein-anthrone-induced laxative effects occur through two distinct mechanisms, an increase in intestinal fluid transport, which causes accumulation of fluid intraluminally, and an increase in intestinal motility. Senna can cause mild abdominal complaints, such as cramps or pain. Other adverse effects are discoloration of the urine and hemorrhoidal congestion. Prolonged use and overdose can result in diarrhea, extreme loss of electrolytes, especially potassium, damage to the surface epithelium, and impairment of bowel function by damage to autonomic nerves. Abuse of senna has also been associated with melanosis coli, but resolution occurs 8–11 months after withdrawal. Tolerance and genotoxicity do not seem to be problems associated with senna, especially when used periodically in therapeutic doses.

Exceptional complications of senna abuse include hepatitis as well as finger clubbing and hypertrophic osteopathy.

An unusual disulfiram-type reaction reported on one occasion seems to have been due to an interaction of metronidazole with the alcohol present in X-Prep (SEDA-15, 398).

Sodium picosulfate (rINN)

Oral sodium picosulfate and oral sodium phosphate have been compared for bowel preparation before elective colorectal surgery and colonoscopy in randomized studies in 256 patients (32). Oral sodium phosphate was superior to sodium picosulfate on surgical assessment of bowel preparation, fecal residue in the resected specimen, and endoscopic score. However, there was no significant difference with regard to abdominal pain, nausea, vomiting, embarrassment, fear, and fatigue between the two groups.

Oral sodium picosulfate plus magnesium citrate (Picolax) has been compared with a self-administered phosphate enema for bowel preparation before flexible sigmoidoscopy in a randomized, single-blind trial in 1142 subjects (33). A single self-administered phosphate enema about 1 hour before leaving home was a more acceptable and effective method of preparing the distal bowel than oral Picolax. Although more patients felt unwell after taking the enema (15%) than after taking Picolax (7%), over 80% in both groups felt normal. More of the itemized adverse effects were rated as moderate or severe in the Picolax group, including wind, incontinence, and sleep disturbance. Anal soreness was reported more frequently in the enema group. The other reported adverse effects were abdominal pain/cramps, nausea/vomiting, and faintness/dizziness.

Two cases of generalized urticarial skin reactions occurred after a first dose of sodium picosulfate (34). This may have represented an interaction with aminosalicylate derivatives, which were being administered at the same time, or a simple adverse effect to one of the agents.

A dubious case of status epilepticus attributed to picosulfate has been published (SEDA-16, 425).

Fecal softeners

Liquid paraffin

It has been recommended for many years that the use of liquid paraffin should be discontinued because of its propensity to cause malabsorption of fat-soluble vitamins, to leak and soil the perineal skin, and to cause lipid pneumonia if aspirated; at the very least it should be avoided in young children (35).

Osmotic laxatives

The osmotic laxatives include inorganic salts and the synthetic disaccharide, lactulose, as well as magnesium salts and sodium phosphate. Osmotic agents are largely free of adverse effects, apart from flatulence, cramps, and abdominal discomfort.

Lactulose (rINN) and lactitol (rINN)

Lactulose is a non-absorbable disaccharide that is hydrolysed in the large bowel by intestinal bacteria, yielding monosaccharides that act as osmotic agents; it is also metabolized to hydrogen and carbon dioxide.

In a double-blind, placebo-controlled study in 10 healthy volunteers, lactulose powder 10 g/day for 26–33 days was an effective food-grade prebiotic (36). Fecal bifidobacteria increased significantly during lactulose intake, with a concomitant decrease in *Clostridia*.

The most common adverse effects of lactulose are flatulence, cramps, and abdominal discomfort. Non-toxic megacolon has been seen in some elderly patients and, as with other laxatives, there is always a possibility of dependence (SEDA-11, 374).

- Two women aged 88 and 82 taking lactulose for constipation, developed life-threatening dilatation of the bowel (16). Both underwent surgery. One had cancer of the bowel and an uneventful postoperative recovery. No mechanical abnormalities were found in the second patient but she died in respiratory insufficiency after aspiration.

© 2006 Elsevier B.V. All rights reserved.

Low-dose polyethylene glycol electrolyte solution and lactulose have been compared in chronic constipation in a randomized multicenter study in 115 patients with chronic constipation (37). After 4 weeks the patients who took polyethylene glycol had a higher number of stools, a lower median daily score for straining at stool, and greater overall improvement than patients who took lactulose. Except that significantly fewer patients who took polyethylene glycol reported flatus, other adverse effects were similar in the two groups and included liquid stools, abdominal pain, bloating, and rumbling.

- Pneumatosis intestinalis and pneumoperitoneum have been reported in a 57-year-old cirrhotic man with colonic inertia who had been taking oral lactulose 30 ml tds (38). Because of constipation the dose of lactulose had been gradually increased to 60 ml qds together with lactulose enemas. Both conditions resolved 3 days after oral lactulose was withdrawn.

Lactitol is another disaccharide, similar to lactulose. It has been claimed to be more palatable and to have fewer adverse effects (SEDA-18, 374), but it has not been used as widely as lactulose.

The effects of lactulose and lactitol in daily doses of 18–36 g for 6 months have been evaluated in a prospective, open study in 31 cirrhotic patients with chronic encephalopathy (38). Mean daily stool frequency (2.5 versus 1.7) and the frequency of reported adverse effects (59 versus 14%) were significantly higher with lactulose. Common adverse effects were nausea, intestinal discomfort, flatulence, and diarrhea.

There has been a systematic review of 30 randomized comparisons in hepatic encephalopathy of lactulose or lactitol with no intervention, placebo, or antibiotics and comparisons of lactulose with lactitol (39). Compared with placebo or no intervention, non-absorbable disaccharides had no statistically significant effect on mortality, but appeared to reduce the risk of no improvement of hepatic encephalopathy. However, this result might have reflected bias, owing to the poor quality of the majority of the studies.

Phosphates

Oral sodium phosphate 90 ml mixed with 300 ml of clear liquid has been compared with 2 liters of polyethylene glycol solution in a colonoscopist-blinded, randomized trial in 100 patients undergoing colonoscopy as a day-care procedure (40). Sodium phosphate was well tolerated and safe and provided bowel cleansing similar to polyethylene glycol. Five patients who received polyethylene glycol and four who received sodium phosphate reported nausea, and eight patients who received polyethylene glycol and one who received sodium phosphate complained of abdominal fullness.

The standard regimen of sodium phosphate used for bowel cleansing before colonoscopy is 40 tablets (60 g). In a randomized, multicenter, endoscopist-blinded trial in 98 patients undergoing colonoscopy, two smaller doses of sodium phosphate, 28 tablets (42 g) and 32 tablets (48 g), were effective (quality of colon cleansing excellent or good in over 80%) and well tolerated (41). The incidences of adverse effects were similar in the two groups. The reported adverse effects were nausea, vomiting, dizziness, and headache.

Tonic-clonic seizures have been reported in four adults who took oral sodium phosphate as Visicol (InKline Pharmaceutical; total 40 tablets) for bowel cleansing before colonoscopy (42). None of the patients had a history of seizures or electrolyte abnormalities. In all cases the seizures were associated with electrolyte abnormalities, mainly hyponatremia, after administration of Visicol.

Aphthous ulcers in the rectal mucosa have been reported in association with the use of Fleet-phospho-soda enema in preparation for colonoscopy in a 54-year-old woman (43).

Bowel cleansing solutions

Colonic ulceration has been attributed to the use of hydrogen peroxide in an enema (44).

- A 13-year-old girl was given 10% hydrogen peroxide as an enema for constipation. She developed severe rectal bleeding, and colonoscopy showed mucosal ulceration up to the splenic flexure. Histology confirmed ulceration due to traumatic burns. She improved gradually on conservative treatment, and 2 months later a repeat colonoscopy was normal.

Lead

General Information

Lead is a heavy soft bluish-gray metal (symbol Pb; atomic no. 82) that is widespread as different salts in minerals such as chromite (oxide), crocoisite (chromate), Jamesonite and zinkenite (sulfides), mimetite (arsenate and chloride), pyromorphite (phosphate and chloride), and vanadinite (vanadate and chloride).

Lead has no place in internal medical treatment, although lead acetate has retained a very small place as an astringent. Its toxic effects are known primarily from environmental and occupational exposure and occasionally

© 2006 Elsevier B.V. All rights reserved.

from the use of alternative remedies or cosmetics. For example, lead sulfide in eye-drops originating in India has caused lead poisoning, and lead has been found in some supposed aphrodisiacs from India. Children with circulating lead concentrations in excess of 600 ng/ml have impaired intellectual performance and electrocardiographic changes, and at any age excessive intake can cause encephalopathy, neuropathies, anemia, anorexia, colic, and renal damage. Lead poisoning from occupational and environmental sources continues to be reported. The biological chemistry of lead has been reviewed (1).

No significant effects have been attributed to lead as a contaminant in infant formulas or total parenteral nutrition. In an investigation of the protective effect of calcium supplements against lead absorption, 103 infants aged 3.5–6.0 months were randomly assigned to receive an infant formula (iron-fortified, containing 465 micrograms/ml of calcium and 317 micrograms/ml of phosphate) or the same formula with added calcium glycerophosphate (1800 micrograms/ml of calcium and 1390 micrograms/ml of phosphate) for 9 months (2). There was no significant difference between the groups in the mean ratio of urinary calcium to creatinine, serum calcium, or serum phosphorus, nor any change in iron status. At month 4, the median increase was 0.07 μmol/l in the control group and 0.04 μmol/l in the supplemented group. This significant effect was attenuated during the latter half of the trial, with overall increases in blood lead of 0.12 μmol/l in controls and 0.10 μmol/l in the supplemented group. Supplementation did not have a measurable effect on urinary calcium excretion, calcium homeostasis, or iron status. The significant effect on blood lead concentration was expected, although it was not sustained during the whole study, and so no prevention could be concluded.

Herbal remedies

Raised blood lead concentrations in an adult have been attributed to an Asian remedy for menstrual cramps ("Koo Sar Pills") (3).

- A Cambodian woman, her husband, and their two children were screened at a free lead-screening event sponsored by a nursing school community health promotion. The husband and children had normal blood lead concentrations, but the woman had a concentration of 440 ng/ml. She reported no symptoms associated with lead poisoning (for example, muscle pains or weakness, headaches, or loss of appetite). Samples of any medicines, teas, or cosmetics that she had used that might have been the source of the lead were analysed. Lead was found only in bottles of red tablets, at concentrations of 3.5 ppm from one bottle and 1.2 ppm in a second bottle. For 3–4 years she had taken six of these tablets a day on 7 days of each month to treat menstrual cramps. She stopped taking them, and her blood lead concentrations fell from 280 to 12 ng/ml over 6 months. Further laboratory analysis of other bottles showed lead in amounts of 12.5 ppm in tablets from a third bottle and 4.5 ppm in tablets from a fourth bottle. The tablets were traced to a San Francisco-based Hong Kong company who sold them in packages with the brand name listed on the outside of the package as "Koo So Pills" and on the package insert as "Koo Sar Pills." The package literature was written in Chinese. Lead was not among the 11 listed ingredients. The insert stated "These medical pills are good for general debility." The directions for dosage were one pill taken with warm water twice a day (not six per day). The lead content in samples purchased at different shops in San Francisco was 2.7 ppm (0.9 micrograms/tablet) and 4.3 ppm (1.4 micrograms/tablet).

No other cases of lead poisoning have been reported in association with Koo Sar tablets, and it is thought that the varying lead concentrations in the different tablets resulted from varying amounts of lead present during the manufacture of the red dye.

- A 23-year-old Asian butcher developed diffuse abdominal pain, vomiting, and diarrhea, followed by constipation (4). He had a sinus tachycardia and generalized abdominal tenderness without peritonism. His serum bilirubin concentration and alanine transaminase activity were raised, but alkaline phosphatase activity, albumin concentration, and prothrombin time were normal. He had a blood lead concentration of 767 ng/ml and a raised zinc protoporphyrin concentration, diagnostic of lead poisoning. He had taken an herbal medicine, purchased in India, for vague ailments. He stopped taking it, and 3 months later was asymptomatic, with normal liver function tests and marked falls in blood lead (387 ng/ml) and zinc protoporphyrin.

Lead toxicity has been reported in a child who was exposed to lead in a Tibetan herbal remedy (5).

- A 5-year-old Indian boy had static encephalopathy, seizures, and developmental delay from neonatal asphyxia and was referred to a hematologist for persistent anemia (hemoglobin 9.2 g/dl) without basophilic stippling, refractory to iron therapy. He was alert and active but nonverbal, able to stand with support but not able to walk, and had no focal neurological defects. Skeletal and abdominal X-rays showed no lead lines and no gastric lead particles. He had normal iron stores and normal hemoglobin electrophoresis. The blood lead concentration was 860 ng/ml. He was given EDTA and dimercaprol (BAL), and his lead concentration fell to 256 ng/ml. His mother had been giving him a Tibetan herbal vitamin, in the form of tablets, three times a day for the previous 5 years. A traditional medicine healer had told her that the tablets were pure medicinal herbs and plants prepared according to ancient Tibetan pharmacological traditions. They were said to be free from harmful or toxic substances and would actually promote brain growth and improve his mental capabilities. The tablets were produced in India and each was individually wrapped. They were analysed for lead, arsenic, cadmium, and mercury, and it was estimated that he had ingested about 63 g of lead over 4 years. Seven months later his blood lead concentration was 760 ng/ml and he was given EDTA and BAL. On day 2 he had a tonic-clonic seizure lasting 1 minute and his urinary lead concentration was 2310 ng/ml. On discharge his blood lead concentration was 413 ng/ml. During the next 4 years he had a further six chelation treatments with succimer when

© 2006 Elsevier B.V. All rights reserved.

his lead concentration was over 450 ng/ml. After 4 years his lead concentration was 245 ng/ml.

Topical lead

A 64-year-old woman had treated extensive ulcers of both legs with daily dressings of diachylon ointment, containing 15% lead oxide, for more than a year. She then developed general weakness, loss of weight, anemia, hypotension, and neuropathy. Lead concentrations in the blood were increased three-fold and urinary lead concentrations ten-fold, and a diagnosis of percutaneous lead intoxication was made. Treatment with dimercaptopropane sulfonic acid resulted in considerable reduction of the lead deposits, and the symptoms of poisoning subsided (6).

Second-Generation Effects

Fetotoxicity

Intrauterine lead intoxication has been reported.

- A 24-year-old pregnant woman, who had recently emigrated from India, had periodically over the course of 9 years taken tablets prescribed by an Ayurvedic doctor for a gastrointestinal complaint. The tablets had a high lead content. She presented at 30 weeks gestation with abdominal pain and progressive confusion, culminating in seizures (7). Her erythrocytes showed typical basophilic stippling and her blood lead concentration was 5.2 (reference range 0.06–0.6) μmol/l. She was given intramuscular dimercaprol and intravenous calcium disodium edetate and 36 hours later had an antepartum hemorrhage; labor was induced and she gave birth by vaginal delivery to a 1.6 kg girl, who was flaccid and areflexic and did not move in response to noxious stimuli, but had spontaneous ocular movements. She had bilateral diaphragmatic palsy. The cord blood lead concentration was 7.6 μmol/l, the erythrocyte porphyrin concentration was 20 (reference range 0.4–1.7) μmol/l, and radiography of the long bones showed increased bone density adjacent to the metaphyses. The infant was given chelation dimercaprol (4 mg/kg every 4 hours) and intravenous calcium disodium edetate 50 mg/kg. The blood lead concentration initially rose to 12 μmol/l and then fell rapidly over the next few days. A high urinary lead concentration on day 4 (52 μmol/l) showed that lead was being excreted. Facial, bulbar, proximal limb, and diaphragmatic muscle activity improved.

Lefetamine

General Information

Lefetamine is an opioid receptor partial agonist, which combines the actions of amphetamines with opioid-like effects. It was a drug of abuse in Japan in the 1950s and later also in Italy (1). In 10 opiate addicts, lefetamine relieved acute opiate withdrawal symptoms and did not precipitate withdrawal symptoms in stable addicts (2).

During ordinary use sedation, tiredness, gastrointestinal disturbances, headache, sweating, and flushing have been observed with lefetamine (3).

Leflunomide

General Information

The prodrug leflunomide (*N*-(4′-trifluoromethylphenyl)-5-methylisoxazole-4-carboxamide) is an isoxazole derivative. Its main metabolite is the active compound, A77 1726 (1).

Mechanism of action

A77 1726 inhibits dihydro-rate dehydrogenase, the rate-limiting enzyme in pyrimidine synthesis. It inhibits the proliferation of T and B cells, and probably acts via the production and action of interleukin-2. Besides its immunomodulatory action, A77 1726 also has an anti-inflammatory action by inhibition of nuclear factor kappa B (NFκB), tumor necrosis factor alfa (TNF-α),

© 2006 Elsevier B.V. All rights reserved.

and interleukin 1 beta (IL-1β), and increased production of transforming growth factor beta-1 (TGF-β1) (2–5).

Pharmacokinetics

After oral administration, leflunomide undergoes rapid metabolism in the gut wall, plasma, and liver to A77 1726 (M1), peak plasma concentrations of which are reached after 6–12 hours. A77 1726 is highly (99%) bound to plasma proteins. Its pharmacokinetics are not affected by food, and dosage requirements are not influenced by age or sex. Enterohepatic recirculation and biliary recycling contribute to the long half-life of 2 weeks. About 90% of a single dose of leflunomide is eliminated, 43% in the urine, primarily as leflunomide glucuronides and an oxalinic acid derivative of A77 1726, and 48% in the feces, primarily as A77 1726. Impaired renal function can result in increased plasma concentrations of A77 1726. Elimination of A77 1726 can be dramatically increased by using colestyramine or activated charcoal (6,7).

Indications and clinical efficacy

Leflunomide has anti-inflammatory, immunosuppressive, and virustatic effects. Its efficacy has been demonstrated in patients with rheumatoid arthritis and psoriatic arthritis and other conditions in randomized, double-blind, placebo-controlled trials and other studies (8–32), and it was approved for treatment of adult rheumatoid arthritis in August 1998 (Table 1) (33). In three large phase III trials (US301, $n = 482$; MN301, $n = 358$; MN302, $n = 999$), leflunomide was as effective and well tolerated as methotrexate and sulfasalazine and superior to placebo (34). These data were confirmed by a meta-analysis (35,36). Leflunomide is therefore indicated for patients with rheumatoid arthritis who have failed first-line disease modifying anti-rheumatic drug therapy on the basis of efficacy, safety, and costs (36). It is effective as monotherapy and in combination with methotrexate or infliximab (6).

Clinical experience with leflunomide in patients with other autoimmune diseases is limited. Extended indications for the use of leflunomide include treatment of Crohn's disease in patients who are intolerant of standard immunomodulator therapy (31), chronic sarcoidosis (32), maintenance therapy of complete or partial remission in Wegener's granulomatosis (30), and mild to moderate systemic lupus erythematosus (29) (Table 1).

Leflunomide has been used as an immunosuppressive agent in kidney and liver transplant recipients to spare calcineurin inhibitors and glucocorticoids and to slow progression of chronic kidney graft dysfunction (28,37) (Table 1).

In animals, leflunomide had excellent antiviral activity against cytomegalovirus (CMV). It is currently indicated as second-line therapy for CMV disease after solid organ transplantation and in recipients intolerant of ganciclovir (38). Leflunomide also reduces HIV replication by about 75% at concentrations that can be obtained with conventional dosing (39).

General adverse drug reactions

The safety profile of leflunomide has been said to be excellent, with no myelosuppressive or nephrotoxic adverse effects (40,41). Its major adverse effects are gastrointestinal symptoms (diarrhea and nausea), abnormal liver function tests, skin rashes and pruritus, allergic reactions, alopecia, infections, weight loss, and hypertension (35,42–45). Minor adverse effects are musculoskeletal disorders. Rare adverse effects include sepsis, pancytopenia, interstitial lung disease, hypertriglyceridemia, vasculitis, aseptic meningitis, reversible neuropathy, and serious skin reactions (35,46–49).

In 3325 patients who took leflunomide, the rate of drug withdrawal was 42% within 33 months after approval by the US Food and Drugs Administration, and was more likely in patients who received a loading dose. The most common causes of discontinuation were inefficacy (30%), gastrointestinal symptoms (29%), non-adherence to therapy or loss to follow-up (14%), and raised liver enzymes (5%) (50).

However, the rate of adverse effects associated with leflunomide was significantly lower than with methotrexate and other disease-modifying antirheumatic drugs (DMARDs) in an analysis of 40 594 patients with rheumatoid arthritis (8,51). The incidences of adverse events per 1000 patient-years were as follows:

- no DMARDs: 383
- methotrexate: 145
- leflunomide monotherapy: 94
- methotrexate + other DMARDs: 70
- leflunomide + other DMARDs: 59
- leflunomide + methotrexate: 43
- other DMARDs: 143.

Leflunomide monotherapy also had the lowest rate of hepatic events in the DMARD monotherapy groups.

Further developments

Synthetic malononitrilamides (MNA) have been derived from A77 1726. FK778 is the most promising derivative, because of its much shorter half-life. It also blocks replication of herpesvirus in vitro and in vivo. It has therefore been used as part of an immunosuppressive regimen and as an antiviral agent after solid organ transplantation (52). FK778 is under investigation in a phase II trial after kidney transplantation (53).

Organs and Systems

Cardiovascular

The incidence of hypertension in patients with rheumatoid arthritis taking leflunomide 25 mg/day was 11% in a phase II trial (54). During phase III trials, there was new-onset hypertension in 2.1–3.7% (9,10). Increased sympathetic drive has been implicated in its pathogenesis, because leflunomide-induced hypertension is accompanied by an increased heart rate (55). However, this hypothesis remains to be tested.

Pulmonary hypertension has been described in association with leflunomide (56).

Respiratory

Respiratory symptoms in the MN301, US301, and MN302 trials in patients with rheumatoid arthritis included respiratory infections (21–27%), bronchitis (5–8%), increased cough (4–5%), rhinitis (2–5%), pharyngitis (2–3%), pneumonia (2–3%), and sinusitis (1–5%) (9,10,12).

Table 1 Summary of the efficacy of leflunomide in controlled trials

Disease	Type of study; duration	Intervention	Outcome	References
Rheumatoid arthritis	Double-blind, randomized, controlled trial; 24 weeks	Leflunomide 50–100 mg/day for 1 day, then 5–25 mg/day ($n = 300$) versus placebo ($n = 102$)	Leflunomide 10 and 25 mg/day was significantly more effective than placebo	(8)
Rheumatoid arthritis	Double-blind, randomized, controlled trial; 12 months	Leflunomide 100 mg/day for 3 days, thereafter 20 mg/day ($n = 182$) versus methotrexate 7.5–15 mg/week ($n = 180$) versus placebo ($n = 118$)	American College of Rheumatology response and success rates were: leflunomide 52% and 41%, methotrexate 46% and 35%, and placebo 26% and 19%	(9)
Rheumatoid arthritis	Double-blind, randomized, controlled trial; 24 weeks	Leflunomide 100 mg/day for 3 days, then 20 mg/day ($n = 133$) versus sulfasalazine 2 g/day ($n = 133$) versus placebo ($n = 92$)	American College of Rheumatology 20 response rates were: leflunomide 55%, sulfasalazine 56%, and placebo 29%	(10,11)
Rheumatoid arthritis	Double-blind, randomized, controlled trial; 52 weeks	Leflunomide 100 mg/day for 3 days, then 20 mg/day ($n = 501$) versus methotrexate 7.5–15 mg/day ($n = 498$)	Both drugs effective, although methotrexate resulted in significantly greater improvement in tender and swollen joint counts compared with leflunomide	(12)
Rheumatoid arthritis	Double–blind, randomized, controlled trial; 6 months	Leflunomide 100 mg/day for 3 days, then 20 mg/day ($n = 133$) versus sulfasalazine 0.5–2 g/day ($n = 133$), versus placebo ($n = 92$)	Leflunomide slowed disease progression as early as 6 months, and there was continued retardation of radiographic progression at 2 years	(13)
Rheumatoid arthritis	Follow-up study; 2 years	Leflunomide ($n = 98$) versus methotrexate ($n = 101$)	American College of Rheumatology 20, 50, and 70 response rates for leflunomide versus methotrexate were 79 versus 67%, 56 versus 43%, and 26 versus 20%	(14)
Rheumatoid arthritis	Follow-up study; 2 years	Leflunomide 20 mg/day versus sulfasalazine 2 g/day	American College of Rheumatology 20 response rates were 82% leflunomide versus 60% sulfasalazine after 24 months	(15)
Rheumatoid arthritis	Follow-up study; 5 years	Leflunomide 10–20 mg/day (phase III) continued ($n = 214$)	American College of Rheumatology 20, 50, and 70 response rates after 1 year were maintained for up to 5 years	(16)
Rheumatoid arthritis	Single-center experience; 32 weeks	Leflunomide 100 mg/day for 3 days, then 20 mg/day plus infliximab 3 mg/kg at 2, 4, 8, 16, and 24 weeks ($n = 20$)	11/20 withdrawn (four infliximab infusion reactions, one Stevens–Johnson syndrome); the other patients achieved American College of Rheumatology 20 and 70 response rates in >80% and 46%	(17)
Rheumatoid arthritis	Double-blind randomized controlled trial; 24 weeks	Leflunomide 100 mg/day for 2 days, then 10 mg/day ($n = 130$) versus placebo ($n = 133$), both with methotrexate 10–25 mg/day	American College of Rheumatology 20 rates at 24 weeks: leflunomide + methotrexate 46% versus placebo + methotrexate 20%; similar drug withdrawal and adverse events rates	(18)
Rheumatoid arthritis	Multicenter experience; 24 weeks	Leflunomide 100 mg/day for 3 days, then 20 mg/day ($n = 969$)	191 withdrawn (107 adverse events, 26 lack of efficacy, 58 other reasons); 24% good and 45% moderate responses on the disease activity score, and 61%, 34%, and 9.6% achieved American College of Rheumatology 20, 50, and 70 response rates	(19)
Rheumatoid arthritis	Single-center experience; 3 months	Leflunomide 100 mg/day for 3 days, then 20 mg/day plus infliximab 3 mg/kg at 0, 6, and every 8 weeks ($n = 17$)	20 adverse effects in 13 patients; 8 discontinued	(20)
Rheumatoid arthritis	Single-center experience; 24 weeks,	Leflunomide 100 mg/day for 3 days, then 100 mg/week ($n = 50$)	American College of Rheumatology 20, 50, and 70 response rates at 24 weeks were 74%, 64%, and 28% (five withdrawn, six lost to follow-up)	(21)

Table 1 Continued

Disease	Type of study; duration	Intervention	Outcome	References
Rheumatoid arthritis	Single-center experience; 6 months	Leflunomide 100 mg/day for 3 days, then 20 mg/day ($n = 378$)	American College of Rheumatology 20, 50, and 70 response rates at 6 months were 48%, 25%, and 12%	(22)
Rheumatoid arthritis	Extension of double-blind, randomized, controlled trial; 48 weeks	Leflunomide + methotrexate continued ($n = 96$) and placebo + methotrexate switched to leflunomide 10 mg/day + methotrexate ($n = 96$)	American College of Rheumatology 20 response rate was 59% at 24 weeks and 55% at 48 weeks in patients maintained on leflunomide + methotrexate, and patients switched from placebo to leflunomide + methotrexate increased their American College of Rheumatology 20 response rates from 25% at 24 weeks to 57% at 48 weeks	(23)
Rheumatoid arthritis	Double-blind, randomized, controlled trial; 24 weeks	Leflunomide 10 mg/day and 100 mg on day 3 ($n = 202$) versus 20 mg/day and 100 mg on days 1–3 ($n = 200$)	American College of Rheumatology (20 response rates: leflunomide 10 mg 50% and 20 mg 57%; adverse events: leflunomide 10 mg 15% and 20 mg 12%	(24)
Rheumatoid arthritis	Multicenter experience; 11–911 days	Leflunomide 100 mg/day for 3 days, then 20 mg/day ($n = 136$)	76% clinical response after 12 months, but 76/136 (56%) leflunomide withdrawn (29% adverse drug reactions and 13% lack of efficacy)	(25)
Psoriatic arthropathy, psoriasis	Double-blind, randomized, controlled trial; 24 weeks	Leflunomide 100 mg/day for 3 days, then 20 mg/day ($n = 95$) versus placebo ($n = 91$)	Leflunomide 59% and placebo 30% were responders at 24 weeks according to the psoriatic arthritis response criteria	(26)
Psoriasis	Phase II study; 12 weeks	Leflunomide 20 mg/day ($n = 8$)	6/8 clinical effectiveness (psoriasis area and severity index score 20 at baseline versus 13 at 12 weeks)	(27)
Liver and kidney transplant recipients	Single-center experience	Leflunomide dosage adjusted to a trough concentration of 100 μg/ml ($n = 53$)	Immunosuppressive potency in liver and kidney transplant recipients, allowing dosage reduction of calcineurin inhibitors and glucocorticoids, but anemia might be dose-limiting after kidney transplantation	(28)
Systemic lupus erythematosus	Single-center experience, double-blind, randomized, controlled trial; 24 weeks	Leflunomide 100 mg/day for 3 days, then 100 mg/day ($n = 6$) versus placebo ($n = 6$)	Disease activity fell significantly in both groups after 6 months, and the reduction in SLE disease activity index from baseline to 24 weeks was significantly greater with leflunomide than with placebo	(29)
Wegener's granulomatosis	Phase II study; 52 weeks	Leflunomide 20–40 mg/day ($n = 20$)	Maintenance of complete or partial remission after cyclophosphamide + glucocorticoid therapy resulted in one major and eight minor relapses	(30)
Crohn's disease	Single-center experience; 3 years	Leflunomide 20 mg/day ($n = 12$)	8/12 clinical responses; seven continued maintenance therapy and one relapsed after follow-up of 6–78 weeks	(31)
Chronic sarcoidosis	Single-center experience; 1 year	Leflunomide 100 mg/day for 3 days, then 10–20 mg/day ($n = 32$; 17 leflunomide and 15 leflunomide + methotrexate)	Complete or partial responses in 13/17 leflunomide and in 12/15 leflunomide + methotrexate	(32)

In Japan, acute interstitial pneumonia due to leflunomide has been mentioned as a serious and severe adverse effect, with an incidence of 1.1% and a fatal outcome in 0.36% (57–59).

- A 49-year-old man with rheumatoid arthritis taking methotrexate developed a skin eruption and a severe non-productive cough after taking leflunomide for 17 days (58). He died of respiratory failure 128 days after the diagnosis of acute interstitial pneumonia.
- A 54-year-old woman with rheumatoid arthritis developed an interstitial pneumonia 2 weeks after the end of a 6-week course of treatment with leflunomide (60).

© 2006 Elsevier B.V. All rights reserved.

The onset of the pneumonia was preceded by raised serum liver enzymes and hypertension. The acute respiratory failure improved with prednisolone and colestyramine.

However, clinical trials and subsequent observational studies outside Japan have not suggested that leflunomide causes an excess of pulmonary adverse effects (61).

Nervous system

Leflunomide can cause a peripheral reversible neuropathy (49,62–65). This neuropathy is usually axonal in nature, affecting multiple sensory or motor nerves of distal extremities. The mean time of onset of peripheral neuropathy was 6 months after the start of leflunomide therapy, with a range of 3 days to 3 years. Neurological improvement was more likely after drug withdrawal within 30 days after the onset of the symptoms of neuropathy compared with continuous administration (63).

Peripheral neuropathy attributed to leflunomide was observed in two patients (49).

- A 76-year-old man, with an 18-month history of seropositive rheumatoid arthritis, chronic emphysema, and pulmonary fibrosis, developed polymyalgia and was treated with glucocorticoids and azathioprine. Azathioprine was withdrawn after a rise in aspartate transaminase. He was then given leflunomide 100 mg over 3 days followed by 10 mg/day as a maintenance dosage. After 2 weeks, he developed a sensory neuropathy with a stocking distribution up to the malleoli and leflunomide was withdrawn 4 weeks later. During this time he had also been taking prednisolone, tramadol, disodium etidronate, indoramin, and celecoxib, none of which is known to cause neuropathy. Glucose, vitamin B12, serum folate, thyroid function, serum proteins, Bence–Jones protein electrophoresis, cryoglobulins, anti-neutrophil cytoplasmic antibodies, antinuclear antibodies, the Venereal Disease Research Laboratory test, and hepatitis B and C serology were all normal or negative. Nerve conduction was consistent with motor sensory axonal peripheral neuropathy of the lower limbs. On review 3 months after withdrawal of leflunomide, there was clear subjective and objective improvement of the neuropathy, confirmed by repeat nerve conduction studies.
- A 69-year-old woman with a 10-year history of seropositive erosive rheumatoid arthritis, previously treated with gold salts followed by methotrexate, started to take leflunomide and 3 months later reported numbness in the fingertips and feet bilaterally, with a glove-and-stocking sensory neuropathy involving all fingertips and extending to the mid-shins. Leflunomide was withdrawn. Other medications included prednisolone, lansoprazole, simvastatin, losartan, and amiodarone, which she had been taking for a long time without adverse effects. Screening tests for neuropathy, as in the previous case, were normal or negative. There was no cord or nerve root compression on magnetic resonance imaging of the cervical spine. Nerve conduction studies confirmed a sensory motor peripheral neuropathy. She reported marked improvement in her symptoms 3 months after withdrawal of treatment, and this was confirmed on clinical examination and repeat nerve conduction studies.

One case of leflunomide-induced aseptic meningitis has been reported (48).

Metabolism

Life-threatening hypertriglyceridemia has been described during treatment with leflunomide (46).

Hematologic

Pancytopenia, thrombocytopenia, and anemia can occur during leflunomide treatment (21,66–68). The risk of pancytopenia is increased when it is used in combination with methotrexate and in elderly patients. Its course can be fatal and the time of onset ranges from 11 days to 4 years (66). Anemia has been reported in renal transplant recipients (28).

Leflunomide-associated thrombocytosis and leukocytosis resolved after colestyramine washout and withdrawal of leflunomide (69).

Mouth and teeth

In the MN301, US301, and MN302 trials, mouth ulceration occurred in 3–5% (9,10,12).

Gastrointestinal

In the MN301, US301, and MN302 trials, gastrointestinal symptoms consisted of diarrhea (22–27%), nausea (13%), dyspepsia (6–10%), abdominal pain (6–8%), mouth ulceration (3–5%), vomiting (3–5%), anorexia (3%), and gastroenteritis (1–3%) (9,10,12). Diarrhea and nausea are more common in patients who receive a loading dose, but the onset of action can be delayed without the loading dose (36). Gastrointestinal symptoms occur mainly during the first 6 months after initiation of leflunomide. The severity of symptoms was mild. If there is severe diarrhea and/or weight loss, withdrawal of leflunomide and endoscopic examination is advised, since ulcerative and microscopic colitis have been detected under such circumstances (70). The pathophysiology of leflunomide-associated diarrhea and weight loss is unclear. Weight loss of 9–24 kg was observed in five of 70 patients who took leflunomide, despite normal concentrations of thyroid-stimulating hormone and no other gastrointestinal complaints (44).

Liver

Leflunomide can cause abnormal liver function tests, but the risk of serious and non-serious hepatic adverse events is not higher than with methotrexate (71). In the MN301, US301, and MN302 trials, there were abnormal liver enzymes in 6–10% (9,10,12). The co-administration of methotrexate is a risk factor (18,72–74). According to the National Cancer Institute Common Toxicity Criteria, 8.9% of patients developed grade 2 or 3 hepatotoxicity within the first year, mainly within 6 months and in combination with methotrexate, after the start of leflunomide therapy based on liver enzyme determinations (72). The use of folate was also associated with less

© 2006 Elsevier B.V. All rights reserved.

frequent changes in liver function tests (9,10,12). Nevertheless, leflunomide can cause severe liver injury (75–78), estimated at a rate of one in 200 users (79). Leflunomide is therefore not recommended in patients with significant liver impairment or evidence of infection with hepatitis B or C virus (80).

A CYP2C9 polymorphism has been implicated in the pathogenesis of leflunomide hepatotoxicity (77).

- A 67-year-old woman with rheumatoid arthritis developed diarrhea and raised liver enzymes after taking leflunomide for 15 days. Histologically, the liver showed acute hepatitis. She was homozygous for the CYP2C9*3 allele. The liver damage subsided within a few weeks.

Urinary tract

Interstitial nephritis occurred in one case of chronic overdose of leflunomide (81).

Skin

Adverse effects of leflunomide on the skin in patients with rheumatoid arthritis include alopecia (9–17%), rash (11–12%), pruritus (5–6%), dry skin (3%), and eczema (1–3%) (9,10,12). Single cases of an erythema multiforme-like drug eruption (82), exfoliative dermatitis (83), a lichenoid drug reaction (84), and skin ulceration (85) have been reported.

Immunologic

In the treatment of rheumatoid arthritis leflunomide can cause a vasculitis, and acute necrotizing vasculitis is rare but serious (47,86).

Long-Term Effects

Mutagenicity

A minor metabolite of leflunomide, 4-Trifluoromethylaniline, was mutagenic in vitro (87).

Tumorigenicity

Male mice had an increased incidence of lymphoma at an oral leflunomide dose of 15 mg/kg, and female mice had a dose-related increased incidence of bronchoalveolar adenomas and carcinomas beginning at 1.5 mg/kg (87).

Second-Generation Effects

Fertility

Leflunomide did not affect fertility in rats (87).

Teratogenicity

In oral embryocytotoxicity and teratogenicity studies in rats and rabbits, leflunomide was embryocytotoxic (growth retardation, embryolethality) and teratogenic (malformations of the head, rump, vertebral column, ribs, and limbs) (87). Not only is leflunomide teratogenic and fetotoxic in animals, but its active metabolite is detectable in plasma up to 2 years after withdrawal. Therefore, the fetus could have in utero exposure to leflunomide up to 2 years after the end of treatment. Leflunomide has been classified as pregnancy category X by the Food and Drug Administration (87,88). However, experience in a very small group of pregnant women who took leflunomide and continued their pregnancy to term gave no indication of an increase in teratogenesis (89). Nevertheless, the majority of 30 pregnant women were elected to interrupt their pregnancies, except three patients (87). At present, withdrawal of leflunomide is mandatory before pregnancy, and colestyramine treatment is advised to wash out leflunomide (80,87,90,91). Both men and women who want to have a child should discontinue leflunomide and take colestyramine to wash it out. Leflunomide has not been studied in children, possibly because of its cytotoxic nature. In particular, its teratogenic potential may be a concern when treating adolescent girls (92).

Lactation

Breastfeeding by nursing mothers is not recommended, because it is unknown if leflunomide is excreted in human milk (80,87).

Drug Administration

Drug dosage regimens

Leflunomide is taken orally. In most regimens it is begun with a loading dose of 100 mg/day over 3 days followed by a maintenance dosage of 10–20 mg/day. Leflunomide 100 mg/week had similar effectiveness and less toxicity in open trials compared with daily dosing (21,93).

Drug–Drug Interactions

Infliximab

The administration of infliximab after or simultaneously with leflunomide seems to be safe and effective in patients with rheumatoid arthritis (20,94,95).

Rifampicin

Multiple doses of rifampicin increase leflunomide concentrations (96).

Warfarin

A case of probable interaction of leflunomide with warfarin has been reported (97).

- A 49-year-old man with resistant rheumatoid arthritis took leflunomide 100 mg/day for 3 days. His international normalized ratio (INR) had been stable for 1 year while he was taking warfarin, and 2 days before starting treatment with leflunomide it was 3.4. After he took the second dose of leflunomide, he developed gross hematuria. His INR had risen to 11, and warfarin was withdrawn. The hematuria resolved spontaneously several hours later, but his INR remained raised for the next 2 days, even though he had stopped taking warfarin. He was given intravenous vitamin K 1 mg on the third day, and 12 hours later the INR fell to 1.9.

© 2006 Elsevier B.V. All rights reserved.

Subsequently he began taking warfarin again, but at a lower dose of 1 mg/day, which was sufficient to maintain his INR within the target range.

A77 1726 inhibits CYP2C9 and might increase the systemic availability of CYP2C9 substrates, such as warfarin and phenytoin (97,98).

Management of Adverse Drug Reactions

Usually, overdosage and adverse events can be managed by dosage reduction, the addition of colestyramine, and symptomatic therapy (36). However, in one study in patients with rheumatoid arthritis, leflunomide 10 mg/day compared with 20 mg/day was associated with less efficacy and more adverse events leading to treatment withdrawal (24). Colestyramine 3 × 8 g/day for 11 days is recommended to wash out leflunomide, if A77 1726 plasma concentrations do not fall to 0.02 mg/l or less, additional colestyramine is advised. Without this washout procedure, it can take up to 2 years to reach A77 1726 plasma concentrations of 0.02 mg/l. Oral activated charcoal 50 g every 6 hours for 24 hours also reduced plasma A77 1726 concentrations (80).

Plasma A77 1726 concentrations can be measured by high-performance liquid chromatography (99,100). Monitoring of platelets, white blood cells, hemoglobin, and alanine transaminase activity is advised at baseline, monthly for 6 months, and every 6–8 weeks thereafter. Leflunomide should be withdrawn if pulmonary symptoms such as cough and dyspnea start or worsen (80).

Lentinan

General Information

Lentinan is an immunomodulating glucan that is extracted from the mushroom *Lentinus edodes*. It has been used in small numbers of patients with gastric cancers (1–3) and malignant effusions (4). It has also been used in HIV-positive patients (5) and to ameliorate impairment of natural killer cell activity after cardiopulmonary bypass (6).

General adverse effects

The incidence of adverse effects due to lentinan, particularly those requiring withdrawal, is low (5). Of 98 patients with HIV infection, treatment had to be withdrawn in four because of adverse effects; other adverse effects included one case each of an anaphylactoid reaction, back pain, leg pain, depression, rigors, fever, chills, granulocytopenia, and raised liver enzymes (5).

Organs and Systems

Hematologic

Leukopenia occurred in one of 19 patients with unresectable or recurrent gastric cancers when they were given lentinan 2 mg/kg intravenously together with TS-1 (tegafur + gimestat + otastat potassium in a molar ratio of 10:4:10) 80 mg/m^2/day (7).

Skin

Skin rashes have been noted in 4% of patients treated with lentinan (8).

Lesopitron

General Information

Lesopitron is a non-benzodiazepine anxiolytic drug. Its structure is similar to that of buspirone, and it is an agonist at central serotonin (5-HT$_{1A}$) receptors.

A 6-week, double-blind, randomized, parallel, phase II, single-center, outpatient study has been performed to study the efficacy and safety of lesopitron 40–80 mg/day compared with lorazepam 2–4 mg/day and placebo in 161

© 2006 Elsevier B.V. All rights reserved.

patients with generalized anxiety disorder (1). The most common adverse events associated with lesopitron were somnolence, headache, and dyspepsia, compared with headache, somnolence, and insomnia with lorazepam. Patients treated with placebo mainly experienced headache, somnolence, and pharyngitis.

Letosteine

General Information

Letosteine is taken orally to loosen bronchial secretions and facilitate expectoration (SEDA-5, 170) (SEDA-7, 191) (1).

Organs and Systems

Gastrointestinal

Two of 37 patients experienced gastralgia and vomiting, severe enough to stop therapy (SEDA-7, 191). In another series of 40 patients, five had gastralgia and nausea, requiring withdrawal of therapy in three.

Leukotriene receptor antagonists

General Information

The leukotriene receptor antagonists are antagonists of cysteinyl leukotrienes at $CysLT_1$ receptors and include zafirlukast, montelukast, and pranlukast.

Therapeutic studies

Placebo-controlled studies

The efficacy and tolerability of montelukast, in combination with a selective histamine H_1 receptor antagonist (loratadine), has been investigated in a randomized, double-blind, crossover study for 2 weeks in 125 asthmatic subjects (mean FEV_1 67% predicted), who took montelukast 10 mg plus loratadine 20 mg or placebo od for 2 weeks (1). The subjects were symptomatic, in that their mean baseline daily use of $beta_2$-adrenoceptor agonists was 5.1 inhaled metered doses. During the study, the percentage increase in FEV_1 from baseline was significantly greater with montelukast plus loratadine than with montelukast alone (14 versus 9.7%). The most common adverse events during the trial were headache and upper respiratory tract infection (each in about 10% of subjects). There were no significant differences in the frequencies of adverse experiences between montelukast plus loratadine and montelukast alone. Ten patients withdrew because of an adverse event; six had exacerbation of asthma requiring steroid administration (three in each of the two arms of the study). One patient taking montelukast plus loratadine and four taking montelukast alone had transient self-limiting laboratory abnormalities.

The acute effects of intravenous and oral montelukast on airway function have been compared in a randomized, double-blind, crossover study in 51 asthmatic patients (mean FEV_1 63.8% predicted) (2). The intravenous dose (7 mg) was known to produce a comparable AUC to that obtained with an oral dose of 10 mg. FEV_1 was measured at 0.25, 0.5, 1, and 2 hours and then at regular intervals up to 24 hours after dosing. After intravenous and oral montelukast, the FEV_1 $AUC_{0–24}$ was significantly greater than after placebo (mean increases 21, 16, and 7.8% for intravenous, oral, and placebo respectively). The mean percentage change in FEV_1 for intravenous montelukast was greater than for oral montelukast in the first hour (18 versus 13%). The most frequently reported adverse events included headaches, which occurred in three patients taking placebo, four taking oral montelukast, and one taking intravenous montelukast. Influenza was reported in two patients taking placebo. It was noteworthy that there were no local adverse events at the intravenous site of the montelukast administration. This study has raised the possibility that a bolus dose of intravenous montelukast may have a role in the management of acute exacerbations of asthma.

Organs and Systems

Respiratory

Leukotriene receptor antagonists and Churg–Strauss syndrome

Churg–Strauss syndrome is a rare form of allergic granulomatous vasculitis, first described in 1951, characterized by the histological findings of eosinophilic tissue infiltration, extravascular eosinophil granulomas, and necrotizing vasculitis. It develops in patients with a history of upper airway disease (especially allergic rhinitis and sinusitis) and asthma. There are different definitions of the syndrome, and it is important to know which definition is being used when the results of different incidence studies are being compared. Clinically the syndrome has been defined (3) as a combination of asthma, peripheral eosinophilia (over 1.5×10^9/l), and a systemic vasculitis involving two or more extrapulmonary organs. Recognized clinical risk factors include moderate to severe asthma, chronic sinusitis, and a recent reduction in systemic corticosteroid therapy (4). An important feature is the phasic developmental pattern of the disease, and corticosteroid therapy suppresses some manifestations of the syndrome, leading to incomplete disease. Churg and colleagues labeled these cases "formes frustes" of Churg–Strauss syndrome (5). Careful monitoring must be ensured when tapering corticosteroids in steroid-dependent patients to avoid development of incomplete disease.

© 2006 Elsevier B.V. All rights reserved.

Presentation

Of 22 asthmatic patients taking leukotriene receptor antagonists who developed Churg–Strauss syndrome, 13 had used zafirlukast, eight montelukast, and one pranlukast (6). All had used inhaled or oral glucocorticoids. The onset of the syndrome was at 2 days to 10 months after starting treatment with the leukotriene receptor antagonist; the interval between the last dose of oral steroids and the recognized onset of Churg–Strauss syndrome ranged from 3 days to 8 months. In several patients the signs and symptoms of Churg–Strauss syndrome became manifest after the start of leukotriene receptor antagonist treatment and tapering of inhaled/oral steroids (13 of 23 patients).

Eight patients with steroid-dependent asthma, who had been able to either discontinue or reduce their oral glucocorticoid requirement subsequent to starting treatment with zafirlukast, developed Churg–Strauss syndrome (7).

- Two 50-year-old men, both using inhaled glucocorticoids, presented with Churg–Strauss syndrome after taking montelukast for 4–5 months, not related to steroid tapering (8). One had a history of asthma and recurrent sinusitis for 5 years with intermittent short-course oral glucocorticoids and continued inhaled steroids, whereas the other had had asthma for 1 year treated with only inhaled glucocorticoids.
- Two women (aged 60 and 62 years) with allergic rhinitis and asthma, one using inhaled glucocorticoids and the other oral glucocorticoids, developed Churg–Strauss syndrome after taking montelukast (9). In the woman using oral steroids, dosage reduction preceded the onset of the syndrome; in the woman using inhaled steroids there was no dosage reduction. The authors also presented the case of a 54-year-old man with a history of Churg–Strauss syndrome who relapsed after taking montelukast.
- A 50-year-old man with a history of severe asthma and tapering of prednisone took montelukast and developed an erythematous rash and mononeuritis multiplex; skin biopsy confirmed the diagnosis of Churg–Strauss syndrome (10).
- A 54-year-old man with no history of glucocorticoid therapy presented with systemic symptoms and a purpuric rash after taking zafirlukast; the diagnosis was Churg–Strauss syndrome (11).
- An 18-year-old woman with childhood asthma, using inhaled glucocorticoids and zafirlukast, developed Churg–Strauss syndrome 10 days after starting to use rokitamycin (12).

Other case reports of interest include pulmonary eosinophilia in association with montelukast (13) and the clinical exacerbation of ulcerative colitis in a patient with steroid-dependent asthma after the introduction of zafirlukast (14). Drug-induced lupus syndrome has been reported in a child with an onset 10 days after beginning treatment with zafirlukast. The child had not been taking oral glucocorticoids (15).

Mechanism

It was originally postulated that the patients had a primary eosinophilic disorder, which was unmasked by the reduction (or withdrawal) of glucocorticoids, which was possible because the addition of zafirlukast had controlled their asthma. A subsequent report of two patients, who were not taking systemic glucocorticoids and developed Churg–Strauss syndrome in association with zafirlukast, raised some doubts about the hypothesis (16). However, there must be uncertainty about implicating zafirlukast in one of these cases, as there appeared to be a delay of 2 months from the withdrawal of zafirlukast to the onset of symptoms, which were subsequently attributed to Churg–Strauss syndrome.

- A 52-year-old woman developed Churg–Strauss syndrome some 12 weeks after beginning treatment with pranlukast and 8 weeks after discontinuing low-dose oral prednisolone (5 mg on alternate days) (17).
- Churg–Strauss syndrome has been reported with montelukast in a patient who had not taken oral glucocorticoids. Symptoms developed within 2 days of beginning treatment with montelukast (18).

The hypothesis of unmasking of Churg–Strauss syndrome (meaning either unmasking of a previously contained pathological condition or the clinical declaration of a "forme fruste") after reduction of glucocorticoid dosage (4,19) is supported by the fact that Churg–Strauss syndrome has also been reported in asthmatic patients who taper their doses of glucocorticoid after the introduction of other antiasthmatic drugs (4). It seems unlikely that leukotriene receptor antagonists themselves provoke Churg–Strauss syndrome, since none of the established mechanisms of adverse drug reactions provides a plausible explanation for the association (4).

There remains the unlikely possibility that in some cases there is direct allergy to the drugs, manifesting as a granulomatous angiitis. In any event, clinicians should be aware of this possibility, although it is rare, and discontinue the drugs in cases of suspicion and undertake appropriate investigations.

Incidence

There are sufficient cases of Churg–Strauss syndrome to estimate its incidence as probably less than one per 20 000 patients. Whilst this may be more than the estimated incidence of this syndrome in the general population, this apparent increase in incidence does not of itself implicate the drugs as being causal. For example, there may be increased detection related to the increased vigilance associated with the introduction of this new class of drugs. If the antileukotriene drugs are implicated in some way in the development of Churg–Strauss syndrome, the precise mechanism is uncertain. Unmasking pre-existing Churg–Strauss syndrome by permitting glucocorticoid withdrawal is one possibility. Another possibility is that the drugs elicit an allergic response that manifests itself as a granulomatous angiitis, a phenomenon that has been reported rarely with other drugs.

The incidence of Churg–Strauss syndrome among asthmatic patients has been calculated in a cohort study of 36 230 patients with asthma (20). The incidence rates of definite Churg–Strauss syndrome were 0–67 cases per million per year, depending on the definition used. The small number of cases did not allow subgroup analysis. The occurrence of Churg–Strauss syndrome during leukotriene receptor antagonist therapy could therefore be coincidental, because the rate of 64 cases per million patients per

© 2006 Elsevier B.V. All rights reserved.

year in association with leukotriene receptor antagonists is comparable to the estimated rate of 18–74 cases per million patients per year in the asthma population observed before the introduction of these drugs (4,6,19). Large epidemiological studies, including data on glucocorticoid-naive patients using leukotriene receptor antagonists, are needed to address this question further.

Liver

Asymptomatic increases in serum liver enzymes, to two or three times the upper limit of the reference ranges, were reported in 1.5% of over 4000 patients in the premarketing clinical trials of zafirlukast, but no severe hepatotoxicity was reported. With more extensive use of zafirlukast, some case reports of severe liver injury appeared. Three patients developed severe liver injury after taking zafirlukast 20 mg bd for several months (21). The evidence that zafirlukast was the probable cause of the hepatic injury was based on the rigorous exclusion of other causes of acute hepatitis, liver biopsies with histological characteristics consistent with toxic injury, the presence of hypersensitivity suggestive of a drug reaction in one patient, and inadvertent rechallenge in one patient. In one case a liver transplant was required. The authors stated that the mechanism of the drug-induced hepatotoxicity was not known but they speculated that it may be of immunological origin or, alternatively, that metabolism by CYP2C9 may create toxic metabolites. Whatever the mechanism, hepatotoxicity with zafirlukast is rare. The Acute Liver Failure Study Group, a consortium of 20 academic medical institutions in the USA cooperating in the prospective collection of data on acute liver failure, has not identified any other cases of acute liver injury associated with zafirlukast.

Urinary tract

Glomerulonephritis has been attributed to montelukast (22).

- A 46-year-old woman developed a severe systemic inflammatory reaction characterized by eosinophilia and necrotizing glomerulonephritis. About 4 months after montelukast was added to her existing treatment with budesonide, formoterol, and terbutaline for asthma. At the time of her initial presentation she was treated with azithromycin and amoxicillin, but these drugs were discounted as possible causes as her illness had already begun before she was treated with them. Once the diagnosis was made, montelukast was withdrawn and she improved with glucocorticoids over the next 4 months.

From the limited detail of this brief case report, it is by no means certain that montelukast was the cause of the systemic illness.

Levamisole

General Information

Levamisole is the levorotatory isomer of tetramisole. Originally used only as an antihelminthic drug, it acts by paralysing the musculature of susceptible nematodes so that they are expelled by peristalsis. It is rapidly metabolized and excreted, with a half-life of about 4 hours.

Use in infective conditions

Treatment of ascariasis with a single oral dose of levamisole 2.5 mg/kg is effective, with evidence of toxicity in under 1% of patients.

Levamisole has been used experimentally in leprosy, particularly in combination with dapsone. This combination was used in a documented series of Indian patients, some currently lepromatous and others in the course of a leprosy reaction (1). When using doses sufficient to provide as good an effect as that obtained with clofazimine + dapsone in a comparison group, adverse effects were limited to gastrointestinal intolerance (which was usually mild), affecting only five of the 30 patients treated; an incidental case developed pyrexia.

Use in non-infective conditions

Levamisole has immunostimulatory activity by modulating the cell-mediated immune response and restoring T cell functions. It has therefore been used extensively and for extended periods of time in various rheumatic and other chronic diseases, in aphthous ulceration, nephrotic syndrome, warts, and malignancies, such as cancers of the head and neck and, in combination with 5-fluorouracil, colorectal cancer (SEDA-20, 348). Under these conditions, its adverse effects are more frequent and rather different because of the differing dosage scheme and presumably also the greater sensitivity of the individual, quite apart from the fact that it is often used in combination, for example with 5-fluorouracil; some 5% of patients fail to complete the course of treatment because of adverse effects. Most of the material in this record is necessarily derived from experience with long-term treatment; where possible a distinction will be drawn between adverse effects occurring under these conditions and those experienced during the acute treatment of tropical disorders.

Observational studies

Aphthous stomatitis

Levamisole has been used in the treatment of recurrent aphthous stomatitis (2) and its value reviewed (3). In four of seven placebo-controlled studies there was a reduction in the frequency and duration of aphthous ulcers during levamisole treatment. Efficacy did not differ whether levamisole was given routinely or started at the first sign of ulcers. In most patients levamisole was well tolerated. Of 128 patients who took levamisole, two withdrew as result of adverse effects (nausea and flu-like symptoms). The most frequent adverse effects were dysgeusia (21%) and nausea (16%). The other adverse effects occurred in less than 10% of the patients and included dysosmia, headaches, diarrhea, flu-like symptoms, and rash, but not all may have been due to levamisole. Levamisole rarely results in objective clinical improvement, and the associated adverse effects discourage its use.

Cancers

In 63 patients with stage III and stage IV squamous cell carcinomas of the oral cavity, oropharynx, hypopharynx, and larynx, with no distant metastases, randomized to either adjuvant oral chemotherapy with futraful, uracil, and levamisole ($n = 29$) or no treatment ($n = 34$), oral chemotherapy showed a trend of better control of distant tumor recurrence (4). However, there was no statistically significant improvement in overall long-term survival. Of the 29 patients who received adjuvant oral chemotherapy, 17 finished the 1-year course without withdrawing. In nine patients futraful, uracil, and levamisole was withdrawn because of local, regional, or distant metastases. Three patients withdrew after 4 months because of vomiting and mucositis. One developed a mild gastric upset and completed the course. There were no major hematological or nephrotoxic adverse effects.

Candidiasis

In two patients with thymoma associated with myasthenia gravis, who both had recurrent oral candidiasis after thymectomy, radiotherapy, and chemotherapy levamisole was added as adjunctive therapy in combination with oral nystatin (5). Oral candidiasis responded favorably and substantial relief was obtained, with a concurrent increase in T cells and CD4/CD8 ratio, suggesting restoration of T cell immunity. Adverse effects were not mentioned.

Glomerulonephritis

In an extensive review of the treatment of minimal lesion glomerulonephritis the use of levamisole was briefly mentioned (6). The author concluded that levamisole has a beneficial effect in this disorder, although no new studies have appeared in recent years and well-controlled studies are scarce. Levamisole appears to be well tolerated in this condition. The adverse effects were neutropenia, rash, and raised liver transaminases.

Nephrotic syndrome

In 11 children with nephrotic syndrome, of whom five were glucocorticoid-sensitive, six glucocorticoid-resistant, and all resistant to other immunosuppressive drugs, levamisole 2.5 mg/kg was given every 48 hours for up to 18 months (7). Two patients were also given ciclosporin. All the patients in the steroid-sensitive group but none in the steroid-resistant group reacted favorably to levamisole, with disappearance of protein from the urine. There

© 2006 Elsevier B.V. All rights reserved.

were serious adverse effects in two patients: one developed a transient leukopenia 2 months after the start of treatment and another developed a severe exacerbation of pre-existing psoriasis, although that may have been due to the withdrawal of cyclophosphamide.

Levamisole 2 mg/kg on alternate days was given to 25 glucocorticoid-dependent children with frequent relapses of idiopathic nephrotic syndrome (8). The steroid was tapered, and continued for 3–14 months. During treatment with levamisole the relapse frequency was reduced by 40%. Two patients developed mild transient leukopenia, which disappeared 2 weeks after withdrawal. One had a slight rash that disappeared while treatment was continued and one complained of epigastric pain, which led to drug withdrawal.

In a detailed review of the management of nephrotic syndrome in childhood, levamisole was advocated as a weak but effective glucocorticoid-sparing agent (9). In a prospective study in 20 children (aged 3–15 years; 16 boys, 4 girls) with steroid-dependent minimal-change nephrotic syndrome, there were no significant adverse effects during adjunctive therapy with levamisole, which led to successful withdrawal of glucocorticoids after 2 months in 11 children (10).

Pediculosis capitis

In 28 patients with pediculosis capitis (aged 7–12 years) levamisole was given in a dose of 3.5 mg/kg for 10 days; there were no adverse reactions (11).

Rheumatoid arthritis

The possible benefits of levamisole in rheumatoid arthritis are generally outweighed by its adverse effects (SEDA-11, 277) (12).

Comparative studies

Colorectal cancer

The efficacy of levamisole has been studied in several studies of patients with colorectal carcinoma (13–15). In a phase III trial 5-fluorouracil alone, 5-fluorouracil with levamisole, and 5-fluorouracil with hepatic irradiation have been compared in patients with residual, non-measurable, intra-abdominal metastases after resection of colorectal carcinoma (13). The adverse effects were as expected, and there were no differences between any of the treatments. The main adverse effects were hematological and gastrointestinal. However, analysis of life-threatening adverse effects showed some slight differences: there were fewer than expected in the 5-fluorouracil alone group, and more than expected in the 5-fluorouracil plus hepatic irradiation group. There was no treatment advantage for any of the combinations over 5-fluorouracil alone.

Levamisole combined with 5-fluorouracil in the adjuvant treatment of resected colon cancer has been studied in a prospective, randomized trial in which 891 patients were randomized to receive either intensive fluorouracil and leucovorin combined with levamisole, or a standard regimen of fluorouracil plus levamisole (16). The patients were then again randomized to receive either 6 or 12 months of treatment. Standard fluorouracil plus levamisole was not as effective as fluorouracil, levamisole, and leucovorin, and treatment for 12 months was not superior to treatment for 6 months. Unfortunately, there was no treatment arm with fluorouracil and leucovorin only, which is now widely considered to be the treatment of choice. Serious grade 3–4 adverse effects were more frequent in the three-drug treatment groups, and consisted of diarrhea (13 versus 3 patients in the 6-month groups, 17 versus 7 in the 12-month groups) and stomatitis (10 versus 3 in the 6-month groups, 11 versus 6 in the 12-month groups). Leukopenia occurred more frequently in the standard treatment groups (10 versus 18, one of whom died, in the 6-month groups, and 13 patients, one of whom died, versus 14, one of whom died). There were four treatment-associated deaths.

In another study combined intravenous and intraperitoneal fluorouracil plus leucovorin was compared with standard treatment with fluorouracil and levamisole in 241 patients with resected stage 3 or high-risk stage 2 colon cancers (17). In the combined treatment group there was an increased disease-free interval, an estimated 43% reduction in death rate, and a reduction in local tumor recurrence. Adverse effects were relatively uncommon and were generally judged to be mild to moderate; they were slightly more common in those treated with fluorouracil and levamisole, and consisted of nausea and vomiting (18 versus 14%), diarrhea (16 versus 10%), mucositis (17 versus 12%), granulocytopenia (29 versus 23%), and thrombocytopenia (5 versus 3%). Four cases of unspecified nervous system toxicity were noted in those given fluorouracil plus levamisole. There was abdominal pain during or shortly after intraperitoneal drug administration in 19% of patients. Overall 53% of the patients given fluorouracil plus levamisole and 56% of those given fluorouracil plus leucovorin had mild to moderate adverse effects. Severe reactions, requiring a 20% dosage reduction of fluorouracil, were more common in the fluorouracil plus levamisole arm (13 versus 3%). There were no deaths. Unfortunately, in this study no patients were treated with fluorouracil and leucovorin intravenously only.

It is likely that most of these reported adverse effects, although perhaps enhanced by levamisole, except for the nervous system toxicity noted in a few individuals, were caused by fluorouracil. This has been further emphasized by a dose-finding study to determine the maximum tolerated dose of levamisole in the treatment of colon cancer in 38 patients with advanced non-resectable colon cancer, treated with fluorouracil 450 mg/m^2 by rapid intravenous infusion for 5 days (18). Levamisole was given orally three times daily for 5 days every 5 weeks until disease progression. The main dose-limiting toxic effects were nausea and vomiting and an unpleasant metallic taste. The dose used was about five times the total amount of levamisole given in the standard fluorouracil plus levamisole regimen. Levamisole enhanced the gastrointestinal toxicity of fluorouracil, with anorexia, nausea, vomiting, and occasional diarrhea, but did not enhance the bone-marrow suppression associated with fluorouracil. Increasing the dose of levamisole to 150 mg/m^2 tds for 5 days resulted in significant nervous system toxicity, with confusion, vertigo, and severe vomiting. None of the patients treated with this dosage were able to complete the course.

Fluorouracil plus leucovorin has been compared with fluorouracil plus levamisole and combined fluorouracil

© 2006 Elsevier B.V. All rights reserved.

plus leucovorin and levamisole in 2151 patients with Dukes B and C colon cancers (19). The regimens were as follows:

- fluorouracil plus leucovorin: six 8-week cycles of leucovorin 500 mg/m^2 as a 2-hour infusion repeated weekly for six doses and fluorouracil 500 mg/m^2, given as an intravenous bolus 1 hour after the start of the leucovorin infusion, also weekly for six doses; the cycle was repeated after a rest period of 2 weeks;
- fluorouracil plus levamisole: fluorouracil 350 mg/m^2 as an intravenous bolus daily for five consecutive days, then once weekly starting on day 29 and levamisole orally tds for 3 days and repeated every 14 days;
- fluorouracil plus leucovorin plus levamisole: the same fluorouracil plus leucovorin treatment as described above, with the addition of levamisole in the dose used in the fluorouracil plus levamisole group.

There was a small prolongation of the disease-free interval and overall survival in favor of fluorouracil plus leucovorin, although of borderline statistical significance. Information on toxicity was obtained in 98% of the patients. Eighteen died while on chemotherapy, four in the fluorouracil plus leucovorin group, three in the fluorouracil plus levamisole group, and 11 in the fluorouracil plus leucovorin and levamisole group. Grade 3–4 toxicity was reported equally in the three groups: fluorouracil plus leucovorin 35%, fluorouracil plus leucovorin and levamisole 36%, and fluorouracil plus levamisole 28%. They consisted mainly of adverse effects attributed to fluorouracil, such as diarrhea, vomiting, and stomatitis. Hematological toxicity was minimal (less than 2% in grades 3–4) and not significantly different across the groups. Neurotoxicity was rare. Ataxia was the most frequent neurological disorder, in 2% of the patients who received fluorouracil plus levamisole and in 1% of the patients in the other two groups combined.

QUASAR was a study of the effects of a higher dose of leucovorin or the addition of levamisole to 5-fluorouracil and leucovorin on survival in 4927 patients with colorectal cancer with no evidence of residual disease after resection (14). High-dose leucovorin was not associated with a survival or recurrence benefit compared with low-dose leucovorin. The addition of levamisole had no apparent survival benefit compared with placebo, with slightly more deaths in patients assigned to levamisole than placebo. Tumor recurrences were also higher in those who took levamisole. Dermatological adverse effects were significantly more frequent in those who took levamisole compared with placebo.

In 680 patients with curatively resected stage III colon cancer, adjuvant treatment with 5-fluorouracil plus leucovorin was significantly more effective than 5-fluorouracil plus levamisole in reducing tumor relapse and improving survival (15). There were fewer adverse effects in those given 5-fluorouracil plus levamisole compared with 5-fluorouracil plus leucovorin (820 versus 1190); the difference was mainly due to gastrointestinal toxicity. Only a few patients developed grade 3 or grade 4 adverse effects. There were no treatment-related deaths in either group.

The Gastrointestinal Intergroup has studied postoperative adjuvant chemotherapy and radiation therapy in 1659 patients with T3/4 and lymph-node-positive rectal cancer after potentially curative surgery to try to improve chemotherapy and to determine the risk of systemic and local failure (20). There was no advantage to regimens containing leucovorin or levamisole over bolus 5-fluorouracil alone in the adjuvant treatment of rectal cancer when combined with irradiation. Local and distant recurrence rates were still high, especially in T3 and T4 lymph node positive patients, even with full adjuvant chemoradiation therapy.

Nephrotic syndrome

In a retrospective analysis in 51 children with glucocorticoid-dependent nephrotic syndrome, the ability of levamisole to reduce the relapse rate and to spare prednisone therapy was compared with that of cyclophosphamide (21). Apart from one patient who had a spontaneously resolving skin rash with levamisole and three patients who had transient neutropenia with cyclophosphamide, there were no other clinically significant adverse effects.

Warts

In 44 patients with multiple recalcitrant warts randomized to either oral cimetidine 30 mg/kg/day in three doses for 12 weeks, or 30 mg/kg/day for 12 weeks plus levamisole 2.5 mg/kg for 2 days per week, cimetidine plus levamisole produced significant improvement (22). Adverse effects of levamisole were infrequent, except for a metallic taste in one patient and nausea in two. In one patient the nausea was severe enough to necessitate withdrawal. There were no significant changes in leukocyte count or differential counts.

Placebo-controlled studies

Colorectal cancer

Fluorouracil (370 mg/m^2) plus high-dose (175 mg) or low-dose (25 mg) folinic acid and either active or placebo levamisole has been evaluated in 4927 patients with colorectal cancer (23). Levamisole produced a significant excess of adverse dermatological events. Serious unexpected adverse events were rare. The authors concluded that the inclusion of levamisole in chemotherapy regimens for colorectal cancer does not delay recurrence or improve survival.

Organs and Systems

Cardiovascular

Hypotension has been attributed to levamisole (24).

Nervous system

Several reports point to a condition that can best be described as multifocal inflammatory leukoencephalopathy, occurring in about four cases in every thousand, during treatment with levamisole either alone (25) or in combination with 5-fluorouracil (SEDA-21, 321) (26,27). It presents with confusion, ataxia, dysarthria, diplopia, focal neurological signs, and seizures, and has been extensively discussed and reviewed (28).

One large literature survey (29) concluded that 6% of patients taking long-term levamisole, mostly for

© 2006 Elsevier B.V. All rights reserved.

malignancies, experienced "sensory stimulation," for example in the form of "hyperalert states" or insomnia, although depression is less commonly on record. Diplopia and tremor have been observed, whilst a number of children treated for juvenile rheumatoid arthritis or nephrotic syndrome have developed generalized convulsions and coma, with EEG abnormalities suggestive of encephalitis (SED-12, 771) (30); the condition recovers spontaneously, but for a time anticonvulsants may be needed.

- A 65-year-old man developed impaired cognition and a disturbed gait 6 months after the removal of a Dukes C colon cancer with adjuvant chemotherapy with fluorouracil and levamisole. Three months later he developed arthralgias in the hands, elbows, and knees, followed 1 month later by intermittent monocular diplopia, an ataxic gait, and deteriorating cognitive function. An MRI scan of the brain showed multiple small round and oval hyperintense lesions in the periventricular white matter, without surrounding edema or mass effect. Most of the lesions showed ring enhancement after intravenous gadolinium. The cerebrospinal fluid protein content was raised, but cytology was normal. A stereotactic biopsy of one of the lesions showed marked cellularity of the white matter, with mononuclear cells in both the parenchyma and perivascular areas, and severe demyelination of the white matter with relative preservation of the axons. Most of the parenchymal cells were macrophages, containing myelin debris. All the findings were consistent with a diagnosis of multifocal inflammatory leukoencephalopathy after treatment with levamisole. The adjuvant therapy was discontinued and he was treated with methylprednisolone 1 g/day intravenously for 3 days, followed by dexamethasone 4 mg qds orally. Within weeks he started to improve, with resolution of the ataxia and improved cognitive function. However, there was residual mild left hemiparesis and he remained moderately unsteady on his feet. The glucocorticoids were slowly tapered and an MRI scan several weeks later still showed multiple patchy areas of bright signal, corresponding to the previous demyelination, but without enhancement. A further MRI scan after 1 year showed complete resolution. His neurological condition and performance had further improved, but there was residual impairment of short-term memory.

The authors suggested that this syndrome may be more common than supposed, and that it is likely that levamisole is the main causal factor, since the same symptoms have been described after treatment with high-dose levamisole alone, but that the effect may be enhanced by the co-administration of fluorouracil, which potentiates the immunostimulatory action of levamisole. Although there is no conclusive evidence of the value of glucocorticoids in this syndrome, an adequate course of glucocorticoids is advised, comparable to the treatment of multiple sclerosis.

- A 57-year-old man had a Dukes C colon cancer removed and was given adjuvant chemotherapy with fluorouracil and levamisole at 4-week intervals (31). Four months later he developed insomnia, diplopia, and a reduced level of consciousness. He was disoriented in time and place, but there were no focal neurological defects. The cerebrospinal fluid protein concentration was slightly raised. A provisional diagnosis of fluorouracil/levamisole-induced neural toxicity was made and he was treated with dexamethasone 4 mg qds. There was an improvement in orientation after 3 days of treatment, but he remained mentally dull. After 28 days of therapy the corticosteroids were tapered. An MRI scan showed multiple focal hyperintensities, with involvement of both deep and subcortical white matter. The lesions were not associated with a mass effect and were mildly enhanced by gadolinium. At 30 months follow-up the patient was well without evidence of relapse. An MRI scan at 24 months showed small, residual, hyperintense lesions, which were not further enhanced by gadolinium, consistent with gliotic scars.
- A 3-year-old girl who took levamisole 100 mg bd for 3 days for anorexia suddenly developed hyperkinesia, paresthesia, fidgetiness, an unstable gait, and frequent falling (32). An MRI scan of the brain did not show any demyelinating changes. She recovered fully within 48 hours without any specific intervention.

The authors suggested that levamisole overdose had contributed to the profound encephalitis-like effects.

Fatal viral encephalitis due to enterovirus type 71 has been reported during use of levamisole (33).

Psychological, psychiatric

Anxiety and depression have been associated with levamisole (34).

Psychosis has also been reported (35).

- A 28-year-old man, without a psychiatric history, developed a paranoid psychosis. He had been taking levamisole twice a week in an unspecified dose for 2 years for a stage 4 melanoma and metastatic lymph nodes in the axilla. Physical examination, a CT scan, an electroencephalogram, and standard laboratory tests were all normal. He was treated with perphenazine, with partial success, but after tapering of the dose his symptoms reappeared. It was thought likely that the psychosis had been caused by levamisole, which was discontinued. Three weeks later he had recovered completely. Levamisole was not reintroduced.

Hematologic

Agranulocytosis has often been reported during long-term treatment with levamisole. Most cases are reversible and transient, but deaths have occurred. In 3900 patients on whom data were available to the manufacturers, there were 88 cases of agranulocytosis and 43 of leukopenia; such dyscrasias occurred in 4% of patients with rheumatoid arthritis and 2% of oncological cases (29). In other published material the incidence has sometimes been higher; such differences do not appear to be related to the dose or duration of therapy. Agranulocytosis is more prevalent in rheumatoid patients with an HLA-B27 genotype (SEDA-7, 317). Children are also susceptible, and fatal outcomes because of hematological disorders have been described in cases of juvenile rheumatoid arthritis treated intermittently with levamisole. Other

© 2006 Elsevier B.V. All rights reserved.

deaths have occurred in adults concurrently taking glucocorticoids for several years.

Agranulocytosis can be asymptomatic and, since it occurs unpredictably, regular monitoring of the leukocyte count is advisable, especially in patients concurrently receiving combination chemotherapy. Whilst the mechanism is not clear, granulocyte-agglutinating antibodies have been found, suggesting that levamisole acts as a hapten on the leukocyte membrane.

Thrombocytopenia has been reported in a woman with rheumatoid arthritis; it recurred after rechallenge (36).

Gastrointestinal

Nausea, vomiting, and diarrhea are very common in patients taking levamisole, and are sometimes accompanied by abdominal pain or constipation, although when such symptoms occur it is not always clear that they are due to the drug rather than to its interaction with the disease.

Exacerbation of peptic ulceration has been described, and mouth ulcers and abnormalities of taste sensation can be troublesome in patients taking long-term therapy.

Liver

Neither animal nor most human studies point to hepatotoxicity, but in a series of 11 patients with pyoderma treated with levamisole two had increases in aspartate transaminase activity. Liver toxicity has also been reported in a child with nephrosis (37).

Urinary tract

There has been one published case of uremia (38) and one of a reversible nephropathy in a patient with rheumatoid arthritis (39).

Skin

Type I allergic reactions have caused pruritic rashes and urticaria.

Ischemic necrosis of the skin, reversible on withdrawal, has been documented (40).

Single cases of erythema multiforme and erythema nodosum have been observed (SEDA-7, 317).

Two patients developed lichenoid skin eruptions, which subsided when the drug was stopped, although one of these was left with severe scarring, alopecia of the scalp, and widespread atrophic and hyperpigmented skin lesions.

A healed varicose ulcer has been observed to break down after treatment (41).

Necrotizing vasculitis

Cutaneous necrotizing vasculitis with histological changes resembling a type III hypersensitivity reaction has been described in patients taking levamisole (42,43). In a well-documented case, a widespread vasculitic rash, chiefly affecting the limbs, appeared in a woman with rheumatoid arthritis treated for 2 months. In these cases, serum complement was normal and there were no circulating immune complexes, although a histamine skin wheal test produced a vasculitis at a clinically non-affected site. Both cases were reversible.

- Leukocytoclastic vasculitis has been attributed to levamisole in a 7-year-old boy with glucocorticoid-dependent nephrotic syndrome (44).

The authors estimated that about 0.5% of patients treated with levamisole develop cutaneous vasculitis with circulating autoantibodies.

Five of 160 children with nephrotic syndrome developed distinctive vascular purpura (45). They had taken levamisole for a mean of 24 months when they developed purpuric erythematous macules, which evolved to ecchymotic and necrotic purpura. The lesions were mostly on the external ear. Biopsies obtained from the ear lesions in four patients showed vasculopathic reaction patterns, ranging from leukocytoclastic and thrombotic vasculitis to vascular occlusive disease without true vasculitis. There were anticardiolipin, antinuclear, and/or antineutrophil cytoplasmic antibodies in four patients. The lesions resolved within 2–3 weeks after levamisole withdrawal, whereas anticardiolipin and antineutrophil cytoplasmic antibodies disappeared after 2–14 months only. A direct effect of levamisole on the endothelial cells or levamisole-induced or unmasked latent immunological abnormalities was suspected.

Musculoskeletal

Arthritis has occurred in patients with Crohn's disease or Behçet's disease treated with levamisole (46,47), although it is well known that this can occur with either disease irrespective of drug treatment.

Muscle pain can be severe when levamisole is given with 5-fluorouracil for colonic cancer (48), or there can be a painless rise in creatine kinase activity (49).

Immunologic

Allergic reactions often reflect the effects of the drug or of parasitic breakdown products. They include pruritic skin eruptions, arthritic pain and swelling, muscular pain and swelling, especially in patients already suffering from rheumatoid arthritis, Sjögren's syndrome (50), or psoriatic arthropathy. Skin reactions of various types can occur and type III reactions have been noted. Influenza-like symptoms might be an unusual form of type I allergy or a consequence of restoration of cellular immunity.

Disseminated autoimmune disease has been described during treatment with levamisole for nephrotic syndrome (51).

- An 8-year-old boy had a 5-year history of steroid-dependent nephrotic syndrome. After half a year of glucocorticoid treatment he was given levamisole 2.5 mg/kg on alternate days for 1 year, with complete suppression of the proteinuria. The proteinuria reappeared after withdrawal of levamisole, and glucocorticoids and levamisole were reintroduced as before. Two years later, while still taking levamisole, he developed hepatosplenomegaly, a low-grade fever, and a Coombs' negative hemolytic anemia. The anticardiolipin IgM titer was high, p-ANCA antibodies were positive, C3 was moderately low and antinuclear anti-DNA antibodies were negative. Levamisole was withdrawn. Two weeks later the clinical parameters had normalized and 4 weeks later the liver enlargement

© 2006 Elsevier B.V. All rights reserved.

had disappeared. Although p-ANCA antibodies persisted at 1 month the anticardiolipin IgM titer had returned to normal. After 6 months there still was splenomegaly but no other symptoms, and proteinuria was absent.

The same group of authors have also described a distinctive vasculitis with circulating antibodies in children with nephrotic syndrome associated with long-term levamisole, presenting with purpura of the ears (45).

- Four boys and one girl (mean age 10 years) had had nephrotic syndrome for 2–8 years and had taken levamisole orally in doses of 1.7–2.5 mg/kg/day for 16–44 months (mean 24 months). All had a sudden onset of rapidly enlarging purpuric and erythematous macules progressing to the formation of necrotic areas, purpuric plaques, and hemorrhagic bullae. The pinnae were involved in all five. In three there were also lesions on the cheek or lower limbs. One had fever and another complained of arthralgia. Routine laboratory tests were all normal. Antibodies to extractable nuclear antigen, cryoglobulin, rheumatoid factor, Coombs' test, circulating immune complexes, and complement and components were all negative or normal. However, antiphospholipid antibodies and/or anticardiolipin IgG and IgM were positive in three patients, p-ANCA was positive in three, and c-ANCA in one. Antinuclear antibodies were positive in two patients and anti-double stranded DNA antibodies were positive in one. Biopsies of the skin lesions in four patients showed vasculitis, ranging from a leukocytoclastic and thrombotic vasculitis to vascular occlusive disease without true vasculitis. Two patients had a hypersensitivity vasculitis in the superficial and deep dermis, with neutrophilic infiltration of the vessel walls and fibrinoid necrosis. Features of panniculitis with occlusion of deep and superficial blood vessels by fibrin-platelet thrombi were found in one patient. The lesions completely resolved in all patients within 2–3 weeks after the withdrawal of levamisole. The serum autoantibodies had disappeared in all cases after 2–14 months.

Although leucocytoclastic immune-complex vasculitis induced by levamisole is well known, this specific presentation with involvement of the ears has not been described before.

Second-Generation Effects

Teratogenicity

Animal studies do not point to a teratogenic effect, but there are insufficient human data to assess the safety of levamisole in pregnancy, and the WHO recommends delaying treatment until after pregnancy when possible.

Susceptibility Factors

Age

The adverse effects that occur after monotherapy with levamisole in children with nephrotic syndrome include taste disturbance (dysgeusia), arthralgia, myalgia, anxiety, sleep disturbances, depression, neutropenia, diarrhea, nausea, and vomiting.

Hepatic disease

Levamisole is mostly metabolized to *para*-hydroxylevamisole (52). It should not be used in severe hepatic disease, nor should it be combined with hepatotoxic antihelminthic drugs or other drugs presenting risks to the liver.

Other features of the patient

Both Sjögren's syndrome (50) and psoriatic arthropathy (53) are conditions in which levamisole is probably better avoided because of the risk of hypersensitivity reactions.

In the treatment of the hyperimmunoglobulin E recurrent infection syndrome (Job's syndrome), infectious complications are more serious when levamisole is given, even where there is normal chemotactic responsiveness (54).

The risk of severe adverse reactions is greater in lymphatic filariasis (55).

Drug Administration

Drug overdose

Acute overdose of levamisole has been described (56).

- A 43-year-old man treated himself with a levamisole enema of 10 g (33 times the therapeutic dose) for a gastrointestinal worm infestation. Soon after he developed malaise, tachycardia, nausea, vertigo, and profuse diarrhea. He lost consciousness and developed generalized seizures and a respiratory arrest. He was intubated, ventilated, and treated with clonazepam. His condition improved after 4 hours. He remained somnolent for 6 hours, and was nauseated and vomited for 24 hours. There was hypokalemia after the diarrhea, raised creatine kinase activity, and a leukocytosis. An electrocardiogram showed ST depression. By the fourth day all his symptoms had subsided.

The symptoms in this case were attributed to the cholinergic effect that levamisole has at this high dose.

Drug–Drug Interactions

Salicylates

Levamisole increases serum concentrations of salicylates, but the effect does not appear to have any clinical consequences (57).

Warfarin

Levamisole and 5-fluorouracil interact with warfarin to produce bleeding (58). The mechanism of this effect is unclear, but the reports are sufficiently clear to point to the need for careful monitoring when this drug combination is used.

Levetiracetam

See also Antiepileptic drugs

General Information

Levetiracetam is a piracetam derivative used in the treatment of refractory partial seizures. In trials it has shown an excellent tolerability profile. The main dose-related adverse effects are sedation, fatigue, and headache. Other possible adverse effects include dizziness, unsteadiness, diplopia, nausea, infection, memory impairment, and disturbances of mood and behavior, although in controlled trials the incidence of most of these was no greater than with placebo (1).

The pharmacology, clinical pharmacology, uses, and adverse reactions and interactions of levetiracetam have been reviewed (2–6).

The safety profile of levetiracetam has been reviewed (7). The authors assessed the integrated summary of safety reports submitted for regulatory review in order to obtain information about abnormal laboratory test values and adverse events collected during the overall levetiracetam development program. The analysis included 3347 patients exposed to levetiracetam in clinical trials for epilepsy, cognition, and anxiety disorders. Safety data from all the studies showed a similar pattern of adverse effects, predominantly somnolence, weakness, and dizziness, which occurred most often during the first month of treatment. Laboratory tests that changed significantly in placebo-controlled trials nevertheless stayed in the reference ranges. The incidences of any types of allergic reactions were similar between levetiracetam and placebo (0.3% and 0.2%). Cases of common cold and upper respiratory infection were significantly more frequent with levetiracetam than placebo (13 versus 7.5%), but were not preceded by low neutrophil counts that might have suggested impaired immunological status. There was worsening of seizures (an increase of over 25%) in 14% of patients taking levetiracetam and 26% of patients taking placebo. There were nine sudden, unexplained deaths; the overall mortality rates and standardized mortality rates were higher in the placebo group (1.8% levetiracetam versus 2.5% placebo). Behavioral problems occurred in 5.2–14% of those taking

© 2006 Elsevier B.V. All rights reserved.

levetiracetam and in 4.1–6.0% of those taking placebo. There were higher incidences of adverse effects, particularly behavioral effects, among patients with epilepsy than in elderly patients with cognitive disorders or in patients with anxiety disorders.

Observational studies

The efficacy and tolerability of levetiracetam 1–4 g/day as add-on treatment for refractory epilepsy have been studied in 29 patients with refractory epilepsy (8). The most common adverse events were somnolence and weakness, the frequency and severity of which increased with increasing doses.

The efficacy and tolerability of levetiracetam 1–2 g/day as add-on therapy have been studied in 324 patients with refractory partial seizures (9). Levetiracetam did not affect the plasma concentrations of other antiepileptic drugs or alter vital signs or laboratory measurements. The most commonly reported adverse effects in patients taking levetiracetam were weakness, headache, and somnolence.

The long-term retention rate, efficacy, and safety of levetiracetam have been evaluated in all patients with epilepsy exposed to the drug during its developmental program ($n = 1422$) (10). The retention rate was 60% after 1 year and 32% after 5 years. Seizures were reduced by over 50% in 39% of the patients, and 13% became seizure free for at least 6 months. The commonest treatment-emergent adverse events requiring withdrawal were convulsions (3.4%), somnolence (2.0%), weakness (0.6%), depression (0.6%), dizziness (0.5%), and headache (0.5%). There was no evidence of idiosyncratic adverse effects or any serious hematological or biochemical abnormalities during exposure to levetiracetam. Eight patients died suddenly and unexpectedly, about one death per 300 patient-years, which is within the expected range in patients with refractory epilepsy.

Placebo-controlled studies

In a pooled analysis of safety data from double-blind, placebo-controlled add-on trials of levetiracetam (1–3 g/day) in adults with refractory partial seizures, adverse events occurring in at least 3% of patients and with at least 3% higher incidence in the active treatment group were tiredness (14 versus 10%), somnolence (15 versus 10%), dizziness (9 versus 4%), and common cold or upper respiratory tract infections (13 versus 7%) (11). The proportions of patients requiring withdrawal of treatment or dosage reduction owing to adverse events were 15% with levetiracetam and 12% with placebo. The efficacy and tolerability of levetiracetam monotherapy in refractory partial seizures have been studied in a double-blind, placebo-controlled study in 286 patients (12). Adverse events that were more common with levetiracetam and that occurred in more than 5% of cases included weakness, infection, and somnolence. Of 181 patients who took levetiracetam, 36 completed the study compared with only 10 of 105 who took placebo. The tolerability and efficacy of levetiracetam, 2 or 4 g/day, as add-on therapy have been studied in 119 patients with refractory epilepsy (13). Somnolence was the most common reason for withdrawal and occurred more often with levetiracetam than placebo, as did weakness. Somnolence was more common with the higher dose, which was not more effective than the lower dose. Nausea, dizziness, and urinary tract infections were also more common with the higher dose. The efficacy and safety of levetiracetam 1 and 3 g/day as adjunctive therapy for refractory partial seizures have been studied in a double-blind, randomized, placebo-controlled trial in 294 patients with uncontrolled partial seizures (14). Treatment-associated adverse events that occurred in at least 10% of patients and had incidences higher than placebo were weakness, dizziness, a flu-like syndrome, headache, infection, rhinitis, and somnolence. These effects were mostly mild to moderate.

Organs and Systems

Psychological, psychiatric

Psychiatric adverse events, most often hostility and irritability, have been reported in children taking levetiracetam. Four cases of acute psychosis have also been reported (15).

- A 5-year-old girl with refractory epilepsy treated with a ketogenic diet was given levetiracetam 250 mg bd (25 mg/kg/day). She had a history of mild mental retardation and was receiving special education. Two weeks later she started to have visual hallucinations, became agitated, bit relatives, and could not sleep. Levetiracetam was withdrawn and her symptoms resolved within 24 hours and did not recur.

Susceptibility Factors

Age

The safety of levetiracetam has been assessed in 24 children with uncontrolled partial-onset seizures in an open study (16). The most commonly reported adverse events were headache (33%), infection (33%), anorexia (25%), and somnolence (25%). The adverse events profile of levetiracetam was similar to that seen in adults. Owing to a dispensing error, one patient received an accidental overdose of 71 mg/kg/day, rather than 40 mg/kg/day, during the last 4 weeks of the evaluable phase of the study. No ill effects were reported or observed on examination or laboratory testing, and the patient completed the trial.

Drug Administration

Drug overdose

Overdosage of levetiracetam can cause respiratory depression (17).

- A 38-year-old woman took 60 tablets of levetiracetam 500 mg. She vomited 4 hours later, and 2 hours after that was obtunded with respiratory depression. Her levetiracetam serum concentration was 400 μg/ml at 6 hours, 72 μg/ml at 18 hours, and 60 μg/ml at 20.5 hours (target serum concentration 10–37 μg/ml). The half-life was 5.1 hours, similar to the usually reported half-life. She was extubated the next day and recovered without sequelae.

Drug–Drug Interactions

Carbamazepine

Four patients with refractory epilepsy taking carbamazepine were given added levetiracetam and developed central nervous system effects (ataxia, diplopia, nystagmus) suggestive of carbamazepine toxicity (18). Reduction in the dose of carbamazepine resolved the symptoms in three cases. Carbamazepine and carbamazepine-epoxide blood concentrations were not altered during levetiracetam co-medication. Thus, a pharmacodynamic interaction between carbamazepine and levetiracetam is likely.

Digoxin

Two placebo-controlled studies in healthy subjects have shown no interaction of levetiracetam with digoxin (19).

Oral contraceptives

In a double-blind, crossover study 18 healthy women taking an oral contraceptive containing ethinylestradiol 30 μg plus levonorgestrel 150 μg took levetiracetam 500 mg/day or placebo (20). The plasma concentration–time curves and pharmacokinetics of ethinylestradiol and levonorgestrel were not altered.

Warfarin

Two placebo-controlled studies in healthy subjects have shown no interactions of levetiracetam with warfarin (21).

Levobupivacaine

See also Local anesthetics

General Information

Levobupivacaine is the levorotatory isomer, *S*(−)-bupivacaine, of bupivacaine, an amide local anesthetic.

In a comparison of the clinical efficacy of epidural *S*(−)-bupivacaine with standard racemic *RS*-bupivacaine in 88 patients *S*(−)-bupivacaine was clinically indistinguishable from *RS*-bupivacaine in the three groups studied (0.75% or 0.5% *S*(−)-bupivacaine and 0.5% *RS*-bupivacaine). Hypotension was distributed evenly across the groups and five patients complained of minor neurological abnormalities (hypesthesia and paresthesia), which resolved quickly after the operation (1).

Organs and Systems

Cardiovascular

Levobupivacaine is less cardiotoxic than racemic bupivacaine (2). In seven sheep, racemic bupivacaine caused

© 2006 Elsevier B.V. All rights reserved.

mild cardiac depression, which was superseded by central nervous system toxicity and then proceeded to severe ventricular dysrhythmias, which were fatal in three sheep, at doses of 125, 150, and 200 mg (3). Levobupivacaine was consistently less toxic than bupivacaine, and higher doses were needed to produce adverse effects. Convulsions were less severe and of shorter duration, and although levobupivacaine produced QRS prolongation and ventricular dysrhythmias, there were no deaths.

Several animal studies have shown that levobupivacaine on an equivalent dose basis is safer than bupivacaine; 32–57% more levobupivacaine is required to cause death (4). In sheep, the mean lethal dose of levobupivacaine was 78% higher than that of bupivacaine; the author suggested that there may be a similar trend in humans and concluded that levobupivacaine should be used in preference to bupivacaine, based on safety data alone.

Nervous system

Tonic-clonic seizures have been attributed to levobupivacaine.

- A 60-year-old 70 kg woman with a fractured radius had an axillary brachial plexus block for postoperative analgesia after uneventful general anesthesia (5). A 50 mm insulated regional block needle attached to a nerve stimulator was used to locate the brachial plexus, and after negative aspiration, levobupivacaine 125 mg was injected with intermittent aspiration. Within 30 seconds the patient had a generalized tonic-clonic seizure which lasted about 30 seconds and self-terminated. She remained cardiovascularly stable and made an uneventful recovery.

The authors proposed that some or all of the local anesthetic had been inadvertently injected intravascularly, despite negative aspiration tests. There were no cardiovascular complications, underlining the proposed greater cardiovascular safety of levobupivacaine over bupivacaine. The authors accepted that if the patient had been awake during the procedure, earlier detection of neurological symptoms might have been possible.

Hematologic

The effects of the low molecular weight heparin enoxaparin in combination with levobupivacaine on coagulation have been studied in vitro (6). Whole blood from 10 patients treated with enoxaparin was mixed with levobupivacaine to concentrations of 2.5 μg/ml and 2.5 mg/ml, followed by thromboelastography. Levobupivacaine produced a dose-dependent reduction in clotting. The clinical implications of these findings are yet to be acknowledged; larger, in vivo studies are required.

Levocabastine

See also Antihistamines

General Information

Levocabastine is a second-generation antihistamine (SEDA-17, 201) (SEDA-18, 183) (SEDA-19, 174) (SEDA-20, 163) (SEDA-21, 176).

Since levocabastine is applied locally in the eye or nose, local reactions are most often seen. Most frequent is ocular irritation followed by nasal irritation. Sedation does not seem to be common and no cardiac effects have been registered.

Drug–Drug Interactions

Erythromycin

Single doses of erythromycin 333 mg or ketoconazole 200 mg were given to healthy men who used levocabastine, two sprays per nostril (0.05 mg/spray) bd for 6 days (1). There were no changes in the pharmacokinetics of levocabastine or in the QT_c interval.

Levocetirizine

See also Antihistamines

General Information

Levocetirizine is the *R*-enantiomer of cetirizine dihydrochloride and, like cetirizine, undergoes minimal hepatic metabolism (1). Levocetirizine has twice the affinity for H_1 receptors as cetirizine (1). It is efficacious and well tolerated in patients with seasonal allergic rhinitis (2).

© 2006 Elsevier B.V. All rights reserved.

Organs and Systems

Nervous system

Two comprehensive studies have suggested that levocetirizine causes little sedation (3,4). The effect of levocetirizine 5 mg/day on actual driving performance by 48 healthy volunteers has been compared with the effect of the first-generation antihistamine diphenhydramine 50 mg/day in a double-blind, placebo-controlled, randomized study (5). Treatments were administered on days 1, 2, 3, and 4, 90 minutes before the start of a standardized driving test on day 1 and day 4. In contrast to diphenhydramine, driving performance was not significantly affected by levocetirizine.

Psychological, psychiatric

The effects of levocetirizine on cognitive function have been assessed in two comprehensive well-controlled studies. The first analysed the effects of single and multiple doses of levocetirizine on measures of nervous system activity, using integrated measures of cognitive and psychometric performance. In a three-way crossover design, 19 healthy men took either levocetirizine 5 mg, diphenhydramine 50 mg (positive control), or placebo once daily on 5 consecutive days. Critical flicker fusion tests were performed on days 1 and 5 at baseline and up to 24 hours after drug administration. The primary outcome was that, in contrast to diphenhydramine, levocetirizine did not have any deleterious effect on any cognitive or psychometric function compared with placebo (3).

In a double-blind, crossover study levocetirizine 5 mg once daily for 4 days was compared with cetirizine 10 mg, loratadine 10 mg, promethazine 30 mg, and placebo in terms of nervous system inhibitory effects in 20 healthy volunteers (4). With the exception of promethazine none of the drugs had disruptive or sedative effects on objective measurements in a comprehensive battery of psychomotor and cognitive tests. These studies suggest that levocetirizine has minimal sedative effects in healthy individuals when given in its recommended dose.

Levodopa and dopa decarboxylase inhibitors

General Information

Nigrostriatal dopamine is depleted in patients with Parkinson's disease, but it cannot be used to treat the disease since it is poorly absorbed from the gastrointestinal tract and is metabolized extensively in the periphery, hardly penetrating the central nervous system. Levodopa, a precursor that is decarboxylated to dopamine, but is much more lipid soluble, was developed to overcome this problem. It was originally given alone, but because of the extent to which it was decarboxylated outside the central nervous system, large doses had to be given, and gastrointestinal intolerance was a problem. By combining levodopa with a decarboxylase inhibitor (carbidopa or benserazide) tolerance is improved and the dose can be reduced. The combination of levodopa + carbidopa is also called co-careldopa and the combination of levodopa + benserazide is also called co-beneldopa.

General adverse effects

When levodopa is given alone, severe gastrointestinal upsets are very common during the first year of treatment; they are much less common when a decarboxylase inhibitor is also given. Postural hypertension is not uncommon. Dyskinesias occur in some patients only after starting therapy. Some mental changes are seen in a high proportion of cases. Psychological dependence occurs in a small subset of patients (1). Effects on the liver, renal function, and hematological parameters are usually slight. Individual prescribers and clinics tend to develop their own approaches to obtaining the best balance between effects and adverse reactions; a "drug holiday" (for example 2 days/week) has long been recommended by some workers to reduce the incidence of adverse effects (2), but others have described a neuroleptic malignant syndrome when the administration of the drug was temporarily discontinued (SEDA-17, 147) (3). Allergic type reactions do not seem to occur, but carbidopa has been reported to produce a fixed drug eruption. Cases of malignant melanoma (on one occasion within a congenital nevus) have been described in patients taking levodopa; the causal link has not been established, but patients should be monitored for skin changes (4).

Organs and Systems

Cardiovascular

Postural hypotension has been estimated to occur in some 15% of patients who take plain levodopa during the first year of treatment, and in 10% of patients who take

© 2006 Elsevier B.V. All rights reserved.

co-careldopa; it is doubtful whether the difference is significant. On the other hand, some patients become hypertensive; they may be individuals who absorb or metabolize the drug at an abnormal rate. Levodopa can cause ventricular dysrhythmias in patients with pre-existing cardiac disorders. Transient flushing of the skin is common; palpitation is unusual.

Respiratory

An isolated case of respiratory dysrhythmia has been reported (5); it was dose-related and impeded adequate treatment, but was ultimately suppressed with tiapride.

Two men with Parkinson's disease, aged 66 and 78 years, developed abnormal respiration (tachypnea and irregularity in the depth of breathing) when levodopa was either introduced at a dose of 300 mg/day in the first case or increased from 300 to 600 mg/day in the other (6). The authors cited a number of earlier similar reports.

Nervous system

Ever since the introduction of levodopa as the mainstay of antiparkinsonian therapy, there has been concern that it may be toxic, causing long-term damage to dopamine neurons. Three reviews have addressed this question in the light of experimental and clinical evidence over the last 30 years. One reviewer concluded that there is no evidence for irreversible levodopa-induced damage in man, only for reversible adverse effects associated with neuronal dysfunction but not neuronal death (7). Others reached broadly the same conclusion, although they noted that there is in vitro evidence of damage associated with oxidative metabolism of levodopa (8). They also described potential toxicity from levodopa in animals in which the nigrostriatal pathway is already damaged by other means. A third reviewer has pointed out that levodopa therapy is an entirely non-physiological means of dopamine replacement, arguing that the intermittent nature of the dopaminergic stimulus provided by most therapies, particularly levodopa, predisposes to motor complications (9). He suggested that more continuous activation of dopamine receptors could minimize or eliminate these problems.

Asterixis, a jerky relaxation of tonically contracted postural muscles, was observed in some patients with structural lesions of the brain or metabolic encephalopathy who were taking levodopa, but not in patients with Parkinson's disease (10).

For most patients fluctuations are variations in the severity of motor manifestations of Parkinson's disease. However, other types of fluctuations can also occur, many of which are of non-motor in nature: these include sensory fluctuations (pain and paresthesia), akathisia or restless legs, autonomic fluctuations (dyspnea, tachycardia, pallor, blood pressure changes, dysphagia, penile erection, urinary frequency) or cognitive effects, such as hallucinations, depression, hypomania, or hypersexuality.

An unusual symptom of Parkinson's disease is apraxia of eyelid opening, a particular aspect of the difficulty in initiating movements (11).

- A 76-year-old woman with atypical Parkinsonism had a poor motor response to levodopa and developed apraxia. An increase in dosage (to levodopa 300 mg/day with benserazide 75 mg/day and selegiline 200 mg/day) caused worsening of the apraxia. Drug withdrawal caused no motor deterioration, but the apraxia disappeared. Challenge with subcutaneous apomorphine reinitiated the symptom, strongly supporting its dopaminergic origin in this patient.

The authors cited the therapeutic use of botulinum toxin in a similar case, but this was ineffective in their patient.

A less well defined adverse effect of levodopa is sedation. This has been studied in 22 volunteers given levodopa 200 mg with benserazide 50 mg or triazolam 0.125 mg or placebo in a randomized crossover design (12). Both active drugs caused drowsiness, more particularly triazolam. During a further 11 days of treatment with levodopa 600 mg/day sedation persisted. Two points are worth noting. First, triazolam was presumably chosen because of its short half-life, but it is a somewhat risky choice, given its known psychiatric adverse effects. Secondly, the very rapid increase in levodopa dosage, from 200 to 600 mg/day, would be unrealistic in a clinical context, when dosage titration would be much more gradual. It is therefore hard to assess the practical relevance of this study.

The advantages and disadvantages of levodopa have been summarized, with particular focus on adverse effects and their management (13). The author concluded that there is no convincing evidence for neurotoxicity of levodopa in humans.

Neurologists from New York and Yugoslavia have noted the variable time to the development of motor complications after starting levodopa (14). Of 40 patients (21 men, mean age 67 years), 17 were at Hoehn and Yahr stage I at the start of levodopa therapy, 13 at stage II, and 10 at stage III. The median times to the development of motor fluctuations were respectively 64, 55, and 14 months in the three groups and the times to onset of dyskinesias were similar. This reinforces the clinical experience of neurologists in general.

Dyskinesias

Dyskinesias occurring during long-term use of levodopa have been classified in various ways. One system presents them as falling broadly into three groups:

- "On" dyskinesias—These coincide with periods of clinical response to the drug; they include chorea, myoclonus, and dystonic movements. They are enhanced by dopamine receptor agonists and reduced by dopamine receptor antagonists.
- "Off" dyskinesias—These coincide with periods of poor response and comprise mainly dystonic postures, affecting in particular the feet; they are inhibited by both dopamine receptor agonists and antagonists.
- "Dysphasic dyskinesias"—These occur at the beginning and end of "on" periods. They involve repetitive stereotyped movements of the lower limbs, and they too react well to both dopamine receptor agonists and antagonists.

There is reason to believe that dyskinesias during prolonged levodopa treatment result from an interaction between the levodopa and the underlying condition rather than from one or the other. In many cases of severe Parkinson's disease one can speak of a "peak dose dyskinesia," which is only problematic when the patient is

© 2006 Elsevier B.V. All rights reserved.

taking a relatively high dose, which tends to be most marked on the most severely diseased side, and which responds to dosage reduction (15).

The long-term consequences of levodopa therapy have been considered in a review by predominantly Canadian authors, but whose senior author was Oleh Hornykiewicz, the doyen of the dopamine concept of Parkinson's disease (16). Their conclusions were not at all unexpected. Levodopa was given to 42 patients (30 men, mean disease duration of 16 years, mean follow-up about 9 years). There were adverse effects in over 70%: dyskinesias in 62%, on–off effects in about 17%, and end-of-dose wearing-off in about 7% (the last perhaps surprisingly low). Dyskinesia was not only the most common but also the earliest adverse effect. It should be noted that the mean levodopa dosage in this population was rather low, only 500 mg/day.

An interesting case report has drawn attention to the fact that severe response fluctuations can occur soon after the start of treatment in patients with severe disease (17).

- Two men aged 76 and 72 years presented with advanced symptoms of Parkinson's disease and were treated with levodopa. Disabling dyskinesia occurred within days of reaching maintenance dosages of levodopa (1–1.5 g/day with benserazide).

Clearly, the disease status of the patients was the determinant for this adverse reaction, not the duration of levodopa therapy.

In 17 parkinsonian patients three tests of proprioception were carried out 1 hour after the administration of levodopa or a dopamine receptor agonist (18). Although data were not provided for individual patients, there was an overall 11–31% deterioration in the mean scores in all three of the tests. There was no difference between patients with and without dyskinesias, but the authors suggested that abnormal proprioception may be a factor in drug-induced dyskinesia.

There is some evidence that the atypical neuroleptic drug clozapine can alleviate levodopa-induced dyskinesia while itself providing additional relief in Parkinson's disease (SEDA-18, 159); clozapine may also relieve levodopa-induced psychosis (SEDA-17, 166).

"Start hesitation" (paradoxical akinesia) is the name given to sudden episodes during which the patient feels a sensation of extreme heaviness of the feet and finds himself unable to start walking; the legs tremble and the patient falls forward; the condition can improve if the levodopa dosage is reduced.

The "on–off effect" seen after prolonged therapy in some patients is characterized by sudden swings between severe parkinsonian symptoms (with freedom from adverse effects) and normal mobility (but with marked adverse drug effects). It is likely that unexplained variations in dopamine concentrations in the central nervous system are responsible; the condition has been seen less often since combinations with decarboxylase inhibitors came into general use.

Hiccups, an unusual form of dyskinesia, have been attributed to levodopa (19).

- An 80-year-old man with Parkinson's disease and dementia developed worsening bradykinesia, and the dose of co-careldopa was increased from 12.5/50 mg bd to 25/100 mg bd. Two days later, he developed hiccups, which lasted for 1 week and which ceased when the dosage was reduced to the previous level. Ocular dyskinesias have been described in a 60-year-old Spanish man who showed intermittent upward and leftward deviations of gaze associated with peak concentrations of levodopa, in doses of up to 800 mg/day plus benserazide (20).

It should be noted that the patient was and apparently still is taking pramipexole and amantadine in addition to levodopa.

Sleep disorders

Daytime sleepiness and nocturnal wakefulness can both occur in relation to dopaminergic drug therapy, but sleep attacks are rare (21). Many factors beside drug treatment can lead to sleep disorders in parkinsonian patients, including the disease process itself and episodes of sleep apnea; some are skeptical about the existence of sleep attacks as a phenomenon distinct from increased general drowsiness (22), although others disagree. Neurologists from King's College London have concluded that all dopaminergic drugs are capable of causing sleepiness and that in a minority of patients it may take the form of a narcolepsy-like phenotype, possibly amenable to improvement by selegiline or modafinil; they have recommended that affected individuals should not drive (23). Although it was their view that this is a class effect of dopamine agonists, they nevertheless suggested that switching from one agonist to another may sometimes be helpful.

Some remarkable case reports have previously been published (SEDA-25, 169) and reports continue to appear, supplemented by prospective studies and other analyses. For instance, 11 studies involving ropinirole or pramipexole in a total of 2066 patients have been reviewed (24). Four of these (two each with ropinirole and pramipexole) were placebo-controlled. The pooled relative risk of somnolence was 4.98 compared with placebo: there was a non-significant trend for greater somnolence with ropinirole, but the confidence intervals were much wider than with pramipexole. In the other studies levodopa alone was compared with levodopa plus the newer drugs; the relative risk was 2.06 compared with levodopa alone. It must be borne in mind that somnolence and sleep attacks may be separate phenomena, although this is controversial.

The whole field of sleep disorders in Parkinson's disease has been reviewed in a consecutive series of 320 patients from Houston, with analysable data from 303 (sex distribution unknown) (25). The mean age was 67 years and the mean duration of the disease was 9.1 years. All the patients completed the Epworth Sleepiness Scale and answered specific questions about falling asleep while driving and about the restless legs syndrome. The mean sleepiness score was 11.1, values greater than 10 being regarded as abnormal. As one would expect, just over half the patients had scores at that level. Higher scores correlated with longer duration and greater severity of the disease, with male sex, and with the use of dopamine receptor agonists. There was no apparent difference in

© 2006 Elsevier B.V. All rights reserved.

this regard between the three most commonly prescribed drugs in these patients (pergolide, ropinirole, and pramipexole, the last being the most frequent). Among those currently driving, 23% reported falling asleep in the car and nearly 20% had features of the restless legs syndrome. This study has therefore reinforced the view that sleep disorders are common in Parkinson's disease, especially in its advanced stages, and are exacerbated by dopamine agonists as a class. However, one can draw no conclusions about individual drugs from this review.

The effects of pramipexole, cabergoline, and levodopa on daytime sleepiness have been assessed in three groups of patients with Parkinson's disease (26). The first group was 19 patients taking pramipexole (mean age 60 years, mean dosage 4.5 mg/day, 8 as monotherapy, the remainder with levodopa); the second group was 22 patients taking cabergoline (mean age 63 years, mean dosage 4.1 mg/day, 10 as monotherapy); the third group was 14 patients taking levodopa (mean age 69 years, mean dosage 789 mg/day) as monotherapy. The scores on the Epworth Sleepiness Scale were virtually identical (8.0, 8.1, 8.1). Scores of greater than 16, indicating excessive daytime sleepiness, were also evenly distributed across the three groups, and were attributed to only four individuals; there were no reports of sleep attacks.

These results have been supported by a study in 160 patients with Parkinson's disease (mean age 66 years) divided into four equal groups and taking levodopa alone, levodopa with bromocriptine, levodopa with ropinirole, or levodopa with pramipexole (27). They were compared with 40 healthy younger controls (mean age 58 years). All the subjects were evaluated using the Epworth Sleepiness Scales. All the drug regimens were associated with increased sleepiness compared with the controls but there were no distinct sleep attacks. The authors noted that all the drug regimens produced similar levels of sedation, although the data appeared to show a trend toward greater somnolence with ropinirole and more particularly pramipexole.

However, these are not uncontested findings. In a study that was described as prospective, but was strictly speaking not, 236 patients (106 men, 130 women, mean age 67 years) were questioned (28). All but one was in Hoehn–Yahr stages II–IV. Sleep attacks were reported by 72 patients, of whom 70% were considered to have autonomic dysfunction. The authors concluded that the highest risk was attributable to ropinirole (OR = 7.35), followed by bromocriptine (5.78) and lisuride (5.68); for comparison, the figure for levodopa was 0.61. No patients took pramipexole. Again, it is uncertain whether sleep attacks can truly be distinguished from "ordinary" sleepiness, but the results emphasize the sedative potential of dopamine receptor agonists.

On the other hand, these results have been disputed in another report, with authors in common with the previous report. They presented four case studies, three men and one woman, aged 49–87 years, who had had Parkinson's disease for 8–17 years; the longest duration was in the youngest patient (29). All four were taking levodopa (300–1500 mg/day) plus a decarboxylase inhibitor. All four reported sudden irresistible sleep episodes, even during conversations: two also complained of sleepiness distinct from these attacks. Two of the patients also had definite autonomic disturbances. The authors concluded that sleep attacks do occur and may be associated with levodopa as well as with dopamine receptor agonists.

The sedative potential of levodopa has been examined in 16 healthy volunteers (mean age 25 years, eight men), although of course this represents a very different neuropsychological context from Parkinson's disease (30). They were given levodopa 200 mg or a placebo as a single dose, with domperidone to minimize peripheral adverse effects, followed by the active drug or control in a crossover design. Sedation was assessed using a visual analogue scale and reaction time by the response to a light stimulus. There was no overall change in reaction time, but this concealed considerable interindividual variation. Four subjects complained of nausea and one of excitation after levodopa and all had slower reaction times without complaining of sedation. However, seven subjects reported a greater level of sedation with levodopa than placebo, and this correlated ($r = 0.7$) with their reaction times. In other words, levodopa can cause sedation in normal young people but does not necessarily do so, at least after a single dose. The extent to which these results can be extrapolated to elderly parkinsonian patients is debatable.

In a Canadian survey of 638 parkinsonian patients who were fully independent and with no evidence of dementia, just over half (327) had excessive daytime sleepiness, as assessed by the Epworth Sleepiness Scale and the Inappropriate Sleep Composite Score (31). Only 16 patients had fallen asleep while driving and of these 3 had no warning; all had high scores on the scales mentioned. Unfortunately, the structure of the survey did not allow conclusions regarding drug therapy, although all the patients were taking levodopa (80%), or a dopamine receptor agonist, or both.

In another survey, from Texas, Epworth scores were studied in 368 patients with Parkinson's disease and 243 with other neurological disorders, mostly other movement disorders, including other causes of parkinsonian syndromes (32). The former had scores 25% higher; however, it should be noted that matching for age and other parameters was not clearly described. Using a multivariate model the authors calculated that levodopa dosage, the use of dopamine receptor agonists, and the severity of the disease accounted for only a minor extent (about 9%) of the variation in scores in the parkinsonian group. Even so, they concluded that progression of the disease, the dosage of levodopa, and the use of dopamine receptor agonists are contributory factors in increased daytime somnolence.

Several smaller-scale studies and case reports have also been published. An Italian group have reported polysomnographic studies in a 44-year-old woman with a 5-year history of idiopathic Parkinson's disease (33). She was taking modified-release levodopa, to which pergolide 3 mg/day was added, titrating up from a lower dose. After taking this dosage for 5 days she developed irresistible sleep attacks up to 5 times a day with no warning or obvious triggers. Polysomnography showed that these episodes closely resembled narcolepsy. The episodes ceased after pergolide withdrawal.

Six German patients (aged 36–68 years, disease duration 7–12 years, four men) were studied after reporting

© 2006 Elsevier B.V. All rights reserved.

sleep attacks following the addition of pramipexole or ropinirole to a levodopa-based treatment regimen (34). Five had abnormal results in the multiple sleep latency test, and three of these also had increased errors in a test of driving vigilance. The authors concluded that patients should be assessed individually in terms of their safety to drive. They also suggested that sleep attacks are at the extreme end of the spectrum of daytime sleepiness, although it is not clear that such a conclusion can be reached so unequivocally from such a small study.

A French group has tested the effects of ropinirole 3 mg on sleep latency in 20 healthy men (mean age 24 years) compared with placebo (35). The time to sleep onset was significantly quicker in the ropinirole-treated subjects (2.6 versus 4.8 minutes), but sleep attacks did not occur. Clearly this is a very different group of individuals from the usually much older group with Parkinson's disease, so again definite conclusions are elusive.

Overall, the current evidence suggests that sedation is a class effect of all dopaminergic drugs, including levodopa. It may be more severe with the newer synthetic agents pramipexole and ropinirole, but this cannot yet be stated with certainty. The existence of discrete sleep attacks also remains controversial, although on balance one would conclude that they can occur.

Psychological, psychiatric

Toxic psychoses and toxic delirium can occur, particularly in individuals with a history of postencephalitic parkinsonism or psychiatric disease (36). Nearly half of all patients with Parkinson's disease are demented or have significant cognitive impairment (37). These patients are particularly susceptible to delirium induced by levodopa and other antiparkinsonian drugs. The author recommended dosage reduction or elimination of drugs that may be responsible, starting with anticholinergic drugs but leaving levodopa unchanged if possible. He also recommended the use of the atypical neuroleptic drugs clozapine or olanzapine in severely disturbed patients in whom drug withdrawal is not feasible.

Much more common are such symptoms as confusion (13% of cases), depression (9% of cases, often requiring antidepressant drugs), and sleep disturbances (20% of cases). Vivid hallucinations are common. Psychotic symptoms appear to be more common when enzyme inhibitors are used or anticholinergic drugs given. Panic attacks seem to occur in some 20% of cases during the "off" phases of an "off/on" cycle (38).

Libido has been found to increase, at least for some time, in a proportion of patients (39); whilst perhaps in part reflecting the improved mobility and sense of well-being, a causative relation with prolactin inhibition by levodopa has been suggested.

There may be subtle neuropsychiatric adverse effects of dopaminergic medication. The syndrome of hedonistic homeostatic dysregulation, generally associated with substance abuse, has been described in 15 patients with Parkinson's disease (40). Four patients were described in detail. The authors noted that 12 of the 15 patients were men (three of the four described in the paper) and had early onset of Parkinson's disease: those described were aged only 36–42 years. Characteristically, these patients were taking large and increasing doses of levodopa (or other dopamine agonists, including apomorphine) despite worsening dyskinesias; they had impaired social functioning, including absence from work, belligerent behavior, and hypersexuality; they had a hypomanic or bipolar affect; they underwent a withdrawal reaction on reducing levodopa dosage, with depression, dysphoria, and anxiety; and they had a disorder with the above features lasting at least 6 months. All of the four patients described in detail had taken apomorphine at some time (75–170 mg/day) and tended to use higher than prescribed doses by intermittent injection. All were also taking levodopa (maximum dose 1875–5500 mg/day). The authors noted that the long-term management of this condition can be very difficult. They suggested management of acute psychosis with atypical neuroleptic drugs, such as olanzapine or risperidone, the use of antidepressants if needed, and careful supervision of patient self-medication. They conceded that this may be extremely difficult.

In a prospective study of 89 patients with Parkinson's disease, of whom 60 were free of hallucinations at entry, though most of these had disturbed sleep patterns, after 4 years 50% of the original non-hallucinators were experiencing hallucinations, while only 14% of those with hallucinations at entry were no longer affected by them (41). Those classified as having severe hallucinations increased from 10% at entry to 35% after 4 years. The development or worsening of hallucinations was not associated with levodopa dosage but was strongly correlated with the use of dopamine receptor agonists in combination with levodopa: some 59% of patients with hallucinations were taking agonists as against 33% of non-hallucinators.

It is a pharmacological truism that exogenous dopamine is not a central dopamine receptor agonist, because it cannot cross the blood–brain barrier. However, the possibility that it might, and could thus contribute to the development of delirium, has been examined (42). Of over 21 000 inpatients in Stanford University Hospital, 1164 were given intravenous dopamine. Although the authors conceded that the methods that they used to assess the presence of delirium were imprecise, they nevertheless calculated that intravenous administration of dopamine nearly triples the likelihood of the need for subsequent antipsychotic medication. This raises at least the possibility that in some pathological states significant amounts of exogenous dopamine can enter the brain. A prospective study is needed to clarify this. Meanwhile the authors have proposed that it might be useful to give dopamine receptor antagonists to patients who are about to receive dopamine infusions. However, most clinicians would probably be reluctant to do this on the existing evidence.

Endocrine

Occasional increases in protein-bound iodine have occurred (43).

Levodopa usually increases plasma growth hormone concentrations (44).

Disruption of diurnal cortisol rhythm has been detected and could explain some of the sleep disturbances and psychic adverse effects that levodopa can have (SEDA-8, 143).

Levodopa can stimulate glucagon secretion (45).

© 2006 Elsevier B.V. All rights reserved.

Metabolism

Carbohydrate tolerance is slightly impaired by levodopa.

Electrolyte balance

There is a tendency to potassium loss and hypokalemia. Some patients are particularly susceptible to this adverse effect. In three patients with hypokalemia and five without, levodopa caused increased excretion of potassium, and sometimes also of sodium, in the hypokalemic but not in the normokalemic patients; this effect was prevented by the administration of a peripheral dopa decarboxylase inhibitor (46).

Hyponatremia has been reported in one published case, and the patient had earlier the same reaction with amantadine (SEDA-18, 159).

Hematologic

Very occasionally there are falls in white blood cell count, hemoglobin, and hematocrit. The Coombs' test can be positive and there is an isolated report of hemolytic anemia and another of thrombocytopenia with a positive antinuclear antibody test (SED-12, 315). An otherwise unexplainable acute severe non-hemolytic anemia in an elderly man taking levodopa with benserazide has also been observed (SEDA-12, 124).

Gastrointestinal

Despite the fact that gastrointestinal tolerance can be improved by cautious dosing, very gradual dosage increases, and the use of antiemetics, anorexia, nausea, and vomiting have been estimated to occur in 36–83% of patients taking levodopa alone, and some 10% of patients never succeed in tolerating the dose that was optimally effective for them (47). Gastrointestinal tolerance is substantially better with the combined products; provided the combination is taken during meals, digestive disturbances are usually mild and transitory, and only a few patients require antiemetics.

Liver

Liver function tests are as a rule unchanged, but isolated changes in aspartate transaminase, alanine transaminase, bilirubin, and lactate dehydrogenase have been recorded.

Urinary tract

Blood urea concentration occasionally rises. One report suggested darkening of the urine, but this seems to have been coincidental.

Urinary retention has been described in a case of hypertonic bladder, but the association may have been fortuitous (48).

There have been several reports of a diuretic effect of levodopa; although it is seldom recognized, the effect is probably fairly consistent and not limited, as was at one time suggested, to obese subjects (49). It is presumably mediated through renal dopamine receptors.

Skin

Pemphigus erythematosus has been reported after 18 months of treatment with co-careldopa (50).

Darkening of the sweat has been described (43).

Darkening of the white hair of a patient who was taking levodopa in combination with bromocriptine for Parkinson's disease has been reported (SEDA-15, 133).

There is some evidence suggesting a link between levodopa and the development of melanoma (SEDA-17, 167), but a prior history of melanoma should not be regarded as a contraindication to levodopa treatment.

Hair

Treatment with levodopa has very rarely been associated with reversible alopecia (51).

Musculoskeletal

There seems to be no doubt that patients who take levodopa are more likely to have a fracture (1). The most likely explanation is simply that they are more mobile and thus more likely to fall than before treatment was begun, but it should be borne in mind that benserazide caused skeletal changes in rats in the original toxicity studies.

"Black cartilage" (intense black pigmentation confined to the costal cartilage) has been found at necropsy in a man who had taken co-careldopa for 13 years (SED-12, 316).

The uric acid concentration can increase and in some cases frank gout occurs, occasionally within a few days of starting treatment (52).

Sexual function

Libido can increase, at least for some time, in a proportion of patients (39); while this perhaps in part reflects improved mobility and sense of well-being, a causative relation with prolactin inhibition by levodopa has been suggested.

Long-Term Effects

Drug withdrawal

A serious relapse of Parkinson's disease can occur after withdrawal. The most dangerous potential consequence is a syndrome identical to the neuroleptic malignant syndrome, with hyperthermia, semistupor, rigidity, and tremor, after withdrawal of levodopa (53,54).

Second-Generation Effects

Teratogenicity

Parkinson's disease is very rare in pregnancy, but has been described (55).

- A 36-year-old woman with a 4-year history of Parkinson's disease, who had been taking pergolide 3 mg/day and levodopa 200 mg/day continued to take it during pregnancy. The end-of-dose wearing-off effect completely disappeared, and reappeared at their previous intensity after delivery. There were no adverse effects in the mother. The baby was healthy at birth and remained so at the time of the report, at the age of 13 months.

Susceptibility Factors

Genetic factors

Drug-induced hallucinations are a more familiar aspect of the treatment of Parkinson's disease. Susceptibility to these shows great interindividual variation and it is hardly surprising that researchers are seeking genetic bases for these. Polymorphisms of dopamine receptor genes seem obvious candidates, and this has been studied by a group in Sheffield (56). They found an association between late-onset hallucinations and a polymorphism close to the D_2 receptor. However, the effect is not overwhelming: the abnormal allele of the Taq IA polymorphism was found in 82% of those who hallucinated and 59% of those who did not. This is statistically significant but, as often in this type of study, the biological and clinical relevance is far from certain.

Other features of the patient

Because of the cardiovascular effects of levodopa, patients with cardiac disorders are at risk.

Levodopa should not be used in patients with a history of mental illness, hemolytic anemia, or any serious organic disease.

Neurologists from Madrid have studied 168 consecutive patients treated for at least 6 months with levodopa (57). About 10% of the patients per year developed dyskinesias over 7 years. Younger age (under 50 years) at the onset of the disease and high initial levodopa dosages (more than 600 mg/day) were the most important susceptibility factors identified.

Drug Administration

Drug formulations

When four patients from Argentina experienced deterioration of their Parkinson's disease it was discovered that their medication contained not 250 mg levodopa plus benserazide, as labeled, but only 60 mg of levodopa alone (58).

Drug–Drug Interactions

Monoamine oxidase inhibitors

The combination of a monoamine oxidase inhibitor with levodopa causes hypertension, sometimes with very high pressures (59,60).

Neuroleptic drugs

Neuroleptic drugs can aggravate parkinsonism; if an antiemetic is required, a non-phenothiazine should therefore be chosen.

Papaverine

Papaverine can reduce the effects of levodopa (61,62).

Propranolol

Propranolol may improve the effect of levodopa on tremor (63).

Pyridoxine

Pyridoxine interferes with the desired nervous system effect of levodopa (64,65), since it is a co-decarboxylase, which facilitates the transformation of levodopa to dopa outside the central nervous system.

Interference with Diagnostic Tests

Urinary glucose

Treatment with levodopa results in false-positive tests for urinary glucose (66).

Urinary ketone bodies

Treatment with levodopa results in false-positive tests for urinary ketone bodies (67).

Diagnosis of Adverse Drug Reactions

A group from the National Hospital for Neurology in London has described the use of continuous subcutaneous apomorphine infusions in 19 patients with Parkinson's disease with severe unpredictable motor fluctuations while taking levodopa (68). The objective was to replace levodopa during waking hours with apomorphine monotherapy. During apomorphine treatment ranging from 9 months to nearly 8 years, there was a 65% reduction in dyskinesia severity and an 85% reduction in frequency and duration, with a 70% reduction in the "off" time. Nearly half the patients stopped taking levodopa altogether.

A less radical and much less expensive approach to the management of motor fluctuations has been described in 14 patients with advanced Parkinson's disease and levodopa-induced motor disorders (69). Amantadine (mean dose 350 mg/day) reduced the severity and duration of dyskinesias by 33–75%, depending on the parameter measured. The rationale was that amantadine blocked *N*-methyl-D-aspartate receptors.

Unilateral stereotactic pallidotomy has been described in 42 patients, with dramatic improvement in dyskinesias at 3 months after surgery: the number of patients with moderate to severe dyskinesias was reduced from 36 to 5, although it is not clear whether there was any change in other aspects of the disease (70).

A novel pharmacological approach has been described by a group in Israel, who have used the glutamate receptor antagonist riluzole in six patients with severe Parkinson's disease and dyskinesias (71). At a dose of up to 50 mg/day riluzole significantly reduced dyskinesias, did not worsen parkinsonian symptoms, and was well tolerated.

As regards susceptibility factors for the development of levodopa-induced dyskinesias, neurologists from Madrid have studied 168 consecutive patients treated for at least 6 months with levodopa (57). About 10% of the patients per year developed dyskinesias over 7 years. Younger age (under 50 years) at the onset of the disease and high initial levodopa dosages (more than 600 mg/day) were the most important susceptibility factors identified.

The efficacy of clozapine has been described in 60 patients with levodopa-induced neuropsychiatric syndromes (32 assigned to the active drug and 28 to placebo) (72). The mean age was 72 years, the mean duration of disease was 12 years (Hoehn and Yahr stage 3.2), and the mean levodopa dosage was 774 mg/day. At a dose of up to 50 mg/day, clozapine significantly improved psychotic features, with minimal effects on parkinsonian symptoms. Clozapine caused somnolence but was otherwise well tolerated.

Levofloxacin

See also Fluoroquinolones

General Information

Levofloxacin, the levorotatory (*S*)-enantiomer of the racemate ofloxacin, is an oral and parenteral fluoroquinolone that has bactericidal activity against a wide spectrum of Gram-negative and Gram-positive bacilli (including *Streptococcus pneumoniae*), as well as atypical respiratory pathogens.

In patients with meningitis, levofloxacin penetration in cerebrospinal fluid and the liquor-to-plasma ratio was assessed at 2 hours after dosing in five patients with spontaneous acute bacterial meningitis. Cerebrospinal fluid levofloxacin concentration at 2 hours after dosing was 2.0 μg/ml, and the liquor-to-plasma ratio at 2 hours after dosing was 0.35 (1).

Observational studies

In 10 patients who took levofloxacin 500 mg/day and rifampicin 600 mg/day for 2–6 months, there were no adverse reactions in 46% of patients, occasional digestive symptoms in 40%, and mild diarrhea in 13%; these patients also took unspecified anti-inflammatory drugs (2). There was sleeplessness in 6% but neither tendinitis nor changes in liver function.

© 2006 Elsevier B.V. All rights reserved.

In a prospective, multicenter open trial, 313 patients with clinical signs and symptoms of bacterial infections of the respiratory tract, skin, or urinary tract were treated with levofloxacin (3). Of these, 134 patients had a pathogen recovered from the primary infection site and had an MIC of the pathogen to levofloxacin determined. Levofloxacin generated clinical and microbiological response rates of about 95%. These response rates included pathogens such as *Streptococcus pneumoniae* and *Staphylococcus aureus*. In a logistic regression analysis, the clinical outcome was predicted by the ratio of peak plasma concentration to MIC and site of infection. Microbiological eradication was predicted by the peak concentration/MIC ratio. Both clinical and microbiological outcomes were most likely to be favorable if the peak concentration/MIC ratio was at least 12.

Of 17 individuals with suspected latent multidrug-resistant tuberculosis treated with pyrazinamide and levofloxacin, 11 developed musculoskeletal adverse effects related to therapy, 5 had nervous system effects, and 15 had raised liver enzymes, uric acid, or creatinine kinase (4).

Comparative studies

In comparative trials involving commonly used regimens, levofloxacin had equivalent if not greater activity in the treatment of community-acquired pneumonia, acute bacterial exacerbations of chronic bronchitis, acute bacterial sinusitis, acute pyelonephritis, and complicated urinary tract infection (5).

General adverse effects

The adverse effects rates of levofloxacin are 1.3% for nausea, 0.1% for anxiety, 0.3% for insomnia, and 0.1% for headache. No levofloxacin-related adverse events were reported at a rate higher than 1.3%, and most were less common. High-dose levofloxacin (750 mg) was also well tolerated. Surveillance data reported low adverse event rates: nausea 0.8%, rash 0.5%, abdominal pain 0.4%, and diarrhea, dizziness, and vomiting 0.3%. The adverse drug reactions rate for levofloxacin is still one of the lowest of any fluoroquinolone, at 2% compared with 2–10% for other fluoroquinolones (6–9).

Organs and Systems

Cardiovascular

Preclinical and clinical trial data and data from phase IV studies have suggested that levofloxacin causes prolongation of the QT interval (10). There were cardiovascular problems in 1 in 15 million prescriptions compared with 1–3% of patients taking sparfloxacin, who had QT_c prolongation to over 500 ms. Polymorphous ventricular tachycardia with a normal QT interval has been associated with oral levofloxacin in the absence of other causes (6,9,11,12).

Among 23 patients who took levofloxacin 500 mg/day there was prolongation of the QT_c interval by more than 30 ms in four patients and 60 ms in two patients (13). There was absolute QT interval prolongation to over 500 ms in four patients, one of whom developed torsade de pointes.

Phlebitis can occur during parenteral administration of levofloxacin. High concentrations of levofloxacin (5 mg/ml) significantly reduced intracellular ATP content in cultured endothelial cells and reduced ADP, GTP, and GDP concentrations (14). These in vitro data suggest that high doses of levofloxacin are not compatible with maintenance of endothelial cell function and may explain the occurrence of phlebitis. Commercial formulations should be diluted and given into large veins.

Respiratory

Eosinophilic pneumonia complicated by bronchial asthma has been attributed to levofloxacin (15).

- A 76-year-old woman took levofloxacin for a productive cough with non-segmental infiltration in both lung fields. She developed eosinophilia in both the peripheral blood (24%) and the sputum (10%), airflow limitation, hypoxemia, and increased airway responsiveness to methacholine. Bronchoalveolar lavage fluid showed increased total cells and a 55% increase in eosinophils, and the CD4/CD8 ratio was reduced to 0.8. Histological features included increased infiltration of eosinophils in the alveolar and interstitial compartments and goblet cell metaplasia. Levofloxacin was withdrawn, and her symptoms improved without steroid therapy. A leukocyte migration test for levofloxacin was weakly positive.

Nervous system

Levofloxacin can cause seizures (16). In one study convulsions occurred in two per million prescriptions (9,17).

- A 75-year-old white woman was given oral levofloxacin (500 mg on day 1 followed by 250 mg/day) for ischemic toes (16). After three doses she had a seizure. One month later, she was challenged with ciprofloxacin 400 mg intravenously every 12 hours and again had a seizure.
- A 74-year-old white woman was given oral levofloxacin 500 mg/day for bacterial pneumonia and had a seizure after five doses (16).

Sensory systems

Taste disturbance occurred in less than three per million prescriptions of levofloxacin (9).

Gastrointestinal

Of 48 patients taking pyrazinamide 30 mg/kg/day plus levofloxacin 500 mg/day for 1 year, 27 discontinued therapy within 4 months owing to adverse events. Gastrointestinal intolerance was the major adverse event that resulted in early withdrawal (18).

Levofloxacin can cause pseudomembranous colitis due to *Clostridium difficile* (19).

© 2006 Elsevier B.V. All rights reserved.

Liver

In a study based on European and international data from about 130 million prescriptions, the adverse effects profile of levofloxacin was compared with that of other fluoroquinolones; there was a low rate of hepatic abnormalities (1/650 000) (6). However, two cases of severe acute liver toxicity were reported in patients who had received intravenous levofloxacin (20,21).

Pancreas

Two case reports have suggested that levofloxacin can cause pancreatitis (22).

Urinary tract

Two reports have suggested that levofloxacin can cause tubulointerstitial nephritis (23). A case of nephrotoxicity and purpura associated with levofloxacin has also been reported; allergic interstitial nephritis or vasculitis was believed to be the underlying pathologic process (24).

- A 73-year-old white man took levofloxacin for a lower urinary tract infection for 3 days and developed palpable purpura and erythematous skin lesions over the lower limbs and trunk, with a markedly reduced urine output. Serum creatinine was 560 μmol/l (6.4 mg/dl). Levofloxacin was withdrawn, and prednisone, furosemide, and intravenous fluids were given. The patient recovered fully over the next 4 weeks.

Skin

In a double-blind, randomized study in 30 healthy adults oral levofloxacin (500 mg/day for 5 days) had a low photosensitizing potential (25), as it did in preclinical animal studies and postmarketing surveillance (26). In preclinical studies levofloxacin was 20 times less phototoxic than sparfloxacin. Phototoxicity occurs in only 1 in 1.8 million cases.

Levofloxacin can cause a rash similar to the ampicillin rash in patients with infectious mononucleosis (27).

- A 78-year-old woman developed a rash with blistering 2 days after completing a course of levofloxacin (28). The rash progressed to toxic epidermal necrolysis in 7 days. She was treated with intravenous fluids and wound dressings. Her condition improved and she was discharged after 22 days.

Musculoskeletal

Tendinopathy has been reported with levofloxacin. Four cases of Achilles tendinitis have been reported in patients taking levofloxacin (29). Two were on chronic dialysis, one was a kidney transplant recipient, and one had chronic vasculitis. In all four cases, tendinitis had an acute onset with bilateral involvement and was incapacitating. In three cases the onset was early during levofloxacin treatment and in one case it began 10 days after the end of treatment. All the patients recovered completely after 3–8 weeks.

Old age, renal dysfunction, and concomitant corticosteroid therapy are predisposing risk factors (30,31). Tendon rupture occurred in less than four per million prescriptions (9).

Immunologic

Anaphylactic and anaphylactoid reactions are rare adverse events after the administration of fluoroquinolones (about 0.46–1.2 per 100 000 patients).

- On two occasions a 49-year-old asthmatic woman who took levofloxacin for a chest infection developed worse respiratory distress, requiring intubation (32). The second reaction was accompanied by a marked skin reaction.

An in vitro study in rat peritoneal mast cells showed that levofloxacin-mediated release of histamine may be closely linked to activation of pertussis toxin-sensitive G proteins (33).

Susceptibility Factors

The pharmacokinetics of intravenous levofloxacin have been studied in intensive care unit patients during continuous venovenous hemofiltration or hemodiafiltration (34,35). Levofloxacin clearance was substantially increased during both types of continuous renal replacement therapy. Levofloxacin 250 mg/day maintained effective plasma drug concentrations in these patients.

Drug–Drug Interactions

Chinese medicines

Chinese medicines did not influence the systemic availability or renal excretion of levofloxacin (36).

Efavirenz

Levofloxacin pharmacokinetics in HIV-positive patients were not altered by steady-state treatment with efavirenz (37).

HIV protease inhibitors

Levofloxacin pharmacokinetics in HIV-positive patients were not altered by steady-state treatment with nelfinavir (37).

Lithium

Co-administration with levofloxacin can cause severe lithium toxicity; the authors did not discuss the mechanism (38).

Theophylline

Theophylline clearance was reduced by levofloxacin plus clarithromycin in a 59-year-old Japanese man, who had stimulation, insomnia, and tachycardia due to theophylline toxicity (39).

The mechanism was probably inhibition of theophylline metabolism by CYP1A2 and CYP3A4.

Warfarin

Enhanced hypoprothrombinemia has been reported when levofloxacin was given with warfarin (40–42).

Levosalbutamol

See also Beta$_2$-adrenoceptor agonists and salbutamol

General Information

Levosalbutamol is the (*R*)-enantiomer of the beta$_2$-adrenoceptor agonist salbutamol. It has been suggested to have a better therapeutic index than racemic salbutamol. As levosalbutamol has a much higher receptor affinity than the (*S*)-enantiomer, the therapeutic effects of racemic salbutamol are assumed to be mediated by levosalbutamol. However, toxicity of levosalbutamol is unrelated to beta$_2$-receptor binding, and so the (*S*)-enantiomer may significantly contribute to the toxicity of racemic salbutamol.

The issue of enantioselective efficacy and safety of salbutamol has been reviewed (1). Interest in "chiral switch," that is the replacement of the racemic formulation by the pharmacologically active (*R*)-enantiomer levosalbutamol, may be hampered by enantiomeric interconversion in vivo and marked interindividual variation in salbutamol pharmacokinetics and pharmacodynamics, owing to complex interactions between genetic and environmental effects. The authors concluded that the advantage of levosalbutamol over the racemic formulation appears to be small with respect to efficacy and controversial with respect to safety. Two large crossover studies with multiple inhaled doses of (*S*)-salbutamol in asthmatic patients showed no evidence of adverse effects on FEV_1 (2,3).

The effects of two doses of inhaled levosalbutamol (0.63 and 1.25 mg) and racemic salbutamol (1.25 and 2.50 mg) on FEV_1 have been studied in a randomized, double-blind trial in 362 asthmatic patients over 4 weeks (4). The average peak FEV_1 for levosalbutamol was significantly greater than that for racemic salbutamol after the first dose but not at week 4. The possible superior bronchodilatation achieved with lower doses of levosalbutamol may be more cost-effective (5).

Lidocaine

See also Local anesthetics

General Information

Lidocaine is the most widely used aminoamide local anesthetic agent, with a low toxic potential; its effects are mostly typical for this class of drug. It can be given by injection or topically and is also combined with prilocaine in Emla for topical administration. It is also used as an antidysrhythmic drug and has occasionally been used in other conditions, such as multiple sclerosis, chronic daily headache, migraine and cluster headaches, and neuropathic pain, such as postherpetic neuralgia.

Local anesthetic gels and creams used liberally on traumatized epithelium can be rapidly absorbed, resulting in systemic effects, such as convulsions, particularly if excessive quantities are used. This has been highlighted in the case of a 40-year-old woman who developed seizures after lidocaine gel 40 ml was injected into the ureter during an attempt to remove a stone (1). Site of administration is also important, as local conditions, particularly vascularity, affect the rate of absorption. Adverse effects of lidocaine when it is used as a local anesthetic can also occur after inadvertent intravascular injection.

The incidence of adverse effects to lidocaine in antidysrhythmic dosages is low. In one series of 750 patients given lidocaine intravenously for cardiac dysrhythmias, adverse reactions occurred in only 47 (6.3%) and were thought to have been life-threatening in 12 (1.6%) (2). However, the risk of adverse effects is dose-related and increases at intravenous infusion rates of around 3 mg/minute (3). Most of the adverse effects are on the cardiovascular and central nervous systems. Nervous system toxicity is directly related to blood concentrations, with symptoms that include light-headedness, headache, dizziness, tremor, confusion, tinnitus, dysarthria, paresthesia, alterations in the level of consciousness from drowsiness to coma, respiratory depression, and convulsions. Cardiovascular effects, including dysrhythmias and very rarely worsening of cardiac function, only occur at very high blood concentrations. The intravenous dose of lidocaine required to produce cardiovascular collapse is seven times that which causes seizures. Risks of serious systemic effects do not increase with age. Deaths have occurred with voluntary intoxication, primarily because of the cardiac effects.

© 2006 Elsevier B.V. All rights reserved.

The active metabolites of lidocaine, glycinexylidide and monoethylglycinexylidide, are toxic and intravenous infusion should not continue for more than 24–48 hours.

Hypersensitivity reactions are rare, and not all reports are clear, but cases do occur and are usually mild (SED-12, 255) (4). Some patients are highly sensitive to lidocaine, yet insensitive to other aminoamide local anesthetics (5), and the reverse has also been found (SEDA-14, 109). True anaphylaxis with rechallenge has been documented (6). A few cases of contact dermatitis have been reported.

Even topical administration of lidocaine continues to generate reports with tragic outcomes, as absorption from mucosal surfaces is underestimated.

- A patient due to have a bronchoscopy was given an overdose of lidocaine to anesthetize the airway by an inexperienced health worker. He was then left unobserved and subsequently developed convulsions and cardiopulmonary arrest (7). He survived with severe cerebral damage.

His lidocaine concentration was 24 μg/ml about 1 hour after initial administration (a blood concentration over 6 μg/ml is considered to be toxic).

Drug studies

Lidocaine has been used to treat some of the symptoms of multiple sclerosis in 30 patients with painful tonic seizures, attacks of neuralgia, paroxysmal itching, and Lhermitte's sign (8). Lidocaine was given by intravenous infusion for 5.5 hours in a maintenance dose of 2.0–2.8 mg/kg/hour after a loading dose, and the mean steady-state concentration was 2.4 μg/ml. Lidocaine almost completely abolished the paroxysmal symptoms and markedly alleviated the persistent symptoms of multiple sclerosis. Adverse effects were not specifically mentioned, but in one case, when the plasma concentration of lidocaine rose above 3.5 μg/ml, weakness of the left leg became marked and was associated with an extensor plantar response; this disappeared when the lidocaine was replaced by saline single-blind, but subsequently the positive symptoms recurred.

Intravenous lidocaine has been used to treat severe chronic daily headache in 19 patients (three men, median age 37 years) (9). There were adverse effects during four infusions of lidocaine: hyperkalemia (6.4 mmol/l), which did not resolve after withdrawal of lidocaine; transient hypotension (75/50 mmHg), which was attributed to concomitant droperidol; an unspecified abnormality of cardiac rhythm and on another occasion a transient bradycardia; and chest pain with a normal electrocardiogram, fever, and intractable nausea. The study was neither randomized nor placebo-controlled, and in no case was the adverse event strongly associated with the administration of lidocaine.

In a double-blind, placebo-controlled study of the use of intravenous lidocaine for neuropathic pain, 16 patients were given 5 ml/kg intravenously over 30 minutes (10). Lidocaine was better than placebo in relieving pain. The major adverse effect was light-headedness, which occurred in seven patients given lidocaine and none given saline. Other adverse effects included somnolence, nausea and vomiting, dysarthria or garbled speech, blurred vision, and malaise. In two patients the rate of infusion had to be reduced because of adverse effects.

Organs and Systems

Cardiovascular

Lidocaine can cause dysrhythmias and hypotension. The dysrhythmias that have been reported include sinus bradycardia, supraventricular tachycardia (11), and rarely torsade de pointes (12). There have also been rare reports of cardiac arrest (2) and worsening heart failure (13). Lidocaine can also cause an increased risk of asystole after repeated attempts at defibrillation (14). Lidocaine may increase mortality after acute myocardial infarction, and it should be used only in patients with specific so-called warning dysrhythmias (that is frequent or multifocal ventricular extra beats, or salvos) (15).

Sinus bradycardia has been seen after a bolus injection of 50 mg, atrioventricular block after a dose of 800 mg given over 12 hours, and left bundle branch block after a mere subconjunctival injection of 2% lidocaine.

- High-grade atrioventricular block has been reported in a 14-day-old infant who was given lidocaine 2 mg/kg intravenously (SED-12, 255) (16).

A death due to ventricular fibrillation after 50 mg and another due to sinus arrest after 100 mg have been reported (SED-12, 255) (17). Two cases of ventricular fibrillation and cardiopulmonary arrest occurred after local infiltration of lidocaine for cardiac catheterization (SEDA-21, 136).

Lidocaine does not usually cause conduction disturbances, but two cases have been reported in the presence of hyperkalemia (18).

- A 57-year-old man with a wide-complex tachycardia was given lidocaine 100 mg intravenously and immediately became asystolic. Resuscitation was unsuccessful.
- A 31-year-old woman had a cardiac arrest and was resuscitated to a wide-complex tachycardia, which was treated with intravenous lidocaine 100 mg. She immediately became asystolic but responded to calcium chloride.

In both cases there was severe hyperkalemia, and the authors suggested that hyperkalemia-induced resting membrane depolarization had increased the number of inactivated sodium channels, thus increasing the binding of lidocaine and potentiating its effects.

The degree of hypotension occurring after epidural anesthesia with alkalinized lidocaine (with adrenaline) was greater than with a standard commercial solution (SED-12, 255) (19).

In 23 patients there was a significant dose-dependent reduction in blood pressure following submucosal infiltration of lidocaine plus adrenaline compared with saline plus adrenaline for orthognathic surgery (20). The study was randomized but small; larger studies are needed to confirm effects that could easily have been due to multifactorial causes in patients undergoing general anesthesia.

Respiratory

Topical anesthesia of the airways is commonly used to facilitate endoscopy and sometimes manipulation of the airways. This can result in an increase in airway flow resistance, possibly due to laryngeal dysfunction (21). Lidocaine spray 10%, used for upper airways anesthesia for fiberoptic intubation in a grossly obese patient, caused acute airway obstruction. The patient went on to have a percutaneous tracheotomy, and it was postulated that the local anesthetic had abolished laryngeal receptors responsible for airway maintenance, or that laryngospasm and reduced muscle tone due to the lidocaine might have been the cause (SEDA-22, 140).

Life-threatening bronchospasm can occur after either spinal or topical use of lidocaine. In one series of patients being treated with lidocaine spray 40 mg for persistent cough, there was an increase of airway resistance (SED-12, 255) (22).

Ear, nose, throat

Local anesthesia to the larynx, for example with 4% lidocaine, is generally safe. Laryngeal edema has been reported in a few cases and could be due to the propellant rather than to lidocaine itself (23).

Intranasal 4% lidocaine has been used for migraine and cluster headaches with success and few serious adverse effects: a bitter taste was common and some patients complained of nasal burning and oropharyngeal numbness (SEDA-20, 127).

Lidocaine gel is not recommended for lubrication of laryngeal masks. It confers no benefits and increases the incidence of adverse effects such as intraoperative hiccups, postoperative hoarseness, nausea, vomiting, and tongue paresthesia (24).

Nervous system

Nervous system toxicity is most often seen with rapid intravenous infusion (3,25,26). The effects include headache, dizziness, tremor, confusion, tinnitus, dysarthria, paresthesia, respiratory depression, altered level of consciousness (from drowsiness to coma), and convulsions.

Two cases have illustrated the effects of lidocaine in precipitating partial seizures in patients with a previous history of epilepsy (27).

- A 36-year-old woman developed chest pain and ventricular tachycardia. She had a 14-year history of right-sided focal motor seizures controlled with phenytoin. After receiving intravenous lidocaine 100 mg to treat the dysrhythmias, she developed a typical seizure involving the right side of her face and arm. She was given a loading dose of phenytoin and the seizure abated. However, the ventricular tachycardia persisted and was treated with additional lidocaine 50 mg followed by an infusion of 3.3 mg/minute; 6 hours later she had a generalized seizure with a venous blood lidocaine concentration of 21 μg/ml. The infusion was stopped and the seizure was treated with intravenous diazepam 10 mg.
- A 41-year-old woman with a long-standing history of focal and secondarily generalized seizures controlled with carbamazepine underwent cerebral arteriography, during which she was inadvertently given lidocaine 20 mg via an intra-arterial catheter in the right internal carotid artery; within 20 seconds she had a focal seizure.

These two patients had their typical partial seizures triggered by high doses of lidocaine. In both cases the serum concentrations of their usual anticonvulsants were initially low. The first patient received a loading dose of phenytoin after the partial seizure, was then given a second bolus of lidocaine and an infusion, and then had a second seizure, which was generalized. There was no evidence that this second seizure evolved from the left seizure focus. The authors concluded that lidocaine can activate seizure foci in patients with a history of partial seizures and that this may be more likely if the serum concentrations of anticonvulsants are low. However, therapeutic concentrations of antiepileptic drugs may not prevent generalized seizures that result from the widespread lowering of seizure threshold caused by high concentrations of lidocaine.

A tonic-clonic seizure occurred after the application of 400 mg of lidocaine jelly to traumatized ureteric mucosa (SEDA-22, 142).

- A 54-year-old woman who was given lidocaine, 200 mg intravenously, for ventricular fibrillation during cardiopulmonary bypass, had a tonic-clonic seizure (28). The seizure occurred immediately after the administration of lidocaine and was relieved by the intravenous administration of thiopental and midazolam. Her ventricular fibrillation responded to procainamide 1 g intravenously over 10 minutes.

The pharmacokinetics of lidocaine are altered by cardiopulmonary bypass, because of hemodilution, changed protein binding, the exclusion of the lungs as an organ for first-pass elimination, altered acid-base balance, and sometimes drug interactions. In particular, reduced protein binding may have contributed in this case to the risk of seizure, but plasma lidocaine concentrations were not measured.

- A 30-year-old woman received two 5 g applications of 40% lidocaine cream with occlusion by plastic wrap during and after laser therapy to areas of her skin (29). She developed dizziness and headache postoperatively, followed 45 minutes later by light-headedness, increasing dizziness, and confusion. The dressings were removed. The lidocaine concentration was 2.7 μg/ml 7 hours later.

It is recommended that repeat applications of lidocaine, especially in high-concentration formulations, be avoided and the area of application limited.

- A 16-year-old woman had had an adverse reaction after administration of an unknown local anesthetic agent for a dental procedure. Patch testing had elicited similar symptoms with lidocaine only, and 20 minutes after subcutaneous lidocaine 0.05 mg she developed perioral paresthesia, nausea, vomiting, vertigo, dizziness, mild agitation, drowsiness, and euphoria. Hemodynamic parameters remained stable but her symptoms were thought to be part of a genuine non-allergic, neuropsychiatric reaction, as the patch testing was double-blind and placebo-controlled (30).

Transient and permanent nerve damage can occur after regional anesthesia, particularly neuraxial anesthesia. The mechanism of this nerve damage is unclear. Some studies have shown an indirect effect. However, in crayfish giant axon, lidocaine had a dose- and time-dependent effect on isolated nerve function in vitro (31). At high concentrations lidocaine caused irreversible conduction block and total loss of resting membrane potential. These results in an isolated nerve suggest a direct neurotoxic effect of lidocaine.

Sensory systems

Tinnitus and visual disturbances are early components of a systemic toxic reaction to lidocaine.

Eyes

A potentially beneficial effect of lidocaine has been studied in a randomized, double-blind, placebo-controlled study of the effects of preinstillation of lidocaine on tropicamide-induced mydriasis (32). Pupillary diameter was significantly increased by the instillation of lidocaine before tropicamide. It was thought that lidocaine can enhance intraocular penetration and hence potentiate the effect of tropicamide.

Double vision and difficulty in focusing have been attributed to lidocaine applied to the tongue (33).

- A 22-year-old man developed double vision and difficulty in focusing after using 2% viscous lidocaine for a painful tongue ulcer. He used viscous 2% lidocaine 10 ml hourly and developed symptoms when the daily dose exceeded 240 ml (4800 mg of lidocaine hydrochloride) after 10 days of use. At that time his serum lidocaine concentration was 6.7 μg/ml. His symptoms persisted when the serum concentration of lidocaine fell to below toxic concentrations, implying that metabolites of lidocaine had contributed.

Temporary blindness, an unusual feature of lidocaine toxicity, has been reported in an otherwise healthy young woman (34).

- A 21-year-old 50 kg woman, previously fit, was to have an open reduction and fixation of a fractured proximal phalanx with intravenous regional anesthesia. As a result of misreading the vial label, 30 ml (600 mg) of 2% lidocaine was injected, and this inadvertent error was immediately recognized. The decision was made to continue with the procedure, which was uneventful, with a tourniquet time of 45 minutes. At this point the patient complained of severe tourniquet pain, and without the anesthesiologist's knowledge the cuff was deflated. Immediately she developed a tachycardia, complained of visual disturbances, and became unconscious. She had a seizure, which lasted 30 seconds and resolved with midazolam. She became more alert, but complained of reduced vision. Neurological examination was normal, apart from temporary blindness; this fully resolved within 10 minutes. There were no long-term neurological or visual sequelae.

The authors suggested that the visual symptoms could have occurred as a result of occipital lobe seizure activity or subcortical stimulation, due to the acute high cerebral concentration of lidocaine. The speed of spontaneous resolution was consistent with the pharmacokinetics of lidocaine.

Pupillary mydriasis occurred in a neonate who was given intravenous lidocaine 3 mg/kg/hour as an anticonvulsant (35).

Taste

Taste disturbance has been reported with lidocaine (36).

- A 73-year-old woman was given a Nadbath Rehman block behind the left pinna to provide motor blockade of cranial nerve VII, before retrobulbar block for cataract surgery. Several minutes later she complained of a metallic taste in her mouth. After surgery she had altered taste sensation on the anterior left side of the tongue, with recovery a day later.

The author postulated this to be due to block of the chorda tympani, which runs with cranial nerve VII close to the site of the Nadbath Rehman block.

Metabolism

High systemic doses of lidocaine can cause transient hypoglycemia (SED-12, 255) (37).

Electrolyte balance

There has been one report of hypokalemia (2.2 mmol/l), probably due to potassium channel blockade, after administration of high-dose intravenous lidocaine (8 mg/l) for raised intracranial pressure (SEDA-21, 136).

Hematologic

Severe thrombocytopenic purpura with a lidocaine-mediated antiplatelet IgM antibody has been reported (SED-12, 255) (38).

Three cases of lidocaine-induced methemoglobinemia have been reported in patients undergoing topical anesthesia of the airway and oropharynx (39).

- A 26-year-old woman undergoing bronchoscopy received lidocaine jelly 2% to each nostril, lidocaine solution 2% sprayed on the throat, and 10 ml of lidocaine solution 2% into the trachea. She was also given intravenous diazepam 5 mg and pethidine 75 mg and intramuscular atropine 0.6 mg. She developed dyspnea and cyanosis after the procedure and despite 100% oxygen, her SpO_2 was 85%. Her methemoglobin concentration was 14%.
- A 61-year-old woman was given 15 ml of lidocaine solution 2% and lidocaine spray 4% for topical anesthesia of the throat and oropharynx before upper gastrointestinal endoscopy. She was also sedated with intravenous midazolam 2 mg and pethidine 75 mg. She became cyanosed and desaturated (SpO_2 78%) immediately after the procedure. Her SpO_2 did not recover, despite 100% oxygen. Her methemoglobin concentration was 37%.
- In preparation for transesophageal echocardiogram, a 73-year-old woman was given 15 ml of lidocaine solution 2% and lidocaine spray 4% to anesthetize the oropharynx, plus intravenous midazolam 1 mg and pethidine 12.5 mg. She very rapidly became cyanosed, but remained

© 2006 Elsevier B.V. All rights reserved.

asymptomatic. Her SpO_2 was 85% on oxygen 2 l/minute and her methemoglobin concentration was 25%.

Liver

Liver damage due to lidocaine has rarely been reported. However, severe liver damage has been reported shortly after the withdrawal of mexiletine 300 mg/day and the introduction of lidocaine 1000 mg/day, although lidocaine in the same dose had been used during the previous week (40). The lidocaine was withdrawn and the liver enzymes normalized after treatment with prednisolone.

Skin

Topical 5% lidocaine to 33 patients with postherpetic neuralgia in a crossover trial provided significantly more pain relief than a vehicle patch placebo (41). There was no difference in reported adverse effects: skin redness or rash was reported by 9 in the lidocaine patch phase and 11 in the placebo phase. One patient stopped using the placebo patch owing to red irritated skin, which resolved after the application of lidocaine patches.

Treatment of 27 HIV-infected patients with distal sensory polyneuropathy (the most common neurological disorder associated with HIV) with 5% lidocaine gel resulted in effective analgesia in 75% of patients; three had dry skin and one had blisters (42).

In a phase IV trial, 66% patients with postherpetic neuralgia gained relief from a 5% lidocaine patch applied to the most painful area of the body (43). The lidocaine patch was well tolerated, a rash being the most common adverse effect, in 14% of patients.

Several cases of contact dermatitis have been reported with lidocaine. Generalized exfoliative dermatitis has also been noted once. Local inflammation and necrosis, possibly due to mechanical pressure, are both complications at the injection site.

- A 60-year-old woman was given infiltration anesthesia with lidocaine hydrochloride for removal of a melanoma (44). She developed an itchy dermatitis over the area 36 hours later. Conventional patch testing was negative at 48 and 72 hours to lidocaine and mepivacaine (both amides), as was intracutaneous testing with lidocaine 2%, mepivacaine 2%, and bupivacaine 0.5%. However, intradermal testing at 1/100 dilutions was positive, with itching and erythema at 48 hours with lidocaine and mepivacaine, suggesting delayed hypersensitivity to these drugs, but not with bupivacaine.

It has previously been reported that lidocaine and mepivacaine have a high degree of cross-reactivity not seen with bupivacaine.

Sexual function

Two cases of impotence after anesthesia for elective circumcision in adults have been described (SED-12, 256) (45), but it is very doubtful whether this was a pharmacological and not merely a psychological effect.

Immunologic

There have been 62 reports of allergic contact dermatitis to lidocaine worldwide between 1972 and 1996; 49 were in Australia and several showed cross-reactivity with other amide local anesthetics, such as bupivacaine, mepivacaine, and prilocaine (46).

Body temperature

There is no reliable evidence to support reports of malignant hyperthermia due to local anesthetic agents. In 307 dental patients susceptible to malignant hyperthermia who received local anesthesia, only one had ever developed symptoms suggestive of malignant hyperthermia, after mepivacaine and on another occasion lidocaine (47). Both reactions resolved without specific therapy. There has been one case report of cyanosis, muscle rigidity, tachycardia, tachypnea, a temperature of 41.5°C, and loss of consciousness in a patient who received epidural lidocaine and bupivacaine (48). However, perioperative stress may itself be a potential trigger of malignant hyperthermia.

Death

In New York City, five of 50 000 deaths over a 5-year period were associated with tumescent liposuction; all had received lidocaine in doses of 10–40 mg/kg in association with general anesthesia and/or intravenous sedation and analgesia (49). Three patients died as a result of severe acute intraoperative hypotension and bradycardia with no identified cause, one died of fluid overload, and another died of pulmonary embolism. The authors speculated that lidocaine toxicity or lidocaine-related drug interactions could have contributed to some of the deaths, but other causes could not be ruled out.

In California, six cases of cardiac arrest or severe hypoxemia associated with outpatient liposuction resulted in four deaths over a 3.5-year period, all in women aged 38–62 years; one had a cardiac arrest after sedation and the administration of local anesthetic but before liposuction was started, four had respiratory difficulties and cardiac arrest after liposuction, and one had respiratory difficulties during liposuction (50). Whether the cause of morbidity and mortality in any of these cases was related to local anesthetic toxicity was not mentioned.

A weak solution of lidocaine has sometimes been injected into excess fat before liposuction, so that the procedure can be carried out without general anesthesia. The technique is generally regarded as safe (51). However, deaths are increasingly reported, associated with local anesthetic toxicity or drug interactions (49).

A 19-year-old healthy volunteer undergoing bronchoscopy was given about 1200 mg of lidocaine to anesthetize the airway and was sent home after the procedure, despite complaining of chest pain. Shortly afterwards she had a tonic-clonic seizure and cardiopulmonary arrest and died 2 days later. The research protocol had failed to specify an upper dose limit for lidocaine (52).

Second-Generation Effects

Fetotoxicity

Because of rapid transfer across the placenta and the prolonged half-life of lidocaine in neonates, lidocaine can cause fetal acidosis (SEDA-8, 127). Fetal bradycardia

© 2006 Elsevier B.V. All rights reserved.

is usually observed only in those fetuses with pre-existing heart rate deceleration. Despite massive intoxication at birth, one child had normal behavioral development at 7 months of age (SED-12, 256) (53).

Lactation

Low concentrations of lidocaine and its metabolite monoethylglycinexylidide (MEGX) have been found in breast milk after a dental procedure, but no risk seems to be involved (54).

Susceptibility Factors

Age

Children

Two reports have illustrated the need for particular care when using local anesthetics in neonates and small children. A 2-year-old child died from the combined effects of chloral hydrate, lidocaine, and nitrous oxide for a dental procedure (55). The doses used were not clarified, but in postmortem blood the plasma concentration of lidocaine was 12 μg/ml. The level and adequacy of perioperative monitoring was also not clear.

A neonate who needed a tracheostomy 10 days after a tracheoesophageal fistula repair was given intravenous lidocaine, 1 mg/kg followed 15–20 minutes later by 0.7 mg/kg. Immediately after, tonic-clonic seizures developed. The child recovered, with no observable ill effects at 6 months.

The authors pointed out that the dose of lidocaine used was well within recommended dosage limits. However, they stressed that a more appropriate dosing schedule should be worked out for neonates.

Lidocaine pharmacokinetics tend to follow a single compartment model in neonates, with an increased half-life, and substantially reduced protein binding, leading to a much larger volume of distribution than in adults, but an increased proportion of unbound drug (56).

Elderly people

In the elderly, some local anesthetics (including lidocaine and bupivacaine) have longer durations of action (57).

Sex

That sex differences can affect lidocaine pharmacokinetics is suggested by a report of higher blood concentrations in men than in women after administration of the same dose (SED-12, 256) (58).

Hepatic disease

In patients with heart and liver disease, the dosage requirement of lidocaine is reduced; the half-life of lidocaine is substantially longer in patients with liver disease (59).

Other features of the patient

The adverse effects of lidocaine are dose-related, and are more common in people of light weight and in patients with acute myocardial infarction or congestive cardiac failure. There is also an increased risk of central nervous system effects during cardiopulmonary bypass (60). In cardiac failure, shock, and postoperatively, there are reductions in both the metabolism and the apparent volume of distribution of lidocaine; dosages should be altered accordingly (61).

Drug Administration

Drug additives

The addition of dextran to a lidocaine + adrenaline solution used for infiltration reduced the absorption of both (62).

Alkalinization of local anesthetic solutions should theoretically lead to a faster onset of effect and prolonged anesthesia. However, raising the pH of the solution can cause the local anesthetic to precipitate out of solution, and one study with 2% lidocaine has shown no difference in quality or onset of anesthesia (SEDA-20, 129).

Adrenaline 1:100 000, added to lidocaine 2%, has caused full-thickness skin necrosis when used for ambulatory phlebectomy for varicose veins (SEDA-21, 136).

Drug administration route

Creams and gels

Cutaneous absorption of lidocaine is negligible through normal skin after short-term application. However, when applied to erosive lesions over large body areas, significant absorption may occur. When the drug is applied to mucous membranes, blood levels simulate those resulting from intravenous injection. Local anesthetic creams and gels used liberally on traumatized epithelium can be rapidly absorbed, resulting in systemic effects, such as convulsions, particularly if excessive quantities are used. This has been highlighted in the case of a 40-year-old woman who developed seizures after lidocaine gel 40 ml was injected into the ureter during an attempt to remove a stone (1).

Topical administration of lidocaine to the nasal mucosa occasionally causes severe methemoglobinemia in patients who have the heterozygous form of NADH methemoglobin reductase deficiency (63).

Subcutaneously in liposuction

Some have suggested that lidocaine is unnecessary and potentially toxic in liposuction, and that it provides no postoperative pain relief (64). Others think that lidocaine toxicity is not a major cause of death during liposuction, stating that all reported deaths after liposuction have been associated with general anesthesia or sedation, including the five in New York, and that doses of lidocaine higher than those used in these cases (10–40 mg/kg) are routinely used in tumescent liposuction, no deaths having been reported (50,65). It is possible that adrenaline, high pressure injection, removal of lidocaine by liposuction, and the development of tolerance all contribute to delay in absorption and lack of toxic symptoms at higher than expected plasma concentrations (66).

Patches

Lidocaine is available as a topical analgesic in an adhesive patch formulation for the pain of postherpetic neuralgia.

© 2006 Elsevier B.V. All rights reserved.

The pharmacokinetics and safety of the 5% lidocaine patches have been studied in 20 healthy volunteers, who applied four patches to the skin either every 24 hours or every 12 hours for 3 days (67). Mean steady-state plasma concentrations were 186 and 225 ng/ml respectively, well below those required for an antidysrhythmic effect (1500 ng/ml) or a risk of toxicity (5000 ng/ml). The patches were well tolerated, with no major cutaneous adverse effects. This is in line with data from postmarketing surveillance studies, which have shown that since the availability of lidocaine patches in 1999, no adverse cardiac or other serious adverse events have been reported (68).

The pharmacokinetics of lidocaine in patches have been investigated in two studies. In 20 healthy volunteers, 5% lidocaine patches were applied for 18 hours/day on 3 consecutive days (69). The mean peak concentrations on days 1, 2, and 3 were 145, 153, and 154 ng/ml respectively; the median values of t_{max} were 18.0, 16.5, and 16.5 hours; and the mean trough concentrations were 83, 86, and 77 ng/ml. The patches were well tolerated; local skin reactions were generally minimal and self-limiting. In 20 healthy volunteers, 4 lidocaine patches were applied every 12 or 24 hours on 3 consecutive days (67). The mean maximum-plasma lidocaine concentrations at steady state were 225 and 186 ng/ml respectively. There was no loss of sensation at the site of application. No patient had edema and most cases of erythema were very slight. No systemic adverse events were judged to be related to the patches.

Drug overdose

Inadvertent intravenous injection of lidocaine 1 g resulted in asystole, apnea, and tonic-clonic seizures, with full recovery after 6 hours of intensive resuscitation (SED-12, 256) (70).

Fatal accidental overdose has been reported in a child (71).

- An 18-month-old infant died after swallowing an unknown amount of 2% viscous lidocaine. He rapidly became unwell at home, with convulsions, followed by an asystolic cardiorespiratory arrest. He was intubated and resuscitated by paramedics, but continued to have seizures. He was given anticonvulsants and cardiorespiratory resuscitation was unsuccessful. Toxicological tests identified high concentrations of lidocaine and its metabolites.

Owing to the rare but serious poisonings reported to date, 2% viscous lidocaine should not be prescribed for children under 6 years of age.

An unusual case of homicide using an overdose of intravenous lidocaine has been described (72).

- A 32-year-old man, who had been in hospital for several months because of acute intermittent porphyria and chronic pancreatitis, had a seizure and an asystolic cardiac arrest. Resuscitation was unsuccessful. There was a suspicion of patient mistreatment by one of the attending nurses, and toxicological analyses showed high blood concentrations of lidocaine, diazepam, phenytoin, and promethazine. Diazepam and phenytoin had been administered during resuscitation but lidocaine had not.

The cause of death was given as a ventricular dysrhythmia caused by a lidocaine overdose (total dose about 1500 mg); a nurse was later arrested and tried for murder.

Drug–Drug Interactions

Argatroban

The thrombin inhibitor argatroban had no effect on the pharmacokinetics of intravenous lidocaine 1.5 mg/kg for 10 minutes followed by 2 mg/kg/hour for 16 hours in 12 healthy volunteers; the argatroban was given as an intravenous infusion of 2 μg/kg/minute for 16 hours (73).

Beta-adrenoceptor antagonists

The combination of lidocaine with beta-adrenoceptor antagonists is associated with a slightly increased risk of some minor non-cardiac adverse events (dizziness, numbness, somnolence, confusion, slurred speech, and nausea and vomiting) (74). The combination is not associated with an increased risk of dysrhythmias.

Some beta-blockers reduce hepatic blood flow and inhibit microsomal enzymes, reducing the clearance of lidocaine; there is a clinically significant increase in the plasma concentration of lidocaine during concomitant propranolol therapy (75).

Cimetidine

Cimetidine inhibits the metabolism of lidocaine (76,77) and reduces protein binding, increasing toxicity.

Erythromycin

The effects of erythromycin, an inhibitor of CYP3A4, on the pharmacokinetics of lidocaine have been studied in nine healthy volunteers. Steady-state oral erythromycin had no effect on the plasma concentration versus time curve of lidocaine after intravenous administration, but erythromycin increased the plasma concentrations of the major metabolite of lidocaine, MEGX (78). It is not clear what the interpretation of these results is, particularly since the authors did not study enough subjects to detect what might have been small but significant changes in various disposition parameters of lidocaine and did not report unbound concentrations of lidocaine or its metabolites. However, whatever the pharmacokinetic explanation, the clinical relevance is that one would expect that erythromycin would potentiate the toxic effects of lidocaine that are mediated by MEGX.

Itraconazole

The effects of itraconazole, an inhibitor of CYP3A4, on the pharmacokinetics of lidocaine have been studied in nine healthy volunteers. Steady-state oral itraconazole had no effect on the plasma concentration versus time curve of lidocaine after intravenous administration nor on the plasma concentrations of the major metabolite of lidocaine, MEGX (78).

© 2006 Elsevier B.V. All rights reserved.

Mexiletine

An interaction of lidocaine with mexiletine, which resulted in toxic concentrations of lidocaine, has been reported (79).

- An 80-year-old man with a dilated cardiomyopathy was given a lidocaine infusion started at 90 mg/hour for a ventricular tachycardia. He was already taking mexiletine 400 mg/day, and the plasma concentration was within the usual target range; however, the dose was reduced to 200 mg/day to avoid possible adverse effects. Intermittent ventricular tachycardia persisted, and so the lidocaine infusion was increased to 120 mg/day, but adverse effects (involuntary movements, muscle rigidity) were observed. The lidocaine infusion was stopped and within 20 minutes the adverse effects abated; the lidocaine concentration was 6.84 μg/ml. The ventricular tachycardia persisted, lidocaine was restarted at a lower rate, and the oral dose of mexiletine was increased to 450 mg/day. This resulted in an unexpectedly high concentration of lidocaine and the lidocaine concentration was significantly higher while the mexiletine dose was high.

Further studies suggested that mexiletine had displaced lidocaine from tissue binding sites. The authors suggested that this finding has implications for loading doses and acute effects of lidocaine in the concurrent therapy of lidocaine and mexiletine and highlighted the importance of close monitoring of lidocaine concentrations in this setting.

Opioid analgesics

A synergistic interaction of intrathecal fentanyl 100 μg and morphine 0.5 mg, given before induction, with systemically administered lidocaine 200 mg 4 hours later for ventricular tachycardia, resulted in potentiation of opioid effects in a 74-year-old man with major heart disease after coronary artery bypass grafting; during the 5 minutes after lidocaine he had a respiratory arrest with loss of consciousness and miotic pupils, all reversed by naloxone (80). The proposed mechanism was thought to be a reduction in calcium ion concentrations in opioid-sensitive CNS sites.

Propafenone

The CNS toxicity of lidocaine was increased in 11 healthy volunteers who simultaneously received propafenone, which reduced the metabolism of lidocaine (81).

Propofol

Propofol dose-dependently reduced the threshold for lidocaine-induced convulsions in rats (82). Higher doses of propofol completely abolished convulsions. However, there was no difference in the dose of lidocaine that caused cardiac arrest and death, when it was given with three different propofol infusions and placebo.

Ranitidine

Ranitidine inhibits the clearance of lidocaine (77).

Suxamethonium

Procaine and cocaine are esters that are hydrolysed by plasma cholinesterase and may therefore competitively enhance the action of suxamethonium (83). Chloroprocaine may have a similar action. Lidocaine also interacts, although the mechanism is not clear unless very high doses are used (84).

Lidoflazine

See also Calcium channel blockers

General Information

Lidoflazine is a calcium channel blocker (1). The use of lidoflazine in patients with microvascular angina has been associated with malignant ventricular dysrhythmias (SEDA-16, 199).

Liliaceae

See also Herbal medicines

General Information

The genera in the family of Liliaceae (Table 1) include various types of lily, amarylis, asphodel, crocus, daffodil, fritillary, hyacinth, onions (including garlic), snowdrop, and tulip.

Food allergy to spices accounts for 2% of all cases of food allergies but 6.4% of cases in adults. Prick tests to native spices in 589 patients with food allergies showed frequent sensitization to the Liliaceae garlic, onion, and chive (4.6% of prick tests in children, 7.7% of prick tests in adults) (1).

Allium sativum

Allium sativum (garlic, camphor of the poor, da suan, poor man's treacle, rustic treacle, stinking rose) contains a variety of amino acids and steroids, including ajoene, alliin, allicin, glutamyl-*S*-allylcysteine, and glutamyl-*S*-(2-carboxy-1-propyl)-cysteinglycine. Traditionally it has been used as an antiseptic, diaphoretic, diuretic, expectorant, and stimulant and in the treatment of asthma, hoarseness, cough, difficulty in breathing, chronic bronchitis, leprosy, tubercular consumption, whooping-cough, worms, epilepsy, rheumatism, dropsy, and hysteria. In modern times it has been used as a hypolipidemic (2), although its effect is small (3).

Table 1 The genera of Liliaceae

Aletris (colicroot)
Allium (onion)
Alstroemeria (lily of the Incas)
Amaryllis (amaryllis)
Amianthium (amianthium)
Androstephium (funnel lily)
Asparagus (asparagus)
Asphodelus (asphodel)
Astelia (pineapple grass)
Bloomeria (golden star)
Brodiaea (brodiaea)
Calochortus (mariposa lily)
Camassia (camas)
Chamaelirium (chamaelirium)
Chionodoxa (chionodoxa)
Chlorogalum (soap plant)
Chlorophytum (chlorophytum)
Clintonia (blue bead)
Colchicum (crocus)
Convallaria (lily of the valley)
Cooperia (rain lily)
Cordyline (cordyline)
Crinum (swamp lily)
Curculigo (curculigo)
Dasylirion (sotol)
Dianella (dianella)
Dichelostemma (snake lily)
Disporum (fairy bells)
Echeandia (echeandia)
Eremocrinum (eremocrinum)
Erythronium (fawn lily)
Eucharis (Amazon lily)
Fritillaria (fritillary)
Gagea (gagea)
Galanthus (snowdrop)
Gloriosa (flame lily)
Habranthus (copper lily)
Harperocallis (harperocallis)
Hastingsia (rush lily)
Helonias (helonias)
Hemerocallis (day lily)
Hesperocallis (desert lily)
Hippeastrum (hippeastrum)
Hosta (plantain lily)
Hyacinthoides (hyacinthoides)
Hyacinthus (hyacinth)
Hymenocallis (spider lily)
Hypoxis (star grass)
Kniphofia (red hot poker)
Leucocrinum (star lily)
Leucojum (snowflake)
Lilium (lily)
Liriope (lily turf)
Lloydia (alp lily)
Lophiola (lophiola)
Lycoris (lycoris)
Maianthemum (may flower)
Medeola (Indian cucumber)
Melanthium (bunch flower)
Merendera
Milla (milla)
Muilla (muilla)
Muscari (grape hyacinth)
Narcissus (daffodil)
Narthecium (asphodel)
Nolina (bear grass)
Nothoscordum (false garlic)
Odontostomum (Hartweg's doll's-lily)
Ophiopogon (ophiopogon)
Ornithogalum (star of Bethlehem)
Ornithoglossum
Pleea (pleea)
Pleomele (hala pepe)
Polygonatum (Solomon's seal)
Ruscus (broom)
Schoenocaulon (feathershank)
Schoenolirion (sunnybell)
Scilla (scilla)
Scoliopus (fetid adder's tongue)
Stenanthium (featherbells)
Sternbergia (winter daffodil)
Streptopus (twisted stalk)
Tofieldia (tofieldia)
Tricyrtis (tricyrtis)
Trillium (trillium)
Tristagma (springstar)
Triteleia (triteleia)
Triteleiopsis (Baja lily)
Tulipa (tulip)
Uvularia (bellwort)
Veratrum (false hellebore)
Xerophyllum (bear grass)
Zephyranthes (zephyr lily)
Zigadenus (death camas)

Adverse effects

Respiratory

Occupational inhalation of garlic powder can lead to asthma (4).

Nervous system

A spontaneous spinal epidural hematoma resulting in paraplegia in an 87-year-old patient was attributed to chronic excessive use of garlic cloves (5).

Hematologic

Bleeding due to impaired platelet function has been attributed to garlic (6).

- A 54-year-old woman underwent strabismus surgery and had bilateral retrobulbar hemorrhages intraoperatively. In the absence of other possible causes, the authors thought that the bleeding had been due to garlic pills prescribed by a naturopath. On the day of surgery, she had taken five pills, equivalent to about 5 g of fresh garlic bulb. Platelet function, measured 2 weeks later, was normal.

Garlic has well-documented effects on platelet aggregation (7).

Skin

Topical administration of garlic can lead to allergic contact dermatitis or burn-like skin lesions (8).

- A 50-year-old Romanian man was advised by his herbalist to treat his asthma with a compress of freshly crushed garlic (9). He wore the compress on his forehead overnight and subsequently developed second-degree burns in this area. Specific IgE RAST tests for

© 2006 Elsevier B.V. All rights reserved.

garlic were negative. He was treated conservatively and made an uneventful recovery.
- Two Korean patients used topical garlic for pruritus and subsequently developed irritant contact dermatitis of the treated skin areas (10). Withdrawal resulted in full recovery.

Of about 1000 patients with occupational skin diseases, five had occupational allergic contact dermatitis from spices (11). They were chefs or workers in kitchens, coffee rooms, and restaurants. In all cases the dermatitis affected the hands. The causative spices were garlic, cinnamon, ginger, allspice, and clove. The same patients had positive patch-test reactions to carrot, lettuce, and tomato.

Drug interactions

The antiplatelet activity of garlic might lead to over-anticoagulation when garlic and warfarin are administered concomitantly (12). However, evidence of such an effect is scanty (13).

Colchicum autumnale

Colchicum autumnale (autumn crocus) and other *Colchicum* species belong to the family known as the Colchicaceae, a proposed subdivision of the Liliaceae. They contain colchicine and related alkaloids. Other members of the Colchicaceae include *Gloriosa* species and *Merendera* species. *C. autumnale* (autumn crocus) is the traditional source of colchicine, which is covered in a separate monograph.

Another plant subdivision, the Wurmbaeoideae, includes *Androcymbium* species, *Iphigenia* species, and *Wurmbea* species, which also contain colchicine. *Iphigenia indica* (shan cigu) is a traditional Chinese herbal medicine (14).

Ruscus aculeatus

Ruscus aculeatus (butcher's broom, knee holy, knee holly, knee holm, Jew's myrtle, sweet broom, pettigree) has been used topically for vasoconstrictor treatment of varicose veins and hemorrhoids (15), and for chronic venous insufficiency, both alone (16,17) and in the combination known as Cyclo 3 fort, marketed in France, which contains an extract of *R. aculeatus* 150 mg, hesperidin methyl chalcone 150 mg, ascorbic acid 100 mg, and metesculetol.

In a meta-analysis of the efficacy of Cyclo 3 fort in patients with chronic venous insufficiency 20 double-blind, randomized, placebo-controlled studies and 5 randomized comparison studies in 10 246 subjects were included (18). Cyclo 3 fort significantly reduced the severity of pain, cramps, heaviness, and paresthesia compared with placebo. There were also significant reductions in venous capacity and severity of edema.

Adverse effects

Gastrointestinal

Chronic diarrhea has been described with Cyclo 3 fort and attributed to a disturbance of gastrointestinal motility (SEDA-16, 205) (SEDA-17, 244). However, the mechanism may be immunological, since lymphocytic colitis has occasionally been reported (19).

Skin

R. aculeatus can cause allergic contact dermatitis (20).

Veratrum species

The rhizome and root of *Veratrum album* (white hellebore) and the rhizome of *Veratrum viride* (green hellebore) contain many alkaloids, including hypotensive ester alkaloids and jervine. *Veratrum californicum* contains the alkaloids cyclopamine, cycloposine, and jervine.

Adverse effects

Among the major toxic symptoms of the veratrum alkaloids are vomiting, hypotension, and bradycardia.

V. californicum is teratogenic activity in livestock (21).

Drug overdose

Veratrum poisoning can cause heartburn and vomiting, bradydysrhythmias, atrioventricular dissociation, and vasodilatation with hypotension (22,23). It can be fatal (24).

Of 12 patients, aged 20–80 years, with acute hellebore (*V. album*) intoxication, 10 had a sinus bradycardia at about 40/minute, shortening of the PR interval down to 0.08–0.12 seconds and of the QT_c interval down to 0.32–0.36 seconds, transient right and incomplete left bundle-branch block, atrial and ventricular extra beats, nodal rhythm ($n = 1$), and altered ventricular repolarization (25). The authors suggested that the bradycardia due to *V. album* is caused by a reflex increase in vagal tone and responds to atropine.

Five patients with acute accidental poisoning with *V. album* rapidly developed nausea, vomiting, abdominal pain, hypotension, and bradycardia (26). In four cases the electrocardiogram showed sinus bradycardia and in one there was complete atrioventricular block with an ectopic atrial bradycardia and an intermittent idioventricular rhythm. Symptomatic treatment and/or atropine led to recovery within a few hours.

Lincosamides

General Information

The two established members of the group of antibiotics known as the lincosamides, lincomycin and its semisynthetic derivative clindamycin, have a narrow antibacterial spectrum involving mostly Gram-positive species and some obligate anerobes, such as *Bacteroides*. Like chloramphenicol and erythromycin, they combine with a subunit of bacterial ribosomes and interfere with protein synthesis.

Whereas oral lincomycin has a systemic availability of about 40%, which may be further compromised by food, clindamycin is absorbed from the gastrointestinal tract about 90–100%. Both are eliminated mainly by hepatic metabolism and biliary excretion.

Observational studies

Long-term oral clindamycin therapy has been successfully used in a 36-year-old woman with late-stage AIDS who presented with disseminated, nodular cutaneous lesions and underlying osteomyelitis due to a microsporidial infection with an Encephalitozoon-like species (1).

Comparative studies

In a multicenter, double-blind, randomized trial in 87 patients, clindamycin + primaquine was compared with co-trimoxazole as therapy for AIDS-related *Pneumocystis jiroveci* pneumonia; efficacy was similar. In patients with a PaO_2 under 70 mmHg, clindamycin + primaquine was associated with fewer adverse events and less glucocorticoid use, but more rashes (2).

In a prospective, open, randomized trial clindamycin (600 mg tds) and quinine (650 mg tds) were compared with atovaquone (750 mg bd) plus azithromycin (500 mg on day 1 followed by 250 mg/day) in 58 patients with non-life-threatening babesiosis (3). Bacterial response was complete 3 months after the end of treatment. Adverse effects were reported by 72% of those who received clindamycin and quinine compared with 15% of those who received atovaquone and azithromycin. The most common adverse effects with clindamycin and quinine were tinnitus (39%), diarrhea (33%), and impaired hearing (28%); the symptoms had resolved in 73% of the patients assigned to clindamycin/quinine 3 months after the start of therapy and in 100% after 6 months.

In 233 women with bacterial vaginosis, a 3-day regimen of clindamycin (intravaginal ovules, 100 mg/day) was as effective as a 7-day regimen of oral metronidazole (500 mg bd) and better tolerated (4). Treatment-related adverse events were reported more often with metronidazole, and systemic symptoms, such as nausea and taste disturbance, accounted for most of the difference between the groups.

Placebo-controlled studies

In a 10-week, multicenter, double-blind study 480 patients with moderate to moderately severe acne were

© 2006 Elsevier B.V. All rights reserved.

randomized to receive twice-daily 5% benzoyl peroxide, 1% clindamycin, 5% benzoyl peroxide plus 1% clindamycin, or vehicle, all topically (5). There were significantly greater reductions in the numbers of inflammatory and total lesions in patients who used combination therapy compared with those who used any of its three individual components. The most frequent adverse effect, dry skin, occurred to a similar extent with the combination and with benzoyl peroxide alone.

General adverse effects

The direct toxicity of the lincosamides is relatively low (SED-7, 389) (6). The adverse effects of clindamycin may be well below 1%. In a tertiary care center, adverse reactions to clindamycin were reported in 0.47% of 3896 courses, and in half of these events an effect of other medications could not be excluded (7). However, clindamycin has not been given in as high doses as lincomycin.

The most common adverse effect is diarrhea, which occurs in as many as 10–20% of patients. The most serious gastrointestinal complication is colitis due to *Clostridium difficile*, which occurs with about equal frequency after oral and parenteral treatment (8,9). Skin rashes, urticaria, and angioedema have been reported with lincomycin, but are rare. In contrast, maculopapular and pruritic eruptions occur after 1–2 weeks of treatment in up to 10% of patients taking clindamycin. Clindamycin has also been incriminated in one case of Stevens–Johnson syndrome and in one of anaphylaxis; in the latter, hemagglutinating antibodies were found against clindamycin and lincomycin (10). Leukocytoclastic angiitis associated with clindamycin is rare. If a similar angiitis can also occur in the colon, the question arises whether some cases of antibiotic-associated colitis might be caused by the drug itself rather than by bacterial toxins. Tumor-inducing effects have not been reported.

Organs and Systems

Cardiovascular

Rapid intravenous infusion of large doses of lincomycin (600 mg in 5–10 minutes) can cause flushing and a sensation of warmth for about 10 minutes.

- A patient who received 200 mg/kg of lincomycin experienced nausea, vomiting, hypotension, dyspnea, and electrocardiographic changes for 20 minutes (SED-7, 389) (11).

Rapid intravenous infusion of lincomycin 1–2 g can cause phlebitis.

Clindamycin can prolong the QT interval and cause ventricular fibrillation (12). Cardiac arrest associated with rapid intravenous administration of clindamycin has been reported (SEDA-8, 258) (13).

Nervous system

Clindamycin, either alone or in combination with neuromuscular blocking drugs or aminoglycosides, has been associated with neuromuscular blockade.

- A 58-year-old woman who was accidentally overdosed with 2400 mg (40 mg/kg) of clindamycin during anesthesia (with tubocurarine and suxamethonium induction) developed prolonged neuromuscular blockade, unresponsive to intravenous calcium or cholinesterase inhibitors (edrophonium and neostigmine), and required assisted ventilation for 11 hours (14). It seems likely that the large dose of clindamycin used in this case produced sustained neuromuscular blockade in the absence of non-depolarizing relaxants and after full recovery from suxamethonium.

Neuromuscular function

Lincosamide antibiotics can produce neuromuscular block postjunctionally by interacting with the open state of the acetylcholine receptor-channel complex. Lipophilicity, rather than stereochemistry of the molecule, is important for open-channel blockade affecting primarily the "off" rate of channel blocking (15). Neuromuscular blockade after clindamycin has been reported (16).

- A 44-year-old woman with mild asthma and mitral valve prolapse was given intravenous clindamycin 300 mg, methylprednisolone 125 mg, and midazolam 2 mg 30 minutes before surgery. Suxamethonium 120 mg was given and general anesthesia was induced with fentanyl 0.1 mg and propofol 120 mg, and maintained with 60% nitrous oxide in oxygen, desflurane, and a single dose of propofol 80 mg. Five hours after uneventful surgery and about 20 minutes after another intravenous dose of clindamycin 600 mg, she complained of profound weakness and had bilateral ptosis, difficulty in speaking, and rapid shallow respiration. Her weakness rapidly became more profound, and she was given neostigmine 4 mg and glycopyrrolate 0.8 mg, after which her muscle strength returned to normal. Electromyography showed no evidence of neuromuscular disease, and acetylcholine receptor antibodies were negative.

An in vitro study has shown a direct effect of clindamycin on nicotinic but not muscarinic acetylcholine receptors (17). This may explain improvement of tremor on treatment with clindamycin in a patient with Parkinson's disease. On each of three occasions, the tremor almost completely disappeared shortly after the start of therapy with clindamycin but reappeared within 1–3 days after withdrawal.

Sensory systems

In a prospective study subconjunctival injections of clindamycin did not produce any general adverse effects (18). However, conjunctival inflammation and keratitis were observed in one of 13 cases, caused by an error in the administered concentration of clindamycin, which was too high.

Hematologic

Granulocytopenia and thrombocytopenia have been described in a few patients taking lincosamides.

© 2006 Elsevier B.V. All rights reserved.

However, a cause-and-effect relation has not been unequivocally established.

Lymphadenitis has been attributed to clindamycin (19).

- A 54-year-old woman with paraplegia due to spina bifida was treated with clindamycin, ciprofloxacin, and gentamicin for osteomyelitis of the ischium and acetabulum, but developed painful swelling of lymph nodes in the neck, which she said occurred with each dose of clindamycin. Withdrawal of gentamicin had no effect, but withdrawal of clindamycin resolved the adenitis over 7 days; the ciprofloxacin was continued.

Gastrointestinal

Drug-induced esophagitis is rare, accounting for about 1% of all cases of esophagitis. An incidence of 3.9 in 100 000 has been reported. After the first description, there have been more than 250 observations, with more than 50 different drugs. Among those, the principal antibiotics included tetracyclines (doxycycline, metacycline, minocycline, oxytetracycline, and tetracycline), penicillins (amoxicillin, cloxacillin, penicillin V, and pivmecillinam), clindamycin (20), co-trimoxazole, erythromycin, lincomycin, spiramycin, and tinidazole. Doxycycline alone was involved in one-third of all cases. Risk factors included prolonged esophageal passage, due to motility disorders, stenosis, cardiomegaly, the formulation, supine position during drug ingestion, and failure to use liquid to wash down the tablet. Direct toxic effects of the drug (pH, accumulation in epithelial cells, non-uniform dispersion) also seem to contribute to the development of drug-induced esophagitis (21). Clindamycin should be taken with a meal or followed by a glass of water (22).

The most prominent adverse reaction of the lincosamides is diarrhea, which varies from mildly loose bowel movements to life-threatening pseudomembranous colitis (see monograph on Beta-lactam antibiotics). Almost all antimicrobial drugs have been associated with severe diarrhea and colitis; however, lincomycin and clindamycin have been particularly incriminated. The incidence of clindamycin-induced diarrhea in hospital is 23%. Diarrhea resolves promptly after withdrawal in most cases. It seems to be dose-related and may result from a direct action on the intestinal mucosa. Severe colitis due to *C. difficile* is not dose-related and occurs in 0.01–10% of recipients. Clustering of cases in time and place suggests the possibility of cross-infection. Even low doses of clindamycin, in some cases after topical administration, can cause marked alterations in several intestinal functions related to bowel flora (23). There was reduced susceptibility of *C. difficile* to clindamycin in 80% of French isolates in 1997 (24). Lincomycin was among the antibiotics that were most often associated with the development of antibiotic-associated diarrhea in a Turkish study of 154 patients; other associated antibiotics were azithromycin and ampicillin (25).

In a one-year retrospective study at a tertiary hospital in Spain, 17% of 148 episodes of diarrhea associated with *C. difficile* developed after therapy with clindamycin (26). The possible association of toxin-positive *C. difficile*-induced colitis and the use of clindamycin phosphate vaginal cream for bacterial vaginosis has been reported in a 25-year-old white woman postpartum (27).

In a prospective study patients treated with antibiotics, including clindamycin, for 3 days had a significantly lower frequency of antibiotic-associated diarrhea than those treated for longer periods (28).

Restricting the use of clindamycin has been successful in terminating outbreaks of *C. difficile* diarrhea associated with its use (29). Between 1989 and 1992, outbreaks of diarrhea due to a clindamycin-resistant strain of *C. difficile* occurred in different parts of the USA. Resistance was mediated by the ermB gene. The use of clindamycin was a specific risk factor for diarrhea due to this strain (30).

- A young otherwise healthy nurse developed severe diarrhea and vomiting, profuse ascites, pleural effusion, abdominal tenderness, peritoneal irritation, and systemic toxicity 10 days after taking oral clindamycin for a dental infection (31). Although the assay for *C. difficile* was repeatedly negative, features compatible with pseudomembranous colitis were seen at sigmoidoscopy, and the diagnosis was confirmed histologically.

Topical application of clindamycin to the skin has been used in acne vulgaris. However, percutaneous absorption can occur (SEDA-8, 160) and several cases of diarrhea have been reported, including cases of pseudomembranous colitis (32).

Clindamycin can rarely cause antibiotic-associated diarrhea after short-term use as vaginal cream (33).

Liver

Since the lincosamides are eliminated by biliary excretion, toxicity would be expected in patients with liver disease. High doses of clindamycin may be hepatotoxic (34). Abnormal liver function tests during treatment with lincomycin are rare, and only in patients who had taken large doses (over 4 g/day) for more than 3 weeks (6). In another series, intravenous lincomycin 4–18 g/day was not associated with renal or hepatic toxicity (SED-7, 388).

Skin

The most common adverse events in patients using clindamycin/benzoyl peroxide were dry skin, peeling, erythema, and rash (35,36). However, withdrawal rates due to adverse events were low (0–0.8%).

- A 57-year-old Caucasian woman with a history of ocular toxoplasmosis, treated with intravitreal clindamycin (1 mg/0.1 ml) and dexamethasone (0.4 mg/0.1 ml), developed a generalized erythematous macular rash over the scalp, face, arms, thighs, and trunk 2 days after the start of treatment (37).

Precautions are necessary to avoid ultraviolet radiation after taking photoreactive drugs (38). Metabolism of lincomycin can lead to the formation of reactive oxygen species and cause tissue injury and damage to various cellular macromolecules, which can result in phototoxicity. Typical photosensitivity with a maculopapular eruption has been observed with lincomycin in two patients treated intramuscularly (6).

- Toxic epidermal necrolysis has been described in a 50-year-old insulin-dependent diabetic who received

© 2006 Elsevier B.V. All rights reserved.

clindamycin (300 mg 8-hourly) (39). On the seventh day, he developed flu-like symptoms, fever, and an erythematous rash, associated with sloughing of 30% of the body surface after a further 4 days (when Nikolsky's sign became positive). He was given oral methylprednisolone 32 mg and eventually made a full recovery.

Lincomycin can cause acne rosacea (40).

A fixed drug eruption has been reported in a patient taking clindamycin (12).

- In a 38-year-old non-atopic man, a generalized pruriginous maculopapular eruption with lip edema and facial erythema developed after 10 days of treatment with oral clindamycin phosphate (300 mg qds) and amoxicillin (500 mg qds) for bronchopneumonia (24). A patch test was positive 2 months later for clindamycin phosphate but negative for penicillin, amoxicillin, ampicillin, and erythromycin. Prick tests and intradermal tests were all negative. Oral rechallenge with clindamycin phosphate 300 mg was positive.

Acute, generalized, exanthematous pustulosis has been associated with clindamycin (41).

Immunologic

Although the risk of drug hypersensitivity is increased in patients with AIDS, clindamycin hypersensitivity has been considered to be relatively uncommon, despite its widespread use, with rash developing in about 9% of patients. However, in a retrospective survey of 50 patients with AIDS recruited in a European multicenter study of treatment for *Toxoplasma* encephalitis, the incidence of rash in 26 patients given pyrimethamine plus clindamycin was 58%, compared with 75% in those given pyrimethamine plus sulfadiazine, a non-significant difference (42). Treatment was initially continued throughout the duration of hypersensitivity, and was tolerated in all patients taking pyrimethamine plus clindamycin, but had to be withdrawn in half of those taking pyrimethamine plus sulfadiazine. Stevens–Johnson syndrome developed in two patients and fatal toxic epidermal necrolysis in one. Thus, the continuation of treatment despite a rash was more likely to succeed with pyrimethamine plus clindamycin but was potentially hazardous with pyrimethamine plus sulfadiazine.

In a prospective study, true-positive patch tests were seen in four of six patients with known clindamycin hypersensitivity, while 22 healthy controls were negative; there was one false positive and one false negative reaction (43).

Successful desensitization has been described in a 35-year-old woman who developed a generalized rash after taking clindamycin (600 mg 6-hourly) and pyrimethamine for 12 days for AIDS-associated cerebral toxoplasmosis; the rash resolved after withdrawal of clindamycin (44). Subsequent oral rechallenge was performed (without pretreatment with glucocorticoids or antihistamines), starting with three doses of 20 mg on day 1, 40 mg on day 2, 80 mg on day 3, and so on, until a dose of 600 mg qds was reached on day 7. A transient rash lasting 5 hours developed after the second dose of 600 mg. She remained free from adverse reactions for the duration of follow-up (13 months).

Infection risk

Superinfection with resistant strains of *Pseudomonas*, *Proteus*, or staphylococci has been observed with lincosamides. Suppression of *Bacteroides* in the intestinal flora may be related to the proliferation of *C. difficile*, which is important in causing pseudomembranous colitis. Excessive growth of *Candida* on the skin occurred when lincomycin was applied topically (6).

Long-Term Effects

Drug resistance

Staphylococcus aureus, pneumococci, Group A streptococci, and viridans streptococci acquire resistance in vitro to the lincosamides regularly, easily, and quickly (SED-8, 638). In endometrial cultures taken after clindamycin therapy, the occurrence of clindamycin-resistant anerobic bacteria was significantly higher than before therapy (45). Their similar mechanism of action has been used to explain cross-resistance between the macrolide antibiotics and the lincosamides. Among erythromycin-resistant staphylococci, 50% of the isolated strains were also resistant to lincomycin (SED-6, 304). In patients who need long-term suppressive therapy, but who are allergic to penicillin, the development of such combined resistance of the oropharyngeal flora can be a serious clinical problem.

The erythromycin ribosomal methylase (erm) genes encode 23S ribosomal RNA methylases. This modification results in reduced binding of all known macrolides, lincosamides, and streptogramin B to the ribosome (MLS resistance). Novel triazine-containing methyltransferase inhibitors that may reverse erm-mediated resistance are under development (46).

The MLS resistance was found in four of 137 consecutive clinical isolates of *Streptococcus pyogenes* (47). In two, both ermB and ermTR genes were present. In the other two, these genes were not identified, suggesting a new mechanism of high-level resistance to these antibiotics. Erm genes were detected in 45% of 173 strains of *Streptococcus pneumoniae* isolated from surveillance studies in day-care centers in Central Italy (48). From 387 clinical strains of erythromycin-resistant strains of *S. pyogenes* isolated in Italian laboratories from 1995 to 1998, 31% were assigned to the inducible and 17% to the constitutive MLS resistance phenotype (49). Resistance to erythromycin increased to 33% in 1997 among community-acquired isolates of *S. pneumoniae* from central Italy (50). Most carried an erm gene and were also resistant to clindamycin. Regulatory regions located upstream of the erm genes were amplified and sequenced in clinical isolates of enterococci and streptococci with either inducible or constitutive resistance. Expression of constitutive resistance in two strains of *S. pneumoniae* and *Enterococcus faecalis* could be accounted for by a large deletion or a DNA duplication within the regulatory regions respectively (51). In 294 macrolide-, lincosamide-, and/or

© 2006 Elsevier B.V. All rights reserved.

streptogramin-resistant clinical isolates of *S. aureus* and coagulase-negative staphylococci isolated in 1995 from 32 French hospitals, ermA or ermC genes were found in 88% (52). Genes related to linA/linA′ and conferring resistance to lincomycin were detected in one strain of *S. aureus* and 7 strains of coagulase-negative staphylococci.

A resistance gene, named linB, which encodes a lincosamide nucleotidyltransferase catalysing the adenylation of the hydroxyl group in position 3 of the molecules of lincomycin and clindamycin has been characterized in a clinical isolate of *Enterococcus faecium* (53). Expression of linB was also observed in *Escherichia coli* and *S. aureus*, and the spread of this gene in other clinical isolates of *E. faecium* has been suggested.

In *Brachyspira hyodysenteriae* (formerly *Serpulina hyodysenteriae*) isolates, resistance to clindamycin was associated with a transversion mutation in the nucleotide position homologous with position 2058 of the *E. coli* 23S rRNA gene (54).

There was a significant increase in the rate of resistance in clinical strains of *Bacteroides fragilis* from Canada (20% in 1997) (55). This trend was also observed in a prospective multicenter survey from the USA (56).

Among *P. acnes* isolated from acne lesions, a resistance level of 4% (of 50 strains) and 6.8% (of 70 strains) were found in Japanese and German studies respectively (57,58).

Of 302 clinical isolates of *S. pyogenes* from Portugal, 108 were resistant to erythromycin, and 86 also had a constitutive resistance to clindamycin (MLSB phenotype) (59). Four isolates had a phenotype characterized by low-level erythromycin resistance and high-level clindamycin resistance. In another European study of 286 *S. pneumoniae* strains, 7% were resistant to penicillin, and 35% were also resistant to clindamycin (60). Of 3205 group A streptococcal strains from Canada, only 18 and 2 strains respectively showed inducible and constitutive resistance to clindamycin (61). Among 180 strains of the *Streptococcus milleri* group isolated in Spain, 17% were resistant to clindamycin (62).

An increase in resistance to clindamycin has been found in group B streptococcal strains causing neonatal infection (63).

Second-Generation Effects

Pregnancy

In pregnant women with bacterial vaginosis, a 7-day regimen of 2% vaginal clindamycin cream was effective and did not alter the rates of preterm deliveries or peripartum infections (64,65).

Fetotoxicity

Although lincomycin penetrates the fetal circulation, no fetal abnormalities were related to lincomycin administration in 302 women who had completed a course of lincomycin therapy (500 mg every 6 hours) for 1 week; all three trimesters of pregnancy were included (66).

Drug Administration

Drug formulations

Whereas only about 4% of clindamycin from a vaginal cream was systemically absorbed, systemic absorption was in the range of 30% when clindamycin was intravaginally administered as a phosphate ovule (67).

Drug–Drug Interactions

Ciclosporin

In two patients who had lung transplants and were taking an immunosuppressive regimen that included ciclosporin, the addition of clindamycin (600 mg tds) resulted in a significant reduction in ciclosporin concentrations (68).

Ganglion blocking agents

Clindamycin may potentiate the effects of some ganglion blocking agents (69).

Macrolides

Antagonism between the lincosamides and the macrolide antibiotics has been observed in vitro and was explained by binding to the same subunit of bacterial ribosomes (70). This mechanism of bacteriostatic action also suggests that the lincosamides might prevent the bactericidal action of the penicillins and the cephalosporins.

Non-depolarizing neuromuscular blocking drugs

Clindamycin and lincomycin potentiate the action of non-depolarizing neuromuscular blocking drugs, such as pancuronium and D-tubocurarine. The lincosamide-induced block cannot be reliably reversed pharmacologically (71).

Lindane

General Information

Lindane is a pesticide that is widely used in the treatment of scabies and pediculosis, usually in a 1% lotion (SEDA-5, 154) (1–4). It is the gamma-isomer of 1,2,3,4,5,6-hexachlorocyclohexane. The hazards of excessive industrial exposure and accidental ingestion have been well documented (3).

© 2006 Elsevier B.V. All rights reserved.

Some feel that 1% lindane is safe when used properly (1,5), but precautionary recommendations have been made (3):

(a) a hot soapy bath before treatment is not necessary;
(b) application for 24 hours may be too long, 6 hours having a cure rate of 96%;
(c) a concentration weaker than 1% may be adequate;
(d) lindane should not be repeated within 8 days, and then only if active parasites can still be demonstrated;
(e) lindane 1% should be used with extreme caution, if at all, in pregnant women, very small infants, and people with massively excoriated skin.

There has been concern from animal experiments that lindane may be mutagenic, carcinogenic, and teratogenic; in therapeutic use, however, such hazards are highly unlikely (1,2).

Organs and Systems

Nervous system

In 1976, the US Food and Drug Administration (FDA) published a "Gamma Benzene Hexachloride (Kwell) Alert," based in part on several poorly documented cases of convulsions after topical treatment with lindane (6). Indeed, several authors have reported convulsions (7–9), but in most cases lindane had been inappropriately used (4,7), while another case took place in unusual therapeutic circumstances (prematurity, marasmus, pneumonia, congestive heart failure, ventricular septal defect) (8). A child with convulsions after the application of lindane had tuberous sclerosis and may therefore have had a reduced threshold for convulsions (9).

Hematologic

Anemia, possibly caused by topical lindane, has been described (10).

Urinary tract

Urinary retention has been ascribed to lindane (SEDA-10, 131).

Skin

Acute generalized exanthematous pustulosis has been attributed to topical lindane (11).

Immunologic

Henoch-Schönlein purpura, possibly caused by topical lindane, has been described (12).

Lipsticks, substances used in

General Information

Branched-chain fatty acid esters, such as glyceryl di-isostearate and di-isostearyl malate, have replaced castor oil and lanolin as major components of lipsticks.

Palmitate-related substances are viscous oils used in cosmetics and topical medicaments. In lipsticks they replace castor oil (1). Allergic reactions to lipsticks have been reported to be caused by a variety of allergens, for example azo dyes, colophony, lanolin, castor oil, sunscreens, and para-tertiary butylphenol.

Organs and Systems

Immunologic

The fatty acid esters have low allergenic potential but cases of contact allergy has been reported, in one case to di-isostearyl malate (patch-tested in 7.7% in petrolatum) (2), and in another case to glyceryl monoisostearate monomyristate in a 23-year-old woman, who had cheilitis from her lipstick (3).

- A 17-year-old woman developed pruritic edematous erythema on her lips after using a lipstick containing isopalmitate (4). A patch test with 10% isopalmitate in petrolatum was positive on day 3, with six negative controls.
- A 27-year-old woman developed papules, scales, and slight swelling of her lips (5). A patch test with isopalmityl diglyceryl sebacate, 10% in petrolatum, was positive.

Lisinopril

See also Angiotensin converting enzyme inhibitors

General Information

Lisinopril is a non-sulfhydryl ACE inhibitor. It has been used in patients with hypertension, heart failure, myocardial infarction, and diabetic nephropathy.

Organs and Systems

Cardiovascular

An updated and comprehensive review of the use of lisinopril in congestive heart failure has been published (1), including a section on tolerability and details of the ATLAS (Assessment with Treatment with Lisinopril and Survival) trial. The tolerance of high doses of lisinopril (32.5–35 mg od) in heart failure, one of the issues addressed by this trial, was not significantly different from that of low doses (2.5–5 mg od). Since high doses were more effective than low doses, the authors recommended that more aggressive use of ACE inhibitors is warranted (2). However, this conclusion is valid only in the conditions of the trial, with careful and slow dose escalation. With such a strategy, most patients with heart failure can be titrated successfully to high maintenance doses.

Shock after myocardial infarction has been attributed to an ACE inhibitor (3).

- A 42-year-old woman suffered an acute anterior myocardial infarction, initially associated with pulmonary edema. After hemodynamic stabilization she was given lisinopril 10 mg orally. Two hours later she developed circulatory failure in conjunction with acute renal insufficiency. Right heart catheterization showed markedly reduced systemic vascular resistance but a normal cardiac index. After the usual causes of cardiogenic shock had been ruled out, repeated fluid challenges and intravenous noradrenaline failed to improve her hemodynamic status. She was therefore given angiotensin II intravenously (5–7.5 μg/minute), which immediately and markedly raised the systematic vascular resistance and resulted in subsequent regression of shock. She was discharged after an otherwise uneventful course.

Endocrine

The syndrome of inappropriate antidiuretic hormone secretion (SIADH) has been attributed to lisinopril (4).

- A 76-year-old woman taking lisinopril 20 mg/day and metoprolol for hypertension developed headaches, nausea, and a tingling sensation in her arms. Her serum sodium was 109 mmol/l, with a serum osmolality of 225 mosm/kg, urine osmolality of 414 mosm/kg, and urine sodium of 122 mmol/l. She had taken diclofenac 75 mg/day for arthritic pain for 6 years and naproxen for about 1 month. Propoxyphene napsylate and paracetamol had then been substituted and zolpidem had been started. A diagnosis of SIADH was postulated and thyroid and adrenal causes were excluded. Lisinopril was withdrawn and fluid was restricted to 100 ml/day. The serum sodium gradually corrected to 143 mmol/l.

The authors referred to three other similar cases, in two of which the diagnosis may have been confused by the concomitant use of diuretics in patients with heart failure. However, the present and one other case had occurred without co-existing risk factors for hyponatremia. They discussed a synergistic effect of zolpidem and/or diclofenac, and suggested a potential mechanism involving non-inhibition of brain ACE, which leaves brain angiotensin II receptors exposed to high circulating concentrations of angiotensin which would strongly stimulate thirst and the release of antidiuretic hormone.

Pancreas

Several cases of pancreatitis have been reported with ACE inhibitors, including lisinopril.

- A 67-year-old man without other risk factors developed acute pancreatitis only 3 hours after taking lisinopril. The originality of this case resides in the fact that the patient had experienced a similar but less severe reaction to the medication 3 months before. Thus, this case probably represents the first time a patient was rechallenged with lisinopril and had a more severe adverse reaction (5).
- A 42-year-old woman, who was taking lisinopril, nicardipine, metoprolol, simvastatin, omeprazole, an estrogen, and sublingual glyceryl trinitrate, presented with epigastric pain and vomiting (6). Pancreatitis was diagnosed on the grounds of raised activities of lipase (200 IU/l) and amylase (117 IU/l) and diffuse homogeneous enlargement of the head and body of the pancreas on CT scan. The pancreatic enzyme activities normalized 5 days after lisinopril and simvastatin withdrawal. Two months later she was taking estrogen and simvastatin, but not lisinopril. Her amylase and lipase were normal.

The temporal relation in the second case suggests that lisinopril was causative. The authors raised the possibility that the concomitant use of an estrogen and simvastatin, as well as a history of familial hypertriglyceridemia, may have predisposed her to pancreatitis.

Skin

Worsening of pre-existing cold urticaria has been associated with lisinopril (7).

- A 43-year-old Caucasian man had a history of mild cold urticaria during the preceding 10 years. Shortly after starting to take lisinopril 20 mg/day and hydrochlorothiazide 25 mg/day for hypertension his condition worsened considerably and he had several bouts of severe cold urticaria. On one occasion, after swimming in water at 24°C, he developed severe urticaria and angioedema, and required emergency hospital admission. Standard ice-cube and cold-water immersion tests were strongly positive within 1 minute. Tests for a variety of causative factors were negative, and a diagnosis of acquired cold urticaria was made. Lisinopril was withdrawn, he was given valsartan 80 mg/day, and the dose of hydrochlorothiazide was reduced to 12.5 mg/day. During the next 24 weeks he had only mild symptoms of cold urticaria. Repeat ice-cube and cold-water immersion tests were negative at 1 and 3 minutes, but positive at 5 minutes.

The authors cited evidence that the kallikrein/kinin system is involved in cold urticaria, that ACE inhibitors increase wheal-and-flare reactions to cutaneously applied bradykinin, and that ACE inhibitor therapy is associated with raised plasma kinin concentrations. They therefore recommended avoidance of ACE inhibitors in patients with cold urticaria.

Erythema multiforme has been attributed to lisinopril (8).

- A 68-year-old man who had taken lisinopril 10 mg/day for several years stopped taking it temporarily because of a cough. It was then restarted in a dosage of 5 mg/day and a few days later he developed several bean-sized non-pruritic erythematous plaques with scales over the whole body, particularly on the chest. The appearance was of seborrheic dermatitis, but histology showed the features of erythema multiforme. The eruptions cleared completely a few days after lisinopril withdrawal. Two months later, a rechallenge test was positive.

Sexual function

Lisinopril 20 mg/day has been compared with atenolol 100 mg/day in a 16-week, double-blind, randomized, controlled trial in 90 hypertensive men aged 40–49 and without a history of sexual dysfunction. The number of occasions on which they had sexual intercourse fell during the first month in both groups (9). Subsequently, sexual activity tended to recover with lisinopril but not atenolol. The authors suggested that lisinopril may cause only a temporary reduction in sexual function.

Drug–Drug Interactions

Clozapine

Raised clozapine blood concentrations have been reported after the introduction of lisinopril (10).

- A 39-year-old man with schizophrenia and diabetes, who had taken clozapine 300 mg/day and glipizide 10 mg/day for a year, took lisinopril 5 mg/day for newly diagnosed hypertension. On several occasions afterwards he had roughly a doubling of his blood concentrations of clozapine and norclozapine. He had typical effects of clozapine toxicity. After replacement of lisinopril by diltiazem, the blood concentrations of clozapine and norclozapine returned to the values that were present before lisinopril was introduced.

The information given here was sketchy and there was no information on the timing of blood samples relative to the dose of clozapine. Clozapine is metabolized by CYP1A2 and CYP3A4, but there is no evidence that lisinopril affects these pathways.

Tizanidine

Hypotension followed the addition of tizanidine to lisinopril (11).

- A 10-year-old boy developed hypotension and reduced alertness. His blood pressure was 56/24 mmHg and his heart rate 88/minute. He had a history of a hypoxic ischemic insult to the central nervous system, subsequent hypertension, and spastic quadriplegia. His blood pressure had been controlled for the last 10 months with lisinopril (dose not stated). Tizanidine had been added 1 week before admission for spasticity. Lisinopril and tizanidine were withdrawn and his blood pressure rose to 149/89 mmHg over the next day. He was discharged and lisinopril was restarted but not tizanidine. He had no further problems with hypotension.

The authors interpreted the finding as a consequence of limited ability of the patient to respond to hypotension because of simultaneous blockade of the sympathetic system with the centrally acting alpha$_2$-adrenoceptor agonist tizanidine.

Lisuride

General Information

Lisuride is a dopamine receptor agonist that is used as an alternative drug in the treatment of Parkinson's disease. The pattern of adverse effects is similar to that seen with most of the ergot alkaloids (SEDA-10, 118). The adverse effects that occurred after subcutaneous administration were so troublesome that the subcutaneous formulation was eventually unmarketable.

Organs and Systems

Respiratory

In one instance to date, pleuropulmonary disease has been observed. Effusions were present but apparently there was no significant fibrosis, and the condition was almost completely reversible.

Nervous system

Vasoconstriction due to ergot-related dopamine receptor agonists can affect the cerebral circulation (1).

- A 33-year-old woman was discharged from hospital after a normal delivery, taking lisuride 0.2 mg/day for suppression of lactation. Within a day, she complained of throbbing headache, which was followed by right hemiparesis and then a generalized tonic-clonic seizure starting from the right arm. She had widespread segmental vasoconstriction in the cerebral arteries and two intracerebral hemorrhages. She recovered fully within 1 month.

The authors commented that there have been at least seven reported cases of postpartum ergot-related angiopathy with bromocriptine and ergonovine.

Because of its serotoninergic properties, lisuride can cause more psychiatric complications than expected (2).

Lithium

General Information

Lithium is an alkaline earth element that is used medicinally in the form of salts such as lithium chloride and lithium carbonate. Its main use is in the prevention or attenuation of recurrent episodes of mania and depression in individuals with bipolar mood disorder (manic depression). Lithium also has clearly established antimanic activity, although its relatively slow onset of action often necessitates the use of ancillary drugs, such as antipsychotic drugs and/or benzodiazepines, at the start of therapy. If lithium alone is ineffective for recurrent bipolar mood disorder, combining it or replacing it with carbamazepine or valproate may be of value; reports with lamotrigine and olanzapine are also encouraging.

Lithium also has antidepressant activity in bipolar disorder, has prophylactic value in recurrent major depression, and is a useful augmenting agent for antidepressant-resistant depression. Other uses in psychiatry include schizoaffective disorder, emotional instability, and pathological aggression. The point prevalence of lithium use has been estimated to be as high as 1 in 1000 people in populations in industrial countries. The complex relation between sub-syndromal manifestations of bipolar disorder, particularly cognitive dysfunction, and the role that lithium might play in alleviating or aggravating this problem have been discussed in a thoughtful review (1).

The well-established effectiveness of long-term lithium in reducing manic-depressive morbidity includes a reduced risk of suicide and suicidal behavior. For example, in one study, suicidal acts per 1000 patient-years were 23 before lithium, 3.6 during lithium, 71 in the first year after withdrawal, and 23 in subsequent years (2). In another study, suicide rates during treatment with lithium were 31 per 1000 person-years (emergency department suicide attempts), 11 per 1000 person-years (suicide attempts resulting in hospitalization), and 1.7 per 1000 person-years (suicide deaths); the risk of suicide death was 2.7 times higher during treatment with divalproex than during treatment with lithium (3). A retrospective study divided high-risk patients into excellent, moderate, and poor responders to lithium and showed that no further suicide attempts occurred in 93%, 83%, and 49% respectively (4). The substantial reduction in suicidal tendency in the poor responder group suggested an antisuicidal effect of lithium beyond its mood-stabilizing properties, although the psychosocial benefits of lithium clinic treatment could have been contributing factors.

Since bipolar disorder is a condition for which long-term treatment is usually necessary, both acute and long-term adverse effects are important, especially since patients in remission are often less likely to tolerate them (5). With this in mind, one might consider some speculatively positive findings involving the neurotropic and neuroprotective effects of lithium (6). The concentration of bcl-2, a cytoprotective protein, was upregulated by lithium in both rodent brains and human neuronal cells, as was the concentration of *N*-acetylaspartate, a marker of neuronal viability and function, in human gray matter

© 2006 Elsevier BV All rights reserved.

(7). In addition, a 3-dimensional magnetic resonance imaging study with quantitative brain-tissue segmentation showed that treatment with lithium for 4 weeks increased the total volume of gray matter by about 3% in eight of 10 patients in the depressed phase of bipolar I disorder.

Beneficial nonpsychiatric uses of lithium

Some collateral drug effects that are not related to the intended therapeutic effect are potentially beneficial. Several beneficial effects of lithium, besides its action in bipolar disorder, have been described.

Nervous system

There has been a spate of publications describing the neuroprotective effects of lithium. By inhibiting glycogen synthase kinase-3, lithium inhibits tau hyperphosphorylation and protects against β-amyloid-induced cell death, suggesting a possible role in the treatment of Alzheimer's disease (8,9). Studies in mice and cell lines show that lithium reduces gp120-associated neurotoxicity, suggesting that it may be useful in preventing progression of HIV-associated cognitive deterioration (10). Low-dose lithium reduced infarct volume and neurological deficits in a rat model of transient focal cerebral ischemia (11).

Overall, the evidence that lithium has neuroprotective and neurotropic effects through a variety of mechanisms is striking (12), although whether those findings will evolve into therapies of practical clinical value remains to be seen.

Chronic cluster headache has responded to lithium (13).

Sensory systems

In cultured mouse retinal ganglion cells, lithium supported the survival and regeneration of axons (14). This led the authors to the very speculative suggestion that lithium might be useful in treating conditions such as glaucoma, optic neuritis, and other neuron loss disorders.

Endocrine

Lithium blocks the release of iodine and thyroid hormones from the thyroid and has been used to treat hyperthyroidism, as an adjunct to radioiodine therapy (15–18) and in metastatic thyroid carcinoma (19). However, it can also cause hyperthyroidism. Lithium enhanced the efficacy of radioiodine in 23 patients (20), but was ineffective in a larger comparison of lithium ($n = 175$) or radioiodine alone ($n = 175$) (21). In 24 patients with Graves' disease, lithium attenuated or prevented increases in thyroid hormone concentration after methimazole withdrawal and radioiodine treatment (15,22).

Lithium has been used, with several other drugs, to treat four patients with amiodarone-associated thyrotoxicosis, but the drugs were ineffective in two patients, who required thyroidectomy (23). One hopes that the authors actually used milligram amounts of lithium carbonate rather than the microgram amounts listed in the article.

Metabolism

Lithium therapy in a 17-year-old man with Kleine–Levin syndrome led to remission of the characteristic manifestations, including hyperphagia (24).

Hematologic

Lithium has beneficial granulocytopoietic effects (25–27). For example, lithium carbonate (800–900 mg/day) effectively corrected neutropenia due to chemotherapy or radiotherapy in over 85% of 100 cancer patients (28). The potential benefit and possible risks of using lithium to treat clozapine-induced neutropenia/agranulocytosis have been reviewed (29).

- A 29-year-old man with agranulocytosis, who could not tolerate granulocyte-colony stimulating factor, had normalization of peripheral granulocyte counts when he took lithium carbonate 800 mg/day (30).
- A 16-year-old with severe aplastic anemia failed to respond to treatment with corticosteroids plus an androgen and to antilymphocyte globulin, but had a strikingly positive response to the combination of lithium and an androgen derivative (31). Leukopenia and thrombocytopenia recurred 2 months after lithium was withdrawn and responded to reintroduction of the drug.

The potential of lithium to prevent or treat clozapine-induced granulocytopenia has been reviewed (29). In a study of 38 patients on clozapine for schizophrenia or schizoaffective disorder, the addition of lithium increased the leukocyte count (32). A 20-year-old man with olanzapine-induced neutropenia 5 mg/day was able to tolerate 20 mg/day while taking lithium (33).

Skin

Lithium succinate is used topically to treat seborrheic dermatitis (34). A topical 8% lithium gluconate ointment was more effective than a placebo ointment in treating 129 patients with facial seborrheic dermatitis (complete remission in 29 versus 3.8%) (35).

Immunologic and infections

Comments on the generally favorable effects of lithium on immune function have been summarized (36). The antiviral and neuroprotective properties of lithium were mentioned in a review of the immune system and bipolar disorder (37). The potential benefit of lithium in treating AIDS and AIDS-related dementia, owing in part to its cytokine-regulating and neuroprotective effects, has been reviewed (38). Genital *Herpes simplex* infection has responded to lithium (39).

- Lithium had an antiviral effect in a 44-year-old woman whose psychiatric symptoms did not improve but who had complete suppression of *Herpes labialis* for 2 years (after a 30-year history of at least twice-yearly episodes) followed by a recurrence, only 5 days after stopping the drug (40).

Cancers

In one study, there was a lower risk of cancer in both 609 lithium patients and 2396 psychiatric controls compared with the general population, and in the lithium group, there was a nonsignificant trend toward an even lower risk of nonepithelial tumors (41).

Lithium gamolenate, a compound with in vitro antitumor activity, given intravenously or orally, was ineffective in treating advanced pancreatic adenocarcinoma ($n = 278$) (42). Adverse effects attributed to lithium

© 2006 Elsevier BV All rights reserved.

(type unspecified) were reported in two of 93 in the oral group (mean serum lithium 0.15 mmol/l), five of 90 with low-dose intravenous administration (mean serum lithium 0.4 mmol/l), and seven of 95 with the high-dose intravenous administration (mean serum lithium 0.8 mmol/l).

Pharmacokinetics

Ionized lithium is readily absorbed from the gastrointestinal tract and is excreted almost entirely by the kidney, which ordinarily clears it at a rate of about one-quarter to that of creatinine clearance (43).

A reduction in glomerular filtration rate (GFR) will reduce lithium clearance, as will a negative sodium balance. Lithium is not metabolized and is not bound to plasma proteins.

Lithium is easily, inexpensively, and accurately measurable in the serum, and serum concentration determination is a useful adjunct to monitoring its therapeutic efficacy and avoiding toxicity (44).

Both immediate-release and modified-release formulations of lithium carbonate are available. Peak blood concentrations are lower and occur more slowly with modified-release formulations than with immediate-release formulations, but all formulations are supposed to deliver equivalent amounts of lithium per millimole. The effectiveness of lithium should not be altered by the formulation used or the number of daily doses (assuming full adherence to therapy), but if it is given once a day the 12-hours serum lithium concentration will be somewhat higher than if the same amount is given in divided doses.

Standardizing the timing of blood sampling to about 12 hours after the last dose (which is preferably taken in the morning) will do much to avoid the vagaries of absorption and should provide a consistency that will allow accurate comparisons across samples (44). Blood concentrations are most useful if a steady state has been reached before sampling (4–5 days after starting treatment or after a dosage change).

Recommended serum lithium concentrations for the treatment of mania and for maintenance treatment are not uniformly agreed on, although differences of opinion are not large. For example, a concentration of 0.5–0.8 mmol/l has been advised for patients starting treatment, with the recognition that both lower and higher concentrations may be necessary. In US product monographs, concentration ranges for acute mania (1.0–1.5 mmol/l) and long-term treatment (0.6–1.2 mmol/l) tend to be higher than currently practiced (mania 0.8–1.2 mmol/l; long-term 0.6–1.0 mmol/l) and considerably higher than concentrations recommended in Europe. While there is uniform agreement that the serum concentration should be kept as low as is compatible with therapeutic efficacy, there is as yet no accurate way to predict this concentration in an individual. Within the target range, one can generally expect efficacy to increase with blood concentration, but at a price—adverse effects are likely to increase. Elderly people will require a lower dosage of lithium to achieve a given serum concentration, and they tend to be more sensitive to adverse effects than younger individuals, but whether they respond better to lower concentrations is unclear.

The frequency with which blood concentrations should be measured varies with the stage of the illness and with a number of patient factors (including age, associated illnesses, concomitant medications, and diet). Generally, concentrations are measured every 5–7 days during the start of therapy, and then less and less often as stability occurs and persists. In reliable patients taking long-term treatment, concentrations may be measured every 3–4 or even 6 months.

Instruction and information

The safe and effective use of lithium is best ensured by close collaboration among patients, physicians, and significant others, all of whom must remain well-informed and up to date about treatment guidelines, benefits, adverse effects, risks, and precautions. While verbal communication and education is invaluable, it should be constructively supplemented with written information (45,46).

Comparative studies

The availability of anticonvulsant mood stabilizers has led to comparative studies with lithium. A review of the comparative efficacy and tolerability of drug treatments for bipolar disorder included tolerability comparisons of lithium versus carbamazepine, lithium versus valproate semisodium, and lithium versus other medications (47).

In 29 patients, the burden of taking lithium ($n = 17$) was compared with that of valproate ($n = 12$) using a visual analogue scale. Adverse effects were common but not significantly different between drugs (48), a finding that contrasts with the common impression that valproate is better tolerated. Indeed, a telephone interview of 11 adolescents taking lithium and 32 taking valproate found more adverse effects, poorer compliance, and greater perceived burden in the lithium group. There was a non-significant trend toward more weight gain with valproate (mean 12 kg) than with lithium (mean 9 kg) (49).

In a 4-week, placebo-controlled study of lithium in 40 hospitalized children and adolescents (mean age 12.5 years) with aggression related to conduct disorder, lithium was "statistically and clinically superior to placebo" (50). Although there were no dropouts related to adverse events, nausea, vomiting, and increased urinary frequency occurred significantly more often in the lithium group. The 55% incidence of vomiting with lithium (versus 20% with placebo) may have been related to the relatively high mean serum lithium concentration of 1.07 mmol/l (range 0.78–1.55 mmol/l).

Lithium versus carbamazepine

In a 2-year, double-blind study, lithium was superior to carbamazepine in prophylactic efficacy, although it caused more adverse effects (Table 1) (51).

Lithium versus divalproex

In a randomized, placebo-controlled, 12-month maintenance comparison of lithium and divalproex in 372 bipolar I outpatients, neither active drug was more effective than placebo on the primary outcome measure—the time to recurrence of any mood episode (52). While a history of intolerance to either lithium or divalproex was an

Table 1 Adverse effects of lithium and carbamazepine in a double-blind trial (in %)

Adverse effect	Lithium ($n = 42$)	Carbamazepine ($n = 46$)
Difficulty concentrating	45	33
Thirst	41	22
Hand tremor	31	4
Blurred vision	26	11
Reduced appetite	21	9
Increased appetite	17	33
Weakness	14	4

exclusion criterion, it was not stated whether or not prior nonresponders were entered and, if so, how many. The following adverse effects were significantly more frequent:

(a) with lithium than with placebo: nausea, diarrhea, and tremor;
(b) with divalproex than with placebo: tremor, weight gain, and alopecia;
(c) with lithium than with divalproex: polyuria, thirst, tachycardia, akathisia, and dry eyes;
(d) with divalproex than with lithium: sedation, infection, and tinnitus.

Unfortunately, all dropouts were pooled, whether due to adverse events or noncompliance, making overall tolerability comparisons impossible.

General adverse effects

The adverse effects of lithium have been reviewed (5,53–55). The adverse effects of lithium range widely in intensity and can be a major cause of nonadherence to therapy. However, with proper attention to the prevention and management of adverse effects, most patients can be treated effectively and safely. Withdrawal of lithium is almost always followed by resolution of adverse effects, although certain problems can sometimes persist (for example renal).

Adverse effects that can occur at concentrations in the target range, especially in the upper part of the range, include mild cognitive complaints, postural tremor, hypothyroidism, weight gain, leukocytosis, hypercalcemia, loss of appetite, nausea, loose stools, acne, and psoriasis. Renal adverse effects include impaired concentrating ability and polyuria with secondary polydipsia. Cardiac adverse effects are rarely symptomatic and are usually reversible. Lithium does not cause physiological dependence, although there may be an increased risk of early recurrence if it is withdrawn rapidly.

When 60 patients (22 men, 38 women) who had taken lithium for 1 year or more (mean 6.9 years; mean serum concentration 0.74 mmol/l) were interviewed about adverse effects, 60% complained of polyuria–polydipsia syndrome (serum creatinine concentrations were normal) and 27% had hypothyroidism requiring treatment (56). Weight gain was more common in women (47 versus 18%) as were hypothyroidism (37 versus 9%) and skin problems (16 versus 9%), while tremor was more common in men (54 versus 26%). Weight gain of over 5 kg in the first year of treatment was the only independent variable predictive of hypothyroidism.

The severity of lithium toxicity depends on the magnitude and duration of exposure and idiosyncratic factors. Manifestations of acute toxicity range in intensity from mild (tremor, unsteadiness, ataxia, dysarthria) to severe (impaired consciousness, neuromuscular irritability, seizures, heart block, and renal insufficiency), and the sequels of toxicity range from none at all to permanent neurological damage (often cerebellar) to death. Causes of raised serum lithium concentrations include increased intake and reduced excretion (due to kidney disease, low sodium intake, drug interactions). Whether long-term lithium use carries a risk of progressive renal insufficiency in a few patients continues to be debated. Reviews have addressed lithium toxicity in the elderly (57) and lithium intoxication with an emphasis on the kidney (58).

Dose- and time-related adverse effects

During initiation and stabilization of treatment, adverse effects, such as gastrointestinal upset, tremor, dysphoria, fatigue, muscle weakness, unsteadiness, thirst, and excessive urination, are not uncommon, but they usually abate with time. Such adverse effects are more likely to occur at higher dosages or higher serum concentrations and can usually be avoided or attenuated by proper attention to dosage, clinical and laboratory monitoring, and, if necessary, the use of adjunctive medication.

Long-term use of lithium is sometimes associated with weight gain, polyuria and polydipsia, and thyroid dysfunction (see below), but many patients have been treated successfully for several decades without developing treatment-limiting adverse effects. However, long-term success should not breed complacency, since there is an ever-present risk of recurrence (if concentrations are too low) and toxicity (if concentrations are too high).

Treatment of toxicity

Two patients with lithium toxicity (serum concentrations 3.5 and 4.2 mmol/l) had the well-recognized rebound increase in serum concentrations after the end of hemodialysis. Both died during hospitalization from what was cryptically described as "unrelated events" (59).

- A 49-year-old with severe lithium toxicity was treated successfully with continuous veno-venous hemodiafiltration; the serum lithium concentration fell from 3.0 to 0.93 mmol/l after 7 hours and there was no rebound increase after the end of the procedure (60). The maximum lithium clearance was 28 ml/minute which is considerably lower than usually attained with hemodialysis.

An all too common treatment error in the face of severe toxicity is "watchful waiting," during which the patient's condition is more likely to worsen than improve.

Organs and Systems

Cardiovascular

Cardiovascular disease is not a contraindication to lithium, but the risks may be greater, in view of factors such as fluid and electrolyte imbalance and the use of

© 2006 Elsevier BV All rights reserved.

concomitant medications. Close clinical and laboratory monitoring is necessary, and an alternative mood stabilizer may be preferred. While long-term tricyclic antidepressant therapy may be more cardiotoxic than lithium, the newer antidepressants (SSRIs and others) seem to be safe.

In two studies of 277 and 133 patients taking long-term lithium, there was no evidence of increased cardiovascular mortality compared with the general population (61,62). While the latter study reported on 16-year mortality, it did not provide information about which patients continued to take lithium after the first 2 years.

Blood pressure

Lithium does not affect blood pressure adversely, nor does it benefit blood pressure, although lithium hippurate was used to treat arterial hypertension in the 1920s.

Cardiac dysrhythmias

Nonspecific, benign ST-T wave electrocardiographic changes are the most common cardiovascular effects of lithium.

- A 13-year-old boy taking lithium developed a "pseudomyocardial infarct pattern" on the electrocardiogram; this may have been an overinterpretation of nonspecific T-wave changes (63).

A very uncommon adverse effect involves sinus node dysfunction (extreme bradycardia, sinus arrest, sinoatrial block), which can be associated with syncopal episodes, perhaps due to hypothyroidism (64,65). In such cases, lithium must either be withdrawn or continued in the presence of a pacemaker. At therapeutic concentrations, other cardiac conduction disturbances have been reported, sometimes in conjunction with hypercalcemia (66), but are uncommon.

Two reviews of the cardiac effects of psychotropic drugs briefly mentioned lithium and dysrhythmias, with a focus on sinus node dysfunction (67,68), reports of which, as manifested by bradycardia, sinoatrial block, and sinus arrest, continue to accumulate in association with both toxic (69) and therapeutic (70,71) serum lithium concentrations. The rhythm disturbance normalized in some cases when lithium was stopped (69,71), persisted despite discontinuation (70), or was treated with a permanent cardiac pacemaker (71). Of historical interest is the observation that the first patient treated with lithium by Cade developed manifestations of toxicity in 1950, including bradycardia (72).

There have been several reports of bradycardia and sinus node dysfunction.

- During an episode of lithium toxicity (serum concentration 3.86 mmol/l), a 42-year-old woman developed sinus bradycardia that required a temporary pacemaker (69). There was marked prolongation of sinus node recovery time. Lithium was withdrawn and the patient underwent hemodialysis once daily for 3 days; sinus node recovery time normalized. The presence of nontoxic concentrations of carbamazepine may have contributed to the condition.
- A 65-year-old man taking lithium for 2 years, with therapeutic concentrations, developed sinus bradycardia (30 beats/minute), which remitted when the drug was stopped and recurred when it was restarted (73). Implantation of a permanent pacemaker allowed lithium to be continued.
- Asymptomatic bradycardia occurred in three of 15 patients treated for mania with a 20 mg/kg oral loading dose of slow-release lithium carbonate (74).
- A 9-year-old boy whose serum lithium concentration was 1.29 mmol/l had a sinus bradycardia with a junctional escape rhythm (40 beats/minute), which normalized at a lower lithium concentration (75).
- A 58-year-old woman with lithium toxicity developed an irregular bradycardia (as low as 20 beats/minute), which resolved during hemodialysis; persistent sinoatrial conduction delay suggested that she was predisposed to the bradydysrhythmia (76).
- A 52-year-old man took an overdose of lithium (serum concentration 4.58 mmol/l) and developed asymptomatic sinus bradycardia with sinus node dysfunction and multiple atrial extra beats, which resolved after hemodialysis (77).
- A 66-year-old woman with pre-existing first-degree AV block, developed sinus bradycardia, a junctional rhythm, a prolonged QT interval, and syncopal episodes (serum lithium concentration 1.4 mmol/l in a 40-hours sample) about 2 weeks after beginning lithium therapy. She was treated successfully with a pacemaker and a lower dose of lithium (78).
- A 36-year-old man became hypomanic after lithium was withdrawn because of symptomatic first-degree atrioventricular block (although, how first-degree block could have caused symptoms is unclear) (79).
- A 44-year-old woman developed atropine-resistant but isoprenaline-sensitive bradycardia (36 beats/minute), thought to be due to sinus node dysfunction related to lithium, fentanyl, and propofol (65).
- A 52-year-old man with a serum lithium concentration of 4.58 mmol/l had sinus node dysfunction with multiple atrial extra beats and an intraventricular conduction delay, which normalized following hemodialysis (77). Two patients, a 58-year-old woman and a 74-year-old woman, developed sick sinus syndrome while taking lithium but were able to continue taking it after pacemaker implantation (80,81).
- A 59-year-old woman with syncope and sick sinus syndrome, which remitted when lithium was withdrawn, recurred when lithium was restarted, and then persisted despite lithium withdrawal; after a pacemaker was implanted she was treated successfully with lithium for 7 years (80).

Lithium can also occasionally cause tachycardia.

- A 59-year-old man was noted to have tachycardia, a shortened QT interval, and nonspecific ST-T changes, while hospitalized with lithium-associated hypercalcemia (82).

An extension of a previously published study (66) added a third comparator group of 18 hypercalcemic non-lithium treated patients and compared them with 12 hypercalcemic lithium patients, 40 normocalcemic lithium patients, and 20 normocalcemic bipolar patients taking anticonvulsant mood stabilizers (83). Both hypercalcemic groups had more conduction abnormalities than the other

© 2006 Elsevier BV All rights reserved.

two groups, but did not differ from each other in this regard. While the authors concluded that both lithium and calcium played important roles in the dysrhythmias, their data suggested that hypercalcemia alone was the critical factor.

Cardiac dysrhythmias associated with lithium intoxication in the elderly included sinus node dysfunction and junctional bradycardia (57). A retrospective chart review of patients on lithium who had mild but persistent hypercalcemia ($n = 12$) showed a greater frequency of cardiographic conduction disturbances compared with normocalcemic patients taking lithium ($n = 40$) and normocalcemic bipolar patients taking anticonvulsant mood stabilizers ($n = 20$), although the overall frequency of cardiographic abnormalities did not differ significantly among the groups (66). When 21 patients without cardiovascular disease (mean serum lithium 0.66 mmol/l) were compared with healthy controls using standard electrocardiography, vector cardiography, and electrocardiographic body surface potential mapping, the only abnormality was a reduction in the initial phase of depolarization, a finding of questionable clinical significance (84).

Abnormalities of the QT_c interval have been explored in 495 psychiatric patients (87 taking lithium, but many of them also taking other drugs) and 101 healthy controls (85). There was no association of lithium with QT_c prolongation but it was associated with nonspecific T-wave abnormalities (odds ratio 1.9) and increased QT dispersion (odds ratio 2.9). Caution was suggested if lithium is used with drugs associated with QT_c prolongation, such as tricyclic antidepressants, droperidol, and thioridazine.

Cardiomyopathies

A study of cardiomyopathies found a specific cause in 614 of 1230 patients (the remainder were diagnosed as idiopathic). One was attributed to lithium but no details were provided (86).

In a study of 1230 patients with initially unexplained cardiomyopathies, lithium was implicated in one case (62). Using a data-based mining Bayesian statistical approach to the WHO database of adverse reactions to examine antipsychotic drugs and heart muscle disorders, a significant association was found between lithium and cardiomyopathy, but not myocarditis (87). The authors acknowledged that further study is needed to determine if the association is causal.

- A 78-year-old woman developed a cardiomyopathy while taking lithium, imipramine, amineptine, levomepromazine, and lorazepam; it resolved when the medications were withdrawn (88). Whether lithium was causally involved is not known.

Respiratory

A 60-year-old woman with bipolar disorder since the age of 29 developed idiopathic pulmonary fibrosis (cryptogenic fibrosing alveolitis) after having taken lithium for 9 years (89). Whether lithium played a causal role is at best highly speculative.

Ear, nose, throat

In two patients, profuse paroxysmal rhinorrhea improved when lithium was withdrawn (90). The rhinorrhea was thought to be a manifestation of mesotemporal lobe epilepsy that had been worsened by lithium.

Nervous system

Reports of overdose-related neurological symptoms abound (91–101). Among these reports, are cases of neurotoxicity at therapeutic serum lithium concentrations (91,99,101) and neurotoxicity associated with nonconvulsive status epilepticus (95,97).

There have been scattered reports of lithium-associated myasthenia gravis, paresthesia, somnambulism (102), seizures and electroencephalographic abnormalities, confusional states, and a reversible Creutzfeldt–Jakob-like syndrome (103). One report rather inconclusively suggested that lithium caused periodic alternating nystagmus in a 61-year-old man (104).

Electroneurographic studies in 34 lithium maintenance patients and controls (both healthy subjects and mood-disorder patients never on lithium) showed statistically significant reductions in sensory and motor conduction in the lithium group (105). None of the decrements was severe enough to be abnormal, and whether these findings have clinical implications is unknown.

Nonreversible lithium neurotoxicity continues to be reported (106,107), including a case of lithium overdose (serum lithium concentration 3.9 mmol/l) with persistent severe ataxia for 9 months that improved markedly when inadvertently treated with high-dose buspirone (120–160 mg/day) (108).

- An 85-year-old woman became gradually toxic (serum lithium 2.9 mmol/l) in a nursing home (109). Despite only conservative management, there was slow but complete resolution of severe neurological symptoms, including coma, fixed pupils, and Cheyne–Stokes respiration.

Twelve patients with mood disorder had electroencephalography before and after taking lithium for an average of 4.4 months (110). Lithium-related changes included:

(a) increased relative power in the delta- and theta-band frequencies;
(b) decreased relative alpha power;
(c) decreased dominant alpha frequency.

The clinical implications of these observations, if any, are unclear.

- A 73-year-old patient had toxic symptoms and moderately severe, generalized slowing on the electroencephalogram at a therapeutic serum concentration (111).

Cerebellar syndromes

Chronic neurological sequelae of intoxication included two patients with a persistent cerebellar syndrome and severe cerebellar atrophy (112), one with subcortical dementia (113), and one with a diffuse sensorimotor peripheral neuropathy (114).

© 2006 Elsevier BV All rights reserved.

- An 86-year-old man with a serum lithium concentration of 0.7 mmol/l presented with a several month history of asterixis which resolved fully within 2 weeks of stopping lithium (115).
- Symptoms suggestive of toxicity at therapeutic serum concentrations also occurred in a 49-year-old man taking lithium (0.7 mmol/l), carbamazepine, and trifluperidol, who developed persistent cerebellar deterioration during a febrile episode of lobar pneumonia (116).
- Another patient who developed cerebellar symptoms consistent with lithium neurotoxicity despite a low therapeutic serum concentration (0.5 mmol/l) was more fortunate, as the symptoms resolved promptly when lithium was withdrawn (117).
- Permanent cerebellar sequelae occurred in a 36-year-old man after intoxication at therapeutic lithium concentrations (118).

A literature review of permanent neurological complications of acute lithium toxicity noted that a cerebellar syndrome is quite common and that neuroleptic drugs can worsen toxicity, as might rapid reduction of raised serum lithium concentrations (119). However, the latter point is speculative at best; hemodialysis remains the treatment of choice for severe lithium poisoning.

Convulsions

A proconvulsive effect of lithium was also suggested in two patients purported to have temporal lobe epilepsy, who improved when carbamazepine replaced lithium (90). Twelve cases of status dystonicus of varying causes included a woman with post-traumatic dystonia, who was treated unsuccessfully with lithium. Despite the lack of response, her muscular spasms worsened when lithium was stopped (120).

Five patients taking lithium for unspecified durations developed multifocal action myoclonus without reflex activation, which resolved fully when the drug was withdrawn (121).

- A patient presented with nonconvulsive status epilepticus and a serum lithium concentration of 1.9 mmol/l (122).
- A prolonged seizure occurred after electroconvulsive therapy (ECT) in a 45-year-old man taking lithium, amfebutamone, and venlafaxine (123).

Creutzfeldt–Jakob-like syndrome

A reversible Creutzfeldt–Jakob-like syndrome has been described in patients taking lithium.

- A 65-year-old woman taking lithium, levomepromazine, and phenobarbital developed a Creutzfeldt–Jakob-like syndrome after she had mistakenly increased her lithium dosage (103).
- A 66-year-old man presented comatose with an EEG suggestive of Creutzfeldt–Jakob encephalopathy after an 11-month history of progressive dementia and parkinsonism (124). Lithium (serum concentration 1.3 mmol/l), which he had been taking for 13 years, was withdrawn, and by day 78, clinical examination showed only mild neurological impairment.

Extrapyramidal effects

Parkinsonism

Occasionally, long-term use of lithium is associated with cogwheel rigidity and a parkinsonian tremor (125). More often than not, concurrent or past treatment with an antipsychotic drug is involved. In a review of SSRI-induced extrapyramidal adverse effects, lithium was listed, but not discussed, as a possible risk factor (126). A review of drug-induced parkinsonism provided references to case reports of lithium's "occasionally inducing or exacerbating parkinsonism" (127).

Two patients developed parkinsonism after taking lithium for many years, but did not improve when the drug was withdrawn and a causal relation could not be established (81).

- An 86-year-old man taking lithium monotherapy (serum concentration 0.7 mmol/l) had asterixis for several months; it resolved fully within 2 weeks of stopping lithium (115).
- A 65-year-old woman, after a brief exposure to lithium, developed severe akathisia and disabling parkinsonism; within 4 days of stopping lithium, the symptoms improved, but orofacial dyskinesia appeared; 10 months later both the parkinsonism and the dyskinesia had improved, but were still present (125).

Dystonias

Reversible tardive dystonia has been attributed to lithium (128).

Neuroleptic malignant syndrome

There have been reports of neuroleptic malignant syndrome in patients taking lithium and a neuroleptic drug (129–131). However, while previous reports have suggested an association between lithium and neuroleptic malignant syndrome (132), a case-control study ($n = 12$ with the syndrome, $n = 24$ controls) found no such association (133). Since none of the patients with neuroleptic malignant syndrome was taking lithium, little can be concluded from such a finding.

However, lithium can be associated with the neuroleptic malignant syndrome in patients who are taking neuroleptic drugs, as in the following cases:

- A 63-year-old man taking lithium and amoxapine (129).
- A 23-year-old woman taking lithium, olanzapine, and fluoxetine (130).
- A 39-year-old woman who had overdosed with lithium and who took a single dose of haloperidol (131).

Headache

A 64-year-old woman had a 2-week history of daily bilateral holocranial headache as the presenting complaint of lithium toxicity (serum concentration 2.5 mmol/l); dosage reduction resolved the headache and the extrapyramidal and cerebellar effects (134).

Myasthenia

A 51-year-old man developed a myasthenic syndrome which resolved when lithium was withdrawn (135). The authors referred to three other previously reported cases of lithium-induced myasthenia.

© 2006 Elsevier BV All rights reserved.

Pseudotumor cerebri
Pseudotumor cerebri (benign intracranial hypertension) has been linked to lithium in over 30 cases, with headache, papilledema, increased intracranial pressure, reduced vision, and a risk of blindness (136). The condition tends to improve on withdrawal, but surgical intervention may sometimes be necessary. A review of pseudotumor cerebri devoted one paragraph to induction of this condition by lithium and provided six references but no new information (137).

- A 17-year-old woman developed pseudotumor cerebri with headache after she had taken lithium for 6.5 weeks (138). Papilledema and increased intracranial pressure resolved fully when lithium was withdrawn, and she was given acetazolamide.

Serotonin syndrome
Serotonin syndrome has been reviewed twice, but mention of lithium as a possible contributing factor was scanty (139,140).

Somnambulism
After almost a two-decade nap, interest in lithium-induced somnambulism was reawakened by a questionnaire survey of 389 clinic patients that found sleepwalking in 6.9% of those taking lithium alone or with other drugs compared with a 2.5% prevalence in the general population (102).

- A 52-year-old man had a 5-year history of sleepwalking 2–3 times a week beginning 3 months after starting lithium (141). On one occasion, he was injured in a fall when sleepwalking through a second-story window. When lithium was stopped for 3 months, the problem resolved only to recur when it was restarted.

Stuttering
Stuttering worsened in a 48-year-old man while he was taking lithium, with improvement when he was switched to valproate (142).

Tremor
Lithium commonly causes a benign postural tremor, especially early in the course of treatment (143,144) and can enhance physiological tremor (144). Risk factors include higher serum lithium concentrations, a family history of tremor, high caffeine intake, and the use of other drugs that cause tremor (for example antidepressants, valproate). The tremor is often well tolerated, but in some cases, it can be socially or occupationally problematic. In such cases, treatment possibilities include reducing the dose of lithium, the use of a modified-release formulation, reducing caffeine intake, or the addition of a tremor-reducing drug, such as a beta-blocker (145), primidone (146), or possibly gabapentin (147).

Tremor was reported as an adverse effect of lithium in 12 of 22 men and 10 of 38 women who had taken it for at least 1 year (56). In an open study, there was full remission of lithium tremor in four of five patients treated with vitamin B6 (148).

A double-blind study in which 31 patients with breakthrough depression taking lithium received augmentation with either paroxetine or amitriptyline and showed a quantitative increase in tremor activity with combined therapy, but no significant change in tremor frequency (149).

- Severe essential tremor, which was at first mistaken for tardive dyskinesia, occurred in an 80-year-old woman taking lithium; it resolved almost completely when lithium was withdrawn (150).

Neuromuscular function

Lithium has been implicated in impaired athletic prowess in two cases (151).

- A 21-year-old man had muscular incoordination while fast bowling (cricket), which improved when he switched to valproate.
- A 71-year-old woman was unable to serve properly at tennis until she stopped taking lithium.

Sensory systems

Eyes
Lithium can alter retinal sensitivity to light, and concern has been expressed that bright light therapy for seasonal mood disorder can increase the risk of photoreceptor cell damage, although such concerns have not been confirmed clinically (152,153).

Other effects on the visual system attributed to lithium include reduced accommodation, exophthalmos, extraocular muscle abnormalities, nystagmus (most characteristically downbeat), oscillopsia, photophobia, and papilledema with visual impairment (pseudotumor cerebri) (136).

- A 21-year-old woman developed temporary blindness possibly related to lithium toxicity (100).

Ears
The finding of reversible lithium-induced moderate hearing loss (especially low frequency) in guinea pigs has led to speculation that similar findings could occur in humans (154).

Psychological, psychiatric

Neuropsychological testing in a 51-year-old woman with a serum lithium concentration of 2.4 mmol/l showed striking cortical and subcortical deficits, which had only partially resolved when she was retested 4 and 14 weeks later (98).

Cognitive effects
Most people taking lithium have no complaints about its effects on mental processes; they feel normal and function normally. Mild cognitive effects can occur, although it is sometimes difficult to determine whether they are due to the lithium, the resolution of manic euphoria, the presence of mild depression or hypothyroidism, or the effects of other medications. Complaints can include reduced reactivity, lack of spontaneity, loss of emotional tone, and patchy memory impairment. Lithium reportedly has adverse effects on memory, speed of information processing, and reaction time (155,156). It has been suggested that the risk of driving accidents may be increased in patients taking lithium, but there is no evidence that this

is so. As with any psychotropic drug, patients should be cautious about driving or operating dangerous machinery until they know how they will react to lithium. These mild cognitive adverse effects can be underappreciated by clinicians, yet be a cause of nonadherence to therapy. The action of lithium on the hypothalamic–pituitary–thyroid axis has been discussed in relation to its cognitive effects (157). Although, the English abstract of a Polish review concluded that there is no evidence of significant cognitive deficits caused by lithium (158), others dispute this conclusion (156).

Assessment of cognitive performance in 43 patients with bipolar I disorder showed no correlation between the use of lithium, carbamazepine, or valproate, and full-scale IQ or general and working memory (all of which were impaired by antipsychotic drugs) (159). While a deficit in sustained attention was noted in 19 euthymic patients with bipolar disorder (17 taking medications, 11 taking lithium alone or in combination), there was no difference between those taking and those not taking lithium (160).
